The search criteria were designed to focus on month-wise data (from April to September) with known fish production. The main goal was to analyze physical and chemical parameters and management data (fish production and supplementary feed supply). The data were further split into three phases of the growing season: spring (April–May; water temperature <14°C), midsummer (June–July; maximum primary production, rapid fish growth), and late summer (August–September; apparent over-exploitation of natural food, frequent oxygen deficits, stagnant fish growth). The data were analyzed using linear regression models and a multivariate approach. Multivariate analyses were used to determine relationships among environmental and fishpond landscape characteristics, including management interventions (mean depth, altitude, feeding, final fish production).

Results

Studied fishponds were classified as mesotrophic to hypertrophic with high nutrient concentrations (median (range) TN: 2 (0.3–9) mg/L; TP: 150 (8–1300) μg/L), resulting in high phytoplankton biomass (median (range) chlorophyll *a* concentration: 70 (1–760) μg/L), and low transparency (median (range) Secchi depth: 50 (5–350) cm).

Multivariate analysis revealed that feeding was positively correlated with fish production while negatively with the DIN:TP ratio. Stoichiometry of available macronutrients showed high variability both on spatial and temporal scales. Despite high total N concentrations, we found decreasing trends in DIN (NH_4-N + NO_3-N) concentrations during the growing seasons. The relationship between chlorophyll *a* and DIN:TP suggests that all fishponds at lower altitudes (<450 m a.s.l.) likely tended to N limitation from mid- to late summer, while ponds at higher altitudes (>450 m a.s.l.) apparently remained P-limited regardless of the season phase.

(Continued on next page)

Discussion

Results of data compiled from studies carried out over various temporal and spatial scales suggest that fishpond might be stressed by seasonal and spatial stochiometric imbalances of available macronutrients.

Wholepond fertilizing „experiments" held in the last century in Czechia suggested P as a nutrient limiting fish production (Pechar et al. 2002). The positive results of P addition were reflected in fish production increment and naturally drew attention away from N availability because, in mesotrophic ponds at that time, P certainly was the limiting resource, unlike in eutrophic ponds at present. Supplementary feeding (e.g., cereals rich in phytate P) seems to be connected to the DIN:TP shift in mid- and late summer. Contrary to cyanobacteria, many algal species are sensitive to a severe shift in stoichiometry balance and unable to grow under N limitation.

Ponds are conceived as a black box with inputs and outputs of nutrients, but little attention has been paid to the process involved and stoichiometry of these inputs and its further manipulation to achieve the desired goal (i.e., good water quality and fish production). The current pond management practices deserve a revision, as warranted by changing nutrient status, stoichiometry, and climate. One of the concepts is the balanced pond feeding concept or nutritious pond concept (e.g., Kabir et al. 2020, Roy et al. 2022) based on a "smart nutrition" and fish bioenergetics aiming to keep current fish production while maintaining good water quality. Such a concept, presently under field evaluation, could manipulate not only the nutrients supplied to fish but also those released *in situ* by fish. For instance, supplementing the missing N (essential amino acids) and reducing the P (phytate) released from fish in late summer is one such strategy (Roy et al. 2022).

Introduction

Marine aquaculture in Europe is evolving into a high-tech industry, with many modern aquaculture systems incorporating the collection of heterogeneous data from multiple sources into their daily routines. Globally, aquaculture and fisheries production are an important source of accessible nutritious food, and form a basis for livelihoods. Fish consumption account for 15-20% of the protein consumption of 2.9 billion people worldwide. They also play a key driving role of coastal and rural economic well-being. However, environmental impacts, fish welfare, and the combined effects of ocean-based activities and climate change on resources and ecosystems, put the sector at risk and undermine the resilience of those relying on it. Improving fisheries and aquaculture management is thus crucial to ensure sustainability and that future generations continue to benefit from ocean resources and ecosystem services.

5G-HEART (5G for Health, Aquaculture and Transport) is an EU project which aims to offer new solutions through advances in 5G technology to facilitate sustainable development. Within the aquaculture sector this includes better environmental monitoring, waste management and improved fish monitoring and performance. Technologies such as the legacy 2G network and current 3G/4G technologies are particularly suited for most current requirements but can be constrained in terms of coverage and data rate. More advanced use cases will require high reliability, low latency, global coverage, energy efficiency and the ability to connect a large number of sensors/devices without loss of performance. All these requirements should be met through the 5G infrastructure.

Methodology

In Greece, the solution proposed aims to cover daily operations, such as automated monitoring of fish health and welfare, optimal feeding and infrastructure integrity, in collaboration with a commercial sea bass and sea bream producer, Skironis SA located in Megara, Athens.

The project aims to develop a complete decision-support solution which provides improved monitoring and management of fish farming operations and planning of production. Part of the solution is the platform (web interface) consisting of two main elements:

1. Environmental (water quality) and stock (fish numbers, feeding rate, health) monitoring in order to optimize daily activities,
2. Supporting management decision making, with proposals based on the possibilities offered by the internet of things (IoT) and artificial intelligence (AI).

Expected Outputs

The project is evaluating key production indices focused on stock monitoring (number of fish per pen, fish behaviour and appearance), with the goal to reduce the number of mortalities, monitor feeding levels in order to optimise the feed conversion ratio (FCR) which will in turn reduce waste (less uneaten food pellets and reduced feed costs). Results on the number of live fish and on the FCR will be presented and assessed, in terms of how well the complete system offered from WINGS performs. Additional data collected on the performance of the 5G network will also be analysed to determine the potential benefits of this infrastructure.

Acknowledgements

5G HEART received funding from the European Union’s Horizon 2020 research and innovation programme under grant agreement No. 857034.

Introduction

Marine larval feed technology is a fast changing field with great progress in manufacture technology. Many of the fish larval feed industries provide small enough feed particles that cover the nutritional needs of newly hatched larvae and have high acceptability and palatability, water stability and low nutrient leaching (Hardy and Barrows, 2002). In the hatchery practice of European seabass *Dicentrarchus labrax*, dry feed is progressively introduced to fish larvae not earlier than 25 days post hatching (dph) with the concomitant use of live feeds (rotifers, *Artemia*) until weaning. However, compared to live feed, dry feeds appropriately manufactured (i.e. physical and nutritional properties) are expected to better provide for all nutritional needs of altricial fish species, such as European seabass. Although the exclusive use of dry feeds is still inefficient, it is widely accepted that the longer the co-feeding period of live and dry feeds, the better the larvae performance at weaning (e.g. Cañavate and Fernández-Díaz, 1999; Khoa et al., 2020). The aim of the present study was to investigate the introduction of dry feed as early as on mouth opening (7 dph) on growth and functional development of the digestive system of European seabass larvae, as well as to monitor post-larvae growth performance and deformities.

Materials and methods

The experimental trial was conducted in two stages: Stage 1, Hatchery rearing (Hr), was performed in a commercial marine fish hatchery. Six tanks of 9 m^3 were stocked, two at a time, with eggs of the same broodstock. In three of the tanks a commercial dry feed (Larviva Prostart, Biomar) was introduced on 7 dph (DF7), while in the other three tanks the dry feed was introduced on 25 dph (DF25) according to a common hatchery protocol. In all experimental tanks, the larvae were fed with rotifers from 7 dph up to 15 dph and with *Artemia* nauplii/metanauplii from 15 dph up to 35 dph. From 36 dph larvae were fed dry feed only. Larvae samples were observed under microscope to confirm food consumption. During larval rearing, water quality was monitored daily and larvae were sampled daily from 7 to 17 dph, and at 5-days intervals up to 42 dph to estimate larvae length and digestive function (i.e. digestive enzymes specific activity). On 68-70 dph larvae of each Hr tank were graded to two size classes (Big, Small). Data obtained were used to calculate survival and performance. Stage 2, Laboratory rearing (Lr), was performed in a recirculating seawater system. On 61-63 dph ungraded larvae of each Hr tank were transferred to laboratory installations. On 64-66 dph, seven hundred and twenty (720) fish from each Hr tank were group weighed and randomly distributed in tetraplicated tanks (180 fish per tank). Fish growth (i.e. body mass, survival, specific growth rate-SGR, thermal growth coefficient-TGC, mass variation) was monitored for eight (8) weeks. All fish were fed the same commercial diet *ad libitum*. Water quality was monitored daily and fish were group weighed (app. 5-10 fish per group) every 15 days, while at the end of rearing fish were individually weighed. Phenotypic deformities were also individually recorded. During the last 15 days of rearing, food consumption was recorded to estimate feed efficiency (food conversion ratio-FCR).

Results and discussion

This is the third part of a general project concerning the early introduction of dry feed in first-feeding marine species larvae (Karakatsouli et al., 2019, 2021a, 2021b). Currently, European seabass Hr rearing has just been completed and Lr rearing is running. In parallel, laboratory work is going on to complete analysis. The present "incomplete" abstract will be replaced in due course.

Introduction

Surrogate reproduction technology in fish has potential for aquaculture as well as preservation and propagation of endangered species or specific experimental lines. Some unfavourable biological characteristics for culturing such as a late maturation or a large body size are ideal candidates for surrogate reproduction using smaller and faster-maturing host. Therefore, surrogacy is well suited for isogenic line production in fish. Conventional methodology for isogenic line production is based on repeated uniparental inheritance to obtain doubled haploids. Each doubled haploid is in turn reproduced again by uniparental inheritance and isogenic line is produced. Although doubled haploid induction procedures have been developed in many fish species, only a few of them were successfully propagated to obtain isogenic lines and further maintained to facilitate their use in experiments. Main problems in isogenic line productions are yield of doubled haploid and their reproductive issues. Also, further interferences are needed to produce the next isogenic generations. We attempted to overcome disadvantages connected with the conventional approach for isogenic generation using germ cell manipulation involving cryopreservation and surrogate reproduction technology.

Materials and methods

Series of experiments were performed to develop optimal procedure for cryopreservation of common carp male and female early-stage germ cell. Mixture of permeating and nonpermeating cryoprotectants were used to firstly identify the optimal composition of the cryomedia. In turn, various freezing rates were tested to define optimal condition favouring germ cell survival.

The second step was verification of the suitable recipient for germ cells of common carp. We have employed ablation of primordial germ cells using injection of antisense oligonucleotide against dead end gene in goldfish. The goldfish were germ cell free. Therefore, we isolated single cell suspension from cryopreserved and fresh gonadal fragments using trypsin/collagenase dissociation, enriched with gradient sorting. Isolated cells were injected into the body cavities of sterilized goldfish and their gonadal development was monitored.

Goldfish surrogates were stimulated for spawning by controlled temperature and light regime. Collected gametes were used for fertilization and genotyping using carp and goldfish specific primers.

Results

Cryopreservation protocols for testicular and ovarian tissue based on DMSO cryoprotectant and slow rate freezing -1 °C/min yielded 40-60% post-thaw viability. Recovery and physiological activity of cryopreserved germ cells was confirmed after transplantation into sterile goldfish when cryopreserved germ cells retained colonization rate comparable to non-cryopreserved control confirmed by detection PKH26 labelling and RT-PCR. Afterwards, goldfish surrogates produced viable common carp progeny confirmed by genotyping and typical phenotype. Both male and female gametes were obtained, even from a single donor confirming feasibility of isogenic line production using transplantation from doubled haploid donor without necessity to reproduce given individual again by uniparental inheritance.

Discussion

Germ cell manipulation is potent biotechnology to ameliorate breeding of aquaculture species and preserve valuable genetic resources in environmentally relevant or even endangered species. This study aimed to introduce a novel and complex strategy capable to overcome shortcomings of the traditional procedure for isogenic lines production. The presented study developed and optimized protocols for common carp germ cell cryopreservation, therefore, the tissue from precious doubled haploid or even isogenic specimen can be safely stored in liquid nitrogen. Of the utmost importance, germ cell-free gonads of goldfish were confirmed to be suitable environment for common carp germ cells. Transplanted cells were able to colonize environment of goldfish genital ridge and differentiate into functional gametes giving rise to viable common carp progeny.

EFFECT OF PHOSPHATIDYLCHOLINE FROM KRILL TOWARDS REDUCING LIPID MALABSORPTION SYNDROME IN ATLANTIC SALMON

Kiranpreet Kaur[1]*, Trond M Kortner[2], Åshild Krogdahl[2]

[1] Aker BioMarine Antarctic AS
[2] Faculty of Veterinary Medicine, Norwegian University of Life Sciences
Kiranpreet.kaur@akerbiomarine.com

Introduction

Lipid malabsorption syndrome (LMS) is a pathological condition associated with limited lipid transport capacity in the enterocytes and results in excessive lipid accumulation in the intestine, most marked in the pyloric region. Recently published studies have demonstrated the importance of choline for prevention of LMS in farmed Atlantic salmon, and that choline levels in today's commercial salmon feeds are often below requirement levels. These studies indicate that a dietary choline level of about 3.4 g/kg is required to prevent LMS. The estimated requirement is based on studies with choline chloride as choline source. No similar documentation exits in which phosphatidylcholine (PC) is used as choline source. Krill meal (KM) is a sustainable source of PC, and the present study aimed to determine the effects of including KM or krill oil (KO), in which PC is the source of choline, for prevention of LMS and for growth in Atlantic salmon.

Material & methods

Two doses KM and KO (one low choline level- 1.5 g/kg; and one two suboptimal inclusion levels of choline-2.6 g/kg) were tested on Atlantic salmon of initial weight of 62g. These diets were tested against two reference diets, one un-supplemented, highly deficient with a choline level of 0.6 g/kg, and one supplemented with choline chloride to a level above the indicated optimum requirement, i.e., 4.0 g/kg. The fish were fed on their respective test diets for 8 weeks in freshwater, with replicate tanks/diet.

Results

After 8 weeks of feeding, the growth of the fish fed the KM and KO diets, at both levels, was significantly increased compared to the growth in fish fed the un-supplemented diet. These results indicate that PC from KM and KO included in the diet at a level resulting in diets with choline levels of about 1.5 g/kg satisfied the needs for growth. A clear dose-dependent, decreasing effect on the pyloric intestine somatic index (PISI) was observed for both KM and KO diets. No significant difference was observed regarding PISI for the fish fed the KM and KO diets with 2.6 g/kg choline and PISI of fish in the high choline reference diet. Accordingly, PC from both KM and KO significantly reduced lipid accumulation in the PI when added to a choline deficient diet. However, histological appearance as well as results from analyses of lipid content in the pyloric caeca, indicated that choline requirement is higher than 2.6 g/kg for diets in which KM and KO are the supplementary sources.

EFFECT OF KRILL MEAL ON THE REPRODUCTIVE PERFORMANCE OF BROODSTOCK NILE TILAPIA (*Oreochromis niloticus*)

Kiranpreet Kaur[1*], Alberto Nunes[2], Hideyoshi Segovia[3], Carlos Lopez[3], Guglielmo Raymo[3], Geronimo Leonardi[1]

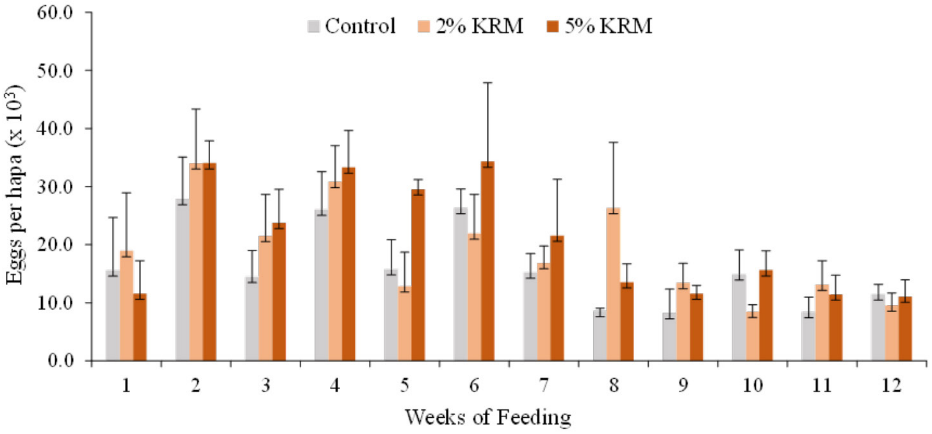
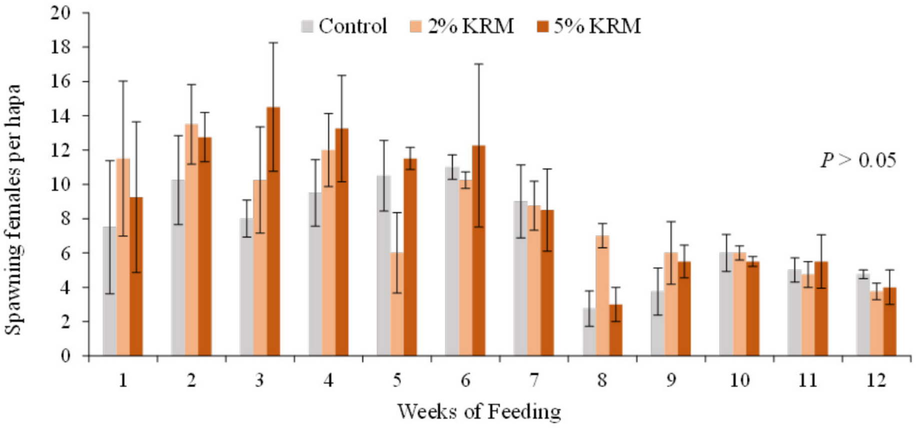
Instituto de Ciências do Mar (LABOMAR)Fortaleza, Brazil
Benchmark Genetics, Miami, USA
Kiranpreet.kaur@akerbiomarine.com

Introduction

Farmed tilapia is currently the second most farmed finfish in aquaculture and represents 5.27% of global aquaculture production. To meet these growth indexes, and to support the increasing aquaculture potential for tilapia, it is critical to provide high-quality offspring. For that, improved nutrition, feeding and management of broodstock are essential tools. Broodstock nutrition is a major factor which influences reproduction spawning frequency, egg quality and larval quality. Hence it is utmost important to obtain knowledge on the nutritional requirements of the broodstock. This could lead to the development of broodstock feeds that are nutritionally optimized, effective, and cost effective to achieve optimal yields. Krill meal (KM), obtained from Antarctic krill (*Euphausia superba*) has rich nutrition profile including phospholipids, high levels of long-chain polyunsaturated fatty acids, such as EPA and DHA, and astaxanthin, and free amino acids, nucleotides and trimethylamine N-oxide (TMAO), has been vastly demonstrated to be beneficial in enhancing growth and health of different fish species including Nile tilapia. However, so far, there are no reports on the effect of KM in enhancing the broodstock performance of tilapia. Hence, the present study was conducted to determine the effect of KRM in broodstock diets for Nile tilapia, on spawning, egg quantity and quality, and survival of larvae of broodfish Nile tilapia.





(Continued on next page)

Materials and methods

Two doses (2% and 5%) of krill meal, KRM (QRILL™ Aqua, Aker BioMarine Antarctic AS, Lysaker, Norway), were tested in the broodstock diets for Nile Tilapia, in comparison to a commercial tilapia broodstock feed produced in the USA. 12 hapas (submerged cages) were employed in this study, with 4 hapas/diet group. Fish were stocked at an industry standard 3:1 sex ratio. The feeding trial was conducted at Benchmark Genetics - Spring Genetics in Florida, USA. The fish were fed their respective test diet for 12 weeks.

Results

Over the course of 12 weeks, trends for positive effect of KRM diets were observed towards total egg production (2% KRM has 20% more total eggs than control; 5% KRM has 30% more total eggs than control), total number of spawning females (2% KRM has 13% more spawning females than control; 5% KRM has 20% more spawning females than control), and larval survival 10 days post-hatching (5% KRM has 10% more larvae than control). In addition, the proximate composition of eggs indicated higher fat content in KRM fed groups in comparison to the control group.

Conclusion

This is first pilot study demonstrating the trends of positive effects of KRM towards reproductive performance and larval survival in Nile Tilapia.

SINTEF ACE ROBOTIC LAB – AUTOMATION AND ROBOTICS TO DRIVE UP EFFICIENCY AND MINIMISE RISKS IN FISH FARMS

Eleni Kelasidi*, Sveinung Johan Ohrem, Herman Biørn Amundsen, Bent Haugaløkken, Linn Danielsen Evjemo, Biao Su, Espen Eilertsen, Magnus Oshaug Pedersen, Leif Magne Sunde

SINTEF Ocean, P.O.Box 4762 Torgarden, 7465 Trondheim, Norway
*E-mail: eleni.kelasidi@sintef.no

Introduction

Aquaculture is an important global contributor to the production of seafood for human consumption. However, this industry is also known for a substantial HSE risks and a high frequency of work-related injuries. Consequently, increasing the automation level of high-risk operations within aquaculture could lead to economical as well as social and ethical benefits. Increased automation can contribute to improving the level of control humans have over aquaculture operations by facilitating increased use of technological solutions and unmanned underwater vehicles (UUVs) [1]. To target these challenges, the newly established SINTEF ACE-RoboticLab aims to be the pioneer for developing both basic and applied research on autonomy and robotics with the overall target being to contribute increasing efficiency and objectivity during daily operations in fish farms, and thus provide solutions that will contribute to addressing the current challenges in the aquaculture domain (Figure 1).

Materials and methods

Research on autonomy and robotic solutions in SINTEF Ocean targets the development of dedicated solutions for the aquaculture industry and thus aims to address the industry's challenges for optimal and sustainable production. Therefore, as a part of the SINTEF ACE infrastructure hub, SINTEF Ocean recently established the SINTEF ACE-RoboticLab which aims to create innovative tools and autonomous solutions which expand the ability of the aquaculture industry and improve precision and efficiency in the aquaculture segment. To accomplish the vision of the lab, we pursue projects focused on autonomous and robotised solutions applied to the aquaculture industry [2]. Our team's vision has targeted research and solutions for autonomous intelligent systems capable of long-term autonomous operations in unknown, complex and dynamically changing environments in the aquaculture industry.

One of the main goals of SINTEF ACE-RoboticLab is to introduce and develop innovative solutions that will be able to operate in any environment and in interaction with the biomass under any possible conditions, while performing demanding aquaculture operations [3]. The SINTEF ACE-RoboticLab research group addresses the challenges related to the development of autonomous technological solutions and control of systems that adapt to different situations and cope with an uncertain and dynamically changing environment. With a large focus on interdisciplinary research linking the fields of technology and biology, we perform fundamental research on the modelling of UUVs, aquaculture structures, fish behaviour and environmental disturbances, and on advanced control strategies for autonomous navigation and exploration of unmanned underwater and surface vehicles operating in dynamically changing environments.

Results

Through variety of projects, we developed methods and robotic solutions for autonomous operations in fish farms (to name few of them: CHANGE, ResiFarm, NetClean 24/7, Autosmolt2025, RACE-Fish Machine Interaction, RACE Digital Cage, SalmonInsight, Indisal, Crowdquard, CageReporter, Artifex, Bioracer, Sensordrone, MerdROV and several others). We own and use a variety of robotic systems including aerial, surface and underwater vehicles. In addition, the group contributes to the development of new, dedicated robotic systems suitable for operating in fish farms. Aquaculture Robotic Simulation Framework has also been developed in our group based on the FhSim – Simulation of Marine Operations and Systems, which features a large collection of mathematical models including ships, fishing trawl systems, aquaculture net cages, closed containment systems, fish behaviour and energetics, feeding systems, remotely operated vehicles (ROVs) [2]. We have a very close collaboration with the SINTEF ACE – Facilities and resources for Precision Fish Farming (PFF), and technology for better fish welfare to secure developing technological solutions that match the biological perspectives. Several autonomous features have been demonstrated in industrial scale fish farms (Figure 2-3).

(Continued on next page)

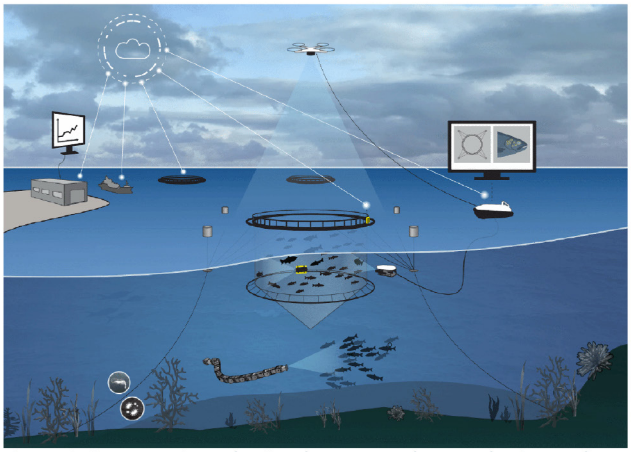


Figure 1: SINTEF ACE-RoboticLab – Aquaculture Robotics and Autonomous Systems Laboratory: Development of new knowledge and technology for optimized operations in fish farms

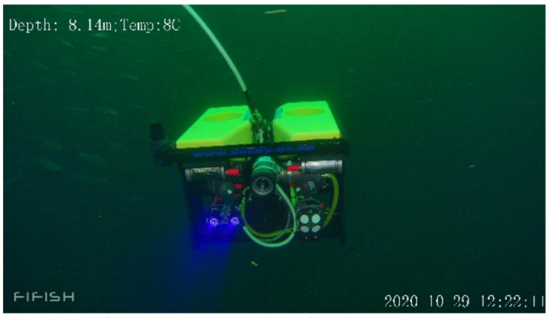

Figure 2: The ROV equipped with a laser.

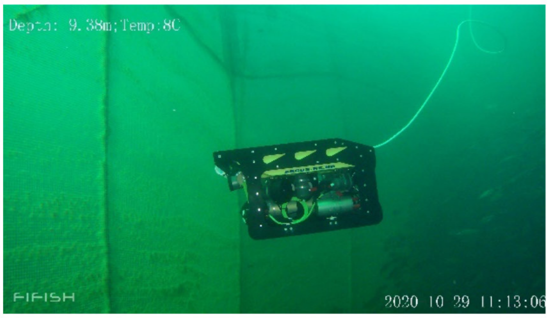

Figure 3: The ROV during net following.

Conclusion and future work

Management of sea-based fish farms typically entails manual, and often challenging, inspection operations to monitor equipment, structures and biomass, which may result in sub-optimal and costly operations, insufficient maintenance, a general lack of control in daily routines and potential high risks for welfare of personnel and fish. This implies a need for new methods and technology for operations in modern fish farms, especially when moving operations to more exposed locations with more challenging environmental conditions, and new farm designs. Therefore, the goal of establishing the SINTEF ACE – RoboticLab is to contribute to making operations in the aquaculture industry more efficient by using different types of autonomous concepts and robotic systems. We aim to develop new knowledge and technology for the underwater robotics systems of the future, where these systems must coexist and cooperate with living fish and flexible structures during operations. By incorporating biological parameters (i.e. fish behaviour) into the mathematical models, this interdisciplinary approach will provide a foundation for the resident underwater robotics systems of the future and thus enable them to operate in adaptation to live fish. This impact will be expressed both in the short term by enabling new research activities, and in the long term by resulting in innovations that help industries to improve the safety and efficiency of using robotics systems in demanding operations.

Introduction

Operational Welfare Indicators (OWIs) are the tools a stakeholder uses for monitoring fish welfare. A welfare indicator that has particular utility is behaviour (e.g., Dawkins, 1999), but it is often difficult to quantify, and the auditing process is usually manual and time consuming (Noble et al., 2018). The emerging digitalisation of fish welfare monitoring can provide automated tools for quantifying fish behaviour in experimental and commercial settings. This can provide stakeholders with a wider and more rapid overview of changes in fish behaviour, helping them make more informed and robust decisions in both the short- and longer-term.

The main goal of this study was to develop a deep learning framework to automatically extract and analyse a variety of behavioural traits of Atlantic salmon parr held in experimental tanks. Specifically, the first aim was i) to apply the deep learning framework DeepLabCut (DLC; Mathis et al., 2018) to identify key body parts on the fish, and ii) use this information to determine the distribution of fish and quantify its activity in relation to feeding events.

Material and Methods

Video footage used in this study was sourced from a series of experiments focusing on social network analysis of Atlantic salmon parr (*Salmo salar* L.) in 300 l plastic circular tanks, holding six fish (137.5±20.1g) at initial stocking densities of 4.1 ± 0.1 kg/m^3 (see Cañon Jones et al., 2010 for more information). A video camera (Panasonic© VWR42 with Panasonic© WV-LA4R5C3B lenses) was placed one metre above the water surface. Two videos, A (10 minutes duration) and B (20 minutes duration) recorded at 25 frames per second (fps), have been used in the study. The first video (A) documents fish in standard non-feeding conditions. The second video (B) includes six feeding events where feed was dispensed for ca. 1 second every 3 minutes by an automatic feeder.

The DLC framework was used to estimate the x and y coordinates of seven keypoints distributed along the dorsal length of the fish. Such keypoints were manually annotated over 700 video frames for model training and validation purposes. A workstation with two instances of NVIDIA GeForce RTX 3090 run on an AMD Ryzen Threadripper 3970X was used for annotation. To visualise the data, fish coordinates were plotted using heatmaps documenting activity over one-minute intervals following feed delivery (i.e., three intervals), and the home range was defined as the region holding 50% of detections in Video A. The probability mass and probability density functions were calculated using the Gaussian Kernel density estimate. The overall DLC framework used in the study is outlined in Figure 1. Heatmaps were quantified based on the proportion of key points that were detected outside the home range of the fish.

Results and discussion

The trained model successfully estimated key points of the fish with less than 1 % error and false detections. Fish distribution in the tanks, within and between feeding events is illustrated as a 3x6 matrix of heatmaps in figure 1(c). The area directly in front of the water inlet was the preferred location for fish in this tank, where fish generally held a stationary position facing the water current. Analysis reveals the fish exhibit a large foraging home range during the first feed of the day. As the number of feeding events increase, the home ranges of individual fish slowly decrease back to baseline non-feeding levels. By the fifth feeding event, home range is similar to baseline levels and fish stop feeding by the sixth feeding event. These results demonstrate that the automated analysis of home range around a feeding event can be a promising feed management tool for small groups of tank-held salmon in experimental studies. Variability in home range around a meal can also be a potential proxy indicator for both appetite and satiation.

(Continued on next page)

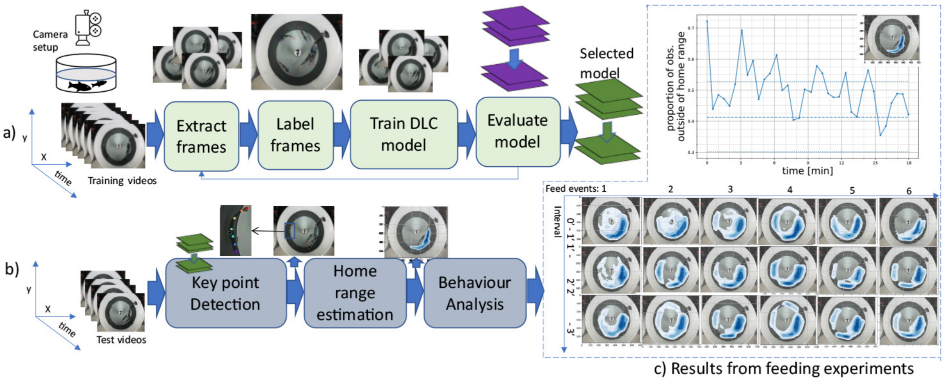

Fig. 1 An overview of the DLC framework used to analyse the home range and distribution of the fish. The first part outlines (a) the steps taken to annotate, train and develop a deep learning model to estimate and predict key body parts of the fish. The second part outlines (b) how fish swimming trajectories were used to assess fish distribution and home range within the tanks in and around a meal. The results of the study are outlined in (c).

FREE AMINO ACIDS MIX SUPPLEMENTATION ON DIET IMPROVES GROWTH PERFORMANCES, FEED UTILIZATION, ANTIOXIDANT AND IMMUNE RESPONSES, DIGESTIVE ENZYMES AND FATTY ACID COMPOSITION OF NILE TILAPIA FINGERLING *(Oreochromis niloticus)*

Kersanté Pierrick*, Eakapol Wangkahart, Le Reste Guillaume

BCF Life Sciences, Boisel, 56140 PLEUCADEUC – France
pkersante@bcf-lifesciences.com

Introduction

Mixes of free amino acids (MFAA) obtained from extensive hydrolysis of full protein chains are interesting candidates for aquaculture feeds. In addition to their specific amino acids profile, their low molecular weight ensure a fast and high level of assimilation with synergetic effects during the first development stages. Previous investigations on shrimp *(L.vannamei)* underline MFAA positive effects on zootechnical performances (Le Reste et al., 2019) and survival in case of bacteriological and viral challenges (Kersanté et al., 2021). The results presented here have been obtained from an eight-week study conducted to investigate the effects of a mix of 17 amino acids obtained from extensive hydrolysis of poultry keratin, on the growth performances, biochemical parameters, innate immune response, muscle composition, digestive enzyme activity and muscle fatty acid composition of Nile tilapia (*Oreochromis niloticus*) (Wangkahart et al., 2022).

Protocol

450 healthy juvenile Tilapia (*O. niloticus*), 4.76 ± 0.05g initial weight (IW) were purchased from Maha Sarakham province, Thailand. The fish were acclimatized to laboratory conditions in circular fiberglass tanks for 2 weeks, in the aquarium of the Division of Fisheries, Mahasarakham University. During this period, fish were fed with a commercial diet containing 32% of protein and 4% of fat (Charoen Pokphand Foods, CP, Thailand). After acclimatization, fish were allocated in 15 floating cages ($2*1.5*1.5m^3$) in five triplicates groups at a stocking density of 30 fish per cage, in an open circulatory freshwater system.

In order to meet or exceed the nutritional requirements of tilapia established by the National Research Council (2011), we formulated five isonitrogenous (32% crude protein) and isolipidic (4.2% crude lipid) diets, supplemented with MFAA.

Four different concentrations of MFAA were tested: 2.5 g/kg of feed, 0.25%, 5 g/kg of feed 0.50%, 7.5 g/kg of feed, 0.75% and 10 g/kg of feed, 1.00%, respectively MFAA0.25, MFAA0.50, MFAA0.75 and MFAA1.00. The MFAA was included into the pellet mix, before pelletizing.

Fish were fed twice a day (8am, 4pm). A daily feeding rate of 5% of the biomass was applied. It was adjusted every 2 weeks, according to fish growth. The experimentation was conducted during 8 weeks.

Results

The data underline interesting improvements of growth parameters with MFAA supplementation. A dose effect could be seen with best performances achieved for animals fed with MFAA1.00 treatment, generating significant gains on biomass evolution with final weight (FW) improved by 28.9%, weight gain (WG) by 31.5%, specific growth rate (SGR) by 8.9% and a feed conversion ratio (FCR) reduction of 24% after 8 weeks ($P<0.05$).

Interestingly, growth performances are also correlated with modifications in body composition indices and feed utilisation. These parameters clearly underlined better performances for all MFAA treatments ($P<0.05$), with significant gains, related to a dosage effect of MFAA, on protein efficiency ratio (PER) improved by 29.2%, carcass yield by 9.3% and a reduction of the viscerosomatic index (VSI) of 19.5% for MFAA1.00 ($P<0.05$).

(Continued on next page)

Fillet composition analysis underlined significant influence of MFAA on the fillet lipid content (+88% with MFAA0.75). Thirty-seven different fatty acids were exanimated in the muscle tissues of the fish following the different diet treatments. Most of the analysed individual monounsaturated fatty acids (MUFA) such as palmitoleic acid (C16:1), oleic acid (C18:1 n9c), and erucic acid (C22:1 n9), as well as the total amount of MUFA, were found to be higher in the muscle from fish fed any MFAA diet compared to the control group ($P<0.05$). Interestingly, linoleic acid (C18:2 n6c) and α–linolenic acid (C18:3 n3) levels were higher in the fish fed MFAA0.75 and MFAA1.00 diets ($P<0.05$).

In relation with these observations, the fillet color measured on ventral and dorsal regions was also significantly influenced with higher value of L, expressing the lightness and white color of the fillet, respectively +13.7% and +7.2% for the L value of the fillet ventral and dorsal regions with MFAA0.75 ($P<0.05$).

Digestive enzyme activies (amylase, lipase and proteinase) were significantly increased with MFAA0.75 and MFAA1.00 treatments, respectively from 34.9%, 10.4% and +39.9%, in comparison with the negative control ($P<0.05$).

Discussion

This study underlined some particularly interesting effects of MFAA when applied on Nile tilapia fingerling feed. Firstly, regarding growth parameters with positive effects on biomass and feed utilization. Interestingly, we underline strong improvements of VSI, fillet composition and fillet color. We can hypothesize a relation between these observations and a better assimilation of the feed due to an optimisation of the energy by the digestive system. In addition, we can hypothesize that the more pronounced white color of the fillet is probably in relation with a reduction of fat oxidation.

Interestingly, we noted a reduction of the VSI, potentially linked with a higher amylase activity generating a better utilization of the polysaccharides. This parameter probably induce a lower fat deposition around the viscera and a higher lipid transfer to the fillet. The results also revealed higher contents of important fatty acids such as oleic acid (C18:1 n9c), linoleic acid (C18:2 n6c) and α–linolenic acid (C18:3 n3) in fish fed with MFAA.
The strong effects of MFAA on digestive enzymatic parameters with positive impact on body condition indices and fillet quality open new development possibilities to improve fish feed utilization and farming performances.

This new field of application confirms their interest as a sustainable protein source converted into an efficient functional ingredient for fish nutrition.

DEVELOPMENT OF A POLYMERASE CHAIN REACTION (PCR) AND DIG-LABELLED *IN SITU* HYBRIDISATION FOR THE DETECTION OF *Vibrio aestuarianus* AND OTHER *Vibrio* BACTERIA

Gary F. Kett[1], Sarah C. Culloty[1,2], Marcel A.K. Jansen[1], Sharon A. Lynch[1]

[1]Aquaculture & Fisheries Development Centre, School of Biological, Earth & Environmental Sciences & Environmental Research Institute, University College Cork, North Mall, Cork, Ireland

Introduction

Vibrio bacteria pose a significant threat to fish and shellfish aquaculture with *Vibrio*-associated mortality episodes impacting stocks in aquaculture settings globally. *Vibrio aestuarianus* is especially problematic in Pacific oyster *Crassostrea gigas* culture. Diagnostic tools currently used to detect or confirm *V. aestuarianus* are real-time quantitative (q)PCR and fluorescent *in situ* hybridisation (FISH). These tools are expensive and can demand highly specialised equipment. This study aimed to develop a novel generic PCR and DIG-labelled *in situ* hybridisation (ISH) for the detection and confirmation of *Vibrio* bacteria. These tools allow for blanket screening of hosts and environmental samples, as well as the microscopic localisation of bacterial infections. Both diagnostic methods were developed for use synchronously with other methods that are specific to certain *Vibrio* spp.

Material and methods

New primers (VibF3/VibR3) were constructed to amplify a partial sequence from the 16S ribosomal RNA gene region which is common to all *Vibrio* spp. with a resulting PCR product of 286 bp. These novel F3/R3 primers were then used to create a DIG-labelled probe for use in a newly designed *in situ* hybridisation technique. Confirmatory positive (plasmid DNA) and negative (dH_2O) controls were used in the PCR and ISH method design. Diagnostic findings were compared to a specific qPCR for *V. aestuarianus*. Direct Sangar sequencing of PCR products, Blastn analysis and Clustal Omega alignments were used to confirm *Vibrio* sp. Identification and assess similarity, histology was used to examine the pathology of *Vibrio* infections in oyster tissues.

Results

The PCR was shown to be sensitive compared to established protocols. A positive ISH signal was observed in qPCR and PCR positive oysters and no signal was detected in uninfected individuals. Pathologies observed in *C. gigas* tissues were similar to those described in other studies. These techniques will increase the diagnostic arsenal against this globally significant genus of bacteria.

Introduction

Genotype-by-environment interaction (GxE) is a measure of the magnitude of re-ranking of genotypes across environments. Significant GxE creates discrepancy between the expected and realized performance when the selected genetic material from the breeding nucleus is reared in divergent environmental conditions in commercial aquaculture. Estimates of GxE are lacking for many economically important traits (Sae-Lim *et al*., 2015) and need to be assessed to enable optimization of breeding programs towards development of robust genetic material for future conditions. Use of alternative raw materials in fish feed formulation is prompted by many regulatory, climatic and societal factors to guarantee future sustainable European aquaculture (Skiba *et al*., 2015). This brings upon a need to assess whether there is significant genotype-by-feed interaction; breeding companies are dependent on the assessment whether their current genetic material can express the production potential when alternative feed sources are utilized. The objective of this study was to estimate genetic parameters of growth in Atlantic salmon when fed with conventional and innovative diets.

Material and methods

Individually tagged Atlantic salmon from 75 full-sib families (Benchmark Genetics Norway) were randomly assigned in four parallel 5m x 5m cages at Gildeskål Research station (Inndyr, Norway), where two of the cages were fed with conventional marine-based diet (N=1993) and two with innovative diet (N=1960). Both feed types were formulated and produced at Aquafeed Technology Center (Nofima AS, Bergen, Norway) and were isoenergetic. In the innovative diet, 50% of the marine oil was replaced by algae and 75% of the fishmeal by insect meal. Additionally, innovative diet had no soya.

In addition to body weight (EWT), $TGC = \frac{\sqrt[3]{EWT} - \sqrt[3]{TAGWT}}{day\ degrees} * 1000$ (thermal growth coefficient) and $ADG = \frac{EWT - TAGWT}{duration\ of\ experiment}$ (average daily gain) were calculated and used as phenotypes. Multivariate model treating phenotypes among diets as different traits was fitted to estimate the genetic parameters using restricted maximum likelihood in BLUPF90 (Misztal *et al*., 2018). Genomic relationship matrix was used in the estimation.

Results and discussion

The fish from the conventional diet were at the end of the trial significantly larger (1581 g) than those fed with innovative diet (1372 g). The mortality rate in groups fed with the innovative diet was 32.2% whereas in cages fed with conventional diet it was 19.4% (overall 25.8%). The frequency of deformities (6%) and wounding (0.6%) were low, and only three individuals were registered as sexually mature. During the summer 2020 high mortalities were registered and the disease heart and skeletal muscle inflammation (HSMI) was verified causing 6% mortality independent on the diet.

Families expressed large phenotypic variation in EWT in both diets (CV=0.28) (Figure 1). Only two families had higher average growth with the innovative diet than with conventional diet. The difference in EWT family average varied from -5.8 to 32.8%. Phenotypic rank correlation for growth phenotype family means varied between 0.81 and 0.85, indicating only low re-ranking of families between the diets.

Estimates of heritability for growth traits were high: 0.41-0.45, and genetic correlations between growth traits among diets were very high (0.96-1.00), indicating no re-ranking of genotypes across diets (Table 1). Heritability for survival was low very low for both innovative (0.03) and conventional diet (0.11). Genetic correlation for survival indicated moderate re-ranking of genotypes across diets: r_g=0.68.

(Continued on next page)

	ADG_fut	**ADG_conv**
ADG_fut	**0.44 ± 0.03**	
ADG_conv	1.0 ±0.01	**0.45 ± 0.03**

Table 1. Estimates of heritability and genetic correlations for growth traits across the diets. Estimates of heritability in sub-diagonals (**bold**).

Our study showed that growth in Atlantic salmon is impaired when fed with innovative feed where large proportions of marine ingredients are replaced by algae and insect meal. We did not detect genotype-by-feed interaction in growth in Atlantic salmon during this limited growth period from average body weight of 135 g until ~1.5 kg, whereas moderate genotype-by-feed interaction was detected for general survival.

EFFECT OF VITAMIN C (L-ASCORBIC ACID) SUPPLEMENTED FEEDS ON THE GROWTH AND NUTRIENT PROFILE OF BULLSEYE SNAKEHEAD *Channa marulius*

Noor Khan*[1], Sadia Nazir[2]

[1]Institute of Zoology, University of the Punjab, Lahore-Pakistan
[2]Department of Fisheries and Aquaculture, University of Veterinary and Animal Sciences, Lahore, Pakistan

This study was conducted to determine the impact of dietary vitamin C (L-ascorbic acid) on the growth, proximate composition, amino acid and fatty acids profile in bullseye snakehead *Channa marulius* (100 g initial body weight body weight) reared in cages for three months. Fish were fed a 40% crude protein diet supplemented with various levels (0, 75, 150, and 300 mg kg^{-1}) of vitamin C in triplicates. After the feeding trial, fish fed 300 mg kg^{-1} dietary ascorbic acid shown significantly ($P<0.05$) better growth including net weight gain (104.33 g), FCR (1.67), and SGR (0.74 %) than those fed 150, 75, and 0 mg kg^{-1} (vitamin C free diet) respectively. Proximate composition of the fish was significantly influenced by the dietary treatments ($P<0.05$). The highest protein content 19.61% and lowest moisture content 72.65 % were found in T1 (75 mg kg^{-1}). Dietary vitamin C levels had also a significant effect ($P<0.05$) on the methionine, threonine, leucine, histidine, lysine, and glutamic acid of fish muscle. There was no significant difference observed in the fatty acid profile ($P>0.05$) of fish. Conclusively, including 300 mgkg^{-1} of vitamin C in the diet for snakehead in artificial pellet feed improved fish growth without affecting nutrients profile.

THE EFFECT OF DIFFERENT LIVE FEED ORGANISMS ON LARVAL LUMPFISH (*Cyclopterus lumpus*)

Introduction

Lumpfish (*Cyclopterus lumpus*) is a cold-water species much used as a cleaner fish to combat the sea lice problem in sea-based salmon farming. The commercial production has increased to around 35 million juveniles in 2020 (Norwegian Directorate of Fisheries, 2022). Lumpfish larvae are commonly fed formulated feeds from 2 to 5 days post hatch (dph). The nutritional requirements of the lumpfish larvae are largely unknown, and the production often results in variable growth, survival and delousing efficiency. Suboptimal nutrition during early life history in any animal may have lasting effects (Winick and Noble 1966), with possible suboptimal health and welfare for later life stages. Wild lumpfish larvae and juveniles mainly feed on crustaceans (Ingólfsson and Kristjánsson, 2002), and copepod and cirripedia early life stages may have the potential to improve their growth and survival. If lumpfish larvae are fed *Artemia*, they grow better than if they are fed formulated diets (Brown, 1986; Kjørsvik, unpublished); but high mortalities can occur during weaning from *Artemia* to formulated diets at 25 – 30 dph (Powell et al., 2018).

Our aim was to evaluate the effects of different feed types (formulated diet, enriched *Artemia*, cryopreserved cirripedia, and cultivated copepods) and different feeding regimes on growth and survival. We evaluated several developmental parameters and functional responses in the larvae such as bone ossification, skeletal muscle and liver development, and molecular as well as microbial and biochemical parameters.

Materials and methods

In a 35-day start feeding experiment (34 ppt salinity, 10 °C) with lumpfish larvae, the larvae received different feeds from 2 - 21 days post hatch (dph). Five different treatments were tested: (1) Control: formulated diet (Gemma micro 150 and 300); (2) enriched *Artemia* nauplii; (3) cirripedia (cryopreserved cirripeds from Planktonic AS); (4) *Acartia tonsa* nauplii and copepodites (2-9 dph, from CFEED AS) and weaned to formulated diet GEMMA micro 150 ("Cop/FD"), and (5) *A. tonsa* nauplii and copepodites and weaned to cirripedis ("Cop/Cir"). All larvae were weaned to a common formulated diet (Gemma micro-300) from day 21 – 35 dph, with a period of co-feeding from day 21 – 25 post hatching.

Results

Growth rates in larvae fed *Artemia* were significantly higher than for all other groups during the first 30 dph, with larvae fed copepods and formulated diet showing the lowest growth (Fig. 1). The larvae fed cirripedia had a slow growth during the live feed period but demonstrated a much higher growth rate after weaning to the formulated diet. At the end of the experiment (34 dph), no difference in SL and DW growth were found between larvae fed *Artemia* and cirripedia, whereas larvae from all other groups were significantly smaller.

Histology showed that the degree of liver vacuolization was a good marker for nutritional condition in lumpfish larvae, and no dietary effects on muscle development were observed in relation to body size. Larvae fed *Artemia* had significantly higher fin ossification scores than larvae from the other groups in relation to both size and age, followed by the Cirripedia- and Cop/Cir- larvae.

Microbiological diversity (*alpha* and *beta* diversity) showed significantly higher microbial diversity in larval samples compared to water samples. The total gene expression profile indicated very similar larval expression profile in all treatments at 10 dph, with more diverse responses between the larval groups at later stages. Lipid analyses are still being processed.

(Continued on next page)

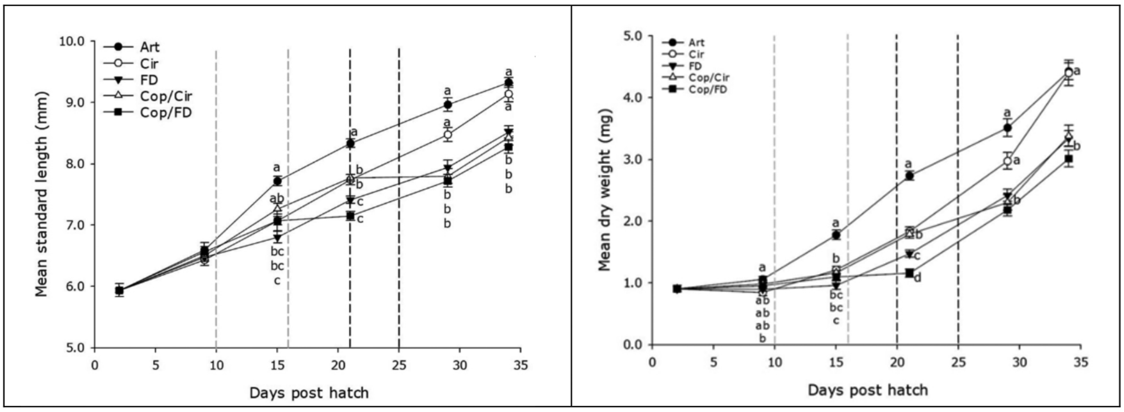

Figure 1. Lumpfish larval growth in relation to start-feeding regimes. Mean standard length (left) and mean dry weight (right) of lumpfish 2-34 dph. Grey dashed lines indicate weaning from A. tonsa *to either formulated diet for the Cop/FD group, and to cirripeds for the Cop/Cirr group. Black dashed lines indicate weaning to formulated diet for all groups. Significant differences (p<0.05) between treatments at a given dph are indicated by different letters. Error bars indicate ± standard error (SE).*

Discussion and conclusions

In our experiment, using enriched *Artemia* nauplii caused early fast growth and good development, whereas feeding with cryopreserved cirripedes lead to higher growth rates in the later stages of the experiment and during weaning onto formulated feeds. These two prey items also resulted in the highest survival and the largest larvae by the end of the experiment. Startfeeding with copepod nauplii or formulated diet both resulted in the overall slowest growth, and the earliest poor nutritional status during the earliest development might have had a long-lasting effect with poor growth and development throughout the whole experiment. The results will be discussed in relation to our mapping of biochemical, histological, molecular and microbial parameters.

Introduction

Environmental enrichment is now a well-established practice to improve fish housing conditions for a positive state of welfare, both mental and physical (Arechavala-Lopez et al., 2021). Occupational enrichment emerges as a promising strategy for improving the welfare of farmed animals. This form of enrichment aims to stimulate cognitive abilities of animals by providing them with more opportunities to interact with and control their environment. However, occupational enrichment, and its effects on fish welfare indicators, remains a recent and understudied topic in fish production. Predictability of salient daily events, and in particular predictability of feeding, is currently one of the most studied occupational enrichment strategies and can take several forms (Bassett & Buchanan-Smith, 2007). In fish, while temporal predictability (based on the time of day) of feeding has been widely investigated (Cañon Jones et al., 2012; Chapman et al., 2010; Holley et al., 2014; Sánchez et al., 2009; Ferrari et al., 2016)but rather as an adaptive benefit. This variability comes from consistent differences in behavioral and physiological responses among individuals to a changing/challenging environment, named \"coping style\", \"temperament\" or \"personality\". Many studies have described how to characterize personality traits and how to assess their consistency over time and between different contexts; however, little is known about the environmental factors shaping personality development. Because contrasting personalities are maintained with evolution, this lead to the widespread assumption that genes play a predominant role in personality. In many cases, personality traits are however also likely to be determined by individual experience, which is probably at least as important as genetics in shaping personality. The aim of this study was to assess how environmental variability (herein food predictability, signalled predictability (based on a signal, such as light or sound) has received little attention (Cerqueira et al., 2017; Galhardo et al., 2011). These studies result in differing effects on fish welfare, depending on the type of predictability used and the ecology of the species. The present study aimed to determine which feeding predictability would be most appropriate for rainbow trout, the main continental farmed fish in Europe, and what the consequences might be for their welfare.

Materials and Methods

We tested four feeding predictability conditions for two weeks: temporal (based on time of day), signalled (based on bubble diffusion), temporal + signalled (based on time and bubble diffusion), and unpredictable (random feeding times). Behavioural and zootechnical outcomes recorded were swimming activity, aggressive and stereotypic behaviours, emotional reactivity, and growth.

Results

Our results revealed that rainbow trout can predict five daily feedings with time as the only predictor as early as two weeks of conditioning. However, this predictor alone also increased aggressive and stereotypic behaviours, suggesting that the use of time as the sole predictor of feedings in husbandry practices may be detrimental to fish welfare. The combination of temporal and signalled predictability elicited the highest conditioned response and the level of pre-feeding aggression and stereotypies tended to be lower than for temporal predictability alone. Rainbow trout were also successfully conditioned to use bubbles as the sole predictor of feeding, and this condition resulted in fewer pre-feeding agonistic and stereotypic behaviours than in the temporal predictability condition. Interestingly, we also found that bubbles were highly attractive regardless of the condition considered.

Conclusions

The use of bubbles as a feeding predictor could be an interesting approach to improve rainbow trout welfare in farms, by acting as both an occupational and physical enrichment.

Introduction

In recent years, a massive invasion of non-native marine species has been observed in the Mediterranean Sea. Particularly, among 17,000 existent species, more than 1,000 are non-native species of which, more than 300 have been recorded in Greece. A large number of those non-native species are considered invasive and have caused significant ecological problems. Some of those are the displacement of native species, genetic drift, structural change of native communities, food web alterations, and others. In addition, their presence has damaged local economies, as fishery and tourism are affected.

A characteristic example of a Lessepsian migrant is the genus *Lagocephalus*. *Lagocephalus* belongs to the family of Tetraodontidae. *Lagocephalus* sp. which is not a target for inshore fishing, due to its toxicity and related marketing restrictions (Katikou et al., 2009). In addition, *Lagocephelus* sp. is less likely to compete or be hunted by other species. All the above factors, as well as the fact that it can be caught by almost all types of fishing gear, lead to its excessive fishing as a bycatch (Nader et al., 2012).

The potent exogenous neurotoxin, TTX, is found in the *Lagocephalus* sp. tissues. TTX is produced by marine bacteria, such as *Vibrio alfinolyticus*. The concentration of this neurotoxin depends on the developmental stage of the fish. Some human case reports demonstrated serious effects at a dose of 0.2 mg, corresponding to 4 μg/kg body weight (EFSA, 2017).

Lagocephalus sp. has already adapted to the habits of the Mediterranean Sea and is causing long-term damage, by disrupting the ecology of its living areas, and short-term damage, by destroying fishing gear and especially those of small-scale coastal fishery. Therefore, it is imperative to find ways to exploit this new fish species, which will augment the revenue of the fishery sector as well as the aquaculture sector. The present study focuses on the use of *Lagocephalus* sp. for fish meal production, as the fundamental ingredient of fish food. Thus, the deactivation of TTX from fish tissues is essential.

Materials and methods

In total 39 individuals of *Lagocephalus sceleratus* were collected from the Aegean Sea and were freshly transferred to the labs of HCMR, where a somatometric analysis took place. Subsequently, the fish were grounded and their sex was determined macroscopically by visual inspection of gonads. The fishmeal was obtained after cooking, press drying the fresh grounded fish and milling successively. In the stage of press drying, most of the moisture and some or all of the oil were removed (stick water, SW). After press drying, the wet meal (WM) was left overnight in an air oven to dry and the final dry meal (DM) was collected the following day. Finally, fishmeal (FM) was treated at different temperatures (ranging from 160 to 510°C) and exposure times (ranging from 10 secs to 40 min). TTX heat inactivation was then analyzed by TTX ELISA (EuroProxima, 5191TTX) and liquid chromatography in combination with sequential mass spectrometry (LC-MS / MS) (Christidis et al., 2021). The statistical analysis was done by the GraphPad Prism v. 8.4.2. software.

Results and Discussion

Total length (TL) ranged from 21.5 to 72cm, total weight from 100 to 4300g. From the 39 *L. sceleratus* samples, 19 were males and 13 females. The initial processing of the samples at three different exposure times (30-60-90 min at 80°C) did not affect the TTX concentration. Furthermore, almost identical concentrations of stick-water and WM (the two products resulting after the press stage) were observed, revealing that approximately 50% of the TTX is removed from the sample at this stage. Nevertheless, the concentration in the samples still remained at a high level. According to both TTX detection methods (LC-MS/MS and ELISA), heat treatment of the samples at 200°C for 5 min, 210°C for 10 min, and 225°C for 1 min resulted in complete inactivation of the toxin (below the detection limit, Figure 1). Specifically, the ELISA method

(Continued on next page)

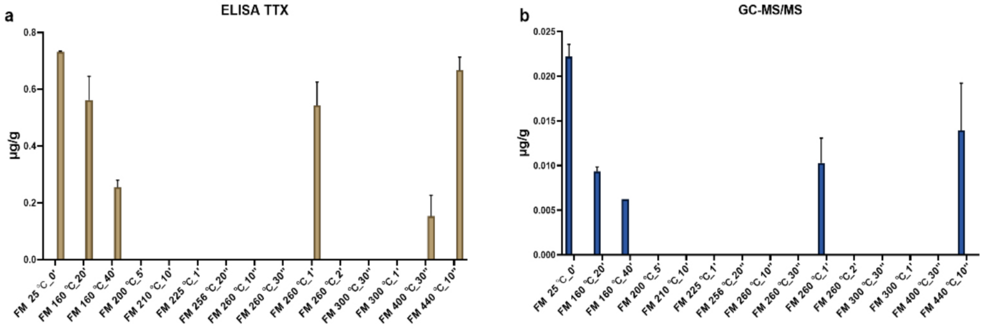

Figure 1: Deactivation of TTX (μg /g) after heat treatment of fishmeal (FM: Fish Meal) at different times and temperatures. **a.** Biochemical ELISA method and **b.** Liquid chromatography method.

showed that treatment at 210°C for 20 min and at 160°C for 40 min, reduced the TTX concentration from 3.4 μg/g to 0.5 μg/g and 0.2 μg/g, respectively. While, very low concentrations were detected at 160°C for 40 min, 260°C for 2 min and 400°C for 30 sec. Analysis of the samples by liquid chromatography showed excellent results (below the detection limit) at 160°C for 40 min and 400°C for 30 sec. Despite the differences in the order of magnitude between the two methods, it appears that both ELISA and chromatography come to common conclusions (Figure 1).

Both temperature and exposure time are equally important factors. Particularly noteworthy is the fact that concentrations below the detection limit were observed at temperature values even 100°C lower compared to previous studies. In conclusion, the present study showed the successful deactivation of TTX in fishmeal produced exclusively by *Lagocephalus*, through its exposure to specific temperature-time conditions, to utilize it for the production of fishmeal. The produced innovative raw material will be evaluated for its nutritional value as the main ingredient for the nutrition, health, and quality of the final product of cultured Mediterranean species.

Introduction

The salmon industry is one of the most important industries in rural Norway and the industry is known for its innovation and use of new technologies, but welfare of farmed salmon is becoming a growing concern (Sommerset et al., 2020). Nephrocalcinosis is one of the challenges in Atlantic salmon, described as mineral deposits in the kidney. Although the prevalence of nephrocalcinosis among wild fish is unknown it is likely that the occurrence in farmed salmon is related to the intensive conditions in aquaculture (Applegate et al., 2016; Béland et al., 2020; Bjerknes et al., 1994; Klosterhoff et al., 2015; Lewisch et al., 2013). The objective of this study was to determine the prevalence and severity of nephrocalcinosis in farmed Atlantic salmon in Mid-Norway, and physiological changes related to the disease.

Material and methods

A total of 810 farmed Atlantic salmon were sampled from 14 fish groups. The fish was euthanized with a tranquilizer overdose and the following were collected; plasma, mid-kidney tissue and mineral deposits when visible. Histopathology was performed on the mid-kidney tissue and nephrocalcinosis was defined as presence of amorphous, basophilic deposits in tubules, collecting ducts and excretory ducts. The mineral deposits were analyzed using by attenuated total reflection Fourier transform infrared spectroscopy and the plasma parameters were measured with an automated dry chemistry analyzer.

Results

Nephrocalcinosis was observed in all the nurseries in this survey, even though the prevalence varied greatly. More than half of the individuals with nephrocalcinosis had mild changes in the kidney tissues. The total proportion of fish with nephrocalcinosis was 45% in the nurseries. Among fish that were sampled one month after transfer to sea, the prevalence of nephrocalcinosis had decreased to 18%.

Amorphous carbonate apatite (amCAP) was the most prevalent mineral. Struvite, brushite, whitlockite and newberyite were found in different combinations together with amCAP. A considerable proportion of fish affected by nephrocalcinosis showed plasma chemistry that differed from unaffected fish in several of the analyzed parameters, with elevated calcium and magnesium being the most predominant changes.

Discussion

The majority of salmon affected by nephrocalcinosis displayed mild changes in the kidney. The mineral deposits were mainly identified as amCAP. amCAP indicates rapid precipitation. The formation of carbonate apatite (CAP) begins at pH ≥ 6.8, with an increasing ability to aggregate with increasing pH (Olszynski et al., 2015). The pH of the urine was not measured in this study, but Roy and Lall (2004) determined that normal values for urine pH in Atlantic salmon, are around 7.5. Considering that amCAP and CAP have similar chemical properties, the normal high urine pH of salmon may predispose it for calcium phosphate precipitation in the kidney, but the underlying mechanisms of nephrocalcinosis in fish not known.

(Continued on next page)

The proportion of fish with nephrocalcinosis decreased after transfer to sea in fish with mild forms. This may indicate that mild changes in the kidney are reversible after the transfer to sea. Our data shows that fish with mild changes display elevated calcium, phosphate, AST, lactate and glucose concentrations in plasma, which are all signs of decreased welfare. Fish that were affected by moderate and severe forms of nephrocalcinosis exhibited much higher concentrations of magnesium in their plasma as well. The primary site of magnesium excretion in fish is the kidney and elevated concentration of plasma magnesium has previously been linked to kidney damage (Nieves-Puigdoller et al., 2007; Singh et al., 2002). This study revealed that plasma chemistry analyses is not adequate to diagnose nephrocalcinosis. Normal blood chemistry values do not necessarily indicate absence of nephrocalcinosis, since a notable proportion of the fish with nephrocalcinosis displayed plasma chemistry values within the normal intervals. On the contrary plasma chemistry values can be used as preliminary diagnosis for the disease, as changes in calcium, magnesium, glucose and AST were observed in a pronounced part of the fish affected by nephrocalcinosis.

E-mail: sophie.koch @wur.nl

Introduction

In recent years, there has been great interest in seaweed farming in Europe for several reasons. Seaweeds are seen as a relevant source of biomass, such as food, feed, materials, biofuels, fertilisers and as a gelling agent and provide positive environmental externalities such as mitigating ocean acidification and maintaining ecosystem services such as generating habitat (Duarte et al., 2020; Duarte, Wu, Xiao, Bruhn, & Krause-Jensen, 2017; Theuerkauf et al., 2019; Xiao et al., 2021).

The European algae market so far represents a marginal portion of global seaweed production, while Asian suppliers account for around 87% of global supply (Vincent, Stanley, & Ring, 2020). Projects such as PROSEAWEED provided options for increasing the sustainable production and sustainable harvesting of algae culture in Europe with the aim to implement a successful large-scale farming, reducing transport costs and increasing the local seaweed industry and its attractiveness on the market.

Problem definition

There are currently no standardized farming methods or cultivation structures, perfectly domesticated seaweed species, or a guidebook for the ideal farming site. The risk seaweed cultivators are facing, such as weather conditions, losing one whole harvest due to unpredictable environmental hazards, or not being able to sell at a profitable price, can hinder the development of the market.

Objective

As part of PROSEAWEED, it was looked into what can be learnt from successful European seaweed farms, and how can that help to improve the business case of other new farms, for instance, in the Dutch North Sea and even large-scale seaweed farming.

Methodology

We conducted a literature research, reviewing publications on the economics of seaweed cultivation in Europe. The quantitative data was very limited and since every farm has their own approach to cultivating and harvesting, comparisons were difficult to make. We then focused on qualitative data, compiling factors that could lead a European seaweed farm to success and discussed them in detail with three successful seaweed companies.

Intended output

Learning from each other in such a young industry is key. The proposed presentation would like to display our findings on success factors for European seaweed farms findings and allow for further knowledge exchange from other seaweed farmers and even more important from other more established aquacultural industries.

Introduction

Selective breeding (SB) is generally a very effective way for the genetic improvement of important quantitative traits in fish (Gjedrem et al., 2012). However, in most cases the SB is practiced in aquacultures with a higher level of man-managed conditions, minimally concerning the feeding of fish. Little is known about performance of genetically improved stocks in nature-close pond management of the Central Europe. Here, ponds resemble shallow natural lakes or wetlands more than man-made water works. The pond management is based on the utilization of natural food developing in ponds by fish and it is often restricted by a local legislation. The best economic model is when the growth of fish is ensured from 50 % by natural food and 50 % by a supplemental feeding. Each pond is unique water ecosystem with productivity influenced by local conditions. There is a question if genetically improved carp stocks can better utilize the pond ecosystem productivity and increase the fish mass yield (MY) per a unit of water area. Otherwise, the SB in such management had very limited applicability. This study was done to answer the open question.

Materials and methods

For the study, one genetical group of carp with lower performance (M2) and the other one with higher performance (M2 x AL) were selected. These two groups of mirror scaliness phenotype were repeatedly reared and monitored under standard pond management (water area of ponds was 0.13 – 14.3 ha) of a Czech fish farm for three years (2019-2021). Altogether, there were 61 ponds monitored, 24 of them for age category (AC) C_0-C_1, and 37 of them for AC C_1-C_2. With each stock, a control group (CG) of scaly phenotype was reared to evaluate the status of pond conditions and to correct obtained data of the two mirror stocks. The CG was of the same origin in all ponds. It was assumed that differences in the performance of the CG among ponds are given by different rearing conditions. Ponds with CG survival less than 5 % for AC C_0-C_1 and less than 40 % for AC C_1-C_2 were discarded out of the study as representing non-standard conditions with unexpected biases. Thus, the statistical analysis concerned 21 ponds with M2 and 19 ponds with M2 x AL mirror group. The data for mean weight and survival of the mirror stocks were corrected according to Linhart et al. (2002). The MY of mirror stocks per ha of pond water area was expressed as a rate corresponding to MY of the CG of the same count as the mirror group. The data were analysed for each AC and in total using several statistical approaches at significance level of $\boldsymbol{\alpha = 0.05}$, namely one-way ANOVA (in case of variance homogeneity for corrected data), non-parametric Mann-Whitney U test (in all cases) and ANCOVA (for mean growth yield and survival) with appropriate value of the control group in the same pond as covariate (Kocour et al., 2005).

Results

It was shown that carp group with expected higher performance (M2 x AL) displayed indeed better performance and MY per water area of pond within each AC as well as in total. Nevertheless, despite differences reaching up to 71 % (in TCY), most of them were insignificant no matter on statistical method used (Table 1). Still, standardized carp MY of M2 x AL group was statistically higher compared to M2 group (Table 1).

Discussion and conclusion

The productivity of ponds in Czechia is influenced by various year-to-year fluctuating factors (Kajgrov**á** et al., 2020). It may be seen on high S.D. values of parameters shown in Table 1. Huge variation among ponds very likely affected the significance of differences observed between M2 and M2 x AL groups in statistical analyses. Still, it was shown that CG M2 x AL reached higher standardized MY per ha of pond water area by 22%. The increased mass of fish resulted from better survival as well as the growth of M2 x AL. It may be suggested that the importance of these two traits on the final mass of fish will vary according to the power they will have in the ecosystem. Thus, it may be supposed that fish with genetically improved growth will use more of the pond productivity, and it will result in an increase of fish MY per ha of a pond water area. As seen from RFC, the increased MY did not change the rate of natural and supplemental food utilized for fish growth.

(Continued on next page)

Table 1. Performance and yields (mean ± S.D.) of two different mirror groups of common carp in ponds. **Corr. S** – corrected survival, **Corr. WY** – corrected weight yield, **Hyp. CY** – hypothetical carp mass yield (MY), **TCY** – Observed total carp MY, **Stand. CY** – standardized carp MY of mirror carp to MY of the control group, **RFC** – relative feeding coefficient. Values with different letter superscript ($^{a.b}$) are significantly different by one-way ANOVA, * - value is significantly higher according to the Mann-Whitney U test.

Mirror group	Corr. S (%)	Corr. WY (g)	Hyp. CY (kg) * 1 ha	TCY (kg) * 1 ha	Stand. CY (kg) * 1 ha	RFC
Age category $C_0 – C_1$						
M2	11.5±14.7	12.6±4.5	249±346.1	257±139.2	0.70±0.317	2.2±1.15
M2 x AL	17.4±13.0	14.7±2.3	373±303.9	440±399.7	0.84±0.173	0.9±0.62

Introduction

Praziquantel (PZQ) is an anthelmintic drug discovered in 1970s. As antiparasitic, is remarkably effective against a broad range of gastrointestinal and external parasites affecting humans while it has also been widely used in veterinary and aquaculture medicine to control Platyhelminthes. Specifically, in captive fish, PZQ has proven an effective chemotherapeutic against monogeneans infecting the gills, skin and branchial cavities. Orally administered PZQ preparations at doses ranging from 50 to 400 mg/kg fish daily for up to 20d have been tested in a variety of cultured fish species (Kim et al., 2001; Tubbs and Tingle, 2006; Shirakashi et al., 2012). In establishing an oral dosing regimen, pharmacokinetic data can be useful for optimising treatment efficiency. However, to our knowledge, there is no literature examining the pharmacokinetic properties of PZQ in gilthead seabream, *Sparus aurata* which is an economically important species in Mediterranean marine fish farming. Thus, the aim of this study was to investigate the pharmacokinetic properties of dietary administered PZQ in gilthead seabream following a single oral dosing as a first step to optimise PZQ dosing regimens for this species.

Materials and methods

Healthy gilthead seabream (52±3.7g), were obtained from a commercial fish farm and transferred to the experimental aquarium facilities. Fish were randomized in 2 groups of tanks; Low (n=100): fish were fed with an experimental diet supplemented with PZQ (75 mg/kg) and High (n=100): fish were fed with an experimental diet supplemented with PZQ (150 mg/kg). Before the experimentation, fish were acclimatized for two weeks and were fasted for 24h. During the experimental procedure, fish were hand-fed once a day, assuring that the feed was consumed. Water temperature was maintained at 21±°C. Ten fish/group were anesthetized (MS-222, 150ppm) and blood samples were collected each at 1, 2, 4, 6, 8, 12, 24, 48, 72 and 96h post treatment. Plasma was separated from blood samples by centrifugation at 3000*g* for 10min at 4°C. A modified method of Ridtitid et al. (2002) was used for the extraction of PZQ in plasma samples which were then analysed by an HPLC-UV chromatographic apparatus.

Results

The concentrations of PZQ found in plasma after oral administration are shown in Figure 1. In detail, plasma PZQ concentrations in gilthead seabream revealed values around 6.3 μg/ml and 6.4μg/ml at 4 and 8 h post feeding, respectively for low dosing regimen and 7.9 and 8.3μg/ml at 1 and 4h post feeding, respectively for high dosing regimen. Maximum plasma concentration (C_{max}) of PZQ for fish fed 75mg/kg BW was achieved at 8h post feeding, while in fish fed 150mg/kg BW was evident at 4h post feeding (8.3μg/ml). These profiles indicate that the clearance of PZQ in gilthead seabream did not follow a simple decay model. Regarding drug clearance from fish circulation, PZQ concentration declined relatively sharply at the 12h sampling point (approximately 50%), however, C_{min} were found to be approximately 1μg/ml 96h post-treatment for both dosing regimens examined. Finally, a two-fold increase in the administered dose only led to an 46.5% increase in the mean plasma concentration of PZQ 2h post-treatment.

Discussion & conclusion

The results of the present study showed that PZQ was readily absorbed in plasma of gilthead seabream while its clearance was found to be relatively sharp for both examined dosing regimens. Rapid absorption of orally administered PZQ preparations has been also demonstrated in other fish species such *Seriola spp*. (Tubbs and Tingle, 2006, Kogiannou et al., 2021). Considering the sharp decrease in PZQ concentration in plasma after 12h after oral administration in the present study, re-treatment at an interval of 24h would possibly enhance eradication of *Sparicotyle chrysophrii*, a polyopisthocotylean gill parasite of gilthead seabream. In conclusion, based on the information obtained from the PZQ analysis in gilthead seabream plasma, there is an apparent benefit from the 150mg/kg dosing regimen, as confirmed by the significantly higher drug levels compared to low dosing. An *in situ* trial against *S. chrysophrii* is required to verify that the high dosing schedule suggested herein is also the most effective medicated scheme.

Introduction

Gilthead seabream (*Sparus aurata*) is considered one of the most valued marine species produced in most Mediterranean countries, including Greece. It is mainly commercialized as whole fish, gutted or not. In recent years, the growing consumer demand for a high quality secondary processing product, i.e. fillet, has led to the beginning of production of sea bream fillets. This brought to surface technical quality issues, such as gaping of the fillets. Fillet gaps result to the downgrading of the food product, and hence economic loss, because of rejection by the consumers due to its unappealing appearance. Briefly, gaping is a phenomenon, in which the connective tissue fails to hold the fish fillet together resulting into gaps and tears at the myofibre–myocommata attachments and between myofibres. Factors that have proven to be strongly associated with the fish propensity to gap, include the species, the biological status, the catch or slaughter history, the temperature during storage (Lavety et al., 1988; Sheehan et al., 1996; Robb et al., 2000). Most studies in fillet gapping refer to salmonids. However, no respevtive data occur for sparidae species. Taking these into account, the aim of this original study was to investigate the seasonal variations of gaping in gilthead seabream fillets and its relative species red seabream (*Pagrus magor*), in order to gain insight into potential causes of gaping in farmed Mediterranean species fillets.

Materials and methods

Market-size (400-800g) gilthead seabream (total N= 274) and red seabream (total N= 186) were harvested from sea cage farms during three seasons (winter, spring and summer), slaughtered according to standard commercial procedures, packed with ice and shipped to a commercial fish processing facilities, where they were stored at 0-4^{o}C for up to two days. After mechanical scale removal by drum, fish were filleted, using a filleting-machine, weighted, ice-packed and transferred to the Hellenic Centre for Marine Research (HCMR). Fillets were assessed for their degree of gaping by a recently developed scale (Kogiannou et al., 2022), pH, water holding capacity (WHC), total composition and total collagen content. The SPSS version 26.0 was used for the statistical analysis. Comparisons among means were made using one-way analysis of variance (ANOVA). The non-parametric χ^2 test was applied to find statistical differences in the frequency of gaping occurrence between the seasons ($P<0.05$).

Results

Seasonal variations in gaping scores frequencies between winter, summer and spring for gilthead seabream and red seabream fillets are presented in Figure 1. For gilthead seabream, distribution of gaping scores frequencies were found to be statistically different among seasons. In particular, during winter and spring the same pattern was observed, while during summer period more gaping was evident (15% of fillets suffered severe gaping-score 5). On the contrary, for red seabream increased high gaping scores incidences were observed during winter as well as summer, while flesh integrity remained quite intact during spring.

Lower post-mortem pH values were found in both species during summer (Table 1). Regarding WHC (Table 1), significantly poorer liquid holding capacity was observed during summer than the other two seasons for gilthead seabream. Similarly, for red seabream also the higher WHC value was observed during spring. Furthermore, a positive correlation between WHC and pH values during the examined seasons was observed in both species. Finally, regarding the chemical parameters examined herein, seasonal variations in total composition and in collagen content for both species were observed.

Conclusions

The results of the present study showed that in Mediterranean species, fillet gaping occurrence is significantly affected by season and specifically a higher gaping problem was observed during summer for both species examined. Overall, the results indicate that there is a relationship between post-mortem fillet pH, WHC, fillet collagen content and fillet gaping, however, further investigations are required.

Introduction

Over the last few years, aquaculture industry contributes half of the global production of aquatic animals. Despite the great diversity in farmed aquatic species, Atlantic salmon (Salmon *salar*) dominates marine aquaculture production in volumes and production (Anrooy et al. 2022). Nowadays, the most pressing problem that salmon farming industry is facing is the infestation caused by the parasitic sea-lice (Lepeophtheirus *salmonis*) (Powell et al. 2018). As sea-lice have become resistant to chemical treatment, several species of cleaner fish are being used as the "biological solution" to the problem. Of them, the lumpfish (Cyclopterus *lumpus*) is looking as one of the most useful as it is easier to breed and keep feeding with see lice in low temperatures (Imsland et al. 2018). Moreover, is widely distributed in both sides of the North Atlantic Ocean and can survive in a wide range of temperatures. As a result, the demand for lumpfish has increased dramatically but most of the lumpfish used in salmon farming are still derived from wild broodstock (Winfield 2018, Powell et al. 2018). In this study, we analysed multiple wild populations, from the most common sources of lumpfish in aquaculture, and four commercial populations from a breeding programme in Scotland at Otter Ferry Seafish (OFS). The objective was to characterize multiple populations of lumpfish to analyse the impact of population structure and estimate the genetic diversity levels within and between the wild and the breeding populations.

Materials and Methods

A total of 631 animals, 500 obtained from the OFS and 131 animals from various wild populations (36 as breeding candidates), were used in this study. Four full sib lumpfish families from wild origin were produced in spring 2019 at OFS facilities and maintained in separate tanks. Fin clips were obtained from all the candidates and the four families including 125 random fish from each family. The ddRAD libraries were prepared, containing all the samples, and were sequenced on Illumina Novaseq 6000 platform. Reads were aligned against the genomic assembly of C. lumpus (NCBI Assembly accession GCA 009769545.1) using bwa v0.7.17 (Li and Durbin 2009) and assembled using Stack v2.41 (Rochette, Rivera-Colón and Catchen 2019)Rivera-Colón and Catchen 2019. Identified SNPs were retrieved from the samples and filtered for quality control, using PLINK software (Purcell et al. 2007), according to different criteria: such as: a) minor allele frequency$\geq$0.005, b) p-value of χ^2 test for Hardy-Weinberg equilibrium$\geq 10^{-6}$ and c) SNP and animal call rate $\geq$ 0.95. SNPs or individuals that failed to pass the criteria were removed. After the quality control filtering, individuals and SNPs that passed the criteria remained for further analysis. Genetic diversity metrics such as inbreeding coefficients and average pairwise genetic distance were used to estimate levels of within and between population genetic diversity. A principal component analysis was used to explore patterns of genome composition between populations and highlight the variation between them. Linkage disequilibrium (LD) levels and persistence of gametic phase disequilibrium (r) were used as criteria of investigation between the lumpfish populations. PLINK and GCTA were used to perform these analyses (Purcell et al. 2007, Yang et al. 2011).

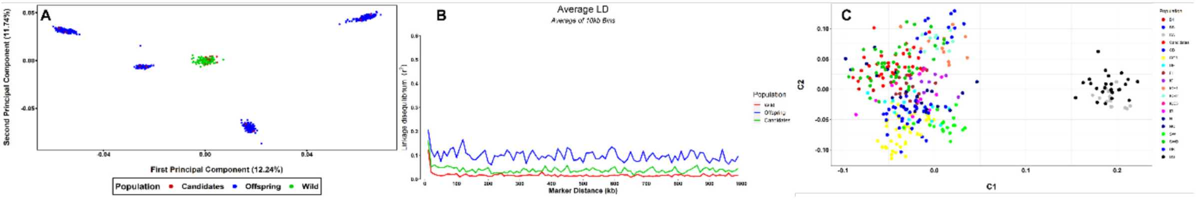

Figure 1 A) Principal component decomposition of the genomic relationship matrix coloured by population B) Average LD (r2) was calculated using 631 individuals within 10kb genomic bins, C) Principal component decomposition of the IBS coloured by location.

(Continued on next page)

Results

The comparison of the first two principal components clearly discriminates the four breeding families and their parents from the wild populations, but there is no evidence of differentiation across the wild populations. Similar levels of genetic diversity were observed among all the wild groups based on the average pairwise IBS distance (0.15 – 0.25). The breeding populations shows a high genetic differentiation between them (0.3) and higher across the wild groups (0.46) (Figure 1A). The estimation of the average LD (r^2) within 10 kb genomic bins and 1,000 KB of maximum distance between two SNPs, by using a subset of common SNPs shows that LD declined rapidly as the physical distance between marker pairs increases (Figure 1B). Both groups have LD values close to 0.2 in small distances but only the "Offspring" population retain extensive LD as the physical distance increases. The consistency of gametic phase was calculated by the Pearson correlation of r values, the higher values was observed between the "Candidates" and the "Offsping" group (Figure 1C). Moreover, the comparison of the genetic differentiation between all the wild individuals from 11 locations shows a distinct differentiation between the American and European individuals.

Conclusions

An overview of population structure, genetic diversity, LD decay and geographic differentiation multiple wild and breeding populations of lumpfish was obtained from the analysed data. Our SNP subset shows a good coverage of the genome and can discriminate the genetic difference between populations even by using a very small number of selected SNPs. Based the genomic information, the PCA shows a strong distinction between the breeding populations and the wild groups. The similar levels of genetic diversity that were observed among the groups indicate that there is a lack of genetic structure based on the origin in the European wild populations but there is a strong differentiation compared with individuals from the American continent. The lack of population differentiation between the groups suggests that there would be a small effect on the genetic diversity from lumpfish escapees. Moreover, the rate of LD decay and the low correlation of phase indicates that this panel will be efficient at estimating the genomic breeding values across the breeding populations.

DIET AND REARING ENVIRONMENT EFFECTS ON MICROBIAL COMPOSITION IN THE GUT: THE CASE OF NILE TILAPIA

F. Kokou*, Y. Deng, R. Maas, E. Eding, M. Verdegem, J. Schrama

Aquaculture and Fisheries Group, Wageningen University, Wageningen, The Netherlands
E-Mail: fotini.kokou@wur.nl

Introduction

Fish harbour a high diversity of microbes in their gut, which plays a crucial role in nutrition and health through host-microbe interaction and microbe-microbe interactions (Wang et al., 2018). While microbes can profoundly affect their hosts, we are only beginning to understand how variation in the microbial colonisation through the rearing environment or the diet may shape host performance throughout life. Moreover, with the current trends in fish diet formulation and the substitution of fish meal with alternative ingredients, there is a higher carbohydrate inclusion, including non-starch polysaccharides (NSP), which are less digestible by fish (Kokou and Fountoulaki, 2018). Understanding how both the environment and the diet affect microbial composition and structure in the gut can assist in shaping rearing protocols, but also dietary formulations leading to better fish performance.

Microbial co-occurrence network analysis can be a powerful tool to explore the forces that affect microbial community structure and its dynamics. Such networks have been recently reported in fish to reveal antibiotic effects (Kokou et al., 2020) or understand microbial dynamics (Abdelhafiz et al., 2021). In this study, we explored the impact of early life rearing environment and diet on the microbial associations and composition in the gut of Nile tilapia (*Oreochromis niloticus*). Nile tilapia has omnivorous dietary habits and the potential for NSP fermentation (Maas et al., 2020), thus making it an interesting species to understand NSP effects on the gut microbiome.

Materials and Methods

Gut samples from two different feeding trials using Nile tilapia post-larvae and juveniles were analyzed for microbiome composition. In Trial I, post-larvae tilapia were exposed to different rearing environments (Biofloc, BFT vs Flow-through, FTS) during the first two weeks of feeding, then transferred to a common garden environment, and fed with two inclusion levels of dietary NSP (17%, M-NSP and 27%, H-NSP). In Trial II, fish were fed with high levels of dietary NSP (~31%, CON), supplemented with enzymes phytase and xylanase (ENZ), or probiotics (PRO), and the combination of the two (ENZ+PRO). For the microbiome analysis, DNA was extracted with commercial kits and the V4 and V3-V4 variable regions of the 16S rRNA gene were sequenced, respectively, using Illumina MiSeq. Taxonomic composition of the microbiome was performed at the single-nucleotide level. For diversity analysis, the '*microbiome*' R package was used. Co-occurrence network analysis (Kokou et al., 2020) was applied to explore microbial association patterns in the different treatments.

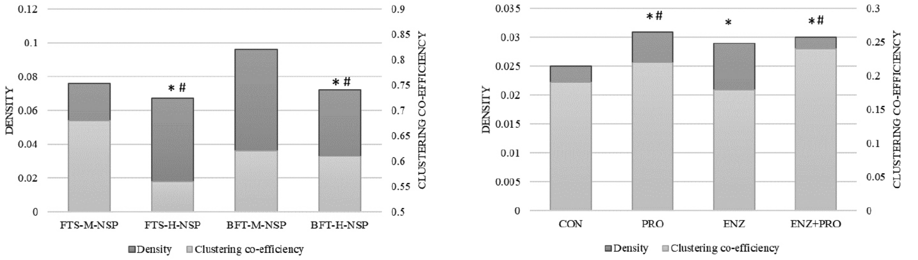

Figure 1. *The density and clustering co-efficiency of the co-occurrence networks in a. Trial I and b. Trial II. Stars and hash indicate significance for the density and clustering co-efficiency, respectively, between M-NSP and H-NSP in Trial I, and between control and the rest of the treatments (PRO, ENZ, ENZ+PRO) in Trial II.*

(Continued on next page)

Results

The results showed that diet and early life environment could affect the gut microbiome composition. Although the developmental stage had a substantial impact on the gut microbiome composition, we observed an effect of both the rearing environment (BFT vs FTS) and the diet on the gut microbial associations. In Trial I, early exposure to BFT led to a significantly higher ratio of positive to negative microbial associations. Moreover, we observed that H-NSP diets led to a significantly lower density of microbial associations (*number of connections between microbes*) and clustering co-efficiency (*the degree to which microbes cluster together*)(Figure 1a). In Trial II, the inclusion of enzymes or probiotics in high NSP diets led to a higher network density and clustering co-efficiency (Figure 1b). These results indicated that high indigestible NSP might interfere with microbial associations. The combination of enzymes and probiotics in the diets can have a complementary effect by increasing the availability of substrates for the probiotic and promoting the abundance of beneficial bacteria while increasing NSP degradation (Maas et al., 2020). Increased network complexity (clustering and density) with probiotics was hypothesized to benefit the gut microbiome homeostasis (Yang et al., 2017).

Conclusion

These findings suggest that diet and the rearing environment play a significant role in modulating the fish gut microbiome. At the same time, the latter is critical during early life stages. The level and potential availability of indigestible NSP in the diets consistently altered microbial networks. Although further exploration is needed to understand microbial networks to optimize their application in aquaculture, such analysis can serve as a tool to better understand microbial dynamics in the fish gut and how such dynamics may be altered by dietary formulations or rearing protocols, ensuring an optimal fish performance.

Introduction

A controlled fish propagation is nowadays the fundamental prerequisite for well-managed aquaculture production. However, despite practices aimed at creating equal conditions during mass spawning, in the condition of sperm overload and short sperm-egg distance the share of males giving offspring is highly diversified. In traditional pond aquaculture, the fish are exposed to various environmental factors that may affect their fertility through immune activation, among which parasites are one of the most influential. It is highly feasible that differences in fertilization success between males are related to sperm characteristics determined by fish fitness. The study aimed to investigate if mounting an immune response induced by parasitic infection affects common carp sperm quality and reproductive success (*Cyrpinus carpio* L).

Materials and methods

Mature carp males were experimentally infected with a dose of 1 x 10^9 blood parasites *Trypanoplasma borreli* by intraperitoneal inoculation. Control fish were PBS-injected. Parasite number was determined at weekly intervals using a Bürker counting chamber. The level of parasitaemia developed within four weeks post-infection was the criterion to classify each individual either as parasite susceptible or resistant. The measured level of *T. borreli*- specific antibodies production gave information on the fish's immune system efficiency. On day 24 post-infection, carp males were engaged in controlled spawning. Equal volumes of quantified semen, obtained by gentle abdominal massage, were used to fertilize the egg portions, obtained from four females of different genetic origins. The calculated hatchability rate was used as the indicator of the males' reproductive success. To evaluate the quality of fish sperm, we measured motility parameters using the CASA system and acridine orange staining for DNA integrity assessment. We also estimated the level of 11-ketotestosterone and its relationship with the antibodies production.

Results

The parasite-infected males demonstrated average hatchability rates of 14.18 ±4.83%, while the control males demonstrated 11.29 ±3.93% rates. Parasites induced a robust adaptive antibody response, but individual antibody levels were not associated with hatchability rate. A significantly higher number of spermatozoids with damaged DNA was detected in parasite-susceptible males than in the resistant ones. The 11-ketotestosterone and most CASA parameters did not differ between parasite-infected and control fish except beat cross frequency (BCF), which was higher in infected fish (57.45 ±18 Hz in infected vs 43.64 ±9 Hz in controls). This CASA parameter alongside the percentage of motile spermatozoa (MOT) was positively associated with hatchability rate.

Discussion

Our study shows that in artificial spawning, a mild level of parasitaemia does not negatively influence the reproductive success of common carp males. The BCF was the only sperm characteristic that "reacted" to the parasite infection, being the highest on average, among most susceptible males. At the same time, the parasite-susceptible group also presented the highest percentage of damaged sperm cells. We suggest that in the conditions of high egg/sperm ratio practised in aquaculture, the negative effect of sperm with damaged DNA can be diminished. In this way, the maximum fertilization potential was exposed. The association of BCF values with carp susceptibility to *T. borreli* infection and with the hatchability rate were the most important relationships among our results. It seems that susceptibility to parasitaemia affects some sperm characteristics, which are manifested through the higher BCF values. However, the mechanism by which the activated immune system can alter BCF values and why this sperm parameter affects hatchability rate remains unknown and requires further investigation.

AUTOMATED FISH MONITORING AND SAMPLING IN RAS USING OAK-D

Introduction

The monitoring of fish for stock assessment in aquaculture and commercial fisheries is essential for the economic and environmental management. Measurement of fish mass as one of the important stock assessment features, is one of the most common and important practice in the aquaculture management. Fish mass information is playing important role in feeding regimes management, oxygen consumption calculation, antibiotic dose, grading time and the optimum time of harvest. Moreover, fish mass measurement has become more critical in recirculating aquaculture system (RAS) which recently became popular among fish farmers (Bergheim et al., 2009). The most conventional method to estimate the mass of a fish population is to net fish samples from a tank and weight them. This method is labour-intensive and stressful for fish. The possibility to measure the fish in a tank without human intervention is therefore of great interest for the aquaculture community. Machine vision system as non-invasive technique is attracting researcher and agriculturists for estimating fish mass and size during cultivation remotely without causing stress in past three decade (Saberioon et al., 2016; Zion, 2012). Usually, it is complicated to transfer the images from the tank camera to the central computer at the aquaculture facility and it became more problematic with the high number of tanks. The need of individual camera for each tank and processing of all data on the central computer makes the system difficult to apply under the real aquaculture conditions. The solution could be to detect the fish, estimate the weight and send the information to the central computer (wireless connection can be used). OpenCV AI Kit with Depth (OAK-D) can effectively solve the described problems. The individual fish is detected using the CNN. The stereo vison system is used to determine the fish depth and estimate weight. The main objective of this study was developing real time monitoring system using OAK-D for remote and automatic estimation of fish biomass in RAS.

Materials and methods

The study was divided into a several phases:

Data collection
OAK-D was mounted on top of fish tank for initial data collection. At first OAK-D was calibrated with a checkerboard (9*6 internal corners and square size is 2.35 cm) according to DepthAI Docs. Disparity map was not good, especially at distances of 2,5 m. In this range of depth, we are using OAK-D in our system. So, calibration procedure was redone with the checkerboard (8*6 internal corners and square size is 9 cm), because DocsAI protocols couldn't detect internal corners of smaller checkerboard at that distance.

Lights condition is very crucial in which our system work. As the water should be transparent enough for good fish detection light conditions source were adjusted. The common carp is using as a testing specie. For estimation biomass and individual fish weight and length/width conversion, we sampled all fishes (Table 1). Each individual fish was captured by OAK-D at closest depth to the surface. Several videos were recorded with different light sources. These data were manually processed and labeled in LabelImg v.1.8.2. Two training data set were created for individual fish detection with 800 of photos each with different resolutions. Tiny Yolo V3 Fish Detector was trained with 416*416 resolution. Second detector was based on SSD MobileNet V2 and it was trained with resolution of 300*300.

The new data set of 2000 photos (300*300 resolution) with different light conditions was sampled. All photos were annotated in a simple graphical tool – imaglab which is part of Dlib library. The data were randomly split into training and testing sets in proportion 90 and 10% respectively. The SSD MobileNet fish detector was trained.

(Continued on next page)

To localize individual landmarks on detected fish we used well-known dlib's shape predictor. dlib's find_min_global function was used to optimize the options and hyperparameters to dlib's shape predictor training. Dlib handles computing the mean average error (MAE) between the predicted landmark coordinates and the ground-truth landmark coordinates.

For conversion pixel size to real length system was calibrated with special white plate. It was captured 10 photos at 3 locations in tank: middle, edge and between by step 10 cm lowering this plate. The distance to the plate was measured with 5 m ruler. The conversion equation was calculated by fitting a linear model.

Implementation and testing performance
SSD MobileNet model was compiled for 4, 5, 6 shaves. After both detectors were applied we had detection of reflections without fish and wrong detections of landmarks. To avoid misestimations of size we used several conditional statements which were calculated according to our data set. These conditions are distance to bounding box and distance between landmarks, as we know real size of our fish. Weight of each detected fish is calculated by conversion models. Number of fish (N) to the day of recording video in the tank was 21. Total biomass was calculated by multiplying average weight of fishes on N.

Stereovision provided distance to the detected fish.

Results and discussion

This automated monitoring and sampling system can help farmers monitor fish welfare and growth rates in high intensity cultivation systems such as RAS continuously in real-time. The SSD MobileNet fish detector showed better performance than Tiny Yolo. The lost on last step of the SSD MobileNet training was 1.32. Best performance was gotten on 6 shaves blob file. FPS is around 16. Dlib MAE of training and testing set was 3.5 and 15 respectively. Despite not so well depth map under water OAK-D shows sufficient performance. As far as we know that it is no such system at the market. It can increase cultural efficiency and productivity. More statistic data will be acquired, and that result will be published in corresponding scientific journal.

GOOD AQUACULTURE PRACTICES; THE COLLABORATIVE USE AND BENEFITS

B. Koonse

POB 1129, Harpers Ferry, WV 25425
Brettkoonse@yahoo.com

The Joint Institute for Food Safety and Applied Nutrition (JIFSAN) is a collaboration between the United States Food and Drug Administration (FDA) and the University of Maryland (UM). JIFSAN has developed an aquaculture program that links food safety and disease prevention. It's called Good Aquaculture Practices (GAqPs). GAqPs are widely used and implemented around the world. This presentation is a short synopsis on GAqPs and a request for to help take GAqPs to the next level where it can be universally used and recognized for a wide variety of purposes. GAqPs could be used or integrated into new or existing programs to show food safety and disease controls are in place by the following:

- Individual aquaculture farms for their buyers;
- Governments for their farm and or processor registration and certification programs;
- Private third-party certification programs to verify food safety and disease prevention;
- Processors in their HACCP or Preventative Control programs to act as their food safety controls for aquaculture related food safety hazards;
- Academia to train future aquaculture professionals in food safety and disease prevention;
- The aquaculture industry and others to demonstrate to the general public that aquaculture products are safe, sustainable, and free of hazardous residues and pathogens.

NERVE REGENERATION IN CRAYFISH

Golara Kor, Kifayatullah Mengal, Miloš Buřič, Hamid Niksirat

Faculty of Fisheries and Protection of Waters, South Bohemian Research Centre of Aquaculture and Biodiversity of Hydrocenoses, the University of South Bohemia in České Budějovice, Vodňany, Czech Republic
Email of presenting author: gkor@frov.jcu.cz

Some species ranging from protozoans to mammals can regenerate their organs after an amputation or injury. Crayfish, as the representative of Decapoda, the most diverse order of crustaceans, exhibits substantial abilities for regeneration. Especially the clonal marbled crayfish (*Procambarus virginalis*) poses an excellent model for understanding arthropod regeneration. Antennae in crayfish are essential for gaining tactile information for sensing the local topography, localizing food and communicating with conspecifics. Therefore, the antennae are sensory organs full of nerve networks, making them a good candidate for the study of nerve regeneration. Crayfish haemolymph contains immune cells which can turn into stem cells and participate in the nerve regeneration in the brain of crayfish. Therefore, we focused on the potential roles of immune cells in the regeneration of antennae at the ultrastructural level using transmission electron microscopy. Our observations showed that immune cells could turn into nerves and provide essential organelles such as mitochondria and Golgi apparatus, which are necessary for the functioning of neurones. In conclusion, we reported morphological changes in immune cells as stem cells during nerve regeneration in crayfish.

PREDICTING THE EVOLUTIONARY TRAJECTORIES OF PARALOGS OF THE COMPLEX V OF OXIDATIVE PHOSPHORYLATION IN *Dicentrarchus labrax*

Introduction

European seabass (*Dicentrarchus labrax*) is a teleost of great economic and cultural importance in the European Union and the Mediterranean, since it is the second non salmonid cultivated species in production volume in the European Union. Teleosts have undergone three rounds of whole genome duplication (WGD). It is believed that the first round of WGD happened early in the Vertebrate lineage (1R), the second after the differentiation of Agnatha and Gnathostoma (2R) and the third (3R) is the Teleost Specific Whole Genome Duplication (TS-WGD) (Kasahara, 2007). After a WGD event, decreased evolutionary pressure allows the paralogs that have been formed to follow different evolutionary trajectories, such as non-functionalization, sub-functionalization or neo-functionalization. Oxidative phosphorylation is a metabolic process, responsible for the 90% of cellular energy production through the synthesis of ATP. Five complexes in the inner mitochondrial membrane take part in this process, with the first four forming the electron transfer chain. The proton gradient generated by the electron transfer chain is used by the complex V or ATP synthase to produce ATP. It is clear that the efficiency of energy production through oxidative phosphorylation is crucial for the fish wellbeing, especially for energy demanding processes such as development and growth. The aim of this study was to explore how the TS-WGD has affected the process of oxidative phosphorylation with focus on the ATP Synthase.

Materials and Methods

The first step in the analysis was database mining for the genes atp5mg, atp5pd, atp5pf and atp5if1 that encode the ATP synthase subunits g, d, F6 and the inhibitory factor IF1, respectively. Using the databases Ensembl and NCBI, sequences of paralogs for the genes of interest were retrieved and their homology was verified using Ensembl's BLAST algorithm. The sequences were first edited and then used in the phylogenetic analysis where phylogenetic trees were created for each gene family, using the Maximum Likelihood Method. The species used were Teleost representatives, Sarcopterygii, Tetrapods representatives, the species Elephant shark and Lamprey, which were used as root for the trees, and Spotted gar, whose lineage differentiated before the TS-WGD. For synteny analysis, circos diagrams (Krzywinski et al., 2009) were created for each gene family, where 50 genes on either side of every gene of interest were mapped on chromosomes, to visualize the level of conservation between orthologous genes on chromosomes of the species European seabass, Spotted gar and Human. The online algorithm Pseudochecker (Alves et al., 2020) was used for pseudogene prediction for European seabass paralogs, using stickleback sequences as reference. TargetP (Armenteros et al., 2019) was used for mitochondrial transit peptide and MPP cleavage site prediction. Finally, the protein database Uniprot was used to identify domains related to the protein structure and function on reviewed human proteins. The human sequences and domains were then compared to those of the European seabass.

Results and Discussion

Different paralogs were identified for every gene and were named based on the phylogenetic analysis. Three paralogs were identified (α1, α2, β) for *atp5mg*, two (α, β) for *atp5pd*, three (α, β, γ) for *atp5pf,* and another three (α, β1, β2) for *atp5if1*. Based on the phylogenetic and synteny analysis the evolutionary origins of the paralogs of each gene family were identified. The paralogs of *atp5mg* and *atp5pd* seem to have originated from TS-WGD. The α paralogue of *atp5pf* originated from 2R duplication, while β and γ, from TS-WGD. The paralogs of *atp5if1*, originated from 2R duplication. Lineage-specific gene duplication seems to be the origin of *atp5mg* α1 and α2, and *atp5if1* β1 and β2. The synteny analysis indicated conservation between the three species chromosomes that contain the paralogs of each gene family, except for the chromosome that contains the *atp5mg* β paralogue and the one that contains the *atp5pf* γ. The prediction for pseudogenes, for mitochondrial transit peptide as well as structural and functional peptide domains were taken into consideration for the prediction of the evolutionary fate of each paralog. The peptide sequences of the genes *atp5mg* α2, *atp5pf* β, *atp5pf* γ and *atp5if1* β2, were predicted to be so differentiated in comparison to the reference sequences, that they cannot accomplish the same function. An absence of mitochondrial transit peptide was observed in the *atp5mg* α2, *atp5pf* γ and *atp5if1* β2.

(Continued on next page)

The parts of *atp5pf* γ and *atp5if1* β2 that in the human peptides contain the mitochondrial transit peptides, seem to have been lost. The β2 paralogue of *atp5if1*, seems to have also lost its functional domain, while in *atp5pf* β, an extra region of about 300 amino acids after the mitochondrial transit peptide that does not appear in the human corresponding peptide, makes the protein three times longer. The results, show that there are different possible evolutionary trajectories between the paralogs of each gene family. Non-functionalization seems to be the case for *atp5mg* α2, *atp5pf* γ and *atp5if1* γ. Regulatory sub-functionalization appears to be the fate of *atp5mg* α1 and β, *atp5pd* α and β and *atp5if1* α and β, as they seem to maintain their functions. For the β paralogue of *atp5pf*, there seems to be an indication for neo-functionalization as it appears to maintain function, yet a large sequence region has been inserted after the mitochondrial transit peptide. Lastly, the only paralog that seems to have retained its ancestral function is the α of *atp5pf*. In the future, experimental evidence is necessary for validating the results of *in silico* analysis for the genes of ATP synthase and also other OXPHOS complexes to discover the influence of TS-WGD in oxidative phosphorylation.

Introduction

Invasive gibel carp, *Carassius gibelio* (Bloch, 1782) has become well established in the Hungarian waters and now are spreading in European waters. It belongs to the Cyprinidae family, the biggest freshwater fish family, and the genus *Carassius* is native in East Asia. The circumstances of its initial introduction to Europe are still unclarified. The species' mass invasion dates back to the second half of the 20th century, which was facilitated by human activities such as intentional introduction for creating aquaculture and accidental introductions with common carp stock and their high ecological tolerance and ability of gynogenetic spawning. On major concern now is the potential hybridization between gibel carp and the other invasive species in the *Carassius auratus* complex (CAC), which may further accelerate the spread of the whole invasive species complex. The identification of gibel carp and their hybrids is difficult because of their morphological similarity to the other species in CAC. Here we carry out a genomic assessment to understand the history of gibel carp invasion and its phylogenetic relationship with the other species in CAC.

Materials and methods

One hundred and thirty-two gibel carp samples were collected from six locations in Hungary including Lake Balaton, two reservoirs of Kis-Balaton Water Protection System and Hőgyész, Siófok-Töreki fish pond system and Öszödi-berek. Following phenotypic identification, three loci of the mitochondrial genome (D-loop, Cytochrome c oxidase I (CoI) and Cytochrome b (Cytb)) were used to determine the phylogenetic origin of individuals and relationships among six gibel carp populations and the other species in the CAC. Successfully identified haplotypes were aligned with reference sequences in nucleotide databases (i.e., NCBI-BLAST: National Centre for Biotechnology Information and BOLD: Barcode of Life Data System). The phylogenetic relationships among gibel carp populations were then analyzed together with the reference sequences to understand the relationship and the level of hybridization with the species in CAC. Haplotypes diversity was calculated based on the polymorphic sites and haplotypes by using the DnaSP version 5 (Librado & Rozas, 2009) software. Pairwise FST, genetic distance and a phylogenetic tree was reconstructed with the Neighbour Joining method by using the MegaX software (Kumar et al., 2018). The network of the D-loop haplotypes was built using a median-joining algorithm byPopART software (Rohl, Bandelt & Forster, 1999)

Results

Among the 132 aligned D-loop sequences 22 haplotypes were identified based on 43 polymorphic sites. For each population, the highest haplotype diversity was in Siófok 0,83 (HD) ± 0,04 (SD), the lowest value was 0,19 (HD) ± 0,11 (SD) for the population of Öszödi-berek. The identified haplotypes were divided into three major groups on the haplotype network figure. The largest group contained sixteen haplotypes (all the common haplotypes belonged to this group), the second contained five low-frequency haplotypes, while the third group contained only one haplotype from our sequences. This latest clustered together with Carassius auratus buergeri reference sequence, then the other Carassius gibelio haplotypes did.

Further examination of representative individuals of the 22 haplotypes, only six Cytb (1057 bp region with polymorphic sites 27) and four CoI (562 bp region with polymorphic sites 26) haplotypes were detected. The largest number of haplotypes of all three loci were found in Lake Balaton, the largest shallow lake in Central Europe. Based on the NCBI-BLAST alignment of the D-loop, haplotypes of *Carassius auratus auratus* and *Carassius a. buergeri* in CAC were identified in the analys*ed* samples. The analysis of Cytb and CoI haplotypes confirmed the occurrence of intragenus hybridization of *C. gibelio* in the Hungarian waters.

(Continued on next page)

Discussion and conclusion

This study is the first genetic diversity assessment for the Hungarian gibel carp complex, in which we reported the recent homogenous genetic background of the studied populations. However, the potential hybrid origins of gibel carp were identified in the studied waters. The origin of the introgressed *C. auratus* sequences is doubtful but denotes the unreliability of morphological-based identification of taxa within the genus *Carassius* and the hidden presence of goldfish in natural waters of Hungary.

The Cytb and CoI have the lowest mutation rate among the mitochondrial protein coding genes in fish. The CoI is used in BOLD system for species identification but our results revealed that Cytb can be used more efficiently for identification the CAC complex because of more reliable databases. This marker showed the highest agreement with the phenotypes. While the D-loop showed the highest genetic variability. It is in agreement with other studies and explained by the highest mutation rate of the only larger non-coding mitochondrial region. It is much more informative than the nuclear markers when used for the analysis of closely related species, subspecies categories or populations. Our results also show that this region can be efficiently used for intrapopulation analyses for identifying hybrids in CAC.

THE ATLANTIC SALMON IMMUNE SYSTEM CHANGES DURING SMOLTIFICATION: ENHANCED ACTIVITY OF B CELLS

A. Krasnov*, M.B. Mira, L. Sveen, E. Burgerhout, J.-E. Dessen, S. Afanasyev, V.C. Mota

[1]Nofima, The Norwegian Institute of Food, Fisheries and Aquaculture Research, 9291 Tromsø, Norway
*Email: aleksei.krasnov@nofima.no

Introduction

Smoltification of farmed Atlantic salmon (*Salmo salar*) is associated with down-regulation of multiple immune genes, as has been shown in several experiments and field studies (1-3). Consequences of these changes remain unknown, although a higher activity of the immune system is not always associated with better resistance to pathogens (4). However, immune suppression can be partly responsible for high mortality of salmon during first months in the sea. In contrast to a general trend to decrease, we noticed enhanced expression of *immunoglobulins* (*ig)* and markers of B cells in smolts. Sequencing of the variable region of *igm* (Ig-seq (5)) has provided novel insights into the repertoire of antibodies and B cells and discovered previously unknown features of the teleost immune system. In particular, we have shown that responses to pathogens and vaccines are associated with increased B cell traffic, which enhances efficiency by delivery of antibodies to the sites exposed to the antigens (6). Increased mobility of B cells in Atlantic salmon smolts was shown in the field (7), but it remained unknown whether the observed changes were associated with smoltification or vaccination. Here, we report results of a controlled trial.

Materials and methods

A total of 330 unvacinated Atlantic salmon parr (~ 20 g) were randomly distributed among three freshwater recirculanting aquaculture systems (RAS) described in (8). The parr were smoltified over 14 weeks using a standard square wave photoperiodic regime. Subsequently, fish (~100 g) were transferred to a seawater flow-through system and grown for an aditional 12 weeks at LD 24:0, until ~500 g. Head kidney, spleen, visceral and dorsal fat, and gill tissues were collected at week 0, 8, 14 and 26.

Ig-seq was performed as described in (6). In brief, cDNA synthesis primed with an oligonucleotide to the end of *igm* constant region was followed with two PCRs that amplified the variable region (CDR3) and inserted adaptors for Illumina sequencing (MiSeq) Each unique sequence of the variable region or clonotype serves as a barcode of clonal B cells and the numbers of reads reflect the size of clones. Co-occurrence of clonotypes in two tissues is explained with traffic of B cells. Ig-seq was performed in the lymphatic (head kidney, spleen) and peripheral (visceral and dorsal fat, gill) tissues. *Membrane* and *secretory igm* expressed in respectively naïve and antibody producing B cells, *igt*, *igd* and gene-markers of immune cells were analysed with RT qPCR.

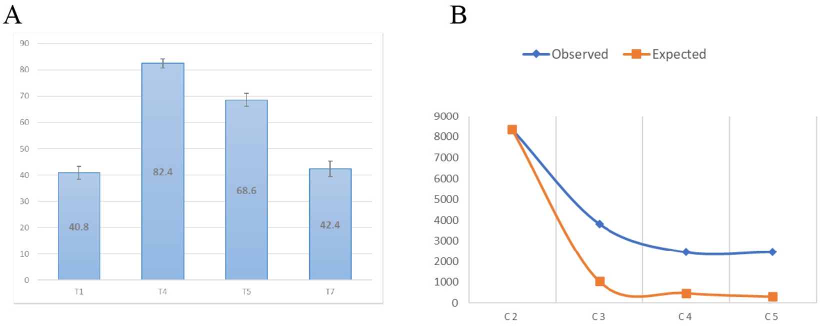

Figure 1. Co-occurrence of *igm* clonotypes reflecting traffic of B cells between organs and tissues of Atlantic salmon. **A**: cumulative frequency (%) of transcripts from clonotypes detected in more than one tissue. **B**: expected (random) and observed co-occurrence of clonotypes.

(Continued on next page)

Results and Discussion

Initial co-occurrence of clonotypes in tissues was relatively low, which is common for Atlantic salmon under basal conditions – the repertoire of B cells is unique at each site (Figure 1A). At T4 (light stimulation) sharing increased two-fold and 82.4% of all *igm* transcripts were from B cells clones detected in more than one tissue. This metric decreased at T5 (prior seawater transfer) and returned to initial levels at the last time-point (T7, 12 weeks after seawater transfer). High co-occurrence of clonotypes in several tissues (Figure 1B) suggested the simultaneous distribution of newly emerged B cells from the lymphatic tissues throughout the body. Active traffic was not associated with changes in the differentiation status of B cells: expression of *membrane* and *secretory igm*, and genes – regulators was not different between the time points. The qPCR confirmed high immune activity of visceral fat with expression of all genes higher than in gill, except for cd28, which is a T-cell marker.

Conclusion

In addition to the dramatic changes in the endocrine system, osmoregulation, metabolism, morphology, and behaviour, smoltification causes remastering of B cells population followed with its subsequent homogenization in the lymphatic and peripheral tissues. Repeated observations in the field and experiments suggest that this is an integral part of the developmental program. The driving force behind this restructuring, its functional importance and implications for aquaculture are waiting for exploration.

Introduction

The United Nations Sustainable Development Goals (SDGs) can be viewed as a bold commitment to produce a set of universal goals that meet the urgent environmental, political and economic challenges of our time, among which food security is at the fore (UN, 2015). To this end, governments of many countries, as well as their supporting organizations, have primarily addressed the biological, technical and economic aspects of aquaculture as one central pillar for food security. In contrast, social and cultural aspects of aquaculture production have taken a backseat. Drawing on the observation that aquaculture development in Western Societies has largely failed to address these social effects across different scales and contexts, this presentation offers a new way of capturing and visualising the diverse social dimensions of aquaculture.

Material and Methods

The UN social dimension categories (Population (P), Health (H), Education (E), Work (W), Housing (HO)) were selected as a point-of-departure, under which each of these umbrella categories a number of sub-categories were defined, i.e. social equity, working conditions, ownership of housing, access to food, etc. Local/regional stakeholder knowledge realms were then combined with scientific expert knowledge to assess aquaculture operations across the North-Atlantic realm (ICES region) against these indicators.

In our case study examples, we focussed on two types of aquaculture production systems, rope mussel (Blue mussels, *Mytilus edulis*) and net-pen finfish (Atlantic salmon, *Salmo salar*), as these were present in all of the case studies selected and represented typical aquaculture set-ups within the respective country for these types of production systems.

Results

The approach indicates that one needs to have a minimum farm size in order to have an impact of a visible scale for the different social dimension categories. The relevance of the finfish farming industry to population is higher on a regional than a local scale in all cases due to job opportunities and associated increased social and economic activity. Despite that finfish aquaculture thus seems to be more social impactful than rope mussel farming, the latter can hold important cultural values and contribute to place-based understanding, connecting people with place and identity, thus playing a vital role in maintaining the working waterfront identity. lt could be shown that aquaculture boosts a potential significant pull-factor to incentivise people to remain in the area, keeping coastal communities viable.

The simultaneous summative visualization of the five social dimension indicators provides a holistic analysis of the impact of both forms of aquaculture production at the local, regional and national scales. It can be shown that there are multiple relationships, effects and trade-offs that warrant consideration if sustainable aquaculture in relation to the United Nations SDGs is taking place.

Conclusions

By visualising the social effects of aquaculture, a door may be opened for new narratives on the sustainability of aquaculture that render social license and social acceptability more positive.

SPATIAL SPILLOVERS IN PRODUCTIVITY DIFFERENCES OF SALMON FARMS

K. Kulmambetova, R. Tveterås

University of Stavanger, Business School, Kjell Arholms gate 41, 4021 Stavanger, Norway
E-mail: ragnar.tveteras@uis.no

Introduction

The main existing regulation in the Norwegian salmon aquaculture industry is a limitation on production at both farm and regional level (maximum allowable biomass and traffic light system). The rationale behind these regulations is to control the level of sea lice and avoid the prevalence of the disease. However, it is a broad measure, and limited research has examined such factors as the farm's regional location and mutual location of farms within a region due to the lack of geodata availability. The purpose of this study is to explore the causes of differences in farms' productivity while accounting for missing spatial determinants. The methodology is twofold. The first step includes the estimation of the farms' productivity following the Levisohn and Pertin semi-parametric approach. The second stage analyses the spatial panel data for the existence of spatial spillovers to the efficiency of other neighbouring farms.

Research significance

According to the existing regulations, limitation of production should put under control the level of sea lice. Nevertheless, this link is not trivial, as shown in Figure 1. There is no clear evidence that low production levels are associated with a low level of sea lice. Such factors as sea temperature might play a key role in farm efficiency. They are defined by farm location.

The investigation in this direction gives a better understanding of what kind of regulations the salmon industry is needed.

Methodology

Productivity of a farm is a good reflector of the farm decision-making process regarding both outcomes: a more efficient farm means that it produces enough to maintain in the market despite (or thank to) the regulations against a bad outcome – externalities. Therefore, the first stage of analysis is productivity measurement of the Norwegian salmon aquaculture industry using Total Factor Productivity (TFP) analysis. It can be done using a semi-parametric approach following Levinsohn, et al., (2003) and Ilke Van Beveren, (2010). Having a distribution of the farm productivity, the next step is to study spatial differences in TFP among regions that might be taken place due to different measures against externalities, and regulation application using spatial econometric analysis (Anselin, 2001).

The first step of the production estimation is done by recovering Solow residual from the natural log of the classic Cobb-Douglas function:

$$\hat{\omega}_{it}=y_{it}-\hat{\beta}_k k_{it}-\hat{\beta}_l l_{it}-\hat{\beta}_m m_{it}$$

Where ω_{it} represents firm-level productivity, y_{it} is the output of firm i at time t, and variables k, l, and m are inputs of capital, labor, and materials (feed costs, operational costs, etc.), respectively.

The second step estimates the spatial Durbin model to examine the influence of spatial spillovers and firms' treatment efforts on total factor productivity. The generalized form of the spatial dynamic models is as follows:

$$y=\varrho Wy+X\beta+\theta WX+\mu_i+\varepsilon_{it}$$

Where y is TFP, ϱ denotes spatial autocorrelation coefficient, W is a non-negative spatial weight matrix, X represents the independent variables, β and θ are the spatial regression coefficients. Wy,WX denote the spatial lag terms of the dependent variable and independent variables, which allow us to analyse the spillover effects of independent variables.

Preliminary results

Figure 2 illustrates preliminary results of the estimated productivity of salmon aquaculture farms from 2012 till 2018. As we can see there is still room for less efficient farms to evolve to the level of most productive farms.

The second part of the research would be devoted to the determination of whether there are spatial spillovers among the factors driving productivity differences.

HYDRAULIC IMPACT ON FISH MIGRATION IN SARIAKANDHI FISH PASS OF BANGLADESH

Bijoy Kumar Ghosh

Bijiy Kumar Ghosh, Institute of Water and Flood Management

E-mail: bkghoshbuet@yahoo.com

The importance of open water fish in our socio-economic regime has recently drawn the attention of the policy makers of the country. FCD/FCDI projects mainly serve the agricultural interests, but it interfere fish migration. This inevitably affects the open water fisheries sector as migratory routes. Nursing grounds of many species of fish are hampered and disturbed for these projects also. In order to permit fish migration in rivers, it is necessary to maintain conditions that help migrants reach their spawning grounds. To overcome obstacles, such as hydraulic structures, placed in the path of migrating fish, structures must be designed to assist the fish to pass them. The periodic and directed travel of fish mainly for feeding, breeding and over coming adverse climatic conditions is called migration. Fish passes are constructed to allow normal breeding migration and to ensure natural route of fish movement.

The concept of a fish passes is relatively new in Bangladesh. At present, two Fish passes and two fish friendly structures are constructed. These are Fish Pass in Jamuna to Bangali River at Sariakandi in Bogra, fish Pass in Kawadighi Haor of Monu river in Moulovibazar, fish friendly structure in Lohajong river of Tangail and fish friendly structure at Morichardanra in Chapainawabganj. Fish fry, spawning and hatchling movement from Jamuna to Bangali River was the main objective of Sariakandi Fish Pass Project. The Fish Pass Project of Sariakandi is necessary for the development of the dominant fishes like catfish and small fishes. The structures will also aid in efficient development of the carp fishes. Spawning migration, mainly in carp fish, in the study area was found to begin at the 2nd week of May and continue up to the 3rd week of July. Catfish migrations began at the last week of March and continue up to the 2nd week of June.

Fish fry and hatching movement from Jamuna to Bangali river was the main objective of Sariakandi fish pass project. The study also found that there were seven major category migratory species in the project area and the fish pass is contributing positively for growth of fishery resources in then study area. During the monsoon carp fish is the dominating migratory species. Carpfish migrates in a higher velocity, whereas, catfish migrates in a lower velocity. Some problems were found in the operation and management of fish pass.

ACROSS SPAWNING SEASON VARIATION OF SPERM QUALITY IN FARMED ARCTIC CHARR (*Salvelinus alpinus*)

K. Kurta[1], H. Jeuthe[1,2], DJ de Koning[1], C. Palaiokostas[1]

Introduction

Arctic charr (*Salvelinus alpinus*) is a species of high economic value for the Nordic aquaculture. The highly variable reproductive performance that is commonly observed in commercial farms is hindering the industry expansion in Sweden. Semen quality characteristics such as motility-related traits and sperm concentration can influence male fertility in farmed fish species. Change in sperm quality across the spawning period is common in fish and can affect their reproductive success (Bobe & Labbé, 2010; Mylonas et al., 2003)in order to monitor changes in sperm quality parameters during a whole spawning period. On11January 2001,60% of the fish were spermiating, increasing to100% in mid-February and dropping to 30% by mid-April. Sperm density showed a slight increasing trend, with mean values ranging between 8.6 and 23.7 Â10 9 spermato-zoa mL À 1. Sperm motility percentage exhibited a sig-nificant improvement during the spawning season (analysis of variance (ANOVA. The present study aimed to investigate variation in sperm quality in Arctic charr breeding candidates across the whole spawning season.

Materials and methods

Arctic charr males from the Swedish breeding program (2017-year class) were used in the present study. Semen sampling was performed three times across the natural spawning season (n = 71; early October – November). Additionally, three samplings were performed in males kept under photoperiod conditions resulting in late spawning (n = 77; late October – December). Evaluation of progressive sperm motility (PM, %) and sperm kinematics, including average path velocity (VAP, µm/s), curvilinear velocity (VCL, µm/s), and straight-line velocity (VSL, µm/s), was performed by using a computer-assisted sperm analysis (CASA, Microptic) system and the SCA®Motility imaging software. Furthermore, sperm concentration (SC, $\times 10^9$cells/mL) was measured using a NucleoCounter® SP-100™ (Chemometec). Descriptive statistics were computed for the CASA-system parameters using statistical R (v.4.0.2). Across-season sperm quality variations were analyzed by non-parametric tests for comparing either two (Wilcoxon test) or multiple groups (Kruskal-Wallis test). Finally, Pearson correlation was used to determine relationships between sperm quality parameters across the spawning season.

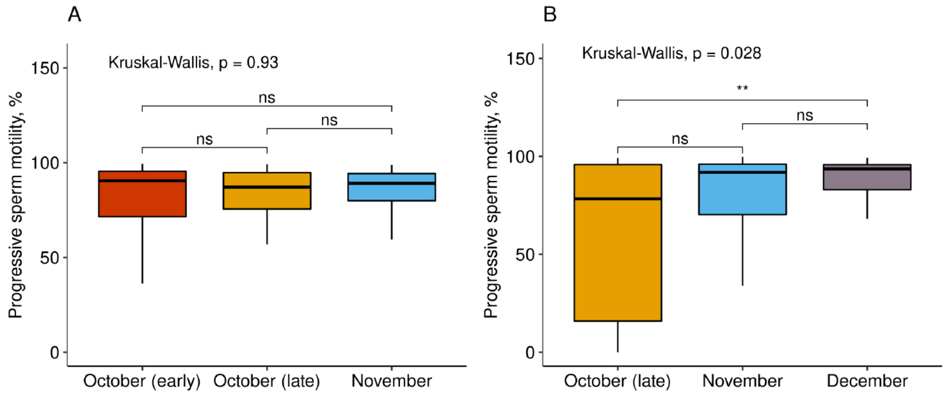

Fig. 1 Progressive sperm motility of Arctic charr males at different times across the spawning season in the groups with the natural (A) and delayed (B) spawning. Wilcoxon test, *P<0.05, **P<0.01, ***P<0.001, ns indicates non-significant difference in means.

(Continued on next page)

Results

Overall, there was a positive trend regarding the mean sperm quality traits in both natural and delayed spawning groups. More specifically, sperm concentration increased by 38% from late October to November in the natural spawning group. In the delayed group, sperm density increased by 39% from October to November and 133% from October to December. Sperm motility parameters increased by 4-13% in October and 8-17% from October to November in the natural group. In the delayed group, the increase was 14-28% from October to November and 38-45% from October to December (Figure 1). In addition, about 30% of the studied males exhibited minor individual variability in sperm quality with the standard deviation for SC $< 0.6\times10^9$ cells/mL and for PM < 5% during the spawning season.

Moderate to high correlations (0.31-0.68, P<0.01) were estimated for sperm concentration measured at different times across the spawning season. While for motility-related parameters, the Person correlations were between 0.41-0.54 (P<0.001) for recordings measured in late October and November in the natural spawning group and between recordings taken in November and December in the delayed spawning group. In the case of the remaining time points, the recorded motility parameters showed low correlations (–0.01-0.26, $P \geq 0.05$).

Discussion and Conclusion

In the present study, the across-season variation in the recorded sperm quality parameters was evident, showing, in general, a positive trend across the sampling points. These variations can explain to a certain degree the highly variable reproductive performance of Arctic charr in captivity. In addition to that, the individual variability in semen parameters during the spawning period was observed among the studied males. Although the reason for that remains poorly understood, environmental factors and genetic background are considered as crucial contributors to male reproductive performance (Jeuthe et al., 2015; Kurta et al., 2021). Understanding the sperm quality changes throughout the breeding period would aid the management of reproduction and selective breeding schemes in Arctic charr hatcheries.

Introduction

Greater amberjack (*Seriola dumerili*) begin to reach sexual maturity after 4 years, and the age can vary in different geographical locations (Kožul, Skaramuca, Glamuzina, Glavić, & Tutman, 2001). A long period of time is required, as only at five to six years of age all the population is considered fully mature. Therefore, shortening the time between generations by advancing the time of puberty might bolster future production (Levavi-Sivan, Bogerd, Mañanós, Gómez, & Lareyre, 2010; Molés et al., 2020)seabream, channel and African catfish, goldfish, eel, tilapia, zebrafish, Manchurian trout and Orange-spotted grouper. The hypothalamus in fishes exerts its regulation on the release of the GtHs via several neurohormones such as GnRH, dopamine, GABA, PACAP, IGF-I, norepinephrine, NPY, kisspeptin, leptin and ghrelin. In addition, gonadal steroids and peptides exert their effects on the gonadotropins either directly or via the hypothalamus. All these are discussed in detail in this review. In mammals, the biological activities of FSH and LH are directed to different gonadal target cells through the cell-specific expression of the FSH receptor (FSHR. We report, here, the *in vivo* efficacy of recombinant gonadotropin-based therapies in promoting gonadal development in 1+ year old, pre-pubertal greater amberjack.

Materials and Methods

An experiment was conducted to determine the minimum effective dose for the administration of recombinant *Seriola dumerili* single-chain gonadotropins (rsdGths), follicle-stimulating (rsdFsh), and luteinizing (rsdLh) hormones. Sixteen-month-old hatchery-produced F1 pre-pubertal male and female greater amberjack (October 2021) were treated with one of three doses of rsdFsh (Saline, 5, 10 or 15 μg kg^{-1}) or two doses of rsdLh (5 or 10 μg kg^{-1}) over six and two weeks, respectively. At the end of rsdFSH administration, gonads were dissected to estimate the gonado-somatic index (GSI) and for histological investigation. Blood samples were obtained from fish treated with rsdFsh as well as from those treated with rsdLh at regular interval to measure sex steroid hormones. In a second experiment, 1+ year old fish were injected with the best doses of rsdFSH and rsdLH established in the previous study, once a week over a period of twelve weeks, during the natural reproductive season for the species (March-June 2022). As above, blood samples were collected regularly to monitor variations in the plasma levels of sex steroids. A week after the last rsdGths administration, fish will be euthanized and gonads collected for the estimation of the gonado-somatic index (GSI) and for histological investigation.

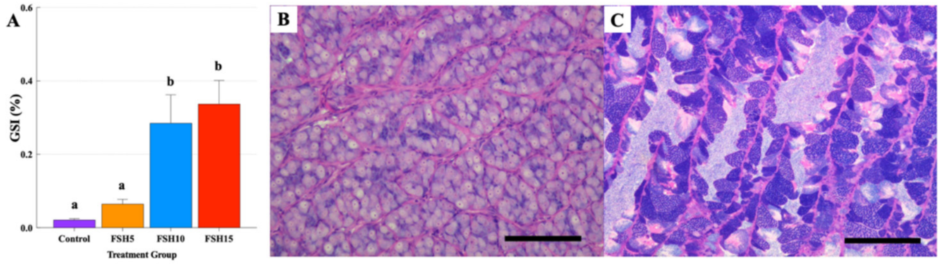

Fig. 1 Response to a sixweek administration of rsdFSH on hatchery-produced F1 immature male greater amberjack. A) Mean Gonado-somatic index (± SEM). B) Testicular sections dominated by spermatogonia. C) Testicular lobules filled with spermatozoa. The scale bar indicates 200 µm (B) and 500 µm (C).

(Continued on next page)

Results

In the Control group, the testes were dominated by spermatogonia, and spermatocytes represented a small fraction of the gonadal content. The administration of 10 and 15 μg kg^{-1} of rsdFsh stimulated proliferation and differentiation of germ cells and a significantly increased GSI values (Fig. 1). Sperm was found within the testes, and histology confirmed the presence of all spermatogenic stages and spermatozoa in the seminiferous lobules. Additionally, male plasma levels of testosterone (T) and 11-keto T differed among groups and with a significant increase after administration of 10 and 15 μg kg^{-1} of rsdFsh.

Contrary to the males, no differences were found in the GSI values of females between groups. However, the mean diameter of the largest primary oocytes differed significantly, with a 27 and 29% increased size in females treated with 10 and 15 μg kg^{-1}, respectively. Although ovarian lamellae filled with oogonia and primary oocytes were found in females from all groups, micrographs of ovarian sections displayed a higher content of oocytes in the perinuclear stage in the ovaries of females treated with 10 and 15 μg kg^{-1}. Significantly increased plasma levels of T were also found in females given 10 and 15 μg kg^{-1} of rsdFsh, but no differences were detected in the plasma levels of 17β-Estradiol. Finally, no differences were found in plasma sex steroid levels in fish after injection with rsdLh.

Collection of experimental data from the second experiment in underway, and the results will be presented at the conference.

Discussion

The administration of rsdFsh only, was effective to induce gonadal development and early maturation in pre-pubertal male greater amberjack. Although oogenesis was not achieved in females, the increase in mean diameter of primary oocytes indicates that a longer administration of recombinant Fsh would have been beneficial for further development of the gonads. All together these results demonstrated the biological potency of rsdFsh, and that it can be used to induce gonadal development in immature greater amberjack, therefore shortening the onset of puberty. The response to a combined usage of rsdLh and rsdFsh in plasma steroid levels and gonadal development is currently under examination, and based on the results, the appropriate doses and timing for administration will serve the purpose of implementing protocols for full maturation on pre-pubertal fish during the regular reproductive season.

The project was funded by the project NewTechAqua (European Union's Programme H2020, GA 862658).

*Email: joseph.laranja@kaust.edu.sa

Introduction

Temperature is considered to be one of the important environmental factors affecting growth in fish (Jobling, 1996). In this study, the gilthead seabream *Sparus aurata*, an aquaculture species that is of commercial importance in Saudi Arabia, was cultured at different Red Sea temperatures to determine its growth, FCR and nutrient utilization. The results obtained from this research will inform the growth performance and FCR of the fish grown in the Red Sea where the water surface temperature of the sea varies during summer and winter months.

Materials and Methods

Juvenile (212 ± 4 g) and pre-adult (492 ± 4 g) gilthead seabream *Sparus aurata* were cultured in separate experiments using 1-ton tanks supplied with seawater from the Red Sea wherein three different rearing temperatures were set as treatments (low: 24°C; mid: 28°C; high: 32°C). The fish were fed with a commercial diet (49% crude protein; 2.9% crude fat; 21.14 MJ kg^{-1} gross energy) to apparent satiation for 10 weeks. Fish were sampled every two weeks to determine growth and survival, while feed intake was determined daily. Whole body proximate composition of the fish was determined at the start and end of the culture trial.

Results

The results showed that growth was significantly higher at 24°C while lowest at 32°C in both the juvenile and preadult size fish. No significant difference on growth was observed between the 24 and 28°C group in the juvenile fish. However, in the pre-adult fish, the growth was significantly lower in the 28°C group than in the 24°C group. A significantly lower FCR value was observed at 24°C, followed by 28°C, while highest FCR was observed in the 32°C temperature in both fish sizes. Regression analysis suggests that SGR and feed conversion efficiency in the smaller fish were optimum at 25.9°C and 24.4°C, respectively, while in bigger fish at 24.8°C.

Protein efficiency ratio was significantly higher in the 24°C as compared to 28 and 32°C in both fish sizes. Body lipid, lipid retention and energy content in juvenile fish showed increasing trend as the temperature increases from 24 to 32°C, while body protein, protein retention and moisture content were significantly reduced as the temperature increases from 24°C to 32°C.

Discussion

Our results showed that better growth performance was observed at 24°C while the lowest growth was observed at 32°C in both the juvenile and pre-adult fish. Our data suggest that smaller size gilthead seabream has higher temperature tolerance range than bigger size gilthead seabream. The optimum temperature for growth observed in this study was between 25.9-24.8°C which is in line from previous report (26-24°C) (Hernández*, et al.*, 2003). As the temperature increases from 24°C to 32°C, the body lipid and energy content in juvenile fish showed increasing trend (fattier) while body protein, protein retention and moisture content were significantly reduced, suggesting that there was an increased utilization of protein over lipid to compensate energy demand at higher temperature. Nutritional manipulation in the diet by (slightly) increasing its protein level to compensate the protein needed by the fish for energy and growth at higher temperature conditions is suggested. The application of feed additives such as probiotics to improve overall status of the fish during temperature stress can be done.

Conclusion

The best temperature for growth of gilthead seabream cultured in the Red Sea was between 25.9-24.8°C while FCR was best at 24.8-24.4°C. Our results suggest that higher protein diet is recommended for gilthead seabream cultured at higher temperature conditions in order to support fish homeostasis and growth. Determining the optimum protein to energy ratio in the feed for gilthead seabream cultured at higher temperature conditions is suggested for an efficient and economical cage culture.

SMELLING THE DANGER OF CLIMATE CHANGE: THE CASE OF ATLANTIC SALMON OLFACTORY ORGAN

C. C. Lazado*, A. Krasnov, N. Albaladejo-Riad, L.H. Johansen, E. Ytteborg

[1]Nofima, The Norwegian Institute of Food, Fisheries and Aquaculture Research, 1433 Ås, Norway
*Email: carlo.lazado@nofima.no

Introduction

Recent studies have revealed the threats of climate change to aquaculture, an industry that has the potential to provide food and employment to the growing world population. To support further growth and expansion, the aquaculture industry must develop robust climate adaptation plans that are evidence-driven and supported by empirical data. This is particularly relevant for Atlantic salmon (Salmo salar), one of the major farmed fish in the world, where the impacts of future climate scenarios have already been identified by several prediction models. Nonetheless, biological relevance of these impacts is not yet fully elucidated.

The mucosal organs (i.e., gills, skin, olfactory organ, gut) of fish are highly sensitive to environmental changes. Their molecular and structural alterations often provide an indication of the quality of the environment; thus, these organs are promising models to study the impacts of climate-related stressors to fish health and welfare. In particular, the olfactory organ, which is a key organ for both immune defence and olfaction, has been shown to be highly affected by elevated near-future CO_2 levels via alteration of responses to sensory cues. In this study, we investigated how long period of elevated temperature and a heatwave, impacted the molecular and cellular properties of Atlantic salmon olfactory organ.

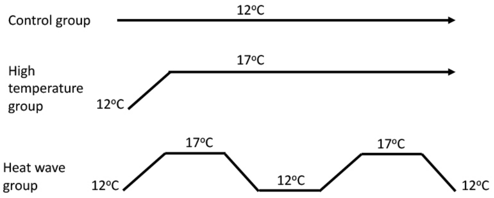
Materials and methods

A group of Atlantic salmon post-smolts were reared under three thermal conditions – Control group was at 12ºC, High temperature group was at 17ºC and Heat wave group was reared at 12ºC then gradually increased to 17ºC, then progressively lowered again to 12ºC. The experiment was carried out over 2 months. There were 2 rounds of heatwave episodes in the trial. The olfactory organs were collected at several time points for gene expression analysis and histology.

Moreover, olfactory organ explants from these groups of fish were developed at several time points during the trial and exposed to hydrogen peroxide to trigger oxidative stress.

Results and Discussion

Concerning responses to the increase of temperature, olfactory organ behaved as an immune tissue: the stressor stimulated expression of immune genes while several other functional groups were downregulated. This trend was seen in both groups (i.e. High and Heat wave groups) and in all time-points with exception of Heat wave group at the end of the first round. The immune responses were complex and include all tiers: pathogen recognition, communication and signalling via chemokines and cytokines, regulators, humoral and cellular effectors, development, and differentiation of lymphocytes. Increase was also observed in recently identified transcription modules (TM) of responses to inflammation, bacterial and viral infections. This was in parallel with the decreased abundance of erythrocyte markers (mainly haemoglobins transcripts) observed in five of eight comparisons, which suggested reduced circulation of blood in the olfactory organ. The greatest immune stimulation was found in the Heat wave group at the peak of the first wave and especially in high temperature (17°C) at the end of the second heatwave.



(Continued on next page)

Development of outgrowths from the olfactory explants were slower in the Heat wave group, especially at the end of the second wave. Inducing oxidative stress in the explants showed varying degrees of alterations, though considerable impacts in the ability to respond to the chemical stressor were identified during the second month of the thermal manipulation. During the first heat wave, all treatment groups showed almost similar tendency in the expression of a panel of antioxidant markers following oxidative stress induction. However, at the peak of the second heat wave, impairment of response to oxidative stress was identified especially in the Heat wave group. In particular, genes regulating the glutathione system did not respond to the oxidative stressor. Moreover, autophagy was induced in the High temperature and Heat wave groups after the end of the second heatwave.

Conclusion

The results reveal that the olfactory organ of Atlantic salmon was sensitive to climate-related stressors. Long period of high temperature and heatwave could alter the immune defences of the olfactory organ. Moreover, a heat wave likely impaired the ability of the olfactory mucosa to respond to oxidative stress.

RISKS OF PERACETIC ACID-BASED DISINFECTANT TO ATLANTIC SALMON PARR REARED IN RECIRCULATING AQUACULTURE SYSTEMS

Lazado, C.C. *, Eggen, M.L., Carletto, D., Mota, V.C.

Nofima, The Norwegian Institute of Food, Fisheries and Aquaculture Research, 1433 Ås, Norway

Introduction

There is a high regard for peracetic acid (PAA)-based disinfectants in recirculating aquaculture systems (RAS) because of the low risk of bioaccumulation, fast degradation with neutral residuals and minimal impact on biofilter performance. There is significant evidence regarding the physiological consequences of PAA in salmon post-smolts but not during the parr stage. Given that PAA efficacy is affected by different factors, it is a not advisable to extrapolate the health consequences in post-smolts to parr. Currently, the no-observed-effect concentration in Atlantic salmon parr is unknown. In addition, it remains to be evaluated how Atlantic salmon response to prolonged exposure to low dose PAA. The present study evaluated the effect of an acute and chronic PAA exposure on Atlantic salmon parr health and welfare.

Material and Methods

In this first trial, nine experimental RAS units were employed, where each unit was dedicated for one PAA concentration (0.0, 0.05, 0.1, 0.2, 0.4, 0.8, 1.6, 3.2 and 6.4 mg/L). Fish were exposed to the target PAA concentration in a static system for 1 h and the exposure protocol was repeated after a 52 h recovery. In the second trial, PAA was applied to Atlantic salmon parr reared in freshwater recirculating aquaculture systems over a 4-week period at a target concentration of 1 mg/L. Two administrations were tested, either in pulse (every 3 days) or continuous. The group that did not receive PAA served as a control. Fish tissue samples were collected for histology, gene expression, and biochemical analyses at day 0 and after 2 and 4 weeks of exposure.

Results

The fish survival was 100, 80 and 0%, respectively ≤ 1.6, 3.2 and 6.4 mg/L (Figure 1).

Fish swimming behaviour was normal in PAA ≤ 1.6 mg/L, whereas it become erratic with air gasping for PAA ≥ 3.2 mg/L. The fish appetite did not change among the different PAA treatment groups. Skin and gill histopathological alterations were pronounced in PAA ≥ 3.2 mg/L, characterized by a poorer skin condition and necrotic gill lamella (Figure 2). The skin acidic mucous cells density was 55% lower in the 6.4 mg/L group than the 0 mg/L group. The sub-lethal water pH values observed in the 6.4 mg/L group after PAA administration may have played a confounding and compounding factor to the PAA toxicity response in this group.

The expression of genes encoding for antioxidant defense in the olfactory organs, skin, and gills changed during the trial, but the time-related effects were more prominent than inter-treatment impacts. The antioxidant system in the mucosa of Atlantic salmon parr was responsive to PAA, corroborating earlier evidence in smolts. We found that the glutathione group of antioxidant genes was more susceptible to PAA. There was a tight regulation of mucosal and systemic oxidative stress as indicated by the profiles of reactive oxygen species and total antioxidant capacity in plasma and in skin mucus. Structural alterations have been identified in the gills, skin and olfactory organs.

Discussion

The current study identified the no-observed-effect concentration for PAA to be below 1.6 mg/L for Atlantic salmon parr and provided insights into its use as a water prophylactic strategy in RAS. Toxicity of PAA-based disinfectants is influenced by its acidified nature, which can interfere with the water pH of low alkalinity aquaculture systems.

The chronic exposure trial revealed that Atlantic salmon parr mobilised mucosal and systemic antioxidant defenses against the oxidative disinfectant PAA, but the mode of application did not impose a strong influence. The minimal effects of PAA application on the indicators of health and welfare of parr underscore the potential use of PAA as a routine disinfectant in recirculating aquaculture systems.

Introduction

Hydrogen sulphide (H_2S) is a naturally occurring compound, which has received more attention in recent years due to its central role as gasotransmitter within many physiological systems, including teleosts. Endogenously generated H_2S controls several important metabolic functions, including angiogenesis, neuronal activity, vascular relaxation, glucose metabolism, energy production, and the inflammatory response. On the other hand, H_2S gas produced by anaerobic bacterial decomposition of protein and other sulphur-containing organic matter can be detrimental to the fish. This water-soluble gas has an identifiable odour of rotten eggs. In recent years, H_2S-related mortality has become a major challenge in saline recirculating aquaculture systems (RAS) of Atlantic salmon. Significant advances have been made in elucidating its formation in these systems, however, the biological processes underlying the adaptive responses of salmon to this molecule remains elusive. In this study, we focused on understanding the mucosal immunotoxicity of H_2S in Atlantic salmon.

Materials and methods

Acute exposure: Atlantic salmon smolts were exposed to low (0.6 µM/L) and high (1.2 µM/L) H_2S for 3 hours and thereafter allowed to recover for 24 hours. Unexposed fish served as the control. Mucosal organs and skin mucus were collected after the recovery period for gene expression analysis and metabolomics.

Chronic exposure: Atlantic salmon smolts reared in recirculating aquaculture system were exposed continuously to either 1 µg/L or 5 µg/L H_2S. The group without H_2S dosing served as the control. Tissue sampling was carried out pre-exposure and at 2-, 4- and 6-weeks post-exposure. To identify whether H_2S exposure affected the stress responses of salmon to a secondary stressor, fish were exposed to a confinement stress at the end of the exposure trial.

Results and Discussion

Acute exposure to H_2S exposure affected the expression of genes involved in sulphide detoxification, stress and immunity. The responses exhibited a concentration and tissue-specific manner. The olfactory organ and gills were behaving similarly towards H_2S. Structural alterations in the different mucosal organs were minimal, however, damage scores were higher in the high dose group.

The results of the chronic exposure trial are currently under processing and are expected to be ready before the meeting.

Conclusion

The results reveal that the immunotoxicity of H_2S in Atlantic salmon. These results offer insights into how fish interact with H_2S and are expected to contribute to addressing the issue of this toxic gas in salmon RAS-based farming.

CHALLENGES AND OPPORTUNITIES IN THE APPLICATION OF THE 3R (REPLACEMENT, REDUCTION, REFINEMENT) PRINCIPLES IN AQUACULTURE RESEARCH: INSIGHTS FROM NORWAY

Carlo C. Lazado* and Elisabeth Ytteborg

[1]Nofima, The Norwegian Institute of Food, Fisheries and Aquaculture Research, 1433 Ås, Norway
*Email: carlo.lazado@nofima.no

Introduction

Excellent science and superior animal welfare go hand in hand. Therefore, ensuring that experimental animals are handled most humanely and ethically possible will significantly impact the scientific robustness of the data generated from a trial. The humane use of animals in scientific research is guided by the principles of the three Rs – REPLACEMENT, REDUCTION and REFINEMENT. Russell and Burch first described the 3R framework in their book The Principles of Humane Experimental Technique, first published in 1959 (WMS and RL., 1959). Since then, the concept has developed into an imperative component of research involving animals (Tannenbaum and Bennett, 2015).

In aquaculture research, the 3R framework has been applied for some time now, and the ethics boards granting licenses to conduct animal experimentation require that the concept will be involved in all aspects of the trial. This is highly relevant in Norway since at least 90% of the animals used in experiments in the country are fish (Norwegian Food Safety Authority or Mattilsynet, http://www.mattilsynet.no/fdu/om/arsrapporter). Therefore, there should be a continuous, upfront, and dynamic discussion from the different sectors, regardless of whether the involvement is direct or indirect in a trial, on how the 3R framework can be best utilised in aquaculture research. Norecopa is Norway's National Consensus Platform for advancing "the 3 Rs" in connection with animal experiments. Norecopa and Mattilsynet have been at the forefront of advancing the 3Rs in all species used for experimentation in Norway.

Unlike other animal models for research (e.g. rodents), you need to account for complex factors in handling aquatic animals. Aquaculture has changed dramatically in the last years (i.e. types of production systems, diversification of farmed species), which has also influenced how research is conducted. It is a must that the 3R framework adapts to this development. In order to achieve a broad, responsive, effective and innovative application of the 3R in aquaculture, sectors involved – from legislators down to the lab personnel - must venture into a learned discussion to identify the challenges and progress, as well as the opportunities that will define its continued relevance in the years to come.

This talk will highlight some of the challenges and opportunities in applying the 3R principles in aquaculture research, with a particular focus on Norway. We will highlight what had transcribed during the recently concluded National Workshop on 3Rs in Aquaculture Research which our group organised. In addition, we will discuss how the 3R principles are applied at different levels of our research at Nofima, especially our *in vitro* models and approaches to reduce the number of animals in fish health research.

GROWTH-INHIBITION EFFECT OF *Phaeobacter inhibens* AGAINST VARIOUS STRAINS OF *Vibrio harveyi* ISOLATED FROM MARINE AQUACULTURE SPECIES

D. Gotz[a]; E. Leclercq*[a], A. Le Breton[b], M. Castex[a], S.M. Picon-Camacho[b]

[a] Lallemand SAS, 19 rue des briquetiers, 31702 Blagnac ; France

* eleclercq@lallemand.com

Introduction

Vibrio harveyi is a Gram (-) pathogenic bacteria that causes high mortalities in temperate and tropical marine aquaculture affecting all developmental stages of important commercial farmed species including fish (e.g. European seabass, gilthead seabream), crustaceans (peneid shrimp) and shellfish (clam, oyster). Currently, there are no commercial vaccines available against *V. harveyi*. Autogenous vaccines are available but, due to the high variability and diversity of the *V. harveyi* group, the industry still mainly relies on the use of antimicrobials. As a consequence, there is an increasing number of *V. harveyi* field-isolates showing reduced susceptibility to the most used antimicrobials. Alternative methods are urgently required to control *V. harveyi* outbreaks in marine aquaculture systems.

The roseobacter *Phaeobacter inhibens* DSM 17395 has been previously evaluated as a safe probiotic candidate with antagonistic activity against pathogenic vibrios in marine aquaculture systems (Sonnenschein et al., 2021).

The study assessed the ability of *P. inhibens* DSM 17395 to inhibit the growth of *V. harveyi* isolates of distinct commercial origin, pathogenicity, serotypes and antibiotic resistance profile to estimate its potential contribution to the biocontrol of *V. harveyi*.

Materials and Methods

The candidate biological control agent *Phaeobacter inhibens* DSM17395 was tested against five distinct *Vibrio harveyi* isolates collected from the field (Table below).

Media

Reduced-carbon marine-broth (RCMB; sea salt 30 g.L^{-1}; bacteriological peptone 5 g.L^{-1}; yeast extracts 1g.L^{-1}); marine-broth (MB; sea salt 30 g.L^{-1}; bacteriological peptone 2,5 g.L^{-1}; yeast extracts 0.5 g.L^{-1})

Co-culture assays

Flasks containing 20 ml of RCMB were inoculated with 100 µl of overnight cultures of *P. inhibens* (~3x10^5 CFU/mL) and with a *V. harveyi* strain (~4x10^6 CFU/mL); or with *V. harveyi* only (Control). Co-cultures were incubated (22°C; 200 rpm) and samples taken after 1, 7 and 14 days of inoculation. Dilutions of the samples were plated onto vibrio-specific TCBS-agar (48h, 30°C) for *V. harveyi* enumeration.

Growth-inhibition assays with *P. inhibens* culture extract

P. inhibens cultures were extracted with ethyl acetate following standard extraction protocols, dried and resuspended in methanol. Various volumes of the extract were added to a multiwell plates and set aside until methanol evaporation. Then, 100 µl *V. harveyi* cultures (MB, OD_{600nm} ~ 0.1) were added to each well, the plates were incubated in a plate reader at 30°C and growth was assessed every 15 min by reading at OD_{600nm}. Growth curves were compared to those of the control cultures without *P. inhibens* extracts.

V. harveyi strain ID	Origin Host, Country, Stage	Clinical case	Antibiogram results
Aq 16-37	*D. labrax;* France; Hatchery	Yes	No resistance
Aq 23-64	*D. labrax;* France; Hatchery	Yes	AMX resistant
Aq 23-66	*S. aurata*; France; Hatchery	Yes	AMX resistant
Aq 20-88	*D. labrax;* Tunisia; Grow-out	Yes	AMX resistant
Aq 20-19	*S. aurata;* France; Grow-out	No	AMX resistant, FLU intermediate

D. labrax, Dicentrarchus labrax (European seabass); *S. aurata, Sparus aurata* (Gilthead seabream); AMX, Amoxicillin, FLU, Fluoroquinolone

(Continued on next page)

Results and Discussion

Co-culture assays **(Fig 1)**

In co-culture there was a clear inhibition of all the *V. harveyi* strains tested when grown with *P. inhibens*. This inhibition was significant 1-day after co-incubation and maintained throughout a long incubation period of 14 days. This indicates that the inhibition is not short lived nor overcome by the typically fast-growing *V. harveyi*.

Growth-inhibition assays with *P. inhibens* culture extract **(Fig 2)**

Growth inhibition was observed for all *V. harveyi* strains when incubated with crude ethyl acetate extract of *P. inhibens* culture, i.e. without *P. inhibens* cells or cellular fractions. *P. inhibens* produces secondary metabolite such as tropodithietic acid (TDA) and other bioactive compounds. TDA is described to have antagonising activity against other bacteria as well as quorum sensing properties.

Conclusion

Phaeobacter inhibens DSM 17395 significantly inhibited the growth of pathogenic *V. harveyi* isolated from distinct commercial origins, and this was at least partially mediated by *P. inhibens* extracts.

This biological control agent is a promising candidate to mitigate the propagation of *Vibrio harveyi* under aquaculture operations, as well as of other *vibrio* spp. of aquaculture significance as was previously documented.

P. inhibens DSM 17395 contribution to *V. harveyi* management should now be tested under commercial operations such as marine hatchery settings.

THE DOSE-RESPONSE OF SEAWATER ATLANTIC SALMON (*Salmo salar*) TO A MANNAN-RICH YEAST CELL WALL INGREDIENT TRADES BETWEEN GROWTH AND HEALTH BENEFITS

E. Leclercq[a]*; M. Rawling[b], M. Castex[a],

[a] Lallemand SAS, 19 rue des briquetiers, 31702 Blagnac, France
[b] School of Biological, Plymouth University, PL4 8AA Plymouth, UK
* eleclercq@lallemand.com

Introduction

Preventive health is a pillar of modern aquaculture that functional nutrition cement. Mannan-rich yeast parietal fractions (MOS) are safe and natural ingredients widely documented to conditionally promote health, growth and/or feed performance across a diversity of farmed animals. To date, no MOS dose-studies are reported in aquatic species limiting the optimal application of this biotechnology. In Atlantic salmon, a specific commercial MOS product (sMOS) was recently confirmed to enhance gut and skin barrier functions (Micallef et al., 2017; Leclercq et al., 2020). The aim of this study was to characterize the dose-response relationship between growth, mucosal health and sMOS dietary intake with the view to inform the strategic use of this ingredient.

Materials and Methods

The 13-week trial tested 4 dietary groups in quadruplicate using Atlantic salmon post-smolt (173 ±3 g; 200 fish / tank; 740 L flow-through tanks; 16 ppt, 16L:8D). The test diets consisted of a “European” post-smolt baseline recipe (17% FM, 17% FO; 45% prot, 23% lip) supplemented pre-extrusion with sMOS (Lallemand SAS, France) at 0, 2, 4 or 6 kg/T (Control, 2-, 4-, 6-sMOS) and hand-fed to apparent appetite 4 times daily across the trial.

The trial (**Fig.1**) comprised an ideal (no challenges), a chronic heat-stress and a recovery period following exposure to hydrogen-peroxide (H_2O_2), together mimicking demanding commercial-conditions. Growth and feed performance were assessed, as well as gut and skin barriers (histomorphometry, skin mucus level and functionality) across sampling points (**Fig 1**). Difference to Control group were assessed using an unpaired t-test, significance was accepted at $P < 0.05$, data are shown as mean ± SEM.

Results and Discussion

There was a significant positive effect of 2-sMOS on SGR over the ideal (+9.6%) and f

In contrast to growth, the excretion of skin mucus overall increased with increasing sMOS intake (up to a significant +24.5% in 6-sMOS, **Fig 3**).

When considering mucus level per body-weight (BW) group and treatment (**Fig 4**), there was a significant negative linear relationship between skin mucus and BW in the Control (**Fig 4**); indicating weaker secretion in larger fish prioritizing for growth. In contrast, 2- and 4-sMOS appeared to remediate this apparent mucus deficiency in larger fish, while 6-sMOS further enhanced and standardized mucus excretion across BW-groups.

Further, an anecdotal reduction of mortality following H_2O_2-bath was recorded, from 3.47% in the Control and 2-sMOS groups to 1.39% in the 4- and 6-sMOS.

Modulation of nutritional markers, gut and skin cytoarchitecture as well as skin mucus properties in response to increasing dietary intake of sMOS will be presented.

Conclusion

Dietary sMOS elicited a growth and skin health benefit that is dose and body-size dependent. At low dose (2 kg/T), sMOS enhanced population growth and appeared to remediate the weak mucus excretion observed in faster growers. Higher intake (6 kg/t) further enhanced skin mucus excretion across body-sizes; without growth penalties but at the expense of the growth benefit observed at lower intake. This together suggests that the nutritional benefits achieved at low sMOS levels are increasingly traded towards health and resilience with increasing intake of this immune-modulatory compound.

These novel findings confirm the contribution of sMOS to overall farm performance and can be used to inform the strategic or seasonal use of this functional technology in support of targeted biomass build-up or mucosal robustness.

MITIGATION OF ATLANTIC SALMON WINTER-ULCER DISEASE (*Moritella viscosa*) USING A NOVEL YEAST-BASED FUNCTIONAL INGREDIENT

E. Leclercq[a]*; M. Rawling[b], M. Castex[a]

[a] Lallemand SAS, 19 rue des briquetiers, 31702 Blagnac, France
[b] School of Biological, Plymouth University, PL4 8AA Plymouth, UK
* eleclercq@lallemand.com

Introduction

The Atlantic salmon winter-ulcer disease generates significant volume and value losses across the industry. Functional feed specifically targeting increased skin robustness and recovery from this pathology must be developed.

Prior studies have documented and part-deciphered the distinctive immune functionalities of contrasted inactivated yeast cell walls (YCW) products of different origins (e.g. species, strain, production process), biochemistry and morpho-functionality. In the Atlantic salmon, some YCW typologies promote, e.g., systemic immune-stimulation while others favor the skin immune barrier (Leclercq et al., 2020) or mechanical wound-healing (Leclercq et al., 2021). Based on this prior knowledge, a novel YCW product was pre- selected for its putative mitigation of infectious skin ulceration.

This study tested the capacity of a novel YCW product (nYCW) to mitigate and resolve a realistic Atlantic salmon winter-ulcer challenge combining exposure to a mild pathogen- load by immersion then to aggravating abiotic factors.

Materials and Methods

The trial lasted 7.5 weeks (102 days) using Atlantic salmon post-smolts (93 ± 4 g; flow- through tank; 80 fish/tank; 10.5°C, 22 to 28 ppt) challenged with the "typical" winter- ulcer agent (*Moritella viscosa*) by immersion at day 39. Abiotic manipulations were applied post-challenge to increase the disease severity or impact (27-day-post-challenge (dpc), temp. drop to 9.5°C; 36-dpc, salinity increase to 30-35 ppt; 63-dpc, 1 min. crowding) then to promote wound-recovery (63-dpc, temp. increase to 11°C).

Two test diets were tested in quadruplicate ($n = 4$) consisting of a base recipe (15% FM, 7% FO) either non-supplemented (Control) or supplemented pre-extrusion with the test ingredient (nYCW, Lallemand SAS, France) at 4 kg/T. Feed were hand-fed to apparent appetite 4 times daily over the trial's duration.

Survival profiles post-challenge were compared using a Mantel-Cox log-rank test. At 37, 50 and 63-dpc, all fish were anaesthetized for semi-quantitative wound-scoring based on worst wound-score (0: no wound; 1: focal scale-loss; 2: cutaneous lesion; 3: muscle exposed; 4: muscle exposed over Ø ≥ 1cm; score 2 to 4 marked either "a" (active) or "r" (recovering) based on wound-edge appearance; R: fully recovered wound(s) only).

Proportion of wound-categories were compared between diets within time-points (Kruskal-Wallis with Dunn's post-hoc tests). Gut and skin histomorphometry, and skin mucus functionality were assessed pre-challenge and at end-point (5 fish/tank/time-point). Data shown as mean ± SEM; significance accepted at $P < 0.05$.

Results and Discussion

Survival post-challenge (**Fig 1**) was significantly higher in the nYCW group showing, in particular, higher resilience following abiotic manipulation and crowding. Population mean-wound score was significantly improved in the nYCW group at all time-points (28%, 21%, 34% improvement compared to Control at 37, 50, 63-dpc respectively). At 37-dpc, 37% of fish had at least one open-wound (score 2 or 3) in the nYCW compared to 50% in the Control-group; followed by 28% and 41% respectively at 50-dpc when score 4 were first observed. Recovering wound were also first observed at 50-dpc and were significantly more prevalent in the nYCW compared to the Control (14.5 ± 0.6 % and 7.4 ± 0.8% respectively, not shown) at that time-point.

At the end of the trial (63-dpc), the proportion of fish showing no or only fully recovered wounds (scores 0 and R) was significantly higher in the nYCW compared to the Control (44.9 ± 6.8% and 20.9 ± 2.0% respectively; **Fig 2a**). Amongst wounded specimens, a higher proportion of fish had at least one recovering wound in the nYCW compared to Control group (51.9 ± 7.2% and 36.6 ± 7.6% respectively; trend, $P < 0.10$; **Fig 2b**).

(Continued on next page)

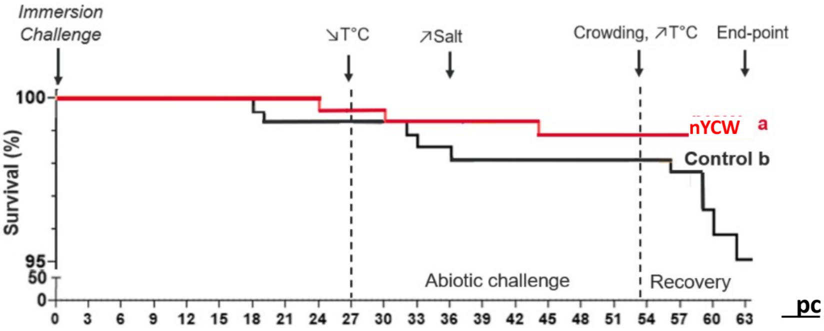

Fig 1. Survival profile following M. viscosa bath-challenge and abiotic manipulations (n = 4; Mantel-cox log-rank test; ^{a,b}: P < 0.05)

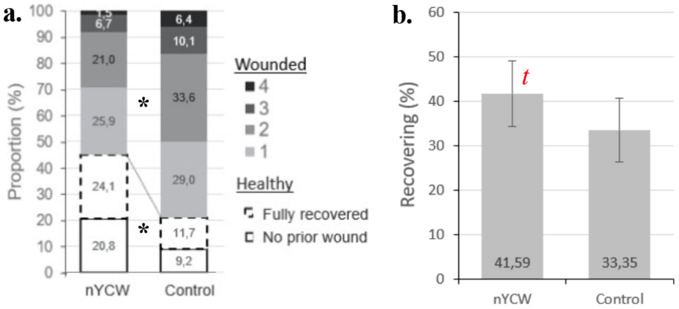

Fig 2. a. Wound-score distribution and **b.** Proportion of wounded fish with at least one recovering wound. Mean ±SEM; *: P < 0.05; ***t***: P < 0.10CV

Further data on gut and skin cytoarchitecture and skin mucus properties will be presented.

Conclusion

Combining a mild *M. viscosa* exposure by immersion with abiotic manipulations induced low mortalities but severe wound development and subsequent wound-recovery, together providing a realistic, commercially relevant winter-ulcer challenge.

Prolonged supplementation with a novel functional ingredient, *i.e.* 5 weeks prior and across the disease period, mitigated the severity of the winter ulcer outbreak and promoted healing of infectious skin ulcers. This ingredient has the potential to contribute to the preventive management of infectious skin diseases in the aquaculture industry.

Introduction

The deployment of cleaner fish is a widely used approach as biological control of the ectoparasitic salmon louse (Lepeophtheirus salmonis), one of the major challenges for the salmon aquaculture industry (Torrissen et al., 2013). However, concerns have been raised about the performance and welfare of cleaner fish under salmon sea cage conditions (Brooker et al., 2018). The two primarily used species, lumpfish (Cyclopterus lumpus) and ballan wrasse (Labrus bergylta) show distinct differences in their biology, life history and thermal tolerance that need to be addressed in husbandry practices and their use in sea cages. Ballan wrasse are known to remain in deeper and warmer waters while entering a dormant state with low activity and low metabolic rates in cold periods (Morel et al., 2013; Yuen et al., 2019). The aim of the current study was to evaluate the effects of enhanced dietary fatty acids and differences in condition factor on performance, welfare, and stress parameters of ballan wrasse reared at two different temperatures.

Materials and Methods

The experimental set-up is shown in fig. 1. During the feeding trial, ballan wrasse were fed with two different diets varying in essential polyunsaturated fatty acid levels (PUFA) in triplicated tanks, respectively. After three months, fish were sampled for chemical and fatty acid composition as well as welfare scoring, while the remaining fish were pit-tagged, and condition factor (CF) registered. Fish were distributed into six new tanks, each tank receiving similar numbers of fish from each diet and with high and low CF. During the temperature trial, three of the tanks were gradually lowered to 6 °C, while the remaining tanks continued at 15 °C. Analyses included mortality, growth and performance, chemical composition, fatty acid composition, morphological welfare scoring, gene expression in liver tissue, and skin histology.

Results

Dietary regimes had profound influence on the fatty acid profile of the fish without affecting growth and performance during the following temperature trial. There was a tendency towards less scale loss in fish fed with enhanced PUFA levels. This might indicate improved skin quality due to high n-3 PUFA levels, which has been previously shown for salmon (Berge et al., 2019). In the second part of the experiment, temperature strongly affected the performance of ballan wrasse. Fish reared at 15 °C showed higher growth rates, more fat and energy reserves and less ash content. On the other hand, fish reared at 6 °C showed negative growth rates, burned higher amounts of fatty acids and had very little energy reserves left at the end of the temperature trial. Concomitant gene expression analyses showed the positive effect of higher temperature on growth markers by up-regulating *GHrα* and downregulating *mstn* in fish reared at 15 °C compared to 6 °C. Moreover, two genes involved synthesis and oxidation of FAs (*elovl5, cpt1*) were upregulated in fish reared at 6 °C compared to 15 °C. Also, fish with high CF showed higher survival, growth rates and performance compared to fish with low CF.

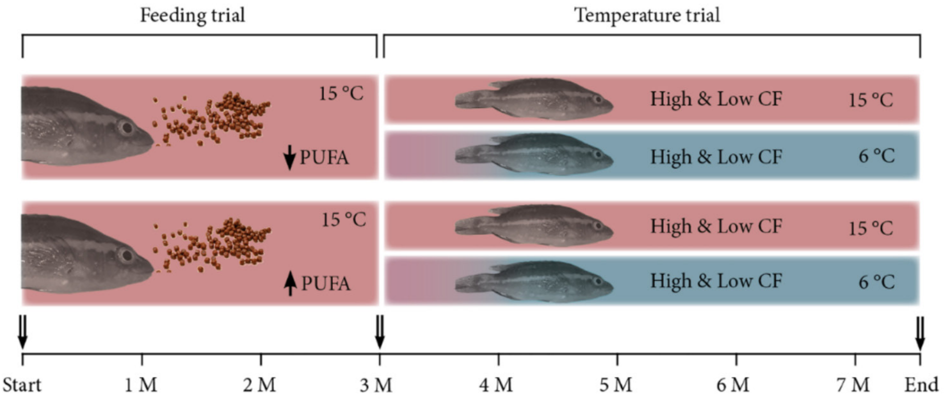

Fig. 1. Experimental design consisting of feeding and temperature trial. The timeline is indicating the start and end as well as the experimental duration in months (M). Errors indicate sampling points.

(Continued on next page)

Furthermore, temperature and CF affected the welfare of ballan wrasse. External welfare scoring showed higher prevalence and severity in emaciation, scale loss and the sum index score (sum of all measured welfare parameters) in fish reared at cold temperatures compared to fish reared at 15°C. Moreover, better welfare scores were found in fish with high CF, indicating those fish were coping better with low temperatures compared to fish with low CF. Fish reared at 6 °C also showed upregulated levels of *il-6* compared to fish at 15 °C, suggesting an enhanced immune reaction in response to cold water temperatures. Lastly, skin histology was assessed for the first time in ballan wrasse in the current study. Here, findings on epidermis thickness, as well as amount and organization of mucous cells showed that fish reared at 15 °C appeared to have better skin quality, while fish reared at 6°C showed signs of stress based on previous experience from skin histology on other teleost species.

Discussion and conclusion

Overall, low temperatures showed profound effects on the performance and external as well as internal welfare parameters of ballan wrasse. Thus, it can be considered a stressor for this species that will likely affect the delousing efficacy during winter. Results further showed that CF is an important factor for ballan wrasse to cope with low winter temperatures. These findings should be considered in the future use of ballan wrasse in salmon cages during winter months and supports the seasonal use of different cleaner fish species. If ballan wrasse are to be kept in sea cages during winter, enhanced feeding for increased storage of fat reserves is recommended. Moreover, assessment of the condition of cleaner fish before deployment is important to ensure sufficient energy resources.

The experiment was funded by the Norwegian Seafood Research Fund (FHF) as part of the project OptiRens (#901563).

INFLUENCE OF PROBIOTIC *(Lactobacillus plantarum)* ADDITIVE IN FEED ON HEALTH STATUS OF RAINBOW TROUT *(Oncorhynchus mykiss)* AFTER EXPERIMENTAL CHALLENGE WITH *Aeromonas salmonicida*

Zuzana Lepková*, Miroslava Palíková, Ivana Mikulíková, Jana Blahová

University of Veterinary Sciences Brno, Palackého tř. 1946/1, 612 42 Brno, Czech Republic
E-mail: H21285@vfu.cz

Nowadays, bacterial diseases are among the major issues of intensive aquaculture. Most infectious bacterial diseases can be controlled by treatment with chemotherapeutic agents, however, these pose a potential hazard to the environment and may also have a negative impact on the quality of the final product and human health. Apart from reducing the introduction of pathogens into the system and providing good living conditions, a number of substances that improve the health of fish are used, such as immunostimulants, probiotics, prebiotics, symbiotics and others (Palíková et al., 2015). Probiotics are microorganisms beneficial to the health of their host that actively inhibit the rate of colonization of the digestive tract by potential pathogens and/or stimulate the host‘s immune response. Bacteria usually do not colonize the intestinal mucosa of fish permanently, but must be continuously supplied to the fish in feed (Autin, 2010). One of the important representatives of the probiotic bacteria is the bacteria of the genus *Lactobacillus* (Balcazar et al., 2009). The effect of allochthonous lactobacilli was verified *in vitro* in a study conducted by Maruščáková et al. (2019). The tested probiotic strain reduced inflammatory changes after *A. salmonicida* infection through decreased expression of pro-inflammatory cytokines and increased expression of anti-inflammatory cytokines (Fečkaninová et al., 2019; Cingelová Maruščáková et al., 2021).

In our experiment we tested the effects of probiotic in the feed on haematological, biochemical and immunological parameters of rainbow trout (*Oncorhynchus mykiss*) as well as on fish ability to resist bacterial infection. The fish were divided into 3 groups: Group 1 was fed a feed with probiotic supplement (bacterial cells of *L. plantarum* R2 Biocenol™ in starch hydrogel layer) for 11 weeks, in group 2, pulsed-feeding was used (4 weeks of probiotic-supplemented feed, 3 weeks of probiotic-free feed and 4 weeks of probiotic-supplemented feed). Group 3 (control) was fed with probiotic free feed throughout the whole experiment (11 weeks). The first sampling was performed 7 weeks after the beginning of the test. On the same day, the remaining fish from all groups including control were infected with *Aeromonas salmonicida*, strain 89409 by immersion. The second and third sampling was done 1 week and 3 weeks after experimental infection, respectively. Blood samples were taken and used for analyses of haematological, biochemical and immunological parameters. Skin mucus samples were collected to determine the level of lysozym.

Mortality, changes of fish behavior and feed intake were monitored throughout the whole experiment.

The aim of the experiment is to verify the effect of probiotic applied in two different feeding regimes on health status of rainbow trout (*Oncorhynchus mykiss*) challenged with *Aeromonas salmonicida*. If positive effects are confirmed, the tested probiotic could be used for preventive treatment of the fish in intensive aquaculture systems and it could reduce the need to use antibiotics for the treatment of bacterial fish diseases.

This study was funded by the Internal Grant Agency of the University of Veterinary Sciences Brno (project no. 221/2022/FVHE).

Introduction

The spotted wolffish (*Anarhichas minor*), is a cold-water teleost that has been identified as a promising candidate for cold-water aquaculture. Wolffish have the advantage of being well developed at hatching, allowing direct weaning onto dry feeds in artificial settings. However, the nutritional requirements are yet to be fully established in its different life stages. The Early life stages of finfish aquaculture represents a crucial bottle neck for production in terms of manual labour, feed costs and survival. Furthermore, the economic and environmental sustainability of the emerging aquaculture sector for this species will depend on the quality of ingredients utilised in future feeds. The challenge of fishmeal replacement with other high quality alternative ingredients for larval stages needs to be assessed for effects on first-feeding behaviour, growth, and survival. To this end, the present study aimed to investigate the potential of two formulated experimental diets (Fishmeal based *vs*. High quality marine ingredients) for differences between first feeding behaviour, growth and survival of Spotted wolffish larvae in a four-week feeding trial.

Materials and methods

Eggs of spotted wolffish (obtained from Akvaplan Niva, Tromsø, Norway) were fertilized in December 2021, incubated over several months at X degress and hatched at Mørkvedbukta research station at Nord University in July 2022 (Bodø). Shortly after hatching, two experimental groups (comparing two test diets) were established containing 700 wolfish larvae per tank (4 tanks/group). The experimental diets were formulated to be isonitrogenous (60% protein), isocalorific (20.3 MJ/Kg) and isolipophilic (12.5% crude fat) but composed of different protein sources. Diet 1 contained 45% fishmeal,10% fish protein concentrate and 5% squidmeal, krillmeal and shrimp powder respectively; whereas diet 2 contained 25% fishmeal, 10% fish protein concentrate 15% squidmeal and krillmeal and 10% shrimp powder. The experiment lasted for four weeks, starting July 18th and was terminated on August 15th 2022. Experimental groups were kept under continuous light and relatively constant temperature (xxx). The experimental diets were provided throughout the study at regular time intervals, 7 rations a day between 08:00 – 23:00. Survival was monitored on a daily basis and samples for biometrics, proximate composition, digestive enzyme activity and muscle histology were taken once a week during the experimental period.

Results

Preliminary results reveal Differences between the two diets for growth and survival, suggesting that replacing fishmeal with more expensive but higher quality marine ingredients needs to be assessed for trade-offs between feed costs against welfare, growth and survival on the economic an environmental sustainability of the emerging spotted wolffish aquaculture sector. The results of this study will be presented in more detail on the poster. Project is being co-funded by the Kolarctic CBC program and Nordland County.

WOMEN EMPOWERMENT AND GENDER MAINSTREAMING IN SUSTAINABLE AQUACULTURE

Women represent 70% of the global aquaculture workforce, nevertheless, the great majority of management of the production is undertaken by men. The lack of comprehensive data on women in aquaculture and gender-oriented training is one reason why women are invisible in aquaculture policy. Empowering women in the aquaculture sector through awareness and specific training activities designed to promote the role of women in aquaculture and increase its visibility in the sector is one of the goals of the ASTRAL project.

ASTRAL (*All Atlantic Ocean Sustainable, Profitable and Resilient Aquaculture*) is a Horizon 2020 project focused on integrated multi-trophic aquaculture (IMTA) farming, aiming to define, support, and promote this type of sustainable aquaculture production across the Atlantic area. IMTA is the farming of species from different trophic levels in a way that allows one species' uneaten feed and wastes to be used as inputs (fertilisers and feed) for another species.

Within the Atlantic region, we continuously organise awareness and training activities to promote not only sustainable aquaculture but also women's empowerment and gender mainstreaming with the goal for these initiatives to continue beyond the project.

All-Atlantic Pledge Campaign (2021)
ASTRAL submitted a pledge at the All-Atlantic Pledging Campaign which aimed to engage with other stakeholders, strengthen collaboration, promote partnerships, mobilise partnerships and establish dialogues.

Training on waste upcycling and women empowerment (2021)
During World Ocean Day in 2021, a several activities were organised in Makoko fishing community of Lagos State in Nigeria, including a training session targeted to women.

Networking Friday on Women Empowerment in Aquaculture (2022)
As a celebration of the International Women's Day, a networking online session was held. The panel was filled with brilliant women in aquaculture working on the most diverse sectors, from international NGO (WWF Africa) to business and industry (Atlantic Sea Farms, EUA) as well as academia (Federal University of Pará, Brazil) and network (Women in Scottish Aquaculture (WISA), Scotland and Catfish Farmers Association of Nigeria) organizations. The session was moderated by a young researcher and Ocean Youth Ambassador at University Cape Town, South Africa.

Sensitisation and Women Mainstreaming into Aquaculture in Nigeria (2022)

A workshop was organised in Nigeria to support women empowerment in aquaculture. This workshop supported women involvement in aquaculture by promoting their entry into new and emerging markets and profitable enterprises/businesses in EU and non-EU Atlantic countries.

ASTRAL continues to work towards promoting sustainable aquaculture, food security and improved nutrition as well as promoting gender quality and empowering women and girls. As a result, we are also contributing to reaching SDG 2 (Zero Hunger), 5 (Gender Equality) and 14 (Life Below Water). Further information at www.astral-project.eu/

This project has received funding from the European Union's Horizon 2020 research and innovation programme under grant agreement No 863034.

Introduction

Nutrition is of prime interest in finfish aquaculture and plays a critical role not only because it influences production costs but also because it affects fish growth and waste production. Protein is the forefront of finfish nutritional research as fish have high dietary protein requirements. In addition, nitrogen derived from protein catabolism is one of the main water pollutants in recirculating aquaculture. The quantitative study of the energy and nutrients entering the organism via food and its partitioning into various metabolic processes, is one of the main goals of many experiments with fish. Such experiments usually involve extensive use of laboratory facilities for long periods, which make, from both ethical (3Rs) and cost perspectives, mathematical models important tools for designing and planning of scientific experiments.

The nutritional bioenergetics model we propose is based on an ensemble of rules that describe the processes of digestion, absorption and the allocation of energy derived from food to metabolic processes of growth, maintenance, maturation, and reproduction according to a set of priority rules. The model is based on the Dynamic Energy Budget (DEB) theory, a qualitative and quantitative framework to study individual metabolism throughout the entire life cycle of an organism making explicit use of energy and mass balances (Kooijman, 2010).

Material and Methods

The model is an extension of the standard DEB model (Sousa et al., 2008; Kooijman, 2010) and assumes three life stages (larvae, juvenile and adult) as well as metabolic accelerated development for early stages which is an established practice for studying fish species in the DEB context (Kooijman, 2014; Lika *et al.,* 2014, Stavrakidis-Zachou, 2019). Additionally, the model incorporates a digestion-assimilation module to simulate the food dynamics in the gut and the process of assimilation of the macronutrients from the gut wall. The model allows to track the fate of nitrogenous waste. The conceptual organization of metabolism is presented in Figure 1.

The model was parametrized for three fish species (*Sparus aurata*, *Salmo salar*, and *Oncorhynchus mykiss*) using commonly available data for fish growth, feeding, reproduction and gastric evacuation time. The model was validated using published data on weight, oxygen consumption, carbon dioxide production and total ammonia nitrogen (TAN) excretion for the three species reared in a range of temperatures and under different food compositions.

Results

Overall, the model performed well and was able to capture the diverse nature of the inputs of the validation datasets. On average the model predicted better the body weight than gaseous exchange and nitrogenous waste. Results of this study show that growth is strongly linked with the amount of feed consumed where a higher ration results in higher weight gain. Moreover, diets rich in protein translate in high production of Total Ammonia Nitrogen while an increase in feeding frequency can result in lower daily fluctuations of gas exchanges.

An emerging property of the model is that it captures the effects of food composition on assimilation, which in essence translates to the effects of protein-energy (PE) ratio in the diet. Food either low or high in protein, results in low assimilation rate. It follows, that for a given ratio of fats and carbohydrates, there exists a specific protein fraction where assimilation is maximized. The protein fraction that maximizes assimilation as well as the maximum value depends on the fat to carbohydrate ratio and, thus, on energy content.

(Continued on next page)

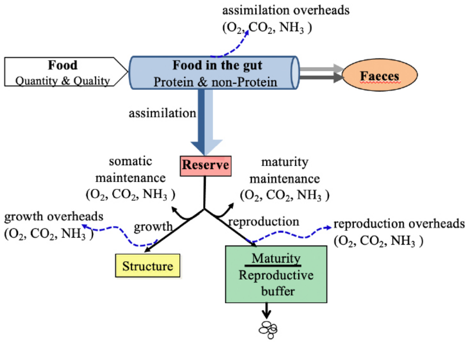

Figure 1. Conceptual representation of the metabolic processes. Food is partitioned into protein and non-protein components. Energy assimilated from food is added into reserves and subsequently allocated to fuel the metabolic processes: A fixed fraction ϰ of the mobilized flux is allocated to somatic maintenance and growth and the remaining (1−ϰ) to increase and maintain maturity or to reproduction.

Conclusions

We have developed a mechanistic model that focus on both energy and nutrient fluxes. The approach followed allowed to model the bioenergetics of fish throughout their life cycle as a function of temperature, food quantity and quality, and feeding frequency. The model allows simulations of growth, feeding, oxygen consumption, carbohydrate production, Total Ammonia Nitrogen, and solids, with hourly resolution. The model is one of the main components in the AQUAEXCEL^{2020} virtual laboratory (https://ae2020virtuallab.sintef.no/), which has been developed to enable virtual experiments in aquaculture research facilities.

Introduction

Norway is the world's second largest exporter of fish and seafood. Since 2019, the export value has surpassed 100 billion NOK. The high degree of export implies dependency between producing and consuming countries. Over the years, the Norwegian seafood industry has experienced several demand and supply shocks, probably influencing how the industry responds to new crises.

In March 2020, a national lock-down due to the Covid-19 pandemic was issued. Value chains related to food production were categorised as critical for society, meaning primary production and processing plants could keep their operation going. Still, outbreaks of the virus had to be handled. In January 2021, closed borders in the middle of the annual cod fisheries raised concern as foreign employees could not enter the country.

As a part of the project "*Seavid19 Ensuring economic sustainability in the seafood industry during crisis*" financed by the Research Council of Norway (grant no. 326647), researchers and industry actors collaborate to study effects and consequences of Covid-19 for the Norwegian seafood industry. Looking at different stages of the pandemic, the response to the pandemic, including effects of governmental strategies, challenges, opportunities and changes, are explored. This knowledge adds to previous studies of Covid-19 impacts in the seafood sector (Love et al. 2021).

Materials and methods

Interviews with 18 persons working in different parts of the seafood industry provide data for the study. This includes actors located in different parts of the country, belonging to the value chains of aquaculture (salmon) and wild fisheries (white fish, pelagic fish, and shellfish). Interviews focused on challenges and opportunities, which types of measures the authorities implemented and the consequences of them, as well as changes or innovations related to the pandemic. In sum, interviews provided learning about the industries' crises handling and potential to handle further crises.

Results

In March 2020, the Norwegian Seafood Association expressed concern about potential consequences for the seafood industry. Reduced capacity on planes affecting transport of seafood was one of the reasons for their worry. Measures such as allowing increased production for farmed salmon and the opportunity to transfer wild fish quotas from one year to the next were suggested.

Defining food production as critical for society was a key government strategy. This meant that schools and kindergartens remained open for children of employees in these industries, and production could be maintained if regulations for contamination were followed. The Norwegian Ministry of Trade, Industry and Fisheries and the trade organisations established regular digital meetings to discuss the current situation for the seafood actors. From the industry's point of view, this was decisive to get through the pandemic.

The interviewed salmon producers experienced both opportunities and challenges during the pandemic. With a large share of the Norwegian salmon being transported with passenger flights, the exporters experienced several challenges when this disappeared almost overnight. Only cargo planes had the possibility to transport seafood to the markets and with other export items competing for the same space, freight rates became very high. However, the market adapted with lower purchase prices and higher sales prices. At the same time, Norwegian salmon experienced other difficulties as well. China introduced double packaging in the beginning of 2022, following a burst of Covid-19 cases in Beijing.

Covid-19 also led to changes in consumer behaviour and commodity flows. While the HoReCa-market was hit hard, supermarkets, online shopping and take-away experienced a large increase, due to national lockdown or people being in quarantine. For the salmon exporters, increased demand from supermarkets has largely compensated for the decline in demand from other customer segments – such as HoReCa. The industry had to restructure – heavily focusing on global marketing and e-commerce.

(Continued on next page)

Interviews showed that the aquaculture industry, who operate in global industries, are used to adapting to change. Compared to other industries, like tourism (Škare, Soriano & Porada- Rochoń, 2021) or cultural and creative sectors (Travkina & Sacco, 2020), the seafood industry did not require significant public support measures.

Conclusion

Export figures show that the Norwegian salmon aquaculture managed to adjust very well to the changes caused by Covid-19. The strategies applied by the government were important for maintaining production throughout the different stages of the pandemic. As with previous experiences, the Norwegian government and seafood industry has gained knowledge that will be valuable in situations of rapid change or crisis in the future.

INTELLIGENT MONITORING SYSTEM FOR INDOORAQUACULTURE TANKS

Ana Paula Lima*, Nuno Dias, Bernardo Teixeira, Diana Viegas, Hugo Silva,Luis Lima, Marco Gonçalves,
Carlos Pinho, José Almeida

INESCTEC Technology and Science. Center for Robotics and Autonomous Systems
email: ana.p.lima@inesctec.pt

Introduction

Global fish consumption has increased at an average annual rate of 3.1% from 1961 to 2017, which ranks higher than all other animal protein foods (meat, dairy, milk, etc.) That puts tremendous pressure on marine ecosystems, as it equates to roughly 180 million tons of fish species being consumed each year [1]. The aquaculture and fish-farming industry has been gaining traction as acommercially viable, sustainable and eco-friendly path forward.

In aquaculture explorations, fish and other aquatic species are bred, nurtured, harvested, and pro-cessed under controlled conditions designed to maximize quality and yield and minimize costs and environmental impacts. Traditionally, indoor aquaculture tanks rely heavily on periodic human inspection and operation. Technological innovation brought forward by aquaculture engineer- ing comes in response to the demand for even tighter control of water quality parameters, more efficient monitoring of fish larvae growth, and more automated "intelligent" feeding processes.

The most studied tasks requiring automation typically revolve around detecting fish size charac-teristics [2] (i.e., length, area, width and/or perimeter), fish counting or direct biomass estimation.Biological models can then be used to derive total fish mass from a single measure [3]. Lopes et al. [4][5] expanded on this notion, developing a robotic system equipped with a camera and two laser projectors capable of directly estimating in real-time the biomass present in a large fish tank,with between 10% and 17% of relative error in biomass volume in a real aquaculture environment.

When it comes to fish biomass estimation in specific, estimates are crucial for evaluating fish growth during its growth cycle in the hatchery/nursery stages. The statistical characterization of a given's tank population is fundamental for aquaculture explorations to control and adjust food and medicine dosage, to be able to detect fish population loss in early stages, and perhaps most importantly, to adequately monitor growth rates to decide the best timeline for financial decisions.Further advancement of economies of scale in industrial aquaculture nursery/hatchery scenarios are thus heavily dependent on the automation of monitoring and quality assurance processes.

To address this problem, this paper will present the Feedfirst Intelligent Monitoring System for Indoor Aquaculture Tanks, a system developed hand-in-hand with industry partners designed withthree goals in mind: (i) continuous monitoring of water quality; (ii) continuous monitoring of larvae growth and population size; and (iii) automation and optimization of daily feeding.

Feedfirst Intelligent Monitoring System

The Feedfirst system was tailored to industry partners requirements in indoor aquaculture scenar- ios and the ultimate design goal is to close the perception-actuation loop, i.e. automate feeding control in accordance to perceived fish growth parameters. All measures from water quality to image data are relayed to a central computer that is responsible for both processing the incomingdata and providing a user-interface to the tank operator (see fig.3).

The machine vision processing pipeline is intended to provide two important metrics: the count ofpopulation size and the size of each larvae fish. To achieve this, the submerged cylinder possesses2 stereo-mounted cameras synced with an illumination system. Red light wavelengths are used so as to keep environmental disturbance to a minimum. Acquired images are subject to an imageprocessing pipeline as shown in fig. 2. The prototype system was tested in operational conditionsin a indoor aquaculture in Portugal.

Introduction

A fully dynamic predictive model for assisting the implementation of the Precision Fish Farming approach in inland cultures of Gilthead seabream (*Sparus aurata*) and European seabass (*Dicentrarchus labrax*) is being built up under the H2020 Project NewTechAqua (New Technologies, Tools and Strategies for a Sustainable, Resilient and Innovative European Aquaculture, Grant Agreement 862658). At the core of this approach is the development and application of a bioenergetic mathematical model for simulating fish growth and metabolism. This bioenergetic model has been applied to real rearing cycles of both target species, delivering long-term predictions (months to years) of weight and metabolism indicators, based on input data characterizing the forcing functions – water temperature, and feed quality and quantity (Lima et al., 2022). Notably, the Root Mean Squared Relative Errors (RMSREs) between predicted and measured weights along the four monitored fish growth cycles were below 10%. Despite these robust long-term estimations, the water temperature alone cannot describe certain unusual environmental conditions which affect the mid-term (weeks to months) productivity of the system.

Here the bioenergetic model is expanded to include the effect of dissolved oxygen (DO). Specifically, the DO saturation level is introduced as a forcing, along with the water temperature and feed quantity and quality. Recent laboratory experiments (Araújo-Luna et al., 2018, McNicholl et al., 2021) have quantified the relationship between DO levels and feed intake and growth for Gilthead seabream. Hypoxia events which may sporadically occur in aquaculture ponds thus affect fish metabolism and the success of farmed fish operations. The proposed model is aimed at providing information for supporting the management of not only the DO supply, but also feed, and sheds light on the link between DO and feed intake.

Methods

The mathematical formulation of the bioenergetic model is based on that of Brigolin et al., 2014, in which the time derivative of the fish weight is described as the difference between the anabolic and catabolic rates divided by energy density of body tissues. Although DO levels also affect the catabolic rates, here the DO saturation is introduced as a component of a hyperbolic function which is directly linked to the feed intake included in the anabolic rate component of the model. The model is applied to three pilot growth cycles of seabream and one of seabass in 500–600m^3 ponds at the Il Vigneto farm, Tuscany, Italy. Water temperature and oxygen concentration data are obtained from probes manufactured by Endress+Hauser, deployed continuously in the ponds along several months and recording data typically once every hour. This monitoring system was designed and implemented in the NTA project for testing the model. Data for the remaining forcings, i.e., feed quantity and quality, are provided by the farmer.

Results and discussion

With the introduction of the effect of DO levels, the RMSREs between calculated and measured fish weights decreased for all the evaluated growth cycles. Figure 1 shows the evolution of the mean fish weight calculated by the state-of the art model (DO not included) and the new model (DO included), along with sampled weights, for one of the evaluated seabream cohorts. The bioenergetic model is run using daily data sets and equally returns daily values of fish weight. The only sampled weight input into the model is the initial weight. For the subsequent times, the model results are calculated independently from the sampled data. Figure 1 shows that the inclusion of DO, apart from increasing the overall accuracy of the model, particularly improves the description of the dynamics in periods when the fish growth is stalled, reducing the amplitudes between local peak-and-troughs and expressing weight growth trends closer to the measurements. Given that these periods of relative stagnation last for few months, information on trends of feed intake and fish growth in these critical times is certainly relevant for preventing overconsumption of resources.

Introduction

Norway is the largest producer of Atlantic salmon (*Salmo salar*), with more than 300 million salmon put out to sea each year (Sommerset et al., 2020). In addition, in 2020 1,701,347 Atlantic salmon were reported used for research in Norway, which accounted for 74.5 percent of the total number of reported research animals (Kristiansen et al., 2021; Mattilsynet, 2021). In both research projects and commercial salmon farming, the welfare of the fish in a production unit is monitored by welfare indicators (WIs) that are either operational (OWIs) or laboratory-based (LABWIs). Morphological OWIs are for the most part manually assessed on a sub-sample of individual fish from the production unit. Examples of morphological OWIs are fin damage, eye damage, skin damage and gill damage, among others. Each OWI can be scored in different ways but an increasingly common approach is to score the injuries on a 0-3 scale, where 0 is basically undamaged and 3 can be classified as a severe injury (Noble et al., 2018). The process of manually assigning these welfare scores is time consuming and prone to both intra- and inter-observer error due to the subjective nature of the scoring method and the motivation and skill of the observer, amongst other factors. This paper discusses the feasibility of using hyperspectral imaging as a rapid and objective method of documenting and quantifying a selection of morphological OWIs.

Material and methods

We sampled n=1834 fish in total, across four experiments, and developed methods for image analysis based on machine learning algorithms using spectral data in the images. Automatic scores from the image analyses were compared to manual scores of WIs for each fish and this was used to evaluate the agreement between the two methods. In all experiments, hyperspectral images were taken on both the left and right side of each fish. The fish were presented to the camera on a conveyor belt moving at a speed between 10 and 20 cm/s. Morphological OWIs were recorded by trained manual observers for the same fish and used as reference data. For each WI the correlation between the hyperspectral index and the manual WI score was calculated. In trial 1, the dorsal fin was analyzed and compared with the manual OWI. The interrater agreement between 2 observers for dorsal injuries was calculated to be 0.66 in percentage agreement with a Spearman's correlation of 0.56 and a Cohen's kappa of 0.40. In trial 2, hyperspectral images of 120 fish, sampled before, during and after smoltification, were analyzed and correlated with smoltification status, assessed by quantifying plasma chloride levels after a 24-hour seawater challenge test. In trial 3, the use of hyperspectral imaging to evaluate eye haemorrhaging was tested. In trial 4, the potential of hyperspectral imaging to detect the degree of sea lice infection was assessed. The reference data in Trial 2 was a LABWI, namely blood serum chloride ion concentration after a 24-hour sea water challenge (Noble, et al., 2018) unlike the other trials which used OWIs as reference data.

Results and discussion

In trial 1 and 3 we observed the lowest correlation between the subjectively human scored OWIs and the hyperspectral scores (table 1). This can be due to a phenomenon called 'attenuation of error' where correlations are generally lower between two variables if one or both is measured with error (Adolph & Hardin, 2007). Part of the error can be attributed to the OWIs scored by human observers. Despite a standardized scoring scheme, different scorers weighted different aspects of an injury differently. Nevertheless, the correlation between the HSI scores and manual OWI scores in trial 1 is on par with the interrater agreement between two human scorers, which demonstrates that the hyperspectral system agrees almost as well with a human observer as two human observers agree with each other. The higher agreement for the LABWI supports this hypothesis. Counting lice is arguably less prone to subjective variation in scoring, although observer fatigue and thoroughness can influence the process, thus possibly resulting in a higher correlation in trial 4.

Conclusions

Together these results demonstrate the feasibility for using hyperspectral imaging as a technique for automatically monitoring welfare in Atlantic salmon and quantifying traits such as fin and eye injuries, smoltification status and lice infection levels.

(Continued on next page)

Table 1: Summary of the four trials and the agreement between manual welfare scores and the corresponding hyperspectral indexes.

	Number of fish scanned with HSI	Number of fish with manual reference	Indicator type	Feature	Agreement with manual WI
Trial 1	725	290	OWI	Dorsal fin injuries	0.54
Trial 2	849	120	LABWI	Plasma chloride	0.73
Trial 3	300	300	OWI	Eye injuries	0.55
Trial 4	1124	1124	OWI	Lice count	0.65

Introduction

The development of fish farm activities in proximity to the Mediterranean coasts may lead to environmental impacts mainly related to the release of organic matter, nutrients, and different elements, like metals, and can have both direct and indirect effects on its marine macrophytes, including its endemic seagrass *Posidonia oceanica* (L.) Delile, (Boudouresque *et al*., 2020).

Seagrasses can serve as biological indicators due to the long-life span of their tissues, relative to the temporal scale of environmental variability, which allows them to integrate the biological signal of environmental quality though time.

In the present study, *P. oceanica* tissues were used as bioindicators of metals and element concentrations in proximity to fish farms units in the Aegean Sea, Greece. A dating technique was applied to reconstruct element concentrations in a decadal scale (2012-2021).

Material and Methods

During September 2021, we sampled *P. oceanic*a meadows in two sites in proximity to fish farm units located in the Aegean Sea, Greece (Chios and Oinouses Islands). In each unit, one station was chosen in proximity (40-80 m,) to the fish cages (hereafter called 'Cage') while another station was chosen as reference in safe distance (~ 800 m) from the cages (hereafter called 'Control'). In each station, fifteen shoots were randomly collected by divers in depths 3 to 5 m. Shoots from each station were dated using the reconstructive technique of lepidochronolgy (Pergent, 1990). All samples were lyophilized and homogenized, and element concentrations were measured in the sheaths, for each reconstructed year, using an Inductively Coupled Plasma Mass Spectometer (ICP-MS).

Results

The lepidochronological dating enabled us to reconstruct the period between 2012 and 2021 for each of our sampling stations. For each year, total concentration (μg g^{-1} dry wt) of thirteen elements (P, Mn, Fe, Co, Ni, Cu, As, Zn, Se, Sr, Mo, Cd, Pb) was measured in *P. oceanica* sheaths.

In both fish farm units, concentrations of the metals Cu, Zn and Mo were higher in "Cage" stations compared to the "Control" ones. In the fish farm unit of Chios Island, P, Mn and Cd concentrations were also higher in "Cage" (Table1). Linear regressions indicated that the concentrations in the cages of most of these elements (P, Mn, Cu, Zn) have shown no significant change within the investigated period (2012-2021). Cd was the only element that has increased by 0.05 μg g^{-1} dry wt y^{-1} ($P < 0.05$, R^2=49 %) in Chios Island, while Mo concentration in Oinouses Island has decreased by 3.52 μg g^{-1} dry wt y^{-1} ($P <0.001$, R2=78 %).

Discussion

Concentrations of P, Mn, Cu, Zn, Mo and Cd were found to be 1.3-fold to 2.2-fold higher in cages compared to the control stations. All of these elements have been previously associated to fish farm activities (Grigorakis and Rigos 2011, Kalantzi *et al*., 2021) Their elevated concentrations are most commonly related to fish feed ingredients and derive from uneaten fish pellets or feed excreta. Apart from the feeds, metal pollutants like Cu, often derive from antifouling paints used in the fish cages' nets (Ratcliff et al. 2016). Nonetheless, concentration of these elements has shown no significant changes within the last decade (2012-2021). Notice should be paid to the increase of Cd concentration in Chios fish farm, since it is a heavy metal, potentially toxic for the marine environment.

(Continued on next page)

Table 1: Mean ± SD element concentrations (μg g^{-1} dry wt) in *P. oceanica* sheaths during 2012-2021 and analysis of variance (ANOVA) between Cage and Control stations for the two fish farm units (Chios and Oinouses Islands). Only significant results are presented ($P < 0.05$).

Introduction

Although quite extensively documented, out-of-season artificial reproduction of pikeperch still presents an issue of uncertainty in commercial hatcheries around Europe. Variability in outcomes is most often visible in fish individuality in response to hormonal stimulation presented in a wide range of latency times and egg quality over each broodstock (Żarski et al., 2019). Nevertheless, several thus far published papers pointed to stabilization of the procedure results with the experience of the breeders toward the reproductive cycle (Zakęś et al., 2013; Żarski et al., 2019; Ljubobratović et al., 2021). Thus, to get fully formed into a stable breeder, fish needs to undergo several reproductive cycles, which might be rather costly in terms of broodstock management economics raising the price of fingerling production. Therefore, we aimed to evaluate if the outdoor farmed breeders could be utilized for out-of-season reproduction batches following the shift of their natural reproductive cycle.

Materials and methods

In early November of 2021 and 2022, females were transferred from intensive outdoor conditions to fully controlled indoor RAS, while all the males were transferred in the first year and sperm quality parameters were evaluated in all of them in both years. During the five-week-long quarantine, the water temperature was raised from 10 to 18 °C and further transferred to a fully controlled climate room. Further on, fish were subjected to the simulation of summer, autumn, and winter as described by Ljubobratović et al. (2022). Finally, fish were artificially reproduced in the October of the following year as described by Żarski et al. (2019) and Ljubobratović et al. (2021), for SHIFT-1 and SHIFT-2. respectively. Egg quality was assessed in a total of 8 and 11 females in the first (SHIFT-1) and second (SHIFT-2) year, respectively.

Results

Female mortality in the period from transport indoors until the reproduction was 8.8 % in SHIFT-1 and 13.6 % in SHIFT-2, while the mortality of males in the first year was 2 % in the first year without any mortalities in the second year. All hormonally treated females ovulated and males spermiated in both years. Obtained embryo survival rate was 71.4 ± 10.8 % for SHIFT-1 and 63.2 ± 26.3 % for SHIFT-2 without significant differences between the two (Fig. 1). The progressive motility of the sperm of 20 evaluated males was 87.6 ± 8.3% and 83.2 ± 5.8 % for SHIFT-1 and SHIFT-2, respectively (Fig.1). A reduction in sperm motility was observed over the two consecutive years (*P* = 0.041, pair samples T-test).

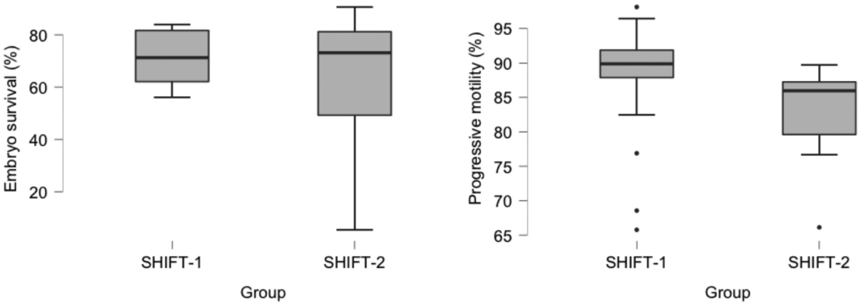

Fig.1. The embryo survival in 8 and 11 females following the reproductive cycle shift in first (SHIFT-1) and second (SHIFT2) reproduction trial as well as sperm motility in 20 males after first and second spawning occasion in out-of-season artificial reproduction of pikeperch *Sander lucioperca*

(Continued on next page)

Discussion

The presented outcome proves that mature pikeperch breeders are able to shift their cycle from natural to artificial and maintain a high quality of gametes. Noticed decrease in sperm quality in males should be the topic of interest in future studies. Likewise, the performance of females over the consecutive reproduction seasons should be evaluated. The procedure could be valorized for full-scale RAS farms in such terms to maintain one batch in partially controlled conditions suitable for preseason and seasonal reproduction while the breeders for out-of-season batches would be recruited following the evaluation of their reproductive performance.

Introduction

Climate change impacts can dramatically affect marine food production systems. Marine microbial biodiversity has the potential to become a strong nature-based solution to increase the adaptation of the aquaculture industry to a warming planet. However, the aquaculture microbiome is still underexplored. In this work we aimed to understand the impact of water increasing temperature to both environmental and fish microbiomes in recirculating aquaculture systems and cascading effects upon fish growth.

Material and Methods

The thermal trial was conducted at certified laboratories (EL91-BIOexp-04; experimental reference Number, 255,344) where three temperatures (24ºC, 29ºC and 33ºC) were tested in triplicate tanks for three months. Bacterial diversity was monthly assessed from fish skin, gills and gut and tank water and sludge through 16S rRNA sequencing. Raw data was processed with QIIME2 and taxonomy analyses performed with R software.

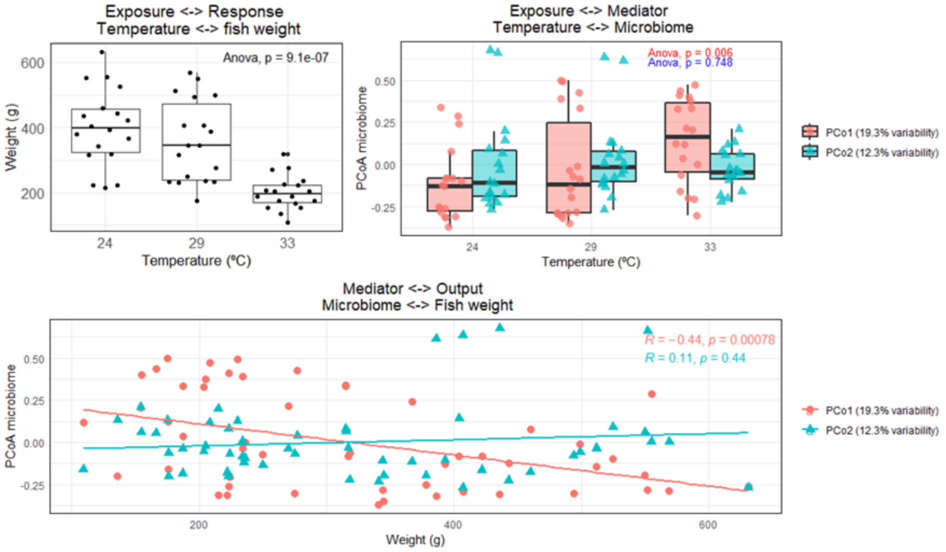

Fig 1. Association study between temperature treatment, fish growth and the microbiome. From left to right and top to bottom, we present the association between the weight and the temperature (top left); the association between the temperature and the microbiome community, summarized in the two principal coordinates of the Bray-Curtis PCoA (top right); and the correlation between the microbiome and the fish weight (bottom). For this analysis, we have considered the three months of experiment together, stratifying only by temperature treatment. The significance of each of the tested associations is presented in the corresponding panel, in the top-right corner. For the comparisons including the microbiome data, we coloured the corresponding points in correspondence tot the PCoA used.

(Continued on next page)

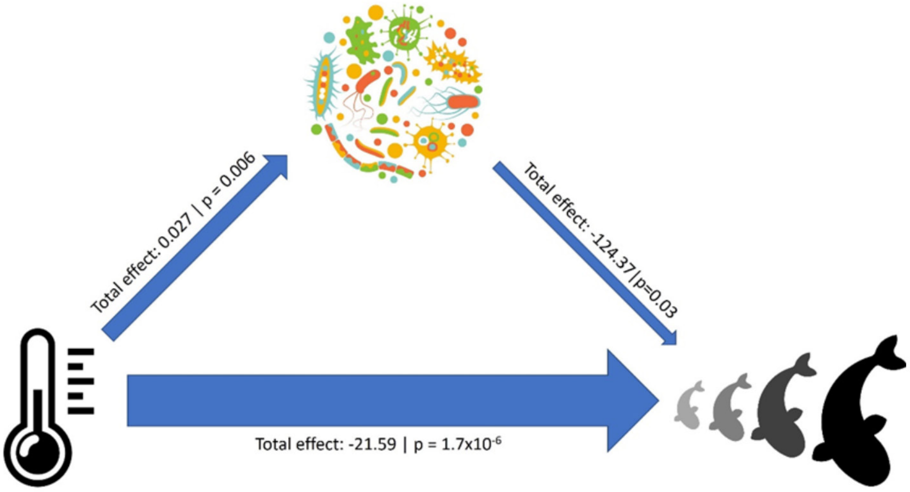

Fig 2. Mediation analysis summary results. The figure shows the effect of Temperature on fish growth and the microbiome and the microbiome effect on fish growth.

Results

Highest water temperature significantly impacted environmental and fish microbiomes and fish growth. Fish sections close to the exterior (gills, skin) were the most affected by temperature. Taxonomically, increase in temperature resulted in an increased abundance of thermo-resistant bacteria such as *Psychrobacter* and nitrogen-metabolism related ones, like *Acinetobacter*. Furthermore, genera such as *Enterovibrio* which has been described as having several pathogenic strains in fish, were only observed in this extreme temperature condition. Mediation analysis revealed a statistically significant influence of the differential microbiome composition upon fish growth.

Conclusions

Aquaculture climate change simulations result in fish microbiome alterations and compromised growth. Thus, paving the way to the development of microbiome-based tools to boost the adaptation of the aquaculture industry.

Introduction

Production of fish larvae is dependent on the use of live feeds for initial feeding. However, live food is costly, and may cause nutritional deficiency and low growth rates. A successful weaning strategy must ensure the production of well-fed larvae with fast growth and high survival, thus reducing production costs (Imentai et al., 2020). The histological study of the liver and intestine might support the evaluation of the nutritional status of larvae during the rearing process.

The flathead grey mullet *Mugil cephalus* is an emergent species for Mediterranean aquaculture diversification. However, little information on its larval nutritional requirements is available, and weaning still represents a bottleneck in this species (Loi et al., 2020). The aim of this work was to test three different co-feeding strategies on *M. cephalus* larvae, to find out whether reducing the level of Artemia sp. in the feeding protocol affected specific indicators of nutritional status, such as growth performances, hepatocyte vacuolization and intestine morphology.

Materials and methods

Larvae (22 dph), previously fed enriched rotifers, were divided into 3 experimental triplicated groups, at initial density of 4 larvae L^{-1} (1090 larvae in each 300 L tank). A 12h L: 12h D artificial photoperiod was set. Main water parameters were regularly monitored. Three weaning protocols: A100, A50 and A0 (2, 1, and 0 Artemia sp. ml^{-1} day^{-1}, respectively) were applied. For A100 (standard protocol), 5 enriched rotifers ml^{-1} day^{-1} were provided until 26 dph, together with 2 enriched Artemia nauplii ml^{-1} day^{-1} until 25 dph, gradually reducing the dose until 32 dph. In A50, the dose of Artemia was halved, while in A0 larvae received only rotifers until 32 dph (end of live prey period). In addition, a commercial microdiet (Gemma micro 0.1, Skretting) was offered in all treatments for the whole experiment, mixed 1:1 with Gemma wean 0.2 (Skretting) from 31 dph to the end of the experiment (36 dph).

Mullet growth performances were assessed at each of 3 sampling points, measuring total length (TL, mm), myotome height (MH, mm), Condition index (CI) and eye diameter (ED, mm). Five fish per tank were also preserved for histological analysis. Liver lipid area was assessed as described in Loi et al. (2020). At the end of the experiment, 10 intestinal fold height (Fh) and 10 enterocyte height (Eh) were measured in the histological sections of each fish and the mean values were used for the analysis. Finally, at the end of the experiment, mortality was also estimated.

Results

All the growth parameters increased over time. TL and MH were significantly ($p<0.05$) higher in the A100 treatment. CI and ED showed no statistical difference between A100 and A50, but in the A100 they were significantly higher than in A0 ($p<0.05$). The liver area covered by lipids grew significantly in the last experimental week, with no difference between treatments. In the intestine, Fh was significantly higher in fish fed Artemia, while Eh in A100 was statistically higher than in the other treatments. The lowest mortality was observed in A0 (35%), while A100 presented the highest mortality percentage (68%), followed by A50 (57%).

Discussion

ED resulted bigger in A100 larvae, implying a larger retinal image and an improved visual acuity (Papadakis et al., 2018). This suggests that fish were better able to catch preys than fish from other treatments and this may have led to a higher growth rate in the larvae fed standard Artemia dosage. The myotome development and the CI are sensitive markers for assessing inappropriate feeding conditions in fish larvae (Yúfera et al., 1993). The lower MH and CI measured in A0 may be a consequence of poor feeding conditions of the larvae fed rotifers only, as previously observed by Imentai et al. (2020).

(Continued on next page)

Histological observations of liver and intestine are considered indicative of the nutritional status of fish larvae (Przybyl et al., 2006). In this study, no significant effect of the dietary protocol was observed at the hepatic level; however, lipid coverage was slightly higher in fish fed Artemia and especially in those from the A100 treatment. This is possibly related to a higher amount of lipids in Artemia compared to rotifers (Imentai et al., 2020). The higher lipid coverage is consistent with better growth performances observed in the Artemia treatment. Significant differences were furthermore observed in the size of intestinal villi and in the height of the enterocytes, which were longer in fish from A100 than in fish from A0. Similar results were observed in pikeperch by Imentai et al. (2020), where larvae fed exclusively rotifers had significantly lower enterocyte height. It is thus plausible that fish from the A100 treatment were better-fed and grew faster as a consequence of a higher surface area for nutrients absorption.

In conclusion, fish fed standard dose of Artemia shown the best growth performances and hepatic and intestinal conditions. This may have been driven by the lowest final density observed in A100 due to the mortality rate, or by the highest nutritional value brought by the Artemia intake. Nonetheless, the data observed in the A50 treatment suggest that halving the Artemia dosage may still result in good larval performances and survival, and lower the production costs of live food.

Introduction

Salinity potentially influences euryhaline fish growth, since the energy employed to maintain homeostasis is not available for development (Cardona, 2000). The optimal salinity for growth and metabolic rates depends on the species life history strategies and developmental stages (Morgan and Iwama, 1991). Exposure to less-than-optimal salinity, and the associated metabolic costs of osmoregulation, may influence the fish energy status and the lipids dynamics between the liver, the muscular mass and body fats reserves (Rabeh et al., 2015), which in turn may compromise growth performances.

Thanks to their low trophic status and their euryhalinity, mullets have recently become a species of interest for aquaculture. In particular, the flathead grey mullet *Mugil cephalus* is appreciated for its salted and dried egg roe, a traditional highly valued product. Despite its importance, little is currently known about its physiological performances under different salinity conditions. The aim of this study was therefore to compare the effects of two salinities on the growth performances, survival rates and nutritional status of juvenile *M. cephalus* born and raised under laboratory conditions.

Materials and methods

Five-month-old juveniles (N=380, 25.33±1.01mm length and 0.18±0.03g weight, mean±s.e.), from the same batch of eggs and reared in intensive conditions, were equally distributed into two experimental triplicated groups. Fishes were reared for 3 months at two salinity levels: freshwater (FW, 0ppt) and saltwater (SW, 36ppt). Fishes were fed *ad libitum* with artificial dry feed (Skretting).

At the end of the test, survival was assessed for each treatment. Growth was evaluated considering mean total length (TL, mm) and body weight (BW, g), Specific Growth Rate (SGR, % day^{-1}) and Condition Index (CI). Liver lipid coverage (ACLV) was histologically monitored as described in Loi et al. (2020). Total lipids, fatty acids, and other lipid bioactive molecules such as endocannabinoids (ECs) and N-acylethanolamines (NAEs) were assessed on juveniles' homogenized whole body.

Results

Survival rate was high and similar ($p>0.05$) between treatments. TL and BW grew over time, and juveniles reared in SW showed a significantly ($p<0.05$) higher SGR for BW. CI was slightly (not significantly) higher in fish reared in FW. ACLV increased along the experiment, with no difference between treatments. At the end of the trial, FW and SW did not differ in terms of total lipids and fatty acids content, while lipid signalling molecules NAEs (specifically AEA, OEA and DHEA) were found significantly higher in fish reared in FW.

Discussion

Either fresh- and saltwater resulted suitable for juvenile survival. The ability to tolerate freshwater is directly proportional to fish size, as demonstrated by Rodriguez et al., 1993 when recorded the lowest (<20%) survival of *M. cephalus* juveniles in freshwater. Interestingly, their experiment involved larger and older individuals compared to those used in the present study, which should have therefore better coped with low salinities. Our survival results similar to that observed for juveniles of another mullet species, *Mugil liza*, reared under salinities below 24ppt, which evidently do not negatively impact survival in this species (Lisboa et al., 2015).

Juveniles reared under the two salinities showed similar growth, except SGR for body weight, higher in SW. CI was slightly higher in juveniles reared in FW, suggesting that extending the experimental period could result in a better growth than at higher salinity levels. Previous works on the same topic are contradictory, suggesting better growth in saltwater (Lisboa et al., 2015), sometimes in freshwater (Cardona, 2000) or even at intermediate salinities (De Silva and Perera, 1976). This variability is possibly due to the different developmental stages of the fish used in the experiments, which can modify the energy cost associated with the maintenance of homeostasis (Lisboa et al., 2015).

(Continued on next page)

ACLV, total lipids and fatty acids resulted similar between treatments. On the other hand, the bioactive fatty acid derivatives NAEs were higher in fish reared in FW, suggesting a different activity of the FAAH2, the NAEs' degrading enzyme involved in hyperosmotic stress responses in other vertebrates.

In conclusion, fish reared in freshwater have similar performances to those reared in saltwater. Our data suggest that the transfer of mullet juveniles from saltwater hatchery conditions to freshwater is a viable commercial scale production strategy, and this could increase the number of suitable spaces available for *M. cephalus* aquaculture.

Introduction

The polyculture of fish with other organisms at different levels of the trophic web (Integrated MultiTrophic Aquaculture, IMTA) is an eco-friendly alternative that has received increasing attention (Bierwirth, et al 2022) due to its environmental benefit and promises considerable economic potential. Among the co-cultured organisms Porifera, or sponges, seem the most promising due to their high efficiency in removing organic particles between 0.1–50 μm (Simpson, 1984; Larsen and Riisgård, 1994; Riisgård and Larsen, 1995; Hadas, et al. 2006), capable to positively affect the quality of the surrounding water and their intrinsic economic value. The present study was undertaken to assess the survival, the growth rate and the effect of rearing methods in different sponge species within the Remedia Life IMTA system.

Materials and methods

The Remedia Life IMTA system, ongoing in the "Maricoltura del Mar Grande" aquaculture plant (Sothern Italy, Northern Ionian Sea; www.remedialife.eu), consists of fish cages producing *Dicentrarchus labrax* (Linnaeus, 1758) and *Sparus aurata* (Linnaeus, 1758), to which an innovative set of bioremediator organisms such as sponges, polychaetes, bivalves and macroalgae have been associated (Giangrande, et al. 2020). Among sponges five species were reared in: *Aplysina aerophoba* (Nardo, 1833), *Geodia cydonium* (Linnaeus, 1767), *Hymeniacidon perlevis* (Montagu, 1814) *Ircinia variabilis* (Schmidt, 1862) and *Sarcotragus spinosulus* (Schmidt, 1862). Specimens were cut into explants of similar size and arranged in the Remedia Life long-line system down to ~6 meters depth. Explants monthly monitoring was performed to evaluate the rearing performance in terms of survival and growth rate. For *S. spinosulus*, an additional comparison among three rearing techniques (fishnet sock, rope and net bag) by means of survival rate was carried out.

Survival rates were assessed by visual observation and calculated from the initial and final number (N) of explants as follows: Survival (%) = $(N_{final} / N_{initial}) \times 100$. Monthly growth rates were calculated measuring volume (V, mL) by water displacement as follows: Growth (%) = $((V_{final} - V_{initial}) / V_{initial}) \times 100$.

Results

All sponge species during the first year of rearing showed a high survival ratio, with values not lower than 82% (for *S. spinosulus*). Similarly, all species showed values of more than 6% monthly biomass increase (with values up to 16% for *A. aerophoba*), with the exception of *H. perlevis*, which showed a volumetric reduction of almost 2%. However, when statistically analysed (Mann-Kendall trend test, Gilbert 1987), this decrease was not significant (p (no trend) = 0.375), nor the increase of *G. cydonium* (p = 0.113); for the rest of the species, a significant increasing trend was detected (p values < 0.01).

Regarding the first-year culture methods of *S. spinosulus*, all of them resulted in a survival rate of more than 82%, reaching 91% of the cases when the net bag was used (figure 1).

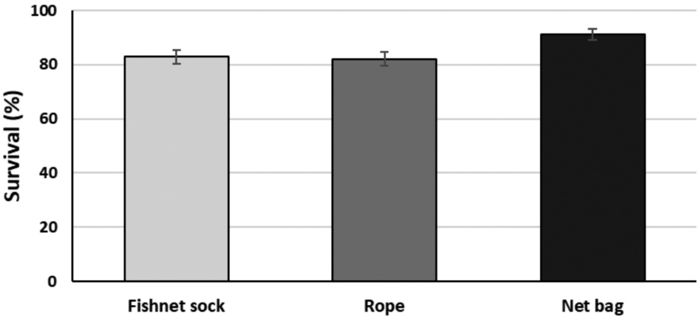

Fig. 1. Effect of the rearing method used in the survival (± SE) of *S. spinosulus*.

(Continued on next page)

Discussion and conclusions

Overall, all tested sponge species promise great results in the IMTA activity, with high survival and growth rates. When compared with same taxonomic subclass sponges reared in net systems, the five species cultured in Remedia Life IMTA plant show a higher mean survival rate, even when rope system was used for *S. spinosulus* (Bierwirth et al. 2022). Growth, however, is a less studied parameter among *in situ* cultured sponges of the selected species and makes the comparisons complicated, which at the same time highlights the importance of the present research in order to improve productivity in this type of aquaculture systems. All in all, the increase up to 300% of additional biomass (for *S. spinosulus*) and high growth rates (as for *A. aerophoba*) together with their demonstrated filtering activities (e.g. Wehrl et al. 2007; Trani et al. 2021) make these sponge species ideal candidates for co-culturing in IMTA plants.

ACUISOST is a project funded by Next Generation EU funds and born inside of ACUIPLUS Cluster. The main goal of ACUISOST is to include the concept of sustainability in aquaculture as a cornerstone of the Blue Economy, as stated by the European Union (Strategic Guidelines for the Sustainable EU Aquaculture), as well as the Spanish authorities (UN Sustainable Development Goals). By this means, ACUISOST aims to explore the use of new nutritional strategies, together with technological additives, that could lead to the manufacturing of new, functional and sustainable fish feeds. This innovation is intended to improve resilience in fish industry, by enhancing fish production, health and welfare under the aquaculture production system and overcoming climatic change issues; thus, promoting a more resilient and sustainable EU aquaculture industry.

As that is an ambitious goal, ACUISOST is not alone in this huge challenge and counts with the backup of many research institutes (and universities), as well as cutting edge companies. The partner companies of this project are: DIBAQ S.A, Health Tech BioActives (HTBA), NATAC Biotech, TEBIO and FAES FARMA – TECNOVIT.
Together, we are committed to develop the following activities:

- Development of new fish feeds based on insect meal along the production cycle as a sustainable substitute of fish meal.
- Development and validation of new sustainable functional fish feeds as an alternative strategy to anti-microbiological compounds, by including bioactive plant-based compounds (phytogenics).
- Inclusion of sustainable additives on aquafeeds to improve the nutritional quality and shelflife of the fillet at chilling and freezing temperatures.

These studies will take place in an integrated and novel way (preliminary screening and functional evaluation of additives of interest by *in vitro* approaches using different cell cultures, followed by their validation by means of an *in vivo* trial), as well as under a scenario focused on climate change. These studies will be addressed in two of the main European farmed species, the gilthead seabream (*Sparus aurata*) and rainbow trout (*Oncorhynchus mykiss*). In addition to this, communication and dissemination plans have been designed to share the knowledge and innovation generated by the project to stakeholders and the general public in order to maximize the socio-economic impact of the project.

ACUISOST has created a multidisciplinary and integrative consortium in which research institutions (IRTA, University of Barcelona, University of Vigo, University of Murcia and ICTAN, CSIC) collaborate together with industrial stakeholders in order to achieve the project's goals. Consequently, the proposal will create a multidisciplinary, inclusive, and cross-cutting framework where the skills and competencies of each of the partners will allow the successful achievement of the project's objectives and generate a positive impact on the aquaculture industry and therefore, on society. In this context, the project is the result of exhaustive study work, in which various scientific groups with a multidisciplinary profile and diverse areas of specialization are involved, but which are rooted in a common point: the sustainable development of aquaculture, under principles of animal welfare, nutrition and circular economy, in which cooperation between the key players, and the transfer between the field of research and industry is key to this development.

During the event, ACUISOST strategy will be described in more detail and the involvement with other key players in the aquaculture industry will be discussed.

Acknowledgements

ACUISOST is funded by the Spanish Ministry of Agriculture, Fisheries and Food (RD 685/2021) within the PRTR program with the support of NextGeneration EU.

ANALYSIS OF DIFFERENTIATION AND INNOVATION STRATEGIES FOR FISHERY AND AQUACULTURE PRODUCTS IN FRANCE AND SPAIN

L. Raquel

Université de Bretagne Occidentale
Email: Raquel.LopezMartine@univ-brest.fr

Today, salmon aquaculture is considered the fastest growing food production system in the world, accounting for 70% (or 2.4 million metric tonnes) of the market (Shepherd & Little 2014). However, since the mid-1990s, the real price has remained relatively stable, indicating that demand growth has kept pace with productivity growth (Asche, F., et al., 2011).

This development has also led to the creation of high-value cuts such as loins, similar to chicken fillets, as well as some products based on nuggets, trimmings and other cuts. Developments in this regard have been limited and whole fish and fillets, whether fresh, frozen or smoked, remain the main end products (Asche, et al., 2018).Study of the different products derived from the Salmoneidae family found in a common supermarket (Carrefour) in two different countries (France and Spain). The objectives of this study are described below.

We constructed a database from products derived from salmon and marketed by the websites of Carrefour France and Carrefour Spain. In Carrefour France, the most present group is still smoked salmon fillets (38%), however, in France the quantity of cooked by-products (36%) is much higher than in Spain (14%) and the next most abundant group is preserved by-products (9%). But for Carrefour Spain which belong to the groups established in the previous sections. It can be seen that most of the products marketed in this chain in Spain belong to the group of smoked salmon fillets (35%), the vast majority of which are marketed as thin slices of smoked salmon. Next, the groups with the greatest number of options are frozen loins (21%) and cooked by-products (14%). As for the other formats, they are represented in very small quantities.

The products with the highest price increases are those with sustainability certifications. This is followed by the products that do not present any kind of specification, closely followed by those with health claims. The difference between prices as a function of differentiating characteristics is significantly different (at all levels according to Tukey's test), with a p-value of 0.32.

The products with the highest value change depending on the country, for example in France, those of superior quality are those with the highest price, whereas in Spain the most highly valued products are those with some alteration in taste, and in this group there is hardly any difference between Spain and France. The difference between prices as a function of innovations is significantly different.

Freshness is one of the most important quality criteria for buyers of Atlantic salmon (Badiola, et al., 2017) and fish products in general and this is perhaps why traditional formats (fillet cuts with preserved shapes that guarantee the highest freshness to the consumer (Asche, et al., 2018)) are dominant in supermarkets.

EUROPEAN CONSUMERS' SUSTAINABILITY BELIEFS: WILD FISH *VERSUS* FARMED FISH

Introduction

Aquaculture may play a crucial role in global sustainability as a valuable source of food and preservation of fish stocks by reducing wild fish catching. Even so, consumers still have a worst perception of fish from aquaculture when compared with their wild counterparts. This worst perception is sometimes translated into lower consumption, as in the European Union (EU) most of the fish consumed comes from wild fisheries (75%) (European Commission, 2020), a higher proportion than the global average (48%) (FAO, 2020). Therefore, understanding European consumers' beliefs about farmed and wild fish is deemed key in building an effective strategy to communicate aquaculture sustainability to consumers.

The main objectives of this study were 1) to assess European consumer sustainability beliefs when farmed and wild fish are compared, and 2) to identify segments of consumers with similar beliefs about fish sustainability.

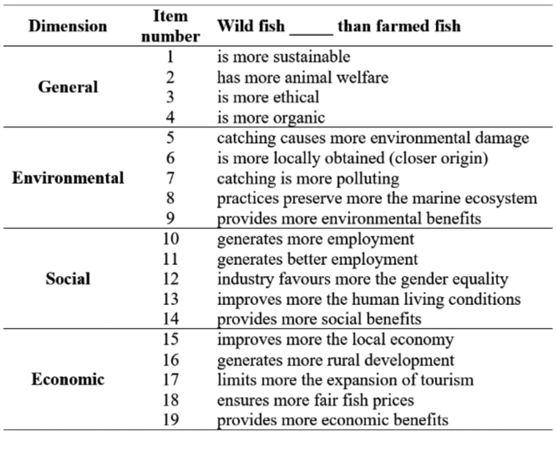
Materials and methods

An online survey was answered by 2,145 fish consumers from five EU countries (France, Germany, Italy, Poland, and Spain). The survey assessed 19 participants' beliefs comparing the sustainability of wild and farmed fish (Table 1). Beliefs covered four areas, including general aspects of sustainability and its three dimensions (environmental, social, and economic). All beliefs were presented in the format "Wild/farmed fish _____ than farmed/wild fish". A 7-point Likert scale, from 1 (strongly disagree) to 7 (strongly agree), was used to measure each belief.

Statistical differences between participants' beliefs from different countries were explored through an ANOVA with Tukey's test.

A two-step cluster analysis was performed to identify segments of consumers with similar beliefs followed by an ANOVA with Tukey's test to find statistical differences between segments. Finally, those segments were profiled using various sociodemographic variables, including country, age, gender, education level, perceived economic situation, and place of living (rural-urban and inland-coastal).

Table 1. Selected beliefs comparing wild *versus* farmed fish.



Dimension	Item number	Wild fish _____ than farmed fish
General	1	is more sustainable
	2	has more animal welfare
	3	is more ethical
	4	is more organic
Environmental	5	catching causes more environmental damage
	6	is more locally obtained (closer origin)
	7	catching is more polluting
	8	practices preserve more the marine ecosystem
	9	provides more environmental benefits
Social	10	generates more employment
	11	generates better employment
	12	industry favours more the gender equality
	13	improves more the human living conditions
	14	provides more social benefits
Economic	15	improves more the local economy
	16	generates more rural development
	17	limits more the expansion of tourism
	18	ensures more fair fish prices
	19	provides more economic benefits

(Continued on next page)

Results

When both production systems were compared, European consumers perceived better the welfare of wild fish, also being more organic, but causing more environmental damage. Farmed fish, instead, was perceived as being more sustainable, being more locally obtained, providing more environmental benefits, generating more employment, improving the human living conditions, generating more rural development, and ensuring fair fish prices.

Four segments of consumers with similar sustainability beliefs were identified. The "pro wild fish" segment (n=653 respondents) grouped participants whose beliefs favoured wild fish. They held the belief that wild fish welfare was better, was more organic, was more ethical, caused less pollution, preserved the marine ecosystem, and improved the local economy. This segment included more females and more French respondents, but less Polish.

The "pro aquaculture" segment (n=472) grouped participants whose beliefs favoured farmed fish, although two exceptions were found. Respondents perceived better welfare of wild fish and also being more organic. This segment grouped older participants, more males, and more Italian and Spanish respondents.

The "strong convictions" segment (n=420) grouped participants whose beliefs sometimes were clearly in favour of wild fish, whereas others were clearly in favour of farmed fish. This segment grouped younger participants, with a higher perceived economic situation, living in urban and coastal areas, from Germany, Poland, and Spain.

The "impartial" segment (n=600) grouped participants whose beliefs did not follow any trend favouring or refusing the sustainability of one or another production system. More French and Polish participants were included in this segment.

Conclusions

The role that aquaculture may play in global sustainability is crucial. Such importance should be translated to citizens with the final aim of increasing farmed fish consumption. Therefore, understanding how European consumers perceive sustainability of farmed fish when compared with wild fish is the first step in improving consumers' perception of aquaculture. The identification of four segments of consumers and its profile could be useful to conduct tailored promotional campaigns to communicate aquaculture benefits and debunk its myths.

LOOKING FOR THE BEST WAY TO INCREASE CONSUMERS' AWARENESS ABOUT AQUACULTURE

L. López-Mas*, A. Claret, L. Guerrero

Institute of Agrifood Research and Technology (IRTA), Monells (Spain)
*E-mail: laura.lopezm@irta.es

Introduction

No matter how important a message is if it is not able to reach the audience. In this sense, despite the multiple advantages of the aquaculture production and the role that it can play in global sustainability, these messages often do not reach the general population due to the existence of a gap between experts' knowledge and consumers. Therefore, finding new channels and ways to reach consumers is crucial to assure the full development of the aquaculture sector and to promote farmed fish consumption.

This study aimed to involve aquaculture sector stakeholders to generate new strategies to increase consumers' awareness of European aquaculture.

Materials and methods

Two creative sessions were carried out in each of the three selected countries (i.e., France, Italy, and Spain), one with four aquaculture experts and the other with eight fish consumers. Experts met the criteria of having a high knowledge and experience about the aquaculture sector (e.g., researchers, professors, farm managers, etc.). Conversely, consumers met the criteria of being around 50% female and 50% male, older than 18 years, responsible for food purchase and preparation within their household, and fish consumers.

Various creative techniques were used to stimulate participants' creativity, including brainwriting, direct analogies, and empathic thinking. The multiple ideas generated in the creative sessions were grouped through an *ex post* process to give structure to the data.

Results

The creative techniques used during creative sessions allowed participants to generate a pool of strategies to increase the awareness of the consumers about European aquaculture. Among the ideas arisen, some were related to the **fish selling places**, such as supermarkets. In this sense, doing tasting or show cooking *in situ* may bring the fish product closer to consumers and, consequently, increase their awareness. Also, giving them brochures or free samples for taking home and share it with the family. Finally, the role that can play personnel's recommendation should not be neglected.

Restaurants are also frequent fish selling places in which consumers can taste different aquaculture species and to test them against their wild counterparts. Even though, as preconceived ideas may play a negative role against farmed fish, a participant proposed to inform the clients, once they have finished eating their dishes, that the fish they just have eaten comes from aquaculture. In addition, a "tapas" route only using aquaculture fish may also encourage participants to taste the product as well as a cooking class in which participants can cook their own fish and eat it later.

If the focus is on **fish packaging**, participants come out with various ideas related to including pictures on the label such as a logo, a quality scheme as PDO (Protected Designation of Origin) or PGI (Protected Geographical Indication), a picture/information about aquaculture, or a QR code that shows informative content. Finally, one participant proposed to print on the label information about a prize, in which the prize is a trip to aquaculture facilities with a tasting.

Many ideas came out related to doing **activities** centred around aquaculture, some examples are to do outdoor events to spend the whole day with the family, to organise the Aquaculture Week plenty of events (e.g., Fashion Week), to celebrate the World Day of Aquaculture, or to create an amusement park about aquaculture.

(Continued on next page)

Some of the activities proposed were in fish **farm facilities**, including organising visits, trips, and guided tours, also for scholars. Organise activities and experiences in seaside or lakes during Summer, a Summer camp for teenagers, or a spot for vacations (e.g., stopping point for motorhomes). Experience a different vacation with a working exchange: work in exchange for housing and food. Doing tastings (e.g., wine cellars), even offering two activities: fishing and eating the fish they just have fished. Organise a competition on who fish more fishes in 5 minutes. Focusing on children, creating an educational path with cartoons or animated videos, or touching and cuddling marine creatures.

Advertising also came out during the sessions. Various channels were mentioned, including television, social media, supermarkets and other selling places, local and ethical markets, posters, signs, brochures, sponsor of show cooking, aquariums, etc.

Education was considered of primordial importance. For example, dedicating more hours at the school to aquaculture or doing experiments at Science subject (e.g., design a Biofloc system). In addition, giving lectures at universities or organising workshops. Also, to learn while playing, creating **board games** for children or **home kits to play** with (e.g., build an "aquaponics" system at home).

Regular communication channels also were stated by participants. For example, casting on **television** documentaries, entertainment programs, debates, interviews, short movies, series, cartoons, famous people talking about aquaculture, programs like "big brother" but for fishes. **Newspaper and magazines** also were mentioned, as well as informative programs or songs for children on the **radio**. More recent communications channels also came out, including **podcasts on Spotify** and **videos on YouTube**. Participants give various examples of the type of content that may be published on YouTube, including food blog channels with receipts using farmed fish, competitions or prizes, and child-accessible protected channels. Finally, **social media** also were mentioned.

Surprisingly, social media did not come out as many times as an expected. The main reason may be participants' age, as younger generations tend to use more frequently social media, although there were few participants between 18-30 years. Therefore, it would be worthwhile to inquire how to communicate to children and teenagers through creative sessions involving only youths. As pointed out by various participants of this study, educate younger generations is essential as they are the future aquaculture fish consumers.

In addition, some participants come out with an invaluable concept as is the "multichannel" or "omnichannel" strategy. That is, approaching consumers not only through one channel but with multiple ones. In a similar vein, an Italian consumer stated, "The promotion of aquaculture must be "multi-level" (institutions, schools, and media) and "multi-disciplinary" (science, market, economy, and health)".

Conclusions

Creative sessions were useful to generate a pool of new strategies to increase consumers' awareness of European aquaculture. Producers and marketers could benefit from the ideas generated to choose the best channel or channels to reach consumers with the final aim of designing more effective aquaculture communication and promotional campaigns.

AQUACULTURE OF RED KING CRAB *(Paralithodes camtchaticus)*: EFFECTS ON MUSCLE PROPERTIES

G. Lorentzen., F. Lian and S.I. Siikavuopio

Nofima AS, Norwegian Institute of Food, Fisheries and Aquaculture Research, Muninbakken 9-13, Breivika, P.O.
Box 6122, NO-9291, Tromsø, Norway
E-mail: grete.lorentzen@nofima.no

Introduction

Red king crab (RKC, *Paralithodes camtschaticus*) has become important for the shellfish industries located in the northern parts of Norway. In fact, in 2020 and 2021, 2016 and 2261 metric tons of RKC was exported from Norway, amounting to NOK 667 and 999 million, respectively. About 60% of the exported volume was traded live, whereas the remaining share was exported as processed fresh or frozen-cooked clusters.

An alternative to the live export or processing right after landing is aquaculture. Aquaculture, with or without feeding enables the industry with a more flexible management of the resource. Besides, aquaculture also facilitates for recovery and improved welfare in case of a rough handling during the capture.

The present study was undertaken to study how the muscle of processed RKC was affected by different aquaculture conditions.

Material and methods

After capture nearby the North Cape in northern Norway, the RKC was transported, landed, and kept in tanks. To screen potential effect from the aquaculture conditions, parameters like water temperature, access to feed, duration, and the time of the year, varied. During the period for aquaculture, the RKC was sampled, slaughtered, processed, and the quality of the muscle was evaluated. The evaluation included meat content, yield, water content, pH, water holding capacity, and microbial growth.

Conclusion

The conditions for aquaculture of RKC clearly affects the properties of the processed muscle. In the future, detailed knowledge on how the aquaculture conditions influences the final quality of the RKC muscle is considered to be of crucial importance.

THE EFFECT OF FEEDING WITH THE COPEPOD *Acartia tonsa* DURING THE FIST DAYS OF LARVAL REARING ON SKELETON ONTOGENY AND SKELETAL DEFORMITIES IN GREATER AMBERJACK (*Seriola dumerili*)

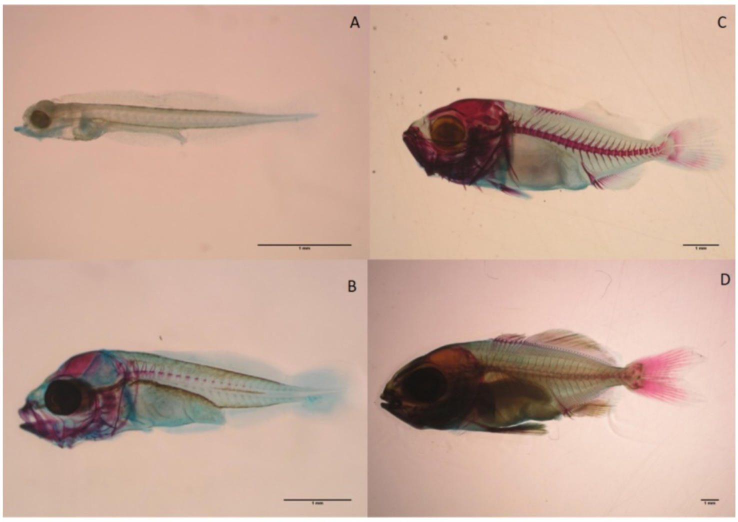
Introduction

Ontogenesis is a process of growth (change in size with age) and differentiation and maturation (cells, tissues, organs and systems) (Chambers and Leggett, 1987), where fish larvae undergo dramatic changes in body shape, in their swimming ability, metabolism and behavior. Nutrition is one of the most important factors affecting the ontogeny of fish which among other things affects skeletal ontogeny and therefore may be responsible for the development of skeletal abnormalities (Chambers and Leggett 1987). Copepods have the advantage that the fatty acids docosahexaenoic acid (DHA) and eicosapentaenoic acid (EPA), are found in the phospholipids of cell membranes. Copepods do not need enrichment like rotifers and *Artemia* metanauplii and so do not burden the surface of the tank with extra fat (Conceição et al. 2010). In addition, copepods are very rich in free amino acids which stimulate the sense of smell of fish larvae and enhance feeding behavior and food search in the tank (Rønnestad et al. 2013).

Materials & Methods

In a commercial fish farm, four cylindroconical tanks were stocked with 3,000 L in each, and we started feeding the larvae 3 days post hatching (DPH) until 30 DPH. In two tanks, the fish larvae were fed with *Acartia tonsa* and *Brachionus* sp., while in the other two only with control animals. On the eleventh day post hatching, fish larvae of all the tanks, started feeding on Artemia nauplii as well. About day 19 all the fish larvae were fed with rotifers, *Artemia* nauplii and large enriched *Artemia* metanauplii. In the last days of breeding, formulated diet was also added. Samples were taken every three days and fixed in 5% formalin (pH = 7.2). Bones and cartilages were stained with Alizarin red and Alcian blue respectively (Park & Kim 1984).



Pic 1: Different stages of development in larvae and juveniles of *S. dumerili*, stained with red and blue for bones and cartilages respectively (A: 3.3 mm, B: 5.1 mm, C: 8.8 mm, D: 18.1 mm) (Scale 1 mm).

(Continued on next page)

Results

In picture 1(a-d) you can see the different stages of development in larvae and juveniles of *Seriola dumerili*.

The majority of the structures appeared earlier in the fish larvae which were also fed with copepods. Exceptions are the Proximal Pterygiofores (**Prx**) and the Distal Radials (**Rd**) of the dorsal fin and the Upper and Lower Supratemporal (**SutUp-Lo**) of the pectoral fins that appeared earlier in the fish larvae which were fed only with rotifers. The osteologic development was completed earlier in the fish larvae which were also fed with copepods, excluding the **Rd** in the dorsal and anal fins, the **Prx** in the pectoral fins and the Lepidotrichia (**R**) in the pelvic fins. The ossification was completed earlier in the copepod-fed larvae. More skeletal deformities were observed in the control group with the exception of the dorsal and the pectoral fins. In the pelvic fins no deformities were observed in either groups.

Conclusions

In conclusion the use of copepods in the breeding of *Seriola dumerili* affected positively the beginning and the completion of the osteological development, the completion of the ossification and the number of skeletal deformities.

Introduction

Bivalve molluscs accounted for 18 million tonnes of aquaculture production in 2018, what represented an increase of *ca*. 3 million tonnes compared to the past years (2010-2015) (Wijsman et al., 2019; FAO, 2020). Despite the efforts to produce and commercialize safe and high-quality seafood, once these organisms are filter-feeders, the accumulation of chemicals and biological contaminants are a huge concern to public health (Oliveira et al., 2013; Sousa & Hinzmann, 2020). This is particularly worrisome since bivalves are commonly consumed live, raw, or slightly cooked (Oliveira et al., 2013; Anacleto et al., 2014; Lattos et al., 2021). Hence, the present study aims to I) to detect and identify the diversity of cultivable pathogenic bacteria isolated from three commercially valuable bivalve species, before and after being depurated and II) evaluate the efficiency of the depuration process in reducing cultivable bacterial load. This work has been developed under the project SEEBug (Development of a sensor for the fast and efficient detection of pathogenic bacteria in Bivalves) funded by MAR2020, and it intends to identify other relevant bacterial pathogens that should eventually be considered within bivalves microbiological monitoring programs.

Materials and methods

This study focused on the bivalves *Venerupis corrugata*, *Cerastoderma edule* and *Solen marginatus* in two debug states. They were harvested in Ria de Aveiro during two seasons of 2021 (summer and autumn). For the purpose to detect and isolate pathogenic bacteria, two procedures were applied on non-depurated (ND) and depurated (D) bivalves, based on: (i) International Organization for Standardization (ISO) 16649-3, ISO 6887-1, and ISO 6887-3 standards for enumeration of *Escherichia coli*, and (ii) the use of selective (MacConkey (MC) and Thiosulfate-Citrate-Bile Salts-Sucrose agar (TCBS)) culture media to quantify and isolate the cultivable bacteria colonizing bivalves. Procedure I allowed determining the MPN (Most Probable Number) of *E. coli* per 100g of bivalve. In Procedure II was analyzed the number of Colony Forming Units (CFU) per 100g of bivalve. For the latter Procedure a Student's *t*-test was performed to identify statistically significant differences in the bacterial CFU detected in each debug state (ND *vs*. D) of the bivalves species under study. Posteriorly, the isolated bacterial clones were subjected to molecular identification through sanger sequencing of the 16S rRNA gene.

Results and discussion

Procedure I data (Table 1) showed that the MPN of *E. coli* in non-depurated *C. edule* in the summer season was below the limit established in current legislation (EU, 2019). On the contrary, the other bivalves species revealed higher values. In autumn, the *E. coli* MPN values in *V. corrugata* and *C. edule* bivalves were within the legally allowed range for human consumption. As expected, in both seasons was observed that after the depuration process there was a significant decrease of *E. coli* MPN/100g bivalve, thereby apparently revealing the efficiency of the depuration method for *E. coli*. However, this trend was an exception for *V. corrugata*, which *E. coli* levels in summer remained equal before and after depuration. Regarding Procedure II, it was observed a decrease of CFUs after the depuration process, except for *S. marginatus* (Fig. 1 (a)) and *C. edule* (Fig. 1 (b)), where it was verified a increase of CFUs. Furthermore, 18 genera of cultivable bacteria were isolated, and some of them represent danger to public health given their pathogenicity. In summary, even though the depuration process appears to be efficient to reduce *E. coli* it may fail to reduce/eliminate other potentially harmful pathogens as *Pseudomonas*, *Serratia* and *Vibrio*.

(Continued on next page)

Table 1 - Mean MPN of *E. coli* obtained in Procedure I for the non-depurated (ND) and depurated (D) *Venerupis corrugata*, *Cerastoderma edule* and *Solen marginatus* samples harvested in **(a)** summer and **(b)** autumn.

	MPN *Escherichia coli* / 100g of bivalve				
	(a) Summer			(b) Autumn	
	V. corrugata	*C. edule*	*S. marginatus*	*V. corrugata*	*C. edule*
ND	18000	130	790	130	230
D	18000	20	50	20	50

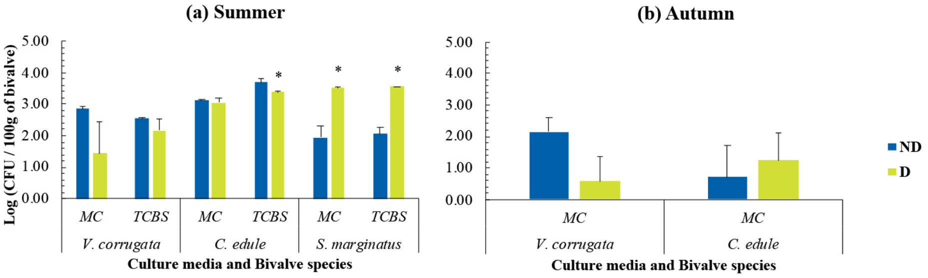

Fig. 1 – Colony Forming Units (CFU/100g bivalve) determined by procedure II in **(a)** summer for *Venerupis corrugata* (N = 45), *Cerastoderma edule* (N = 45) and *Solen marginatus* (N = 14) (harvested in July) in each culture media (MacConkey (MC) and Thiosulfate-Citrate-Bile Salts-Sucrose (TCBS) agar); and **(b)** autumn for *V. corrugata* (N = 45) and *C. edule* (N = 45) bivalves (harvested in September) in MC medium. No growth was observed on TCBS agar in autumn. Error bars represent standard deviation. * represent statistically significant differences ($p \leq 0.05$) between debug states.

ASSESSING THE EFFECTS OF ROTIFER FEED ENRICHMENTS ON BACTERIAL COMMUNITIES OF TURBOT (*Scophthalmus maximus*) LARVAE

Louvado, António[1]*; Castro, Carolina[2]; Silva, D.A.M.[1]; Oliveira, Vanessa[1]; Conceição, Luís E. C.[3]; Cleary, D.F.R. [1]; Gomes, N.C.M.[1]

Introduction

Rotifer and artemia are commonly used in larviculture as first feeds, but both are poor in essential fatty acids (EFA). To overcome this problem, a range of commercial products are currently available for live feed enrichment with EFA [1]. However, little is known about how live feed enrichment products affect the initial microbe recruitment of newly hatched larvae. In this study we attempted to determine the microbiome dynamics and their putative functioning in turbot larvae (*Scophthalmus maximus*) and rearing water in response to two distinct commercial rotifer feed enrichments.

Methods

Here, turbot larvae originated from Flatlantic (Portugal), three days after hatching (DAH), were reared in flow-through larviculture tanks during 27 days. The feeding regime was based on rotifers enriched with two different commercial rotifer enrichments (ER1 or ER2), and artemia given the same commercial enrichment (ER2; from 11 to 30 DAH). A mature culture of *Tetraselmis* sp. was added daily from 3 to 15 DAH (green water technique). Three independent larviculture tanks were used for each rotifer feed diet investigated (ER1 and ER2) and maintained under similar physicochemical conditions (temperature, salinity, pH and O_2) for 27 days. Samples for bacterial community analysis (high-throughput sequencing of the 16S rRNA gene) of the whole turbot larvae (10 DAH) and the post larval gut (30 DAH) were obtained after 7 days and 27 days of growth in the rearing tanks, respectively. The bacterial communities of rearing water and live feed [rotifer (7 days), and artemia (27 days)] were also analyzed [2]"ISSN":"0044-8486","abstract":"The stressful conditions of intensive aquaculture systems, combined with excessive antibiotic use, may have dysbiotic effects on aquaculture microbiomes and promote the spread of opportunistic pathogens. Here, we hypothesized that humic substances (HS.

Results

Our results show that rotifer enriched with different commercial enrichments (ER1 and ER2) did not significantly affect overall bacterial structure and diversity of fish larvae and water-associated bacterial communities at both sampling points (Figure 1). However, larvae fed rotifer enriched with ER1 was associated with a significantly lower relative abundance of Vibrionales at 10 and 30 DAH and an increase of Rhodobacterales members when compared with ER2 (Figure 2). Curiously, the lower *Vibrio* abundance was also followed by a strong increase in the abundance of an amplicon sequence variant (ASV) closely related to *Sulfitobacter* sp. (Roseobacter clade) [3]. Predictive metagenomic analysis also showed that KEGG orthologs related to infection disease tended to be less abundant in the treatment ER1. Interestingly, ER1 had a significant and higher survival rate (8.0 ± 0.9%) than ER2 (4.34 ± 0.89%). Overall, bacterioplankton mainly consisted of ASVs assigned to the genus *Polaribacter* and with high abundance of Roseobacter clade members.

Conclusion

Overall, this study showed that live feed enrichment formulas have the potential to affect the balance of pathogenic and antagonist microbes in larviculture. Our findings highlight the importance of analyzing the effects of rotifer enriched with different enrichment products on the dynamics of microbial communities in fish larviculture. Due to the unique structural composition of each aquaculture system, such an approach is critical for better evaluation and selection of the optimal enrichment strategy for live feed production.

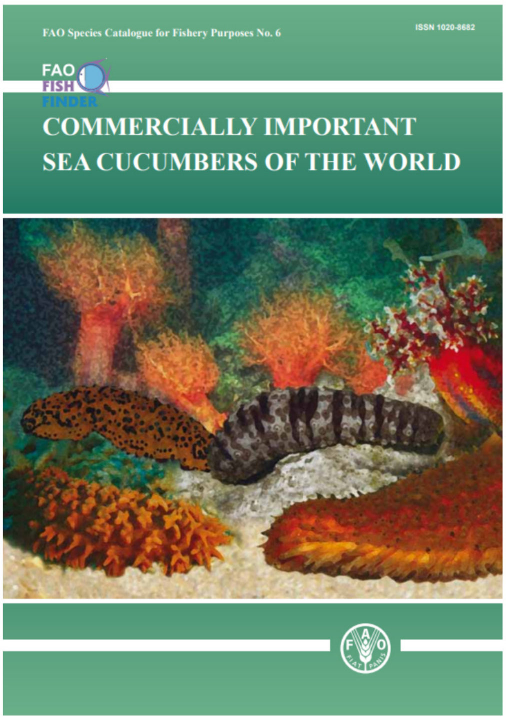
WHY IS FAO WORKING ON THE SECOND EDITION OF ITS GUIDEBOOK ON COMMERCIALLY IMPORTANT SEA CUCUMBER SPECIES OF THE WORLD FIRST PUBLISHED IN 2012?

A. Lovatelli* and S.W. Purcell

Food and Agriculture Organization of the United Nations, Viale Terme di Caracalla, 00153 Rome (Italy)
Email: Alessandro.Lovatelli@fao.org

Sea cucumbers (a class of echinoderm) are a high-value traded commodity primarily consumed fresh or processed in East Asia, and now sought after by pharmaceutical and cosmetics industries. Demand for sea cucumbers has risen since the 1980s, at a rate faster than the average CPI in China. To meet the demand, extensive harvesting and trade of sea cucumbers has spread to nearly all seas and oceans, and perhaps as many as 100 species are now harvested in at least 80 countries worldwide.

Many of the species sell for over USD 100 per kg dried, and a few sell for over USD 1 000 per kg. Wild stocks in some countries have been severely overexploited, so trade expanded to new countries, and IUU fishing has risen considerably. Encouragingly, many countries have placed moratoria on their sea cucumber fisheries to allow for stock recovery or have placed stricter regulatory controls. As sea cucumbers do not form large dense aggregations, and many species coexist relatively close, the fisheries for these species are typically multispecies and scattered, with many disperse landing sites not needing specialized infrastructure, but the product usually converges on a few trade routes. This means that management of these fisheries has to rely heavily on trade regulations, including those managed through CITES. One species from the eastern Pacific is already regulated by CITES Appendix III for Ecuador. In 2019, three species from the Indo-Pacific region were placed on CITES Appendix II. More species are likely to be proposed at future CITES CoP meetings.



FAO Species Catalogue for Fishery Purposes No. 6
ISSN 1020-8682
FAO FISH FINDER
COMMERCIALLY IMPORTANT SEA CUCUMBERS OF THE WORLD

Using trade regulations as management tools requires the availability of suitable tools to identify the products of many species in trade, and these were previously lacking. In 2012, FAO published the first global identification guidebook for these resources, entitled *Commercially Important Sea Cucumbers of the World*. It illustrated 65 species, provided information to enable identification of species in live or dried forms and described the preferred habitats, fisheries, market prices and distributions. However, data were lacking at the time on numerous species from the Mediterranean Sea, West Africa, Latin America and the Caribbean. In addition, the publication did not include practical dichotomous keys for easy systematic identification of the species in fresh and/or processed product.

The 2012 guidebook has been an incredible success. More than 1 250 hard copies were distributed worldwide to target users (and a top downloaded document from the FAO Web site) and it has been cited in literature 392 times. A second edition of the guidebook is needed to provide a complete coverage of commonly exploited species worldwide, including a number of new species from the Indian and Pacific Ocean that have entered the international trade market since the publication of the first issue of the FAO guidebook. The new guidebook will contribute to the management of the fisheries for sea cucumber, particularly as it concerns knowledge generation and enforcement, contribute to reduce under-reporting of certain species in trade, and facilitate better species-specific reporting of species by exporting and importing countries. The development of this guide will thus contribute directly to the programme of work of the FAO Fisheries and Aquaculture Division by making available an essential tool for effective management of sea cucumber fisheries.

The presentation will outline the process followed in collaboration with world experts and specialist scientists to obtain new information, data and photographs of species that were not illustrated in the first edition of the guidebook. New data on retail prices from dried seafood markets will enable the guidebook to present updated market information. Recent changes to taxonomy of species will be captured in the guidebook, and novel dichotomous keys will be produced for identifying live and dried specimens.

APPARENT NUTRIENT AND ENERGY DIGESTIBILITY OF COMMERCIAL FEED INGREDIENTS WITH OR WITHOUT PROTEASE IN RAINBOW TROUT

Introduction

One of the most important aspects in the evaluation of the effectiveness of alternative feed ingredients is the determination of its digestibility. Several alternative feed ingredients have been tested in aquaculture feeds to replace fishmeal for sustainable aquaculture. Nevertheless, imbalanced amino acid profiles, poor digestibility and palatability, and presence of anti-nutritional factors (ANFs) limit their use in aquafeeds (NRC, 2011). Therefore, one of the strategies is to supplement exogenous enzyme(s) for improving the nutrient digestibility. Among enzymes, proteases have potential use in reducing or counteracting ANFs negative impacts, such as protease inhibitors, and breaking down macromolecular proteins (Li et al., 2016). The efficacy of supplemental exogenous protease across a wide range of protein ingredients has not been previously investigated. Therefore, this study was conducted to evaluate the effects on apparent digestibility coefficients (ADCs) of dry matter, crude protein, amino acids, and gross energy of a dietary protease added to 17 different protein ingredients using rainbow trout as a model species.

Materials and Methods

In vivo digestibility was determined for 17 ingredients with and without protease supplementation (175 mg.kg^{-1}, Jefo Nutrition Inc., Quebec, Canada) fed to rainbow trout. The ingredients consisted of two feather meals, two poultry by-product meals, two meat and bone meals, sardine meal, menhaden meal, black soldier fly larvae meal, *Methanococcus maripaludis* single cell protein, soybean meal, canola meal, distiller's dried grains with solubles (DDGS), cottonseed meal, peanut meal, sunflower meal, and algae (*Spirulina* sp.) meal. A batch of test diet containing 30% test ingredient and 70% reference diet mash (combined on a dry-matter basis) was prepared and analyzed. Trout (average weight, 250 g) was used in the digestibility trial. Each of the experimental diets (reference and 34 test diets) was fed to two replicate tanks of fish in a completely randomized design to apparent satiation. Feces were expelled from each fish using gentle pressure on the lower abdomen of fish. ADC of diets and ingredients, for dry matter, protein, amino acids and energy were calculated using the following formula described by Bureau et al. (1999). Apparent digestibility was calculated using fecal material pooled from 30 fish/tank, and all data are expressed as the mean ± standard error of the mean (SE). Data were subjected to a Student's t-test to test for protease effect using SPSS Version 20.0 (SPSS Inc., Chicago, IL, USA).

Results

ADC of dry matter for rainbow trout ranged 51.0–86.6% for animal products and single cell protein and 33.1–70.1% for plant products without protease supplementation. ADC (without protease supplementation) of protein and energy ranged from 55.4–84.5% and 58.1–90.2%, respectively, for animal products, and 70.0–83.8% and 32.9–76.0%, respectively, for plant products. Supplementation with the commercial protease (175 mg protease/kg of diet) resulted in ingredient-specific ADC increases for dry matter, energy, cysteine, isoleucine, leucine, lysine, methionine, phenylalanine, threonine, tyrosine, alanine, aspartic acid and glutamic acid, with most ingredients having improved digestibility of at least one amino acid. Protease supplementation had the most profound improvement on ADCs for soybean meal, including dry matter and the majority of individual amino acids.

Conclusion

Supplementation with the exogenous protease resulted in ingredient-specific ADC increases for dry matter, energy, cysteine, isoleucine, leucine, lysine, methionine, phenylalanine, threonine, tyrosine, alanine, aspartic acid and glutamic acid, with most ingredients having improved digestibility of at least one amino acid. Protease supplementation had the most profound improvement on ADCs for soybean meal, including dry matter and the majority of individual amino acids. Overall, although the degree of improvement in digestibility varied among ingredients, this research demonstrates the benefit of the evaluated protease supplementation on the digestibility of feed ingredients commonly used in rainbow trout and other commercially cultured fish feeds.

Introduction

Meagre is one of the most promising species for the diversification of European aquaculture. However, nutritional requirements for early larval stages are not sufficiently known. Due to their fast growth rate, high demand for essential fatty acids (EFA) is expected 1there is a lack of information on nutrition along larval development. Importance of highly unsaturated fatty acids (HUFA. Among them, Docosahexaenoic acid (DHA) is crucial for marine fish larval growth and development. Dietary deficiencies have been associated with increasing skeletal malformations, whereas high DHA levels have produced controversial results. The oxidative potential of elevated DHA levels has been related to deleterious results when inadequate amounts of antioxidants are included. 2but high DHA levels have produced controversial results that could relate to the oxidative status of fish tissues in the different reports. In the present study, gilthead seabream (Sparus aurata. To study optimal levels of DHA supplementation and the most optimal level of antioxidant, meagre larvae were fed diets presenting increasing levels of DHA. In addition, the impact of the antioxidant level was examined by employing a diet with a deficient level of vitamin E. Furthermore, a commercial diet, presenting the lowest level of DHA was used as Control to compare larval culture success. The results of this comparative study including assessment of growth, skeletal development, and presence of skeletal deformities will be discussed together with the analysis of antioxidants enzymes activity. These insights will contribute to our understanding of the biochemical mechanisms employed by DHA in controlling skeletal metabolism, offering important knowledge to improve dietary formulations.

Material and methods

Fish larvae of A. regius from the same spawn were distributed by 9 rearing tanks of 300 L from 0 DAH to 42 DAH covering the period from the beginning of skeletogenesis, until the end of skeletal ossification. The larvae were fed with three different experimental diets (live preys and inert micro-diets) which presented increasing levels of DHA: CONTROL, MD with 2.6, and HD with 3.6 (% DW) with the adequate level of antioxidant for each level of DHA respectively. Furthermore, a fourth diet (MD-VE) with 2.6 of DHA (% DW) but a deficient level of antioxidant Vitamin E. All the emulsions and diets were produced by SPAROS, including the diet employed as a control for culture performance named WINFAST. Fish larvae were periodically sampled (at 12, 22, 32, and 42 DAH), photographed to assess larval growth, and stained with Alcian Blue and Alizarin S to assess the coefficient of mineralization and frequency of anomalies. Culture performance was further characterized by calculating daily growth (DGI, %), and specific growth rate (SGR, %). Besides, at 14, 28, and 42 DAH larvae were sampled for biochemical analysis including antioxidants enzymes activity (CAT, SOD, and GPX) and lipid composition of larval tissues. All the remaining larvae at the end of the trial were counted to determine the survival rate.

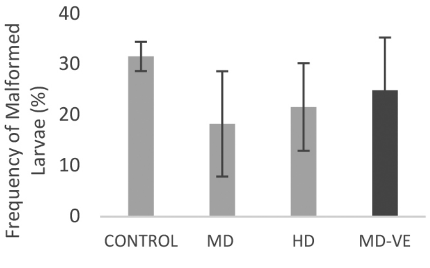

Figure 2. Frequency of malformed larvae per treatment at 42 Days After Hatching (p<0.05).

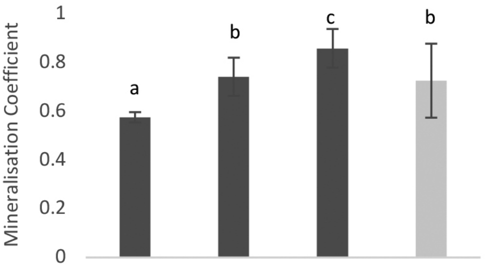

Figure 1. Coefficient of mineralization per treatment at 42 Days After Hatching (p<0.05).

(Continued on next page)

Results and Discussion

Fish larvae promptly accepted the experimental diets supplemented with ω3 fatty acids and survival was not affected by dietary treatment. However, growth performance in larval cultures seemed to improve by the supplementation with n-3 PUFAs, being the larvae fed with the HD diet exhibited the highest growth at the end of the trial. However, no linearity was observed between growth and DHA dietary level since meagre larvae fed MD diet with the intermedium level of n-3 supplementation exhibited lower growth at 42 DAH than the CONTROL. Similar results were also observed regarding DW. However, no significant differences were observed among treatments regarding SGR, and only HD presented a significantly higher DGI than the rest of the treatments. When growth performance was compared among the two intermedium diets with different content of Vitamin E, no differences were observed in TL whereas the lower level of Vitamin E presented in diet MD-VE improved DW significantly at the end of the trial.

Regarding the progress of ossification, the results reflected a similar tendency to growth, where the diet with the highest content of ω3 fatty acids presented the fastest results. However, contrary to growth the MD presented a faster rate of mineralization than the CONTROL diet, denoting that the improvement in the ossification was linearly correlated to the n-3 DHA dietary content. Moreover, no differences were observed between the diet MD and MD-VE denoting that Vitamin E levels didn't affect mineralization progress. However, regarding the activity of the antioxidant enzymes in larval tissues, some differences in GPX total and GPX Se-Dependent were observed when treatments were compared regarding both conditions, the level of DHA in diet and the level of Vitamin E.

Despite no differences were observed a 42 DAH regarding the frequency of malformed larvae, some differences were observed during the trial regarding the type of malformities and the frequency of anomalies by body region. Therefore, we can conclude that the supplementation of high levels of DHA n-3 fatty acids improved growth and accelerated larval skeletal development in this specie without increase significantly the percentage of malformed individuals. However, the different dietary levels of DHA and the level of Vitamin E in the diet affected differently the type, the region, or the severity of malformations during the trial.

INTERACTION BETWEEN DIETARY OMEGA-3 FATTY ACIDS AND FILLET COLOR IN ATLANTIC SALMON (*Salmo salar*): A TRANSCRIPTOME STUDY

E. Lutfi[1]*, S. Velzi[1], S. Horn[1], A. Krasnov[1], T. Ytrestøyl[2], B. Ruyter[1], A. Norris[3] and B. Hatlen[2]

[1]Nofima, (Norwegian Institute of Food, Fisheries and Aquaculture Research), N-1432 Ås, Norway; [2]Nofima, N-6600 Sunndalsøra, Norway; [3] Mowi Genetics AS, Sandviksbodene 77AB, 5035 Bergen, Norway
email: esmail.lutfi.royo@nofima.no

Introduction

Fillet color is one important trait defining flesh quality in Atlantic salmon. Dietary supplementation of carotenoids, mainly astaxanthin, is a common strategy to increase fillet pigmentation and its retention in tissues appear to be influenced by nutritional factors. Recent studies have shown a link between omega-3 levels in the diet, particularly EPA and DHA, and fillet color in Atlantic salmon (Bou et al., 2017, Lutfi et al., 2022). Nevertheless, the specific regulation of factors determining the deposition of astaxanthin in different tissues and the fillet color is still not clearly elucidated. The present study aims to evaluate the potential relationship between omega-3 fatty acids and fillet color by looking into transcriptional and metabolic regulations in the three main tissues involved in astaxanthin metabolism (muscle, liver, and intestine).

Materials and methods

Atlantic salmon from Mowi Genetics were distributed across six sea cages (5x5m^2) located at the Mowi's research station in Averøy (Norway) and fed 2 different diets based on a common low marine base formulation (Skretting ARC) coated with either a high vegetable oil/low fish oil mix (Control diet, **CT**) or an omega-3 LC-PUFA-rich microalgal oil from Veramaris® (Omega3, **Ω3**). At the final sampling, all fish from each sea cage were randomly taken and 10 fish from each dietary group were selected for **High** (5 fish) and **Low** (5 fish) fillet color based on VIS/NIR spectroscopy. The main purpose of this selection strategy was to create high contrast among the different conditions (**CT-High, CT-Low, Ω3-High and Ω3-Low)** in order to establish potential correlations between results obtained by transcriptomics, metabolomics and chemical analyses. Samples of muscle, liver, and intestine were taken for different analyses. The present study was conducted within the AquaIMPACT project (H2020 BG2018-818367) and analyses were co-financed by Nofima's internal projects.

Results

The microarray results showed that the "pigment selection" had the most significant impact, particularly in the liver (Fig.1A). The PCA plots display a clustering of samples with similar gene expression profiles in the same area. Scores of samples belonging to either high pigment or low pigment, were located together respectively and slightly influenced by the dietary treatments, particularly within the low pigment group (in green). In this regard, 23.94% (muscle), 28.17% (liver) and 24.94% (intestine) of the variation was explained by the first principal component (x-axis), which distributed the samples along the axis from high pigment, in the left quadrants, to low pigment, in the right quadrants (Fig. 1B-D). This distribution is again particularly evident in the liver. Moreover, the liver showed the largest number of unique differentially expressed genes (315) compared to intestine (139) and muscle (144) (Fig. 1E). However, no differential regulation of the common genes (9) was observed in the different tissues. Further analyses comparing common genes in one-by-one tissues (i.e. intestine vs. muscle) will be conducted.

Discussion and conclusions

Overall, our results showed a clear effect of the fillet pigment selection on the transcriptional regulation of all tissues and particularly in the liver (also with the highest number of differentially expressed genes) highlighting the potential involvement of this tissue in regulating astaxanthin deposition and fillet color. Moreover, diets also had a significant differential effect within the high and specially the low pigment group supporting the idea that dietary omega-3 fatty acids also influence fillet color. Additional integrative analyses including transcriptomics, metabolomics and fatty acid composition analyses are currently being conducted.

THE EFFICACY OF USING PINE (*Pinus massoniana*) POLLEN AS AN ALTERNATIVE TO SYNTHETIC STEROIDS IN PRODUCING MONOSEX MALE NILE TILAPIA (*Oreochromis niloticus*, L.)

Md. Abdul Aziz[1], Mst. Momtaz Mostary[1], M. Sadiqul Islam*[2]

Synthetic sex steroids are widely used to produce all-male stocks in Nile tilapia (*Oreochromis niloticus*). However, there is a growing concern of the use of synthetic steroid hormone in fish as food. We investigated the efficacy of a natural sex hormone as an alternative to synthetic steroids in producing monosex male tilapia. Two-day old fry was fed with pine pollen powder at three different concentrations (0.5, 1.0, 1.5%) for 28 days and subsequently reared for three months to observe the efficacy of pine pollen as well as to optimize the concentration for sex reversal. As positive control, same-aged fry of three different commercial tilapia hatcheries was fed with synthetic steroid, 17-α-methyl testosterone treated feed (60 mg/kg) for the same duration. Before analyzing the phenotypic sex, the fish were reared on untreated commercial feed for 90 days in a separate tank. The 1.0% pine pollen treatment yielded a mean of 92.50% males among the progeny, higher than the mean (89.94%) obtained from synthetic steroid treatments. This result demonstrates that pollen of pine could be an effective compound for the direct masculinization of Nile tilapia. We also obtained a significant difference ($p<0.05$) in the growth performance and survival rate of tilapia using dietary allotment of pine pollen. Our work suggests the feasibility of this compound as an eco-friendly method of masculinization of tilapia and can be tried in commercial aquaculture practice.

EFFECT OF DIETARY PHOSPHORUS LEVELS, WATER PHOSPHORUS LEVELS AND THEIR COMBINATION ON GROWTH PERFORMANCE AND PHOSPHORUS UTILISATION IN NILE TILAPIA

Introduction

Replacing fishmeal with plant ingredients coincides with decreased bioavailability of dietary phosphorus (P) in fish feeds, since phytate bound P is poorly absorbed by fish. In aquafeeds that contain more plant-based ingredients, inorganic P needs to be supplemented in order to fulfil the P requirements for growth. However, using P from (mined) phosphate rock deposits is unsustainable, given that natural reserves of phosphate are limited (Prabhu et al., 2013; Obersteiner et al., 2013). It is essential that sufficient levels of bioavailable P are present in aquafeeds, as P plays a fundamental role in the synthesis of ATP and nucleic acid, and the formation of bones and scales (Fontagne et al., 2009). By improving the bioavailability of phytate bound P from plant ingredients, the dependency of aquaculture on inorganic mined P sources and the level of dietary P in aquaculture effluent can be reduced. In recirculating aquaculture systems (RAS), minerals can accumulate in the water (including P), which can lead to waterborne mineral uptake by fish. Whether or not fish take up P (and other minerals) from the water is most likely related to the amount of available minerals in the feed, as well as the concentration of available minerals in the water (Rodehutscord et al., 2000; Prabhu et al., 2017). When denitrification occurs, phytate can be partly broken down (when faecal waste is used as carbon source) and P becomes soluble in water (Goddek et al., 2016; Goddek et al., 2018); this, in combination with low water exchange, can lead to accumulation of P in the water. The use of phytase in aquafeeds is getting more attention as a way to break down phytate and improve the dietary P availability (Kumar et al. 2012). The presented experiment evaluated two potential ways to increase the P availability in aquafeeds (high in phytate): 1) increasing the dietary availability of P through the diet with the use of phytase, and 2) increasing the P availability in the water using a system low in water refreshment with the use of a sludge denitrification reactor. With the experimental setup, the contribution of water born P uptake to growth was determined, and whether the effect of water born P uptake is dependent on the availability of dietary P.

Materials and Methods

A plant-based diet high in phytate and non-starch polysaccharides (carbon source denitrification) was used. The effect of available dietary P level was tested by supplementing phytase (PHY) versus a control without phytase (CON). The contrast in water available P was achieved by using a system with a high water refreshment (HR, low in water P) versus a system low in water refreshment (LR, high water P), using RAS with a denitrification reactor. The four treatments were studied over a period of 56 days according to a 2 x 2 factorial design. Tanks in the HR system were stocked with 30 and the LR with 40 Tilapia (mean initial weight 30 g). Fish were restrictively fed twice a day (aimed feeding level: 17 g/kg$^{0.8}$). For each tank growth performance was measured and the P utilisation calculated/estimated. The digestibility and the effect of phytase on the digestibility were only tested in the LR system (the faecal waste in the HR system was used as carbon source for the denitrification reactor).

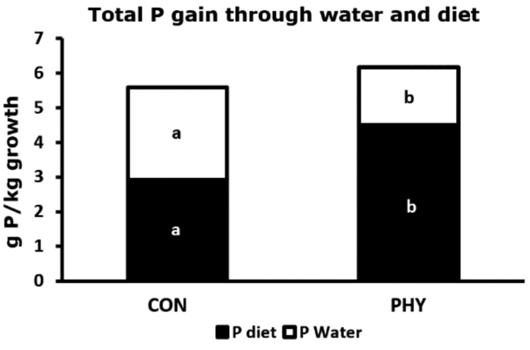

Figure 1. Mean minimum phosphorus (P) gain from the water and maximum P gain through the diet (g/kg growth) in the low water refreshment treatments (CON, control diet; PHY, diet supplemented with phytase). Bars with different lower-case letters are significantly different (p<0.01).

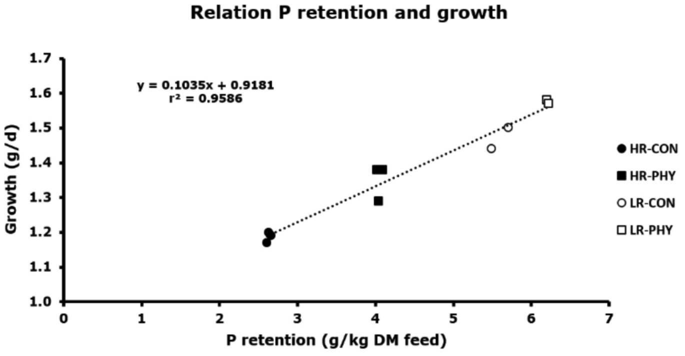

Figure 2. Correlation between P retention (g/kg DM feed) and growth (g/d). P retention in HR-CON and LR-PHY were estimated as 90% of the available P. HR-CON, high-water refreshment + control diet; HR-PHY, high-water refreshment + phytase diet; LR-CON, low-water refreshment + control diet; LR-PH, Low-water refreshment + phytase diet

(Continued on next page)

Results

Phytase improved the dietary P availability with 56% (to 4.5 g P/kg DM), in both water P levels, resulting in higher growth (g/d). Increasing the water P levels using a denitrification reactor, resulted in higher growth (g/d). The effect of phytase on growth (SGR, %/d), was larger in the low water P treatment (interaction effect, $P<0.05$). For both diets, water P uptake occurred. However, the water P uptake was larger for the control diet, low in available P (figure 1; $P<0.05$). For the control treatment in the high water P treatment (HR-CON), at least 47% of the P retained was taken up from the water. Improving the P retention by increasing the P availability in the diet and/or increasing the water P levels, correlated with improved growth (figure 2).

Conclusion

Water P utpake under high water P conditions can partly compensate a P deficiency for P retention. The effect of increasing P retention on growth suggest that the P availability was limiting growth (figure 2) for the low water P and low dietary P levels. This study shows that at least 6.5 g P retention is needed per kg weight gain to sustain maximal growth. Meaning the P availability in the diet should be above 6.5 g P/kg DM when the diet is the only P source (and has a FCR of 1).

IMPACT OF *Ulva lacinulata* ON THE MICROBIOME OF ABALONE-ULVA IMTA SYSTEMS

Introduction

Several land-based abalone, *Haliotis midae*, farms in South Africa practice integrated multi-tropic aquaculture (IMTA) by growing *Ulva lacinulata* in abalone effluent. The *Ulva* serves as a biofilter, allows partial recirculation (saving on pumping costs), and the co-produced *Ulva* is often used as supplementary feed. Dietary seaweed supplementation has also previously been shown to improve feed consumption, growth and health of cultured abalone (Naidoo et al., 2006; Mulvaney et al., 2013; Kemp et al. 2015; Bansemer *et al*., 2016). Despite these benefits, biosecurity concerns associated with water recirculation and use of effluent-grown *Ulva* as feed are preventing wider adoption of this technology on abalone farms in South Africa. To better understand potential benefits and risks associated with IMTA, this study characterized the microbiome associated with seawater, *Ulva* and abalone from integrated abalone-*Ulva* systems.

Materials and Methods

Ulva and seawater samples were collected across seasons from four *Ulva* paddle-raceway systems receiving abalone effluent water (AEW), and the microbiome was characterized using culture-dependent and -independent techniques. *Ulva* grown in a raceway receiving seawater (SW) directly from the adjacent coastline was included as a control. Culture-dependent approach used three selective media to assess changes in the abundance of specific bacteria, whereas the non-culture-based approach used next generation sequencing (NGS) and downstream bioinformatics analysis to describe the microbiome. A separate controlled laboratory trial was conducted to assess the effects of *Ulva* and specific components of *Ulva* on abalone gut microbiome. Abalone were fed four isonitrogenous diets consisting of formulated feed (AB), and AB supplemented with dried *Ulva* (10% w/w; AB10U), Ulvan (1% w/w; AB1U), and glucuronic acid (0.1% w/w; AB0.1U). Abalone fed fresh IMTA-grown *Ulva* (FU) and a combination of FU and AB served as controls. The bacterial microbiome was characterised by sequencing the V3-4 hyper-variable region of the 16S rRNA gene. NGS was performed on an Illumina MiSeq sequencing platform, sequence data assessed using QIIME2 (Boylen et al., 2019), reads mapped against the SILVA 16S rRNA database (Quast et al., 2013) and summarized taxonomic abundance at different hierarchical levels were assessed using MicrobiomeAnalyst (Dhariwal et al., 2017).

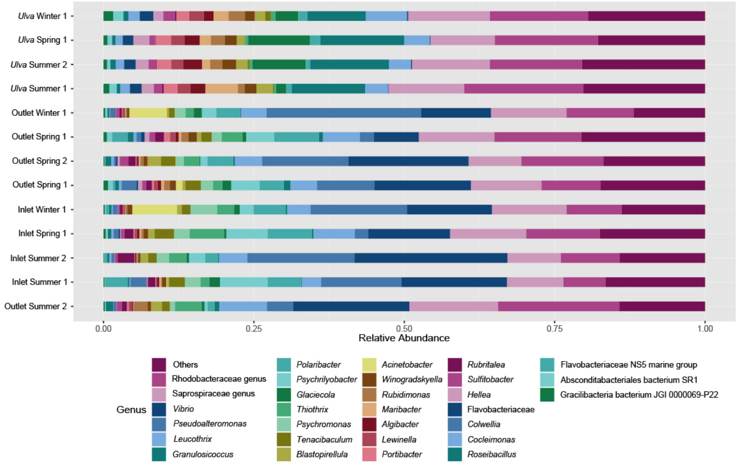

Fig.1. Relative ASV abundance (%) of inlets and outlets of *Ulva* raceways and *Ulva* itself (n = 60) at genus level, across seasons where ASV abundance is indicated for the 30 most abundant ASVs.

(Continued on next page)

Results and Discussion

Culturable bacterial numbers were significantly higher ($p<0.05$) in water than on the *Ulva* collected from each *Ulva* raceway system, with a reduction in bacterial abundance recorded from the inlet to outlet of each raceway. In the culture-independent approach, the genera *Vibrio* and *Psuedoalteromonas* were shown to be more prevalent in water samples than on *Ulva*, decreasing in abundance from the inlet to outlet of each *Ulva* raceway (Fig.1). Conversely, genera such as the *Granulosicoccus* and *Glaciecola* were more prevalent on *Ulva.* Across all seasons, *Ulva lacinulata* or its associated microbiome had a modulatory effect on the microbiome of the *Ulva* paddle-raceway systems.

Non-metric multidimensional scaling (NMDS) analysis of microbiome data revealed that abalone fed FU diets, and its components, produced significant associations in their intestinal bacterial communities, suggesting specific bacterial species are selected for and are associated with the digestive tract of abalone fed components of *Ulva*. Using DESeq2, several differentially abundant amplicon sequence variants (ASVs) were identified across dietary treatments, with various bacterial genera, including members of the genus *Vibrio* found to be less abundant in the gut of abalone fed FU supplemented diets compared to AB alone.

Conclusion

We demonstrated that inclusion of *Ulva lacinulata* in IMTA systems can beneficially alter the microbiome of the water and aquacultured products grown within the system. The findings from this study are providing critical information on biosecurity of IMTA systems, species health and system health that may promote broader uptake of these more sustainable aquaculture production technologies.

MODELING AQUACULTURE SUITABILITY IN A CHANGING CLIMATE

A. Mackintosh, G. Hill

Nord University, PO Box 1490, 8049 Bodø, Norway
Email: amy.mackintosh@nord.no

Introduction

Climate change-induced ocean warming is a major driver of distributional changes in global marine biodiversity (Cheung et al., 2009; Poloczanska et al., 2013; Chaundhary et al., 2021). The cascading effects brought about by anthropogenic climate change will impact the way in which humans utilize marine resources in the near future. Already the annual global demand for seafood has risen steadily since 1960 and this need is only projected to grow further, driven by increasing global populations and shifting economies (FAO, 2016, Naylor 2021). World aquaculture production has increased every year since 1990 (FAO 2020), while at the same time, up to 89% of the world's capture fisheries are fully exploited, overexploited, or have collapsed (Froese et al. 2012). Continued expansion of aquaculture to meet global demand is contingent upon climate adaptation and forward-thinking development. We show that models have an important role to play in guiding and predicting future highly productive aquaculture regions. This study seeks to create a multi-dimensional metric incorporating environmental, economic, and demographic shifts to identify regions of rapidly changing aquaculture suitability under different climate change scenarios.

Modeling approach

While species distribution models (SDMs) have long been used to assess the impact of climate change on populations, climate analogue modeling provides a systems-level approach to identifying likely disruption due to climate change. Climate analogues, areas that provide in future climatic conditions similar to those in a given location in the present, are already being used to determine necessary shifts in agriculture to track productive climates (Ramírez Villegas et al. 2011). Climate analogue development uses environmental parameters (such as temperature, salinity, current velocity, and dissolved oxygen) relevant to species identified in our aquaculture inventory. By carrying out this analysis on a global scale for aquaculture species and future climate change scenarios, such as RCP 2.6, 6.0, and 8.5 as described by the IPCC (IPCC 2014), we can identify areas likely to lose or inherit climates traditionally associated with aquaculture production of a wide variety of species. Previous such aquaculture studies have ignored certain groups, such as seaweeds, or extreme climate change scenarios, such as RCP 8.5, the high emissions scenario. Particular emphasis is placed on previously unidentified "bright spots" (Bennett et al. 2016, Queirós et al. 2021) where, based on models, aquaculture is projected to be more viable in the future, even under intense climate change scenarios.

Research outcomes

Current areas of aquaculture suitability, where optimal environmental conditions and species' physiological tolerances intersect, will shift to varying degrees within the different climate change scenarios (Vaz et al., 2021). Determining areas of future aquaculture suitability not only depends on the environmental variables of available areas and the species that will be cultivated but also on socioeconomic factors. Infrastructure, zoning legislation, seafood demand, farmed seafood price, and fish meal and fish oil supply are among the parameters which will further limit the conditions for aquaculture suitability (Cisneros-Montemayor et al., 2021; Oyinlola et al., 2021). This research will present alternative and under-utilised modeling tools to build on previous studies (Froelich et al., 2018; Oyinlola et al. 2018), identifying future locations ideal for aquaculture development. Additionally, this research will explore a broader definition of aquaculture suitability to include socioeconomic factors. The described modeling framework will produce estimates of future aquaculture suitability relative to the present, with an emphasis on areas experiencing exceptionally high or low climate displacement, as well as on those predicted to experience novel climate regimes. The results of this modeling will be a projection of the geographic distribution of suitable environments for each species, which can be used to identify current aquaculture areas at risk to become non-viable, as well as prospective new areas for at-sea culture.

OPTIMISING SEEDING AND PRODUCTION METHODS FOR COMMERCIAL KELP CULTIVATION

Adrian Macleod*[1], Kati Michalek[1], Callum O'Connell[1], Alison Mair[1], Adam Hughes[1] and Michele Stanley[1]

1: The Scottish Association for Marine Science, Oban, Argyll, Scotland
Adrian.Macleod@sams.ac.uk

The cost of seeded material, either through on-site or outsourced production, is often seen as a constraint to the development of seaweed aquaculture in Europe. The mechanical application of fertilised gametophyte fragments to cultivation materials with the use of a hydrocolloid binder provides a low-cost seeding solution that is rapidly scalable. However, "direct-seeding" is not widely regarded as a reliable method to seed cultivation materials and guarantee adequate yield performance. High operational costs, combined with inefficient farm designs, generate further economic challenges for cultivators, narrowing profit margins and intensifying current operational and market uncertainties.

To improve the reliability of direct-seeding protocols, several controlled mesocosm experiments were combined with flume studies to assess binder performance under controlled flow conditions. New binder chemistries, seeding protocols and cultivation materials were tested to optimise conditions which promote successful attachment of juvenile kelp. High performing treatments were validated in the field following deployments at two cultivation sites and at two time points allowing for a comparison of yield and seeding density to be made against existing direct seeding protocols.

Deployment strategies that improve crop performance and farm efficiency were tested at an experimental seaweed farm located on the west coast of Scotland. Optimum stocking densities (2 - 0.5 $m^{-1}m^{2}$) were assessed for two commercially important species of kelp (*Saccharina latissima* and *Alaria esculenta*). Similarly, the optimum cultivation depth following deployment was also established and yield and morphology data linked to Photosynthetically Active Radiation (PAR) across 9 cultivation depths ranging from 0.1-4m water depth.

In this presentation I will compare results from single-step and two-step seeding protocols which demonstrate the vulnerability inherent with viscosity-based binder solutions used to date and discuss improvements we have made to alter binder chemistry to protect sporophytes throughout the attachment phase (ca. 14 days). I will provide an overview of our approach to the production and delivery of direct seeded materials which is tailored to customer requirements and improved circularity of cultivation materials. Finally, I will share results from trials that highlight deployment strategies (optimal stocking density and variable depth systems) that improve crop performance and farm efficiency.

ASSESSING THE BEST FEEDING STRATEGY IN GSB AND ESB TO MODULATE FILLETS' N3/N6 FATTY ACIDS RATIO

S. Magalhães*, T. Aires

SORGAL, S.A., Sociedade de Óleos e Rações, EN109 Pardala, 3880-728 São João Ovar

Introduction

Fish consumption is widely recognized as the healthiest way to ensure a proper intake of n3 long chain highly unsaturated fatty acids (LC-HUFA) such as EPA (C20:5n3) and DHA (C22:6n3). The benefits of these FA for human health are well known and relate with fetal, brain and vision development, cardiovascular function, cognition, or depression disorders. The European Food Safety Agency (EFSA) even recommends for European adults a daily intake of 250-500mg of EPA and DHA based on cardiovascular risk consideration. Aquaculture fish, whose global consumption has been rising every year, will increasingly play a crucial role in delivering healthy n3 LC-HUFA to the population.

In the last decades there was an important shift in aquafeed recipes towards higher inclusion levels of vegetables, with an impact on fillets n3 and n6 FA pattern and, consequently, on their nutritional value for human consumption. It is known that n3 and n6 FA are precursors of signaling molecules with opposite effects, namely anti-inflammatory and pro-inflammatory, respectively. Gilthead seabream (GSB) and European seabass (ESB) have limited or no ability to synthesize n3 HUFAs from C18 FA [such as LA (C18:2n6) or ALA (C18:3n3)] present in vegetable ingredients. Therefore, the feed must be a direct source of EPA and DHA. The strategy to enrich fish fillets in n3 FA has been the adoption of finishing diets, for 120-150 days pre-harvesting, with greater inclusion levels of fish oil (FO), to compensate for the low intake of EPA and DHA throughout the cycle and to allow for their restoration in the fillet. Switching to a diet rich in fish oil during the late growout is likely to adjust fish FA profile for better n3 FA content. However, all lipid sources consumed during the growout period will influence the final lipid composition and fat distribution in the tissues of farmed fish.

Going further on this topic, i.e., considering not only the amount of EPA and DHA in the fillet but also the ratio n3/n6, the goal of this work was to assess the best nutritional strategy for GSB and ESB, for both species to deliver more interesting and healthy fillets for the final consumer.

Material and methods

GSB and ESB batches from 2018, 2019 and 2020, raised in a Spanish industrial land production facility, were divided in two groups considering the nutritional strategy adopted in terms of lipid sources in the feed: FORO) a mixture of fish oil and rapeseed oil or FO) 100% FO (high in n3-LC HUFA). FORO diet presented 6g EPA+DHA/100g fat and a n3/n6 ratio of 0,9, whereas FO diet presented 26g EPA+DHA/100g fat and a n3/n6 ratio of 3,5. The experiment started in September 2020 and lasted for 12 months. Initial, intermediate, and final samplings were performed, each consisting of 5 individuals per group; all fish were weighted and filleted; a composite muscle sample was therefore analyzed for the fat content and for the FA profile by Mérieux NutriSciences (Portugal).

Results

The fish sampled varied in size from 94 to 771g in GSB and from 299 to 1372g in ESB. As expected, fillet fat content positively correlated with fish body weight in both species ($R^2>0,5$). The season effect in GSB in terms of fatty acid deposition in the fillet was very clear, with the increase in fat during the summer months and its loss during the winter season. During fat loss process, EPA and DHA are preferentially oxidized comparing to n6 FA as their proportion in fat decrease. Nonetheless, EPA and DHA in total fat amount tends to be above total n6 FA. Feeding with 100% FO diets allowed GSB to go from a n3/n6 ratio of 0,9 in April to 1,4 in September, whereas the usage of FORO diet allowed to go from 0,9 to 1,2. In seabass there was a clear response of fillet lipid profile to the diet throughout the cycle, without a season effect. The intake of 100% FO diet allowed for seabass to shift to a higher proportion of EPA and DHA in the fat over n6 FA, increasing therefore the ratio n3/n6. In fact, with a FO-based diet, seabass was able to attain 1,1 of ratio n3/n6 whereas with the FORO-based diet seabass was in average around 0,9. Both GSB and ESB showed EPA and DHA content between 500 and 1500mg/100g fillet, meaning that 100g of all sampled fish were enough to meet the recommended daily intake by EFSA of these FA.

Conclusions

This experiment conducted in industrial conditions, aimed at understanding the modulation of FA in GSB and ESB muscle depending on feed lipid sources, showed that GSB is likely to improve the characteristics of its fillets towards higher EPA and DHA levels and greater n3/n6 ratio during the summer period, whereas ESB may need a continuous feeding on selected high in n3-LC HUFA FO diets to attain this goal.

ARE ARA, DHA, AND CARBOHYDRATES KEY PLAYERS TO MODULATE THE IMMUNE STATUS OF GILTHEAD SEA BREAM JUVENILES?

Introduction

The aquafeeds industry for marine carnivorous fish such as gilthead sea bream (*Sparus aurata*) is increasing the dietary incorporation of plant feedstuffs and vegetable oil (VO), leading to an increase in the dietary content of carbohydrates and a reduction of long-chain polyunsaturated fatty acids (LC-PUFA). However, VOs are devoid of LC-PUFA such as docosahexaenoic (DHA) and arachidonic (ARA) acids, which are key protagonists of the immune response as precursors of eicosanoids and in the induction of immune-related transcription factors. Marine fish are not able to meet their ARA and DHA requirements by endogenous synthesis from their C-18 precursors, thus it is important to understand how novel diets rich in plant feedstuffs and VO may affect gilthead sea bream immunological status, particularly when challenged by a pathological agent.

Material and methods

Groups of 20 gilthead sea bream juveniles (initial body weight = 47.5 g) were distributed in 12 tanks and fed four isoproteic (47%) and isolipidic (18%) diets with high or low gelatinized starch (HS or LS diets) content and dietary ARA/DHA ratios of 2.3/03 (ARA diets) or 0/2.6 (DHA diets). The growth trial lasted for 84 days and then the blood and plasma of 9 fish per diet were sampled. Thereafter, 24 fish from each dietary treatment were randomly selected and intraperitoneally injected (i.p.) with 0.6 mL of killed *P. damselae* subsp. *piscicida* (*Phdp*) ($1x10^8$ CFU mL^{-1}) or PBS (control group). Blood and plasma of these fish were sampled 4 and 24 hours after i.p..

Results

At the end of the growth trial, it was observed that DHA-rich diets increased red blood cell (RBC) numbers, hemoglobin, and plasmatic nitric oxide (NO) levels, antiproteases, and alternative complement activities. Fish fed the ARA/HS diet had increased thrombocytes and plasmatic bactericidal activity against *Vibrio anguillarum* compared with fish fed ARA/LS diet.

At 4 hours after i.p., fish fed with the DHA diet presented increased RBC numbers within HS groups as well as hematocrit, and thrombocytes numbers. Fish fed the ARA diets had increased total immunoglobulins and plasmatic bactericidal activity against *Vibrio anguillarum*. Within the ARA groups, fish fed the HS diet had increased white blood cell (WBC) and lymphocytes numbers, and alternative complement activity.
At 24 hours after i.p., fish fed the ARA diets had higher RBC, WBC, and thrombocytes numbers and increased plasma IG concentration and peroxidase activity. Compared with the LS groups, fish fed with the HS diets had higher plasmatic NO content and bactericidal activity against *Phdp* and lower proteases, antiproteases, and bactericidal activities against *Vibrio anguillarum*.

Conclusions

DHA-rich diets seemed to enhance the immune status of gilthead sea bream juveniles after the growth trial while ARA-rich diets seemed to improve the immune response after a *Phdp* challenge. The effect on the immune response of dietary carbohydrates and its interaction with dietary DHA and ARA were inconclusive. Further research is required to establish the optimum dietary ARA/DHA ratio for optimization of the immune response of gilthead sea bream juveniles.

NUTRITIONAL EVALUATION OF SOME ECONOMICALLY IMPORTANT MARINE AND FRESHWATER SHELLFISH SPECIES OF BANGLADESH

Yahia Mahmud[a*] Mohammad Moniruzzaman[a,b], Sonia Sku[a], Parvez Chowdhury[a], Mohosena Begum Tanu[a], Selina Yasmine[a], Md. Nazmul Hossen[a], Taesun Min[b] and Sungchul C. Bai[c]

[a]Bangladesh Fisheries Research Institute (BFRI), Mymensingh 2201, Bangladesh
E-mail: yahiamahmud@yahoo.com

Molluscs are the most important resources among all the seafood items in South-East Asian countries. However, very little information available on nutritional value of molluscs in these regions. In this study, we evaluated the 7 economically important species of molluscs in terms of proximate composition, amino acids profile, fatty acids profile, cholesterol and heavy metal contents in the bivalves (mussels, oysters, clams and cockles) and univalve (snail) collected from freshwater and marine environments of Bangladesh. The results of the proximate analyses revealed that significantly higher amount of crude protein contents were present in marine water oysters, clams and cockles (59.3 ± 0.3 to 75.4 ± 0.2%) than the freshwater mussels and snail (36.9 ± 0.4 to 49.6 ± 0.6%) on dry matter basis. However, carbohydrate contents were significantly higher in freshwater mussels and snail (30.2±± 0.9 to 57.3±0.2%) compared to the marine water bivalves (8.1 ± 0.4 to 20.2 ± 0.6%). Crude lipid contents were ranged from 2.5 ± 0.2 to 11.2 ± 0.1% and ash from 11.4 ± 0.1 to 16.8 ± 0.6% among the bivalves and snail species. The amino acid contents were comparatively higher in marine water bivalves than their freshwater counterparts. Saturated fatty acid contents were found to be higher in marine water bivalves than the freshwater mollusc species. The results also show that the omega-3 (eicosapentaenoic acid, EPA and docosahexaenoic acid, DHA) fatty acids were comparatively higher in oysters, clams and cockles in marine water than those in freshwater mussels and snail. However, omega-6 fatty acids like linoleic acid (LA), α- linolenic acid (ALA) and arachidonic acid (ARA) were higher in freshwater mussels and snail than in the marine bivalves. The n-3/n-6 ratio were significantly higher in oysters and cockle species than the other groups of bivalves and snail. The index of atherogenicity and index of thrombogenicity of the mollusc species ranged from 0.74 ± 0.1 to 1.74 ± 0.2 and 0.5 ± 0.1 to 2.6 ± 0.2, respectively. The results show that marine water bivalves contained higher amount of potassium, sodium, iron, chlorine especially oyster species contained significantly higher iodine than the freshwater bivalves and snail. However, freshwater mussels and snail showed significantly higher amount of zinc contents than the marine bivalves. The heavy metal contents such as arsenic, chromium and mercury were absent or present in very tiny amounts among the mollusc species. Significantly higher amount of cholesterol was present in marine bivalves and freshwater snail species than the freshwater mussels. Overall, the results indicate that marine bivalves can be good sources of high quality protein and lipid especially EPA and DHA. On the other hand, freshwater mussels and snails also could be good sources of protein, LA and ARA but scarcity of EPA and DHA.

EXPERIMENTAL EXPOSURE OF TUNICATES *Clavelina oblonga* TO REDUCED SALINITIES AS A POSSIBLE ERADICATION MEASURE OF ITS INVASION IN MUSSEL MARICULTURE

N. Majnarić[1*], D. Pavičić-Hamer[1], A. Jaklin[1], B. Hamer[1]

[1] Laboratory for Marine Nanotechnology and Biotechnology, Center for Marine Research
Ruđer Bošković Institute, Giordana Paliaga 5, 52210 Rovinj

Introduction

In the Adriatic Sea, tunicates are a common occurrence, but invasive species *Clavelina oblonga* Herdman, 1880 (Ascidiacea, Aplousobranchia, Clavelinidae) because of its intense presence, can cause both ecological and economic losses. *C. oblonga* is a distinctive and conspicuous epi/benthic colonial tunicate naturally distributed in the Gulf of Mexico´s tropical area, on the west coast of the Atlantic, in the Azores and on the west coast of Spain (Herdman, 1880; Scarponi et al., 2018). In the Mediterranean Sea, it has been reported as invasive species (Monniot, 2001; Shenkar et al., 2022). According to the latest invasion in Northern Adriatic, beginning in the summer of 2020, the major impacts reported were associated with the bivalve industry, as aquaculture facilities with abundant suspended food and large surfaces suitable for attachment create an ideal environment for ascidians. Mussel stocks affected by biofouling can experience reduced growth, fitness and survival, with further negative impacts on shellfish farm productivity, changes in handling and defouling removal procedures, as well as the implementation of regulatory restrictions to reduce the risk of spread to unaffected areas. Considering the extent of *C. oblonga* fouling at endangered aquaculture locations, laboratory experimental exposure of *C. oblonga* to different reduced s.w. salinities (37, 30, 20 and 11) were performed during November 2020.

Materials and methods

Colonial corpuses consisting of ten to twelve *C. oblonga* zoids were placed in 8 x 5 L glass with aeration and exposed to reduced salinities of 37, 30, 20 and 11 for 14 days. Glass with s.w. salinity 37 was used as a control. Distilled water was used to achieve the wanted salinities (30, 20 and 11). Three empty, clean, complete *Mytilus galloprovincialis* shells were placed in each glass and hanged on the rope for possible *C. oblonga* larval settlement observation. After exposure, all used specimens were kept for additional 14 days in s.w. with salinity 37 for recovery treatment. Additionally, to assess the impact of treatment and to avoid feeding competition, mussels *Mytilus galloprovincialis* Lamarck, 1829 were kept separately under the same treatment as *C. oblonga* (5 L glass, aeration, feeding and salinities 37, 30, 20 and 11). Both mussels and *C. oblonga* were observed daily for filtration (valve gaping), food uptake and faeces production.

Results and Discussion

Laboratory experimental exposure of *C. oblonga* to different salinities (37, 30, 20 and 11) has shown that during the total observation time (14 days exposure + 14 days of recovery) the effects of s.w. salinity 30 did not differ in comparison to control 37, while salinities of 20 and 11 provoked disorder in *C. oblonga* feed uptake and feeding itself, leading to change of corpus colour, tissue necrosis and finally body fragmentation (Figure 1).

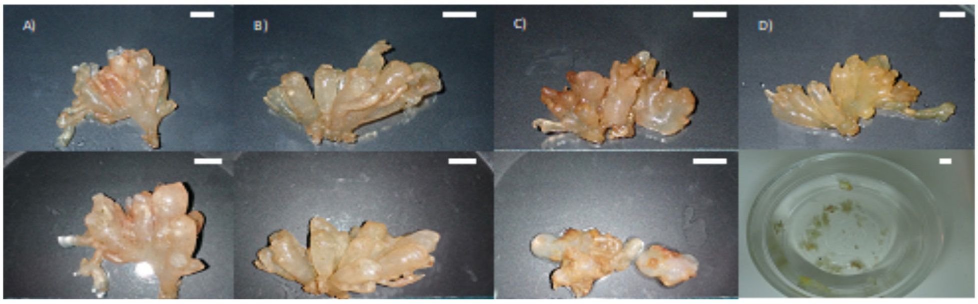

Fig. 1. Morphology of *C. oblonga* after 14 days of exposure to different salinities: A) 37, B) 30, C) 20 and D) 11 (upper row), and after 14 days recovery at 37 (lower row). The bar represents 1 cm.

(Continued on next page)

Furthermore, there was no observed egg development into lecithotrophic larva, and larvae settlement before metamorphosing into benthic adults on mussel shells or/and glass surfaces, which is in concordance with previous findings (Christianson and Eggleston, 2021). Mussels *M. galloprovincialis* kept under the same conditions as *C. oblonga* resulted in no mortality during all 14+14 days and finally, no significant fitness decrease was noticed. Only on the first day of exposure to s.w. set to salinity 11 and on the first day of the recovery period no mussel filtration activity-faeces production was observed. Based on our research, we can assume that the hypothetical translocation of mussels and whole cages with holding nets to locations of lower s.w. salinity (<20) for 7-10 days could be a natural and effective way to eradicate this invasive species. Off course, the effectiveness cannot be directly compared with the results of mussel mechanical cleaning and pressurized s.w. antifouling treatment, as well as reactive pest treatment with commercial products (Arens et al., 2011; Cahill et al., 2021), however, it can help and prevent further spreading of *C. oblonga* invasion.

Introduction

Sea bream (*Sparus aurata*) and European sea bass (*Dicentrarchus labrax*) are the main cultured fish species in the Mediterranean basin. Optimization of growth performance and feed efficiency has been usually done by feed formulation but the tendency to find alternatives increased. Phytogenic feed additives could contribute to those targets with a sustainable approach due to the increase of raw materials used in aquafeeds. The aim of these studies was to determine if a specific combination of essential oils, saponins and pungent substances (Syrena® Boost) can help in the continuous development of performance parameters.

Materials and methods

The first trial was run in the facilities of the Parque Científico-Tecnológico Marino (PCTM) at University of Las Palmas de Gran Canaria (Telde, Canary Islands, Spain). Sea bream juveniles of 30.7 ± 0.4 g were randomly distributed in 12 tanks of 500 L (50 fish/tank) and fed a standard diet supplemented with 2 dosages (200 & 400 mg/kg of the phytogenic combination for 12 weeks. Growth performance and feed efficiency parameters were measured along the feeding trial. Afterwards, fish were used for determination of variations in the pattern of secretion of several digestive enzymes (0, 2, 4, 8 and 24 hours post feeding (5 fish/sample, 45 fish/diet). The second trial was run in European sea bass in the facilities of the Laboratory of Applied Hydrobiology from the Agricultural University of Athens (Greece). European sea bass juveniles of 49.0 ± 0.18 g were randomly distributed in 6 tanks of 88.4 L (14 fish/tank) at a density of 7.8 kg/m^3 and fed a common commercial formulated diet supplemented with 200 mg/kg of the phytogenic combination for 20 weeks. Growth performance and feed efficiency parameters were calculated at different timepoints, and fish were sampled for somatic indexes and hematological parameters at the end of the feeding trial.

Results

Sea bream juveniles showed an improvement of FCR at both inclusion levels compared to the control diet, being better at the higher level of supplementation (1.11, 1.09 and 1.05, respectively). SGR was not affected by the inclusion of the phytogenic combination (Fig 1). Digestive enzymes patterns of secretion and response were correlated to the feed efficiency values obtained.

In European sea bass juveniles, there was a reduction of FCR in fish fed the additive of 11% compared to the control diet (1.62 ± 0.2 and 1.44 ± 0.1, respectively). SGR was significantly improved ($p<0.1$) by 13.3% as well in fish fed the diet containing the phytogenic combination (0.58 ± 0.1% and 0.66 ± 0.0 %, respectively) (Fig. 2). Final weight was also significantly ($p<0.1$) improved when fish were fed the phytogenic combination diet by 11.3% (113.1 ± 9.1g and 125.9 ± 4.5g, respectively). Blood hematocrit and hepato-somatic and spleen-somatic indices were not significantly different between treatments.

EFFECTS OF A SPECIFIC COMBINATION OF ESSENTIAL OILS, SAPONINS AND PUNGENT SUBSTANCES ON GROWTH PERFORMANCE PARAMETERS AND ANTIOXIDANT CAPACITY OF WHITELEG SHRIMP (*Penaeus vannamei*)

Alex Makol*, Tobias Aumiller and Karola R. Wendler

Delacon Biotechnik GmbH, Langwiesen 24, 4209 Engerwitzdorf, Austria
Email: alex.makol@delacon.com

Introduction

Crustacean production in 2018 reached 9.4 million tonnes, being marine shrimps dominating the production of crustaceans typically farmed in coastal aquaculture. Besides, they are an important source of earnings for a number of developing countries in Asia and Latin America. Whiteleg shrimp (*Penaeus vannamei*) is the largest produced species with 4.9 million tonnes, accounting for the 52.9% of total crusteans produced. Optimizing shrimp production performance is crucial to the success of the sector. Efficient diet formulation together with successful health and welfare management determines higher production output. As part of a proactive approach to production health and performance, the use of functional and sustainable additives, such as phytogenics, has demonstrated to be an effective tool to boost shrimp performance.

Materials and methods

Two different studies were conducted to determine the efficacy of a new phytogenic feed additive (PFA) mixture (saponins, spices and essential oils) on whiteleg shrimp growth performance and feed efficiency. In the first one, six hundred SPF shrimps of average initial weight of 1.9±0.26 g were allocated into three groups using with four replications for each treatment in 350 L tanks. In the second one, two hundred and forty shrimps of average initial weight of 1±0.01 g were randomly allocated into three groups with four replications for each treatment in 20 L baskets. In both studies, shrimps were fed for 6 weeks the different treatments: one control group (basal diet) and two groups receiving Syrena® Boost included at 200 & 400 mg/kg of feed, respectively.

Results

After 6 weeks of feeding, results in the first study showed that shrimp survival did not differ between treatments being above 80%. In terms of growth performance, shrimps fed Syrena® Boost at both inclusion rates showed an increase of weight gain of 12.5% and 13.3%, respectively, with an increase in average daily growth (ADG) of 12.9% and 13.5%, respectively. Feed conversion ratio (FCR) was similar between treatments. In the second study, again shrimp survival did not differ between treatments being above 94% in all treatments. Shrimps fed Syrena® Boost at both inclusion rates showed again an increase of weight gain of 10.1% and 7.9%, respectively, being statistically significant ($p \leq 0.1$) at the lowest dose. ADG was also improved by 9.7% and 7.9%, respectively, again being statistically significant ($p \leq 0.1$) at the lowest dose. FCR was reduced by 3.7% and 1.7%, respectively. Altogether, these results indicate the positive growth performance effects of this new PFA in whiteleg shrimp.

ANTIMICROBIAL ACTIVITY IN MICROALGAE: A WAY TO IMPROVE SUSTAINABILITY IN AQUACULTURE

P. Makridis* and C. Androutsopoulou

Laboratory of Zoology, University of Patras, 26504 Rio Achaias, Greece
E-mail: makridis@upatras.gr

Introduction

High population densities and stress in intensive fish farming may lead to problems with diseases, which result in the use of antibiotics. The development of resistant strains in fish farms makes the use of antibiotics inefficient. At the same time, a negative image of the aquaculture industry among consumers is formed. (Martinez et al., 2012). In the present study, antimicrobial activity against three fish pathogenic bacteria *Vibrio anguillarum*, *Aeromonas veronii*, and *Vibrio alginolyticus* was determined in cultures of seven microalgae species (*Amphidinium carterae*, *Asteromonas gracilis*, *Tetraselmis* sp. (red var.), *Tetraselmis* sp. (Pappas), *Tetraselmis* sp. (red var., Kotichi), *Tetraselmis* sp. (palmella), and *Tetraselmis marina* (var. Messolonghi), isolated from lagoons in Western Greece.

Materials and methods

Bacterium-free microalgae cultures were obtained after treatment with a mixture of antibiotics (oxolinic acid 10 µg/mL, kanamycin 10 µg/mL, penicillin G 150 µg/mL, streptomycin 75 µg/mL) (Munro et al., 1995), to kill bacteria present in the cultures. The absence of live bacteria was verified by plating on tryptic soy agar (TSA) dishes added 2% NaCl (w/v). The antibiotic was removed after successive dilutions over 3-4 weeks. *Chlorella minutissima* was used as a reference species, as it has shown antibacterial properties in an earlier study (Kokou et al., 2011). After algae cultures reached the late exponential phase, aliquots of 5 mL of each of the microalgae cultures were inoculated with different bacterial pathogens in test tubes. The pathogenic bacteria were added at a final concentration of 10^4 CFU/mL. The growth of the added pathogens was followed 0, 1, 2, 4, and 6 days after inoculations by spreading 10-fold dilutions on TSA dishes, and the colonies were counted after incubation for 7 days (Kokou et al., 2011). A positive control treatment was run for each pathogen, where pathogenic bacteria were added in 25 ppt sterile seawater, enriched with Walne's medium. The experiments were performed both in the presence and absence of light.

Results and Discussion

In all microalgae cultures, the numbers of bacteria were lower compared with the positive control treatments, where the numbers of bacteria increased exponentially. In general, antimicrobial activity was higher in light, especially in the case of *A. gracilis*. Weaker antimicrobial activity was observed in cultures of *Tetraselmis* sp. (palmella), *Tetraselmis* sp. (red var., Kotichi) and *Tetraselmis* sp. (red var., Pappas). In cultures of *A. carterae*, no difference between light and dark was observed. Its antimicrobial activity was lower compared with the other cultures, except in the case of *A. veronii* where it proved to be the most effective. Among *Tetraselmis* isolates, the highest antimicrobial activity was detected in *Tetraselmis* sp. (red var). Cultures of *A. carterae*, *Tetraselmis* sp. (red var.) and *A. gracilis* reduced dramatically the number of cells of *A. veronii* after 7 days of observation, as shown in Figure 1. In the case of *A. gracilis* and *Tetraselmis* sp. (red var.), the numbers of pathogenic bacteria decreased dramatically on the second day of the experiment, while in *A. carterae* this occurred on the fourth day of the experiment.

Acknowledgements

This study was supported through the project "Isolation and cultivation of local microalgae species from lagoons with the vision of mass production of antimicrobial substances, fatty acids, pigments and antioxidants" funded by the General Secretariat for Research and Innovation and EU funds.

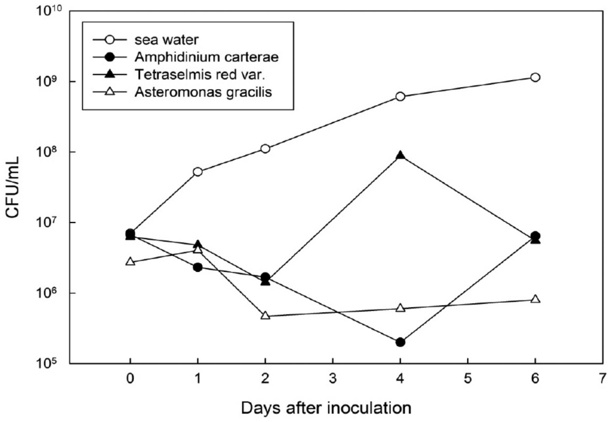

Fig. 1. Colony-forming units/mL (in log scale) of *A. veronii* in experiments performed with cultures of *A. carterae*, *Tetraselmis* sp. (red var.) and *A. gracilis* compared with sterile seawater 25 ppt, through time in light conditions.

- The strongest antimicrobial activity against *V. anguillarum* was shown by the cultures of *Tetraselmis* sp. (red var., Pappas) and *Asteromonas gracilis* both in dark and light conditions.
- In the presence of light, the cultures of *A. carterae*, *Tetraselmis* sp. (red var.) and *A. gracilis* were the most efficient against *A. veronii*, and in the dark, the cultures of *Tetraselmis* sp. (red var.) and *A. gracilis*.
- Against *V. alginolyticus*, in light conditions, the cultures of *A. carterae*, *Tetraselmis* sp. (red var.) and *A. gracilis* were the most effective, and in the dark the cultures of *A. gracilis*.

EFFECT OF OXYGEN SATURATION ON EXPRESSION OF *TRYPSIN*, *PLA2,* AND *HSL* IN EUROPEAN SEA BASS (*Dicentrarchus labrax* L.)

Introduction

In commercial fish farming, the oxygen dissolved in water (DO) and water temperature are the main environmental parameters that directly affect the physiological functions of the cultured fish. In summer and early autumn, low DO levels will cause the fish to become stressed and may decrease appetite and feed/energy utilization, ultimately leading to lower growth (Vanderplancke *et al*., 2015), which again reduces productivity in fish farming. In this study, we investigated the effects of three different DO saturation ranges (40-60%, 60-80%, and 80-100%) on the expression of three key enzymes involved in lipid and protein metabolism, namely phospholipase (PLA2), hormone-sensitive lipase (HSL), and trypsin in European sea bass (*Dicentrarchus labrax* L.).

Materials & Methods

The effect of DO saturation was studied in an experimental recirculating land-based system, at HCMR, Crete. Seabass juveniles with an initial weight of 88 g were stocked in 500 L tanks (35 fish per tank). Three treatments with different DO saturation ranges of 40-60%, 60-80%, and 80-100% were used with three replicate tanks per treatment for 98 days. The weight of fish populations was measured at the beginning of rearing conditions, as well as at the end, when tissue samples were isolated from the anterior and distal intestine (AI and PI), liver (L) and pyloric ceca (PC) of the fish. Expression of each gene was studied in six samples per tissue and tank. After total RNA extraction, a two-step qRT-PCR was performed, and the relative transcript abundance of each gene was normalized to *L17a* expression. All primers were taken from existing literature. Analysis of qPCR results was carried out using the $2^{-\Delta\Delta Ct}$ method. Statistical significance of differences in gene expression between treatments was tested with ANOVA.

Results and Discussion

At the end of the experiment, the average weight at 40-60% DO saturation (197.2±0.8 g) was significantly lower compared with 80-100% (252.4±4.5 g) and 60-80% (230.7±7.3 g). *PLA2* was expressed in PC, AI, and DI samples, while no expression was detected in the liver. In contrast, *HSL* expression was limited to the liver, while expression of *trypsin* was detected in all four tissues. Expression of *trypsin* and *PLA2* was found significantly lower at 80-100%, compared with the other two treatments ($p<0.05$), while expression of HSL was found significantly higher at 60-80% and 80-100% DO saturation ranges, compared with 40-60% ($p<0.05$). A similar expression pattern to *trypsin* was found in AI samples, and similar pattern to *PLA2* in AI and DI samples, but this was not verified statistically ($p>0.05$). Although low DO conditions are usually linked to low digestive enzyme activity (and low gene expression), several studies suggested that under moderate hypoxia, the organism turns to a "digestion-priority mode" (Zhang *et al*., 2010). This may explain the higher expression levels of *trypsin* and *PLA2* in the lower DO ranges, in our study. *HSL* is activated during periods of energy demand when the organism needs to mobilize energy stores. Higher expression of *HSL* at high DO saturation levels may indicate this mobilization of energy stores, associated with an increased metabolic rate, a possible result of a long-term acclimation to an increased oxygen uptake. Further analysis, including digestive enzyme activity, is required to explain the underlying mechanisms by which DO variations affect the physiology and performance of fish.

(Continued on next page)

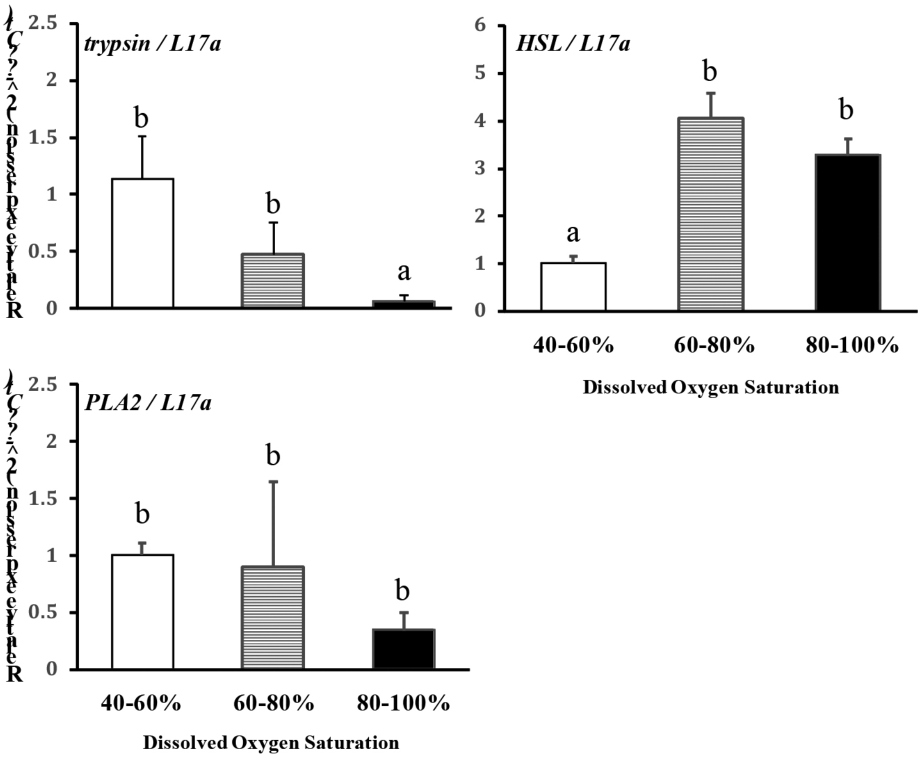

Fig. 1. Relative expression (mean±SE n=3) of *trypsin* and *PLA2* as quantified in pyloric ceca) and *HSL* in the liver, under the effect of different DO saturation levels in seabass. The numbers in brackets indicate the number of samples used for the analysis. Different letters indicate statistically significant differences between groups (p<0.05).

In conclusion:

- expression of trypsin and PLA2 was significantly lower at 80-100% DO compared with other two treatments, while
- expression of HSL was significantly higher at 60-80% and 80-100% compared with 40-60% DO saturation range.

DEVELOPMENT OF A HISTOLOGY-BASED HEALTH ASSESMENT PROTOCOL FOR FISH REARED IN RASs

P. Makridis[1]*, E. Sergi[1], I. Georga[1] and A. Glaropoulos[2]

[1]Department of Biology, University of Patras, 26504, Patras, Greece
[2]ANDROMEDA GROUP, Vonitsa – Paliovarka, 30002, Aitoloakarnania, Greece
Email: makridis@upatras.gr

Introduction

Recirculating aquaculture systems (RASs) show several advantages compared with flow-through systems, such as year-round production, reduced ecological footprint, reduced costs for temperature regulation, and increased biosecurity (Badiola *et al*. 2012). Despite the long-term use of RAS technology (Campanati et al., 2021), there is still a lack of monitoring tools - and therefore a lack of control - over the parameters related to fish health and, with various biotic and abiotic factors affecting the health status and thus the quality of the fish. The effect of such factors can be monitored through histological analysis of specific organs (Saraiva et al. 2015) even well before affecting the overall health status of the fish. The objective of the present study was to monitor and assess the health status of seabass and seabream, reared in RASs (Andromeda facilities, Western Greece), using a qualitative histological analysis.

Materials & Methods

Two seabass (*Dicentrarchus labrax*) and two seabream (*Sparus aurata*) populations reared at Andromeda facilities were monitored in different RAS for each fish species. Four samples were taken from the seabream populations, from March to June 2021 (54-167 dph, 0.07-3.19 g average weight), and three samples were taken from the seabass from March to April 2021 (91-142 dph, 1.07-5.05 g average weight). Five to ten fish or isolated organs (liver, spleen, intestine, and gills) were fixed in 4% formaldehyde for histological analysis. Three fish were selected from each sampling point and pieces of tissue from targeted organs were embedded in Technovit 7100 (Heraeus Kulzer, Germany), sectioned at 5 μm thickness and stained with Polychrome I / Polychrome II. Ten sections per targeted tissue of each fish were examined under a light microscope (Observer Z1, Zeiss, Germany) and photos were taken at 10×, 20×, and 40× magnification. Histological changes were assessed qualitatively by noting the presence or absence of specific deviation from healthy tissues.

Results and Discussion

The preliminary results of this study showed only slight deviations from healthy tissues in the gills, liver, spleen, and intestine of both fish species. No cause-specific mortality and no disease outbreaks were observed during the sampling period, indicating an overall good health of the monitored fish. Deviation from healthy tissues, as determined by histological observations included: uplifting of the epithelium of secondary lamellae was observed in gills, as well as a basal fusion of secondary lamellae (Fig.1, top left), an abnormality related with parasite infestation in various fish species. The histological analysis showed a healthy or slightly modified liver with vacuoles consisting of dead cells and neutrophil liquid in some cases (Fig.1, top right), or an accumulation of glycogen. Histology of the intestine was normal or presented slight aggregation of myxospores in rare cases (Fig.1, bottom right). Finally, histological analysis revealed multifocal lipid accumulation in the spleen, in rare cases (Fig.1, bottom left). Multifocal melanomacrophage centers were also observed in the spleen and liver.

Fish histology is a tool to evaluate rearing conditions in rearing system and is widely used as a health assessment tool. In our study, we used descriptive histology to make a preliminary evaluation of the health status of seabass and seabream reared in RASs. The final aim was to quantify histological alterations observed in targeted organs of fish reared in RASs and develop a histology-based quantitative health assessment protocol through which monitoring of the health status of fish and – on a second level – of the parameters that prevail in RASs will be possible.

(Continued on next page)

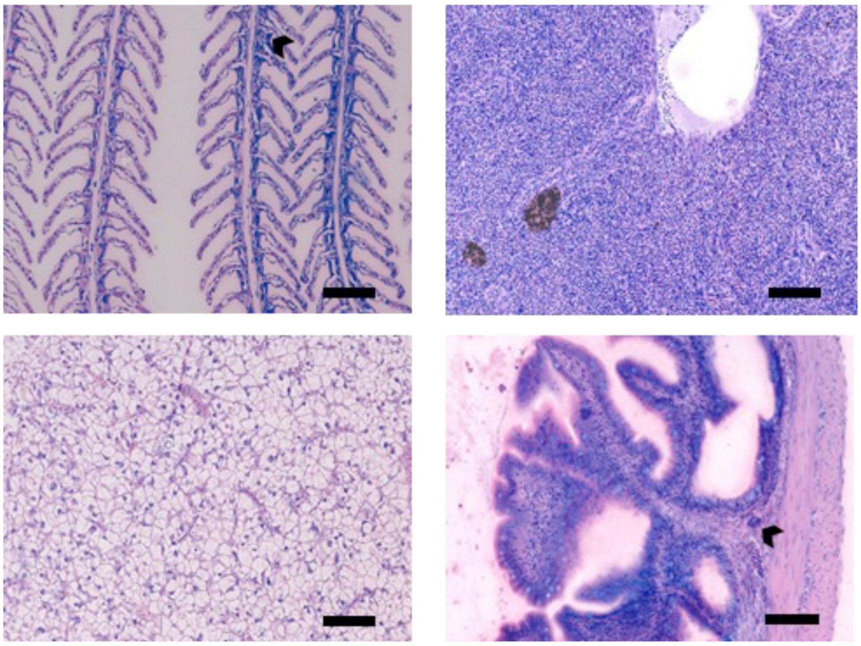

Fig. 1: Basal fusion of secondary lamellae (arrowhead) in gills (top left). Space consisted of dead cells and neutrophil liquid in the liver (top right). Multifocal lipid accumulation in the spleen (bottom left). Aggregation of myxospores (arrowhead) in the intestine (bottom right). 20× magnification and bar 100 µm.

Introduction

The rapid development of global aquaculture sector led the research interest in issues concerning the nutrition of intensively reared fish. The establishment of efficient feeding protocols is essential for optimizing fish growth and improving feed conversion rates, as food must be available in sufficient quantities and with appropriate composition to maintain fish health. The use of functional feed additives has been increased the interest of the aquaculture sector, since the improvement of the fish feeds' quality and fish health is increasingly becoming an important topic for producers. Yeasts and their bioactive compounds can enhance fish growth, immunity, and performance (Agboola *et al*., 2021). The yeast *Rhodotorula mucilaginosa,* that can be found in the gut microbiota of wild fish species, could be a useful and promising additive with growth and immune boosting properties (Wang *et al*., 2019; Chen *et al*., 2019). The aim of this study was to evaluate the effects of fish feed containing three different inclusion levels of lyophilized *R. mucilaginosa*, on growth of the gilthead seabream *Sparus aurata*, a species of great economic importance for the Mediterranean aquaculture.

Materials and methods

Four experimental isolipidic, isoproteic and isoenergetic pelleted diets containing lyophilized *Rhodotorula mucilaginosa* ACA-DC 5340 at the inclusion levels of 0%, 1%, 2% and 3% (C, R1, R2 and R3, respectively), were formulated at the Aquaculture Laboratory of the University of Thessaly. The yeast was obtained by the ACA-DC Collection of the Agricultural University of Athens, grown on Potato Dextrose Agar (PDA) plates and lyophilized into a dry powder. The experimental diets were performed with a laboratory California Pellet Mill (CL-2, Irmeco GmbH, Netherlands). Gilthead seabream individuals were obtained from a commercial fish hatchery (Philosofish S.A.) and transferred to the experimental fish facilities at the Laboratory of Applied Hydrobiology of the Agricultural University of Athens. One hundred twenty fish were acclimated to laboratory conditions, under a controlled photoperiod (12h:12 h light/dark) and were randomly distributed into 12 tanks (174L). Fish with a mean weight of 199,8±1,56g were classified into four groups and each group included three replicates. Fish were fed, by hand twice daily, at a rate of 1,2% BW. During the whole experimental period, water quality parameters were monitored routinely with water temperature being maintained at 20.7 ± 0.07°C, pH at 7.4±0.03 dissolved oxygen at 6.6±0.5mg/L. Fish were individually weighed on a regular basis and food quantity was adjusted accordingly. Growth performance was determined and feed utilization was calculated as follows:
Weight gain rate (WGR, %) = 100 × (final body weight-initial body weight)/initial body weight.

Fulton's condition factor K (gr/cm3) = 100 × final weight × fork length^{-3}
SGR (% day^{-1}) = 100 × (ln final body weight - ln initial body weight) × days^{-1}
FCR = Feed consumed × Body weight gain^{-1}
TGC = 1000 × (Final body weight$^{1/3}$- Initial body weight$^{1/3}$) × temperature degree days^{-1}

Results

The total weight gain did not differ significantly between the four groups. The R1 group, exhibited the highest weight gain rate. No differences were observed for the final weights among groups. The SGR and FCR ratios did not differ significantly. However, R1 group exhibited a higher SGR and a lower FCR ratio compared to the C, R2 and R3 groups. On the other hand, R3 group recorded the lowest feed consumption. TCG was also higher for group R1. Finally, although the condition factor did not differ significantly, the control group exhibited a slightly higher condition factor than groups fed diets with *R. mucilaginosa* inclusion.

Discussion

Yeasts are promising ingredients that can be used as supplements in feeds due to their relatively high protein, energy, and micronutrient content (Glencross *et al*., 2020). In the present study, sea bream fed diets with 1% inclusion of *Rhodotorula mucilaginosa* exhibited better somatic indices. Similar results were observed in Nile tilapia (*Oreochromis niloticus*) fed diets with 1% of the same yeast in a hydrolyzed form (Chen *et al.,* 2019). Nevertheless, it has been shown that higher dietary levels of yeast may result in reduced palatability, feed intake and growth (Gamboa-Delgado & Marquez-Reyes, 2016). This may explain the lower feed consumption in the experimental group fed 3% of yeast. Further investigation is necessary to assess the different levels of *R. mucilaginosa* inclusion and the benefits that could have on the overall fish health and performance.

Introduction

The pikeperch is valuable for aquaculture production due to its flesh quality and high market value (Blecha et al. 2015; Nebeský et al. 2016). However, more than 95% of the market supply has been provided by capture (FAO, 2018; Policar et al. 2013; Steenfeldt et al. 2015), leading to the decline of wild populations in central, eastern, and northern Europe (Policar et al. 2016)frequency of fin erosion, skeletal and gill covers deformities, proximal composition of fish body with special emphasis on fatty acid contents in liver and muscle, oxidative stress and antioxidant response in gill, liver, muscle and intestine were analyzed and compared in exclusively RAS- and POND-cultured juveniles and juveniles produced with the combination of POND and RAS aquaculture in pikeperch (Sander lucioperca L..

One of the concerns in pikeperch populations dynamics is the disproportion of the sex ratio, where females dominate in a size group above 550 mm TL (total length) (Raikova-Petrova and Živkov 1998; Gröger et al. 2007; M'Hetli et al. 2011) Stizostedion lucioperca (L.. Gillnet fishing has the most significant impact on the disproportion, as the most prominent individuals are usually among fisheries catches (Gröger et al. 2007; Vainikka and Hyvärinen 2012)biomass B, recruitment R, spawning stock biomass SSB, yield-per-recruit Y/R, catch-to-biomass ratios Y/B. Such imbalances occurring within the wild population of pikeperch could favour a decrease in reproduction efficiency. It can drastically affect the amount of energy the population invests in reproduction since larger females contribute disproportionally more to population replenishment (Barneche et al. 2018; Olin et al. 2018); therefore, the most productive specimens pair with an unequally sized partner.

This study aimed to investigate the preference of male size by the female during natural spawning on the nest. We hypothesise that variations in spawning behaviour related to the different sizes of partners could influence the reproduction process and the success of pikeperch.

Material and methods

In late October, adult pikeperch individuals were collected from the production ponds of the Nove Hrady Ltd. and transferred to a small earthen pond (0.25 ha) for overwintering. At the beginning of April, females with oocytes in stage V (BW = 920 ± 69; Bodyweight) and males of two sizes: large (BW = 1388 ± 163 g) and small (BW = 566.7 ± 66.9 g); released milt, were selected for spawning in the nests. A set of fish consisting of one female and two different sized males were transferred to an outdoor flow-through aquaculture spawning chamber: Length: 2.8m; Width: 1.5m; Height: 0.8m; total volume of 5.6 m^3) with two artificial spawning nests (0.9 m in diameter) made of stiff long hair brush (Malinovskyi et al. 2018). The water temperature was measured at 1-hour intervals using Minikin Tie digital thermometer (Enviromental Measuring System s.r.o., Czech Republic) placed inside the inflow water pipe. Nests in the spawning chamber were checked twice a day with a 12-hour interval until the female had paired with one of the males. Male size and occurrence of the spawning were recorded. All nests were photographed, and photos were processed using QuickPHOTO MICRO 3.0 software. The empty nests processing included calculation of: (I) cleaned nest area, % of total nest area; (II) cleaned area centring, mm from the centre of the nest. For the nest with egg processing, they further included (III) calculation of egg distribution area, % of total nest area; (IV) clustered eggs area, % of total nest area; (V) clustered eggs area, % of the distribution area. Subsequently, the nests with eggs were transported to the RAS system for further incubation under controlled conditions.

After each successful spawning, blood samples from all fish were collected to determine testosterone for males and estradiol for females in the blood plasma. The testosterone and estradiol levels in the blood plasma were measured by immunoanalytical ECLIA methods (Cobas 6000, Roche, Manheim, Germany).

(Continued on next page)

Results and discussion

Observed behavioural patterns have indicated that the differences in cleaning efforts of pikeperch males were recognised by females and determined the selection of the partner. Generally, pikeperch females have preferred bigger males in 77% of recorded spawning events. However, statistical analysis has indicated that the mechanism of selection was not related to the bodyweight of the male but rather to its efforts in nest preparation. All big males have exhibited cleaning efforts toward the nest, compared to just 50% among small males, confirming the suggestion of better consistency and efficiency of spawning behaviour expression in larger fish. Despite appropriate body weight and cleaning efforts, 33% of the big males were not selected for spawning due to their inability to efficiently recognise and utilise the nest area. The preferred small males were significantly more precise in identifying and using the nest area compared to unpreferred big and small fish. This could be crucial for expressing paternal care and an explanation for females' selection.

The statistical model indicated the male size, plasma testosterone, and average daily temperature significantly affected the parameters of cleaned nest area, % and cleaned nest area centring, mm (Table 1). Higher testosterone values were associated with the larger cleaned size of the nest and its more precise placement relative to the total nest area, e. g., the lower distance between centres of the areas. Similarly, a lower temperature (range: 11.3 – 12.5 °C) was associated with a better cleaning performance of pikeperch males, regardless of the size (Table 1; Figure 1). Therefore, females preferred males cleaning larger nest areas and more precise placements on the nest.

The statistical analysis has also indicated that the water temperature significantly influenced the testosterone levels of males (Figure 1). Females paired with big males showed an insignificant tendency of higher estradiol levels than those selected small males. In addition, testosterone in male blood plasma had increased within a temperature range of 11.6 - 12.5 °, which explains the better cleaning performance of males in this temperature range.

There were no significant effects of the factors mentioned above on parameters of egg distribution, egg clustering and larvae production (Table 1). These characteristics were stable through the experiment, suggesting that selection availability allowed females to exhibit consistent spawning behaviour.

To the best of our knowledge, this is the first study on pikeperch describing a relation between water temperature and testosterone levels in the blood plasma of males. This study confirms the importance of male spawning behaviour in the natural reproduction of pikeperch. Such data could be valuable in predicting the reproduction output in wild pikeperch populations and may guide the controlled reproduction of wild and pond-cultured pikeperch broodstock.

Introduction

The interest in micro- and macroalgal biomass for use in human and animal food and feed products, newly developed applications as seaweed carbohydrates for biodegradable plastics packagings among others is growing exponentially worldwide. Large-scale cultivation is required to meet this growing demand of seaweed biomass. Although it has been known for a very long time that the seaweed microbiome is essential for their healthy growth and development (e.g. Provasoli & Pintner, 1980), many questions are still open considering the mechanism to which the microbiome influences growth and composition and how this is influenced by cultivation conditions (temperature, light, nutrients, etc.).

Within the framework of the SIMBA project (Sustainable innovation of microbiome applications in food systems), growth and chemical composition of the chlorophyte seaweed species *Ulva ohnoi* and the composition of its microbiome has been studied. Causal relationships will provide links between microbiome and algal morphogenesis, growth and nutritious values will be studied. The final ambition of this activity of the SIMBA project is to formulate the optimal microbiome composition for sustainable seaweed production (Ulva) in large outdoor tanks.

Material and methods

Ulva ohnoi M.Hiraoka & S.Shimada, collected from a former salt evaporation pond in the south of Spain, was grown in three different types of cultivation systems with an increasing degree of control on the growth conditions (Fig. 1).

- System 1 (EP): cultivation in floating cages in its natural environment (former salt evaporation ponds), renewal of natural seawater by tidal movements.
- System 2 (OT): cultivation of seaweed biomass in outdoor 400 L tanks. Weekly medium change with nutrient enriched treated natural seawater.
- System 3 (PBR): cultivation in 80 L fiberglass photobioreactors in cultivation chamber (constant temperature and controlled illumination). Weekly medium change with nutrient enriched, filtered and treated natural seawater.

Relative growth rates of the seaweeds were calculated monthly to bimonthly in the EP systems and weekly in the other two systems as weight increase assuming exponential growth. Every month, biomass was harvested from all three cultivation systems, seaweed thalli were gently rinsed in sterilized artificial seawater and spread in petri dishes in a flow cabinet. Samples of the seaweed microbiome were obtained by swiping sterile cotton swabs over the thallus (Fig. 2), after which they were stored at -80 °C until analyses. To be able to discriminate between the seaweed microbiome and the water microbiome, 2 L water samples were taken on each sampling event and filtered through a series of sterile filters (20, 5 and 0,45 µm); microbiomes were finally collected in 0.22 µm Sterivex filters. Additional biomass samples were frozen for later determination of proximate composition. Microbiome composition of the seaweeds and water samples was determined through ribosomal RNA (partial 16S rRNA gene) amplicon sequencing.

Results and discussion

Growth in EP and OT peaked in June and July and was lowest in winter and early spring. In general, growth in OT and EP appeared to be mainly driven by irradiance and water temperature. Episodes of high salinity (50 psu) in EP might have had a negative effect on growth rates in late summer. In EP biomass disappeared completely in December and January, whereas in OT positive growth rates were recorded whole year long, albeit low (< 1% d^{-1}) in winter. Growth in PBRs was generally quite constant (8-10 % d^{-1}), although sudden collapses ocurred, characterised by thallus degradation and negative growth rates. The latter was also observed two times in the outdoor tanks. In one occasion, this collapse was probably related to an outbreak of the parasitic brown macroalga of the *Myrionema* genus both in the PBR and OT systems. Proximate composition of the seaweed biomass was constant in the PBR systems but showed seasonal variation in both outdoor systems.

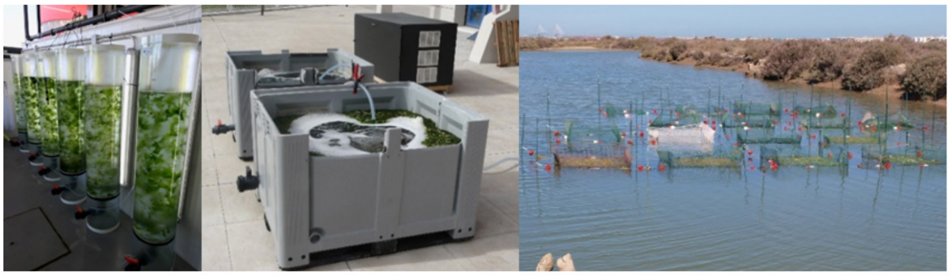

Fig. 1: Cultivation systems for the chlorophyte *Ulva ohnoi;* indoor photobioreactors (left), outdoor tanks (centre), outdoor floating cages (right).

Fig. 2: Seaweed thallus microbiome sampling using sterile cotton swabs.

Laboratory studies have shown that the seaweed chemosphere, related to its microbiome can affect growth rates and possibly chemical composition (Wichard 2015; Ghaderiardakani et al. 2020). In this study, microbiome composition on the seaweed thalli will be compared both within system in time and between systems, focusing on the periods of maximum growth and the collapses. This way, the intention is to identify the bacterial species that might have a positive effect on seaweed growth and form the basis of an optimal microbiome inoculum

Introduction

The rapid development of aquaculture, in last decade, has made this sector one of the most important both at economic and social level gaining a main role in human nutrition, but this industry is severely limited by the lack of proteins intended for animal feed (as a competitor of human nutrition) (Wang et al. 2015). Fishery and aquaculture by-products can be considered as promising alternative feed ingredients in terms of nutritional quality and availability; however, these products are still underused resulting in economic and environmental issues (Gasco et al. 2020)that is, insect meal and fish by-products, as alternatives to conventional animal protein sources. After an introductory part that highlights the need for sustainable development of animal production, the alternative protein sources are discussed. In particular, after providing some indications on their production and supply focussing on EU, a SWOT (Strengths, Weaknesses, Opportunities, and Threats. At the same time, limiting the use of soy in fish diets has become necessary for the sustainability of aquaculture production. In past years, due to emerging health concern, gluten meal has become an even more significant cereal by-product of agriculture that is spreading thanks to its high protein content (Tapia-Hernández et al. 2019). The effects of total replacement of wild fish meal, (FM) fishoil (FO) and soy product (SP) by using fishery and aquaculture by-products and gluten were tested on the growth, gut health and fish quality parameters of European seabass.

Materials and Method

Five experimental diets (control C, 0FM100FO, 0FMFO, 0FMFO-50SP, 0FMFO-0SP) were formulated to totally replace wild fishmeal (FM), wild fish oil (FO) and soy protein using fisheries and aquaculture by-product, and gluten protein. 50 Sea bass individuals (initial weight: 75.96±6.99g) were reared in recirculated aquaculture system for 119 days, during the on-growing phase. Temperature was maintained constant at 22±0.5°, photoperiod was set on 12h day length through artificial light and water parameters, as salinity, dissolved oxygen and nitrogen compound were daily monitored. At the end of the trial, growth indexes, feed intake (FI), proximate composition, somatometric indexes, blood plasma biochemistry were detected. The assessment of gut microbiota (GM) was made by Next-generation sequencing. The assignment of all major NMR signals of the perchloric extracts was performed and a multivariate classification analysis was applied on the entire dataset to reveal metabolites important for characterizing samples according to the diets. Differences among treatments were considered significant at $P < 0.05$.

Results

Final body weight was significantly higher in diet C and 0FM100FO compared to other treatments. Specific growth rate and weigh gain were higher in C compared to 0FM100FO. 0FM0FO-50SP was lower than 0FM100FO, but meantime, 0FM0FO and 0FM0FO-0SP were lower compared to other treatments. FI values were significantly higher in 0FM0FO then 0FM0FO-0SP. FCR, was statistically lower in C compared to 0FM0FO, 0FM0FO-50SP and 0FM0FO-0SP. Values of proteins in 0FM100FO were significantly higher compared to 0FM0FO. Protein efficiency ratio was statistically higher in C then 0FM0FO, 0FM0FO-50SP and 0FM0FO-0SP, while 0FM0F0-0SP was higher than 0FM0FO and 0FM0FO-50SP. Gross protein efficiency was lower in 0FM0FO and 0FM0FO-50SP compared to C and 0FM100FO. Results of viscerosomatic index were statistically lower in diet C compared to 0FM0FO-0SP. 0FM0FO-0SP value of hepatosomatic index was higher compared to 0FM0FO-50SP, 0FM0FO and C, at the same time 0FM0FO-50SP was lower than 0FM0FO-0SP. Results of Lipid efficiency rate and inorganic phosphorus shown a P-value lower than 0.05 but not specific difference among treatments was evaluated by multiple comparison Tukey's test. In animal fed with C diet, creatine value was higher confronted to other treatments. Results of Uric acid shown higher value in diet C confronted to 0FM0FO, 0FM0FO-50SP

(Continued on next page)

and 0FM0FO-0SP. Alkaline phosphatase and Total protein were both lower in diet 0FM100FO compared to 0FM0FO-0SP. Magnesium shown higher value in diet C compared to 0FM0FO-0SP. High density lipoprotein value was lower in 0FM0FO compared to 0FM0FO-0SP. Albumine/Globulin was higher in 0FM0FO compared to 0FM0FO-0SP. Values of Lactate were lower in OFM100FO, 0FM0FO-50SP and 0FM0FO-0SP compared to other treatments.

Discussion

This study highlighted the possibility to total replace wild FM and FO using by-product from fisheries and aquaculture with only a marginal reduction of the overall performance and considering the positive implication on the economic and environmental impact at industrial level. In particular, when only wild FM was totally replaced by fisheries by-product no differences were recorded, while the combine replacement of wild FM and FO resulted in a performance reduction. Interestingly, the further replacement of soy products by alternative plant proteins in the free wild fish diet did not result in a decline of performance. As the fish quality is a broad and complex concept embracing many components, the metabolomics study applied in this work will provide a comprehensive descriptor consisting of a pattern of molecular components undergoing metabolic changes related to the different diets.

Introduction

AquaVitae (AV) is a research and innovation project funded by the EU's Horizon 2020 program. AV's overall objective is to introduce new, and expand existing, low trophic species (LTS) products and processes to marine aquaculture value chains across the Atlantic. The value chains that AV focuses on include macroalgae, integrated multi-trophic aquaculture, echinoderms, underutilized shellfish species and low trophic finfish species. Moreover, AV includes analysis of value chains, market development and profitability, and other biological and socioeconomic aspects, including sustainability, environmental monitoring, and risk assessment of LTS aquaculture.

The achievement of sustainable aquaculture requires consideration of the positive and negative impacts of aquaculture on the environment, economy, and society. The identification and quantification of the ecosystem services (ES) derived from LTS aquaculture can provide useful information to support a rigorous sustainability assessment of the three sustainability dimensions (environmental, economic, and social). Nature's Contributions to People (NCP) is a novel framework for ES, defined as all the contributions (positive and negative) of nature to people's quality of life, and include the role that humans play in the co-production of benefits from nature. This framekork fits well the scope of AV and was therefore selected for the quantification of ES as part of the sustainability analysis of LTS aquaculture in the Atlantic Region. The present work aims to identify and quantify the NCPs provided by LTS aquaculture, based on the case studies (CS) investigated within AV. Additionally, it identifies knowledge gaps in terms of what NCPs are supported by LTS aquaculture, and what data were missing for quantification of the services provided.

Material and methods

The work was deconstructed into four sub-tasks: i) identification of the NCPs provided by LTS (based on the CS investigated within AV) and identification of current knowledge gaps in terms of qualitative contributions of LTS aquaculture to the NCPs using expert judgements and literature; ii) selection of specific CS to be included in the evaluation of NCPs provided by LTS aquaculture based on the number of identified NCPs and overall knowledge level (estimated based on the data quality scoring for the identified NCPs in the previous step); iii) selection of indicators for NCPs quantification (based on the framework developed in a previous task from AV); and iv) quantification and analysis of selected NCPs using the most appropriate valuation method for each indicator using data from CSs within AV and literature reviews.

Results and Discussion

Overall, a relatively high number of NCPs were identified and confirmed for all CSs assessed. The highest number of identified NCPs was reported for CS4 *Sea-based IMTA* and CS9 *Mussels*, both with 15 identified NCPs out of 18, followed by CS2 *Offshore macroalgae* and CS8 *Oysters* both with 14 identified NCPs, and two land-based systems, CS1 *New macroalgae species* (13 NCPs) and CS3 *Land-based IMTA* (11 NCPs). The lowest number of identified NCPs was reported for CS6 *Sea urchins* with 9 identified NCPs, which may be explained by the immaturity of this industry compared to other more established LTS aquaculture industries. Based on defined selection criteria, the CSs *Offshore kelp production*, *Land-based IMTA*, *Oysters*, and *Mussels* were selected for the subsequent NCP analysis and quantification.

The indicators Nutrient cycling and Eutrophication index were used for the quantification of the NCP *Regulation of coastal water quality*, the Carbon footprint was used to estimate the NCP *Regulation of climate*, the Ocean acidification index indicator was applied to estimate the NCP *Regulation of ocean acidification*, and food and feed production were used for the NCP *Food and feed provision*. The performance of the selected LTS aquaculture systems was subsequently

(Continued on next page)

analysed and quantified using the selected indicators and NCPs, and the results were compared to each other, and to other common food production systems. Of the LTS evaluated in this report, sugar kelp production showed lower eutrophication mitigation potential than mussels and oysters and had a much lower farm-gate price compared to oysters and abalone, yet was found to be the only LTS to counteract ocean acidification. Bivalve production (mussel and oyster culture), on the other hand, was found to have a significant bioremediation capacity, with mussels displaying a higher capacity compared to all organism groups in this report. Compared to mussels, oysters obtained a higher farm-gate price, but also demonstrated a higher ocean acidification index, and the highest carbon footprint per unit of food produced among all LTS culture systems studied. In comparison, most mussel production systems had a lower ocean acidification index and a lower total carbon footprint per unit of food produced, than abalone and oysters. Abalone was the only LTS production system that showed a net release of nutrients, its ocean acidification index was set at the mid-range of values reported for oysters and at the upper range for mussels, and its carbon footprint per unit of food was similar to the higher values reported for mussels, while its farm-gate-price was considerably higher and only comparable to premium price oysters from Northern Europe. In terms of the total carbon footprint, mussels and abalone were found to have the lowest CF among the analysed shellfish production systems, equivalent to primary producers, oysters were found to be comparable to poultry and pig meat, but lower than e.g., lamb, beef, or other farmed marine species (e.g., fish and prawns), while sugar kelp had a residual carbon footprint and consequently may support climate change mitigation. It should be noted that all mussels, abalone, and even oysters may also indirectly support climate change mitigation e.g., by replacing other meat products. However, analysis of indirect effects of LTS aquaculture on the combined CF of food production around the Atlantic is not included in the scope of this study.

The quantification identified significant contributions to society, e.g., in terms of NCP *Regulation of coastal water quality*, as well as sustainable *Food and feed provision*. Some disservices were also identified, e.g., linked to the NCP *Regulation of climate* as the carbon footprint of shellfish culture was found to be in line with other traditional food sources, but generally lower than other meat products. In view of these results, a well-planned expansion of macroalgae and shellfish aquaculture together with campaigns that promote the consumption of these products over other meat products may contribute to cover the increasing demand for food in the world while mitigating eutrophication effects and reducing the current contribution of food production systems to the global GHG emissions. This includes developing context-dependent recommendations for expansion of LTS aquaculture where regional differences related to species and system performance are accounted for.

The results here presented will be integrated in the upcoming sustainability analysis of LTS aquaculture and will form the basis for the economic valuation of marine ecosystem services linked to LTS aquaculture in upcoming tasks from AV. Finally, identified knowledge gaps related to the link between some NCPs and LTS aquaculture, and data deficiencies are highlighted in this study to support future research needs in this field.

Acknowledgments

This research is supported by the European Union's H2020 Research and Innovation program within the collaborative project "AQUAVITAE– New species, processes and products contributing to increased production and improved sustainability in emerging low trophic, and existing low and high trophic aquaculture value chains in the Atlantic" under Grant Agreement No. 818173.

Introduction

For many consumers, aquaculture is not a well-known sector of food production (Fernández-Polanco & Luna 2012). To study the potential ways to increase the awareness, in Finland, France and Spain we assessed consumers’ perceptions on fish farming and on the information they receive and would like to receive. Our previous results showed that consumers receive a limited information about fish farming but are open to receive more (Latvala et al., 2021). The present work is focusing the perceptions of consumers about their knowledge on fish farming techniques and related fields, and their interest to learn about them.

Material and methods

To identify the key questions to be studied, during an initial workshop we collected the opinions of the AquaImpact program partners, researchers and professionals. Then a qualitative study was elaborated and carried out in five consumers focus groups in the three countries in 2019 (Mariojouls et al., 2021). Using the results of the qualitative study, we elaborated a quantitative study, carried out by online survey on a representative sample (415 people per country) in 2021. The master questionnaire included different parts, and we present here mainly results about farming practices. We asked questions such as “How do you think that farmed salmons in Europe are fed ? with…”, ”How do you think that farmed salmons in Europe are cared ? with...?”; How do you do you think that farmed salmons in Europe are reproduced and selected ? …”, proposing several techniques for every question, the respondent giving for each technique a level of agreement (always, occasionally, never, I don’t know). Some questions targeting on emerging techniques (in feed, genetics, RAS, fish welfare) concerned their acceptability.

Results and discussion

The limits of knowledge are reflected in the difficulty for answering certain technical questions, translated into consistent or high rates of «I don’t know».

The comparative approach between countries shows that there are significantly different response profiles in the three countries for most questions.

Regarding feeding practices, there are highly significant differences (at 0.1%) between countries for the two following techniques: the technique «with fishmeal» is considered effective (ratio of sum of shares for «always» and «occasionally» on total, after exclusion of “I don’t now”) by 95% of respondents in Finland, 92% in France, 74% in Spain where 65% choose “I don’t know” VS 23% in Finland and 34% in France, and “with a mixture of ingredients” considered effective by 93% in Finland, 94% in France, 89% in Spain, with shares of “I don’t know” at respectively 33%, 39% and 40%. For the other proposed techniques, the differences between countries were significant but less marked (at 5%). They were considered effective by 65 to 75% for “with little wild fish”, by 79 to 84% for “with plant ingredients” and by 71 to 81% “with animal meals”, and the shares for “I don’t know” are in the range of 37 to 47%. Finland shows the lowest share of “I don’t know” except in one case, meaning the best level of knowledge in salmon feeding.

Regarding care practices, we found highly significant differences between countries for all proposals (at 0.1%) except for ”with vaccines” (significant at 1%). The shares of answer “I don’t know” are high (41 to 54%) in all countries for three techniques (“vaccines”, “other medicines”, “cleaner fish to limit external parasites”), the lowest for “with high sanitary practices” (20 to 39%), and consistent for the others (29 to 54%), and for all techniques Finland has the lowest share meaning the best level of knowledge in care of farmed salmon. The method «with high sanitary practices» is considered effective at the highest level (Finland 96%, France 89%, Spain 94%) meaning a positive view of caring salmon in farms, while «with vaccines» is considered effective at the lowest level (Finland 66%, France 70%, Spain 64%) meaning a limited knowledge about the real use of this technique. Other techniques are considered effective by 71 to 90% of respondents.

The questions on reproduction and selection show that the shares for “I don’t know” are in a range of 35 to 58%, the highest being for the proposed technique “Mating of close relatives is avoided to prevent inbreeding”. We found again the lowest shares of “I don’t know” in Finland, meaning a better knowledge in fish breeding than in France and Spain. The technique “males and females mate naturally” is considered effective by the lowest shares (Finland 76%, France 73%, Spain 85%), while other techniques are at high levels (82 to 92%) except “Mating of close relatives is avoided to prevent inbreeding” with great discrepancies between Finland (82%) VS France (45%) and Spain (40%), confirming a better knowledge in Finland.

Questions about acceptance of emerging techniques in feeding had rather limited shares of “I don’t know” (23 to 31%). In total panel, the acceptance (sum of « totally acceptable » and « weakly acceptable » on total incl. “I don’t know”, in whole panel) is high (52 to 63% according to techniques) for feed containing insects, micro-algae, only plant ingredients, only local ingredients, but more limited for feed containing oil rich in omega 3 from GM seeds (45%), and feed containing authorized animal meals (42%), and low only for feed containing yeasts (34%). About genetics, « I don’t know » is expressed by a limited share of respondents : 22% to 26 %. There is a good or very good acceptance for traditional selection (67%) and genomic selection (58%), and unsurprisingly, GMO shows the lowest acceptance (29%), as found in previous research (Barrey et al., 2011). For other emerging techniques, « I don’t know » is expressed by a limited share of respondents (21 to 25 %), and the acceptance is high for proposal on improvement of fish welfare (67%) and for RAS technology (62%). Between countries there are significant differences for all proposed techniques at 0.1%, except for feed containing local ingredients (at 5%), and no significant differences for proposals on GMO, fish welfare, RAS.

Consumers in all countries consider that the information received today is insufficient, and that receiving information would be really useful at high rates, from 73 to 91% (sum of shares for “slightly useful”, “useful and “very useful” on total by country) with lesser levels in France, about a wide range of topics (farming practices, regulation & controls, nutritional content, economics) with various levels of interest for these topics according to countries.

Conclusion : Our results suggest the need for dissemination to consumers of information on fish farming, in forms adapted to the subject and the population of each country.

Acknowledgments: This study is part of the AquaIMPACT project and was funded by the European Union’s Horizon 2020 research and innovation programme under grant agreement No 818367.

Introduction

Several contaminants affect the productivity and safety of bivalve fisheries sectors, such as phytoplankton-produced biotoxins, metals and microbiological agents (Shi et al. 2016; Blanco, 2018; Martin et al. 2019). Pathogenic microorganisms are commonly associated with foodborne diseases in humans from shellfish consumption and can be caused by a variety of bacterial genera (Grevskott et al. 2017). In order to protect consumers from these pathogens, methods like depuration are used to reduce the content of microbiological contaminants in bivalves (Polo et al. 2015). Nonetheless, there are bacterial strains capable of resisting the depuration process, potentially causing problems to public health (Martínez et al. 2009). The aim of this work, which was conducted under the research project SEEBug (Development of a sensor for the fast and efficient detection of pathogenic bacteria in Bivalves; funded by MAR 2020) is being to isolate and identify the cultivable bacteria associated with two bivalves species.

Materials and methods

Specimens of depurated and non-depurated *Venerupis Corrugata* and non-depurated *Mytillus* sp. were collected in Ria de Aveiro (Aveiro, Portugal), in July 2021. The microbiological analysis was performed according to two different methodologies: P1 - The processing, extraction, and detection of *Escherichia coli* in bivalves species following standardized procedures (ISO 6887-3:2017, ISO 16649-3:2015 and ISO 7218:2007) in compliance with the approved Regulations, namely Reg. (CE) N.º 854/2004, Reg. (CE) N.º 1021/2008 e Reg. (EU) 2015/2285). MPN values were calculated to assess the health status of processed bivalves and production zones; and P2 - MacConkey Agar (MC) and Thiosulfate-citrate-bile salts-sucrose (TCBS) served as selective culture media and Tryptic soy agar (TSA) as a non-selective medium to obtain bacterial isolates, to enable the counting of colony forming units (CFUs) and the preliminary description of the cultivable microbial diversity present in the shellfish biomass. Molecular techniques (amplification and sequencing of 16S rRNA gene) were applied for the taxonomic identification of the isolated bacteria.

Results

By following the standard protocols in P1 it was possible to successfully identify *E. coli* from non-depurated Pullet carpet shell (*V. corrugata*) individuals. The MPN values obtained are within the legal limit set for the health status class C (> 4.600 to ≤ 46.000 E. coli MPN / 100 g), according to Reg. (CE) No. 854/2004, Reg. (CE) No. 1021/2008 and Reg. (EU) 2015/2285. Regarding the P2 methodology, several genera of cultivable bacteria were detected in both bivalves. Cultures on MacConkey agar showed a greater number of bacterial isolates and therefore higher CFU values. Molecular methodologies allowed the identification of eight bacterial genera (*Aeromonas* sp., *Escherichia* sp., *Photobacterium* sp., *Pseudomonas* sp., *Serratia* sp., *Shewanella* sp., *Klebsiella* sp. and *Providencia* sp.).

Conclusion

Through the detection of *E. coli* isolates, it was confirmed that the application of ISO protocols are effective in determining the level of *E. coli* in for regulatory purposes. The MPN values demonstrated that the depuration process reduces the concentration of viable *E. coli* in bivalves. However, the health status remained the same for *V. corrugata*. In this case, the depuration period would probably have to be longer to decrease the MPN values, and thus contribute to the consumers' food safety. The cultivation of bacteria isolated from bivalves, on selective and non-selective media, constituted a first approach to the diversity study of the cultivable microbial community and to identify *taxa* that are commonly considered pathogenic (belonging to Pseudomonadaceae, Aeromonadaceae, Vibrionaceae and Enterobacteriaceae). Obtaining these pathogenic isolates will enable the development of early detection sensors in bivalves of economic interest.

Introduction

The need to replace fish oils (FO), rich in long-chain (C20-24) polyunsaturated fatty acids (LC-PUFA), by vegetable oils (VO), devoid of LC-PUFA but rich in their C18 precursors, has led to a growing interest in understanding how the LC-PUFA biosynthetic pathways can be regulated in fish species of commercial importance. *Chelon labrosus* is an euryhaline teleost able to live in environments of different salinities such as estuaries and coastal waters. *C. labrosus* has been proposed as a good candidate for aquaculture diversification due to its omnivorous profile, rapid growth and resistance to environmental variations (Abellan and Arnal, 2013). Moreover, the functions of the LC-PUFA biosynthesizing enzymes fatty acyl desaturase (Fads2) and elongase (Elovl5) from *C. labrosus* has recently reported, demonstrating its capacity to produce the physiologically essential 20:5n-3 (EPA) and 22:6n-3 (DHA) from the C18 precursor 18:3n-3 (ALA) (Galindo et al., 2021). These characteristics make this species a perfect model to evaluate dietary and salinity modulation of EPA and DHA endogenous production. The present study assessed the combined effects of two dietary LC-PUFA contents and two salinities in the regulation of LC-PUFA biosynthesis in *C. labrosus* juveniles through the modification of the muscle fatty acid profiles and the regulation of the expression of *fads2* and *elovl5* genes in liver.

Material and methods

C. labrosus juveniles with an average body weight of 14.6 ± 1.6 g were randomly distributed into four quadrangular flat bottom 1000 L-tanks (15 fish each) and reared for 10 weeks in an aquaponic system at Fundación Neotrópico (Tenerife, Spain) facilities, at a temperature of 19.5 ± 0.4 °C, and under a natural photoperiod regime. Fish from two tanks were fed a FO-based diet (TI-5 Tilapia; Skretting + 4% Croda's Incromega™ oil), while the other two tanks received a VO-based diet (TI-5 Tilapia; Skretting + 4% olive oil). For manufacturing both experimental diets, the commercial TI-5 Tilapia feed was crumbled, the oil added, and the mixture finally repelletized. FO diet contained 6-fold more DHA and near 2-fold higher EPA than the VO diet. Fish were fed twice daily at a rate of 3-5% of their total biomass. Each diet was tested at 35 ppt and 20 ppt, resulting in four experimental treatments: FO35, FO20, VO35 and VO20. At the end of the experimental period, fish were individually measured and weighed, and subsequently pooled into five groups of three fish (n=5) per tank. Pooled samples of muscle were collected for fatty acid analysis. In addition, a portion of liver (~100 mg wet weight) was collected in RNAlater®, stored for the first 24 h at 4 ºC and then frozen at -20 ºC until further analysis of gene expression of the *C. labrosus fads2* and *elovl5* genes by qPCR. *ef1α* and *β-actin* were used as reference genes to normalize the expression of *fads2* and *elovl5*.

Results

Survival was 100% in all experimental groups. No significant differences in fish growth and total lipid content of muscle were registered among treatments. In addition, muscle EPA contents did not vary between fish groups. In contrast, FO20-fish displayed the highest amount of DHA. Relative expression in liver showed greater effects of salinity than dietary regime, with both *fads2* and *elovl5* being upregulated in fish reared at 20 ppt.

(Continued on next page)

Discussion and conclusions

The present study showed that *fads2* and *elovl5* in liver were upregulated in fish reared at 20 ppt, indicating that salinity is a key parameter in the expression of these genes, independently of the diet. These results are consistent with other studies in marine teleosts such as *Pagrus major* or *Siganus canaliculatus* reared at a lower salinity than that of seawater (Sarker et al., 2011; Xie et al., 2015). Indeed, low salinity has been reported to increase the content of LC-PUFA in other mugilid species such as *Mugil cephalus* (Khériji et al., 2003). LC-PUFA biosynthesis can also be stimulated with low dietary levels of LC-PUFA in combination with changes in the environmental salinity (Marrero et al., 2021). In fact, a higher hepatic expression of both enzymes at low-salinity was found, albeit this only implied a difference in the amount of DHA levels in FO-fish flesh. Meanwhile, VO-fish showed no significant differences between salinities with respect to this omega-3 LC-PUFA, despite VO20-fish being upregulated for both genes. In conclusion, *C. labrosus* was able to compensate the lower dietary input of DHA with respect to the control treatment (FO35) despite VO diet provided 6-fold less DHA and 2-fold less EPA than FO diet.

Introduction

Viral Hemorrhagic Septicemia (VHS) and Infectious Hematopoietic Necrosis (IHN) have a great impact on the Italian rainbow trout farming industry and the availability of vaccines is a key point in controlling and reducing their effect on productions. DNA vaccines have proved to be effective in protecting rainbow trout from VHS and IHN in controlled settings, but no data are available about their efficacy in intensive rainbow trout farming conditions.

Materials and methods

Italian VHSV and IHNV glycoprotein gene sequences were used to design two DNA vaccines tailored towards current virus variants causing disease in rainbow trout farms in Italy. An experimental trial was first conducted at the IZSVe Experimental Aquarium in order to obtain efficacy and safety baseline data. Water temperature was set at 12°C along the whole trial. Ten-gram rainbow trout (*Oncorhynchus mykiss*) juveniles were treated with 0.1 or 1 mg/fish of the plasmids, injected singularly and combined. Fish were bath challenged 60 days post vaccination (dpv) with two recently isolated Italian VHSV and IHNV, singularly and in combination at the dose of 10^4 TCID50/ml. Cumulative mortality in control groups resulted to be 85.2%, 38.2% and 92.4% for IHN, VHS and coinfection respectively. Dose of 1 mg/fish produced the highest RPS and was selected for the field trial. Due to lower mortality in the IHN control group and the farm epidemiological situation, only the VHS and the VHS/IHN treatments were selected for the field trial.

One Category I hatchery supplied 15,000 rainbow trouts weighing approximately 8 grams that were then divided into three experimental groups of 5,000 fish each: one injected with PBS (Group 1), one injected with 1 mg/fish of VHS vaccine (Group 2) and the last group treated with 1 mg/fish of each plasmid mixed together (Group 3). Fish were then moved to a VHS/IHN infected facility 60 days post vaccination and positioned in a single raceways divided by grid. For 60 day post transfer (dpt), symptomatic fish from Group 2 and 3 were individually collected and subjected to qPCR for VHSv and IHNv in order to identify the viral species causing mortality in these groups. In Group 1, fish were monitored in pool daily or weekly once mortality began due to the high number of fish which died for 60 dpt. Afterward, anatomopathological examinations were performed in all the three groups monthly or in case of variation of the mortality trends. At 270 dpv fish reached the marketable size and were destined to human consumption and the field trial ended.

Results

Mortality began 7 days post transfer (dpt) with different trends in the three groups. In Group 1, VHS resulted to be responsible for the mortality in the first 30 dpt and was replaced by IHN which persisted along all the trial, causing low and constant mortality. No bacterial pathogens were identified except for *Yersinia ruckeri* biotype II which caused mortality in all the three experimental groups between 200 and 240 dpv. Based on antibiogram, medical treatment was performed *per os* for 10 days and proved effective. At 30 days post transfer, mortality resulted to be 10.5 % in Group 1, 3.3% in Group 2 and 1.0% in Group 3, with a RPS of 69.3% and 90.5% provided by VHS and VHS/IHN vaccine respectively. At 60 dpt, RPS decreased for the VHS vaccine only (59.6%) due to the mortality caused by IHN, while the VHS/IHN vaccine maintained the same level of protection (87.1%).

At the end of the field trial (270 dpv), cumulative mortality was 35.3% in the control group, 26.0% in the VHS-vaccinated group, and 20.0% in the bivalently-vaccinated group and the mean weight was approximately 430.7±143.7 grams, 404.1±106.4 grams, 429.9±110.5 grams in Group 1, 2 and 3 respectively confirming that tested vaccines didn't produce any adverse zootechnical effect.

Conclusions

DNA vaccines confirmed to be safe for injected fish and effectively reduced the impact of VHS and IHN also under field conditions.

Research project IZSVe RC 09/18 was funded by the Italian Ministry of Health.

EFFECTS OF MICRODIETS ENRICHED WITH THE MICROALGAE *Nannochloropsis gaditana* ON MUSCLE COMPOSITION, OXIDATIVE CONDITION AND DIGESTIVE FUNCTIONALITY OF SEA BREAM (*Sparus aurata*) LARVAE

Introduction

Early life stages of marine fish are critical to the morphological and physiological changes that determine their further viability thorough their productive cycle. In this regard, the inclusion of functional additives in microdiets is currently a hot topic in aquaculture research. Among the wide variety of those functional additives, microalgae have proven their value owing to their richness in biostimulant compounds. Nevertheless, some microalgae species rich in these bioactive substances have a thick cell wall that might impair their release, and therefore, their physiological effects (Wu *et al*., 2017). Even if raw microalgae biomass is routinely added to weaning diets, however, when the potential biological effects depend on microalgae inner compounds, a pre-treatment might increase their bioavailability. In this regard, enzymatic hydrolysis may represent a useful strategy aimed at weakening the microalgae cell wall, thus increasing the release of bioactive compounds. In this context, we hypothesize that low dietary inclusion level (up to 5%) of *N. gaditana* either crude or hydrolysed, might improve the digestive functionality of larvae. With this purpose, a 45-d feeding trial was set out, after which several parameters related to body composition, antioxidant status, and digestive morphology and physiology of gilthead seabream (*Sparus aurata*) larvae were assessed.

Materials and methods

Nannochloropsis gaditana was cultured in tubular photobioreactors at the pilot plant (EU-H2020 SABANA facilities) of the Universidad de Almería (Spain). Subsequently, enzymatic hydrolysis of raw algal biomass was carried out as reported in Ayala *et al.* (2020). Five isonitrogenous and isolipidic (46% and 16% DM, respectively) experimental diets were elaborated at the CEIA3-University of Almería facilities (Service of Experimental Diets). Two inclusion levels (25 and 50 g kg^{-1} w/w), and two microalgae formats (raw and enzymatically hydrolysed) were considered in 0.2 to 0.4 mm microdiets. Therefore, diets were designed as R25 and R50 for raw microalgae lots, and H25 and H50 for diets containing enzymatically-hydrolysed biomass. A microalgae-free diet was used as control (CT). Gilthead sea bream larvae were randomly distributed in 15 tanks and fed daily at 5% of their biomass. At day 22 and 45 of the feeding trial, fish were sampled for determinations of muscle proximate composition and lipid oxidation status by thiobarbituric acid reactive substances (TBARS). In addition, some digestive enzymatic activities, transcriptomic profiling of intestinal markers and the study of the intestinal mucosa by scanning electron microscopy (SEM) were evaluated.

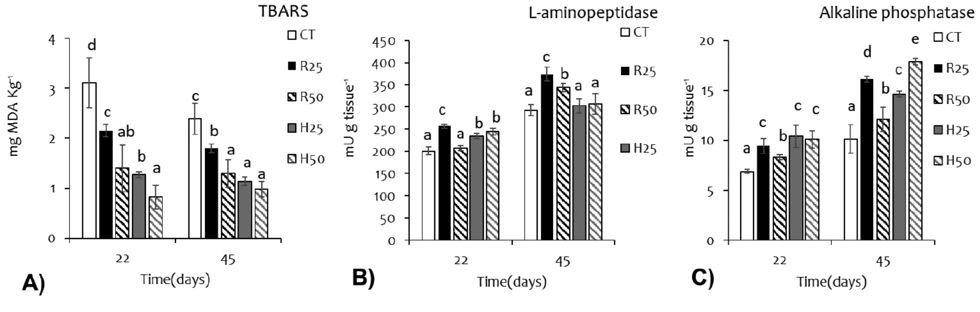

Figure 1. A) TBARS content in *S. aurata*. B and C) Digestive enzyme activities measured on intestinal extracts after 22 and 45 d of the feeding trial. CT: controls. R25 and R50 stand for 25 and 50 g Kg^{-1} of raw algal biomass, respectively. H25 and H50 stand for 25 and 50 g Kg^{-1} of hydrolyzed algal biomass, respectively. Values are mean ± sd (n=15). Different lowercase letters indicate significant differences ($P<0.05$).

(Continued on next page)

Results and discussion

Overall, the use of *N. gaditana* as functional additive in diets did not cause any difference in proximate analysis. Nevertheless, *N. gaditana* meal at low inclusion level in microdiets improved the antioxidant response ($p<0.001$) compared to CT fish. This effect was more evident when microalgae biomass was pre-treated with cellulase (H25 and H50, $p< 0.001$) at any sampling time (Figure 1). It is likely that the richness of *N. gaditana* in natural antioxidants (carotenes, polyphenols, etc.) and other bioactive compounds underpins these effects on lipid oxidation.

On the other hand, at 22 d animals fed on CT, R25 and R50 diets showed significantly higher trypsin, chymotrypsin and total alkaline protease enzyme activities. However, this effect was less evident after 45d, time at which the specific enzyme activities measured did not differ among dietary treatments. With regard to brush border enzymes (alkaline phosphatase and leucine aminopeptidase), all the microalgae-enriched diets increased their activities, compared to CT. However, such increase dependent more clearly on the inclusion level than on biomass pre-treatment. These enzyme activities play a fundamental role in the final stages of digestion, allowing the absorption and transport of nutrients through the enterocytes, and they are used as indicators of the intestinal integrity or as general markers of nutrient absorption. The intestinal mucosa plays a key role not only in digestion and absorption processes, but also as a protective barrier against pathogenic microorganisms. These results are in agreement with gene expression analyses of intestinal markers, and also with the findings after the electron microscopy studies of the intestinal epithelium.

Conclusions

The results obtained indicate that the inclusion of *N. gaditana* meal at low level (25 and 50 g kg^{-1}) in microdiets had an impact on different aspects related to antioxidant activity and certain digestive functionality parameters of sea bream at initial stages of their productive cycle. The enzymatic pre-treatment of the microalgae with celullase enzymes can increase the antioxidant effects, but no influence was observed in most of the parameters related to the intestinal functionality. Further research assessing the potential effects on intermediary metabolism and fish immune response are needed as well.

Introduction

Nannochloropsis gaditana is a microalgae species characterized by having adequate protein content, as well as valuable amino acid profile, together with significant concentration of liposoluble vitamins and carotenoids with antioxidant properties, so that its inclusion as feed additive at low concentration might well be promising in the context of fish fillet preservation (Sales *et al.,* 2021). Nevertheless, the existence of a cellulose-rich cell wall could limit the *in vivo* bioavailability of the bioactive intracellular components when *N. gaditana* is included in aquafeeds. For the abovementioned reasons, simple, economical, or at least, cost-effective cell-wall disruption protocols, aimed at easing industrial scaling, are still needed. In this regard, the use of hydrolytic enzymes capable of weakening *N. gaditana* cell walls, namely cellulases, prior to its incorporation into feeds is among the most feasible strategies. Bearing in mind previous premises, the bioavailability of the intracellular compounds of *N. gaditana* might be improved, compared to crude microalgae, by pre-treating enzymatically the biomass, compared with crude microalgal biomass. Moreover, this increased release could improve objective quality parameters and shelf-life of cultured gilthead seabream (*Sparus aurata*) fillets when hydrolysates are included finishing diets for this fish species.

Materials and methods

Nannochloropsis gaditana was obtained from EU-H2020 SABANA facilities of the Universidad de Almería (Spain). Five iso-nitrogenous (45.5%, DW) and iso-lipidic (15.5%, DW) experimental feeds were formulated; two of them contained 25 and 50 g kg-1 *N. gaditana* raw biomass (labelled as R25 and R50, respectively); other two experimental groups included 25 and 50 g kg^{-1} *N. gaditana* hydrolysates (designated as H25 and H50, respectively), and a fifth diet, microalgae-free, was used as the control batch (CT). The feeding trial was carried out at the aquaculture facilities of Centro Oceanográfico de Murcia (Mazarrón, Spain), Instituto Español de Oceanografía (IEO-CSIC). Gilthead seabream (400 g average initial body weight) were randomly distributed in 15 tanks (triplicate tanks per dietary treatment). Fish were fed with CT diet (microalgae-free) during a 15-d acclimation period prior to the beginning of the feeding trial. Afterwards, the experimental diets were offered at 2% of the biomass during a 42-d period. At the end of feeding assay, 10 fish per tank (30 animals per dietary treatment) were withdrawn. Immediately after slaughtering, specimens were gutted, filleted and packed in transparent sterile polyethylene bags. These bags were directly stored at 4 ºC in a cold room (4 ºC ± 1 ºC) for a period of 15 d with the aim of assessing changes in quality parameters throughout the fillet shelf life. Samples were extracted from each lot at 1, 2, 4, 7, 9, 11 and 15 days post-mortem (dpm), and total viable counts, lipid oxidation, texture profile analysis (TPA), pH, water holding capacity (WHC), skin pigmentation were determined at each sampling time.

Results and discussion

At the end of the production cycle, feeding can play a key role in the final quality of the final product. The results obtained indicate that microalgae supplement ($P<0.01$) and storage time ($P<0.01$) were responsible for significant differences in psychrophilic bacterial counts (PBC). However, from 7 days *post-mortem* (dpm) onwards microalgae inclusion lowered microbial growth up to 15 dpm compared to CT batch. However, neither microalgae dose ($P=0.581$) nor enzyme pre-treatment of the biomass ($P=0.989$) affected bacterial counts.

Lipid peroxidation is one of the main concerns during fish storage, as it contributes to quality deterioration and shortens fillet shelf life. In this regard, microalgae supplementation in aquafeeds has shown positive effects, slowing down lipid oxidation phenomena (Shah *et al.,* 2018). In this assay, from 4 dpm onwards CT fillets yielded higher TBARS values compared to any of the batches fed with *N. gaditana*-containing diets ($P<0.01$). In addition, a dose-dependent effect was observed, with lower values in R50 and H50 fillets, although, these differences became significant only at later stages of the storage period (after day 11). Concerning fillet hardness, overall, the inclusion of *N. gaditana* in diets yielded higher values

(Continued on next page)

(P<0.01) for this parameter compared to CT fillets, especially for 5% inclusion level. In addition, Also, the dietary inclusion of raw biomass tended to yield fillets with higher hardness than those obtained from fish fed with the hydrolysed biomass, although differences didn't reach statistical significance (P=0.069). Roughly, springiness, cohesiveness, gumminess, and chewiness followed a tendency similar to that observed for hardness. Also, pH was influenced by both dietary treatment and dosage, and thus, higher *N. gaditana* inclusion level (R50 and H50) yielded lower values (P<0.01 in both cases). On the other hand, WHC, which represents the percentage of water retained in the muscle, was not affected by *N. gaditana* inclusion (P=0.055), even if average values tended to be lower in CT batch than in H50 and R50 fillets. Skin colour is a key parameter influencing consumer acceptability. At the beginning of the storage period, dorsal skin of microalgae-fed lots showed higher values for L* (lightness) and b* (yellowness), but lower for a* (greenness) than CT fillets. Nevertheless, during cold storage time, L* decreased significantly in microalgae-fed lots throughout the 15-d period, with similar final values in all batches. On the other hand, a* parameter decreased in all fillets, although microalgae-fed groups yielded consistently lower values (more greenish) than CT. Finally, b* parameter also decreased owing to storage time in all experimental groups, being values for this parameter consistently higher in R50 and H50 fillets compared to CT lot up to 11 dpm.

Conclusions

The results obtained indicated that the inclusion of *N. gaditana* meal in diets at low concentration (25 and 50 g kg^{-1}) in finishing diets influenced different organoleptic parameters, improving textural properties and maximizing skin pigmentation. Fillet shelf-life was also affected by microalgae supplementation, yielding lower values of lipid oxidation and psychrophilic bacterial counts. Nevertheless, enzymatic pre-treatment of *N. gaditana* biomass did not have a significant impact on these parameters.

Introduction

Currently, aquaculture is based on the use of intensive systems that are characterized by increasing environmental stress agents and reduced water quality what facilitates the appearance of pathologies in individuals. Taking this into account, more attention is being paid to the inclusion of ingredients with biological activity that can improve fish health status. In the context of the circular economy, it is of great interest to evaluate the potential of many agri-food by-products as important source of bioactive products with antioxidant capacity (terpenes, carotenoids, phenolic compounds, etc.). Among these, it is worth mentioning the wine by-products (WB) such as grape pomace and lees, which have traditionally been used in feeding terrestrial animals, but whose application in aquaculture is yet to be developed. However, some of these compounds like polyphenols, that present interesting properties as antioxidants, may also interact with other nutrients during digestion, modifying their bioaccessibility and hence their potential bioavailability. In the present study some of these aspects were evaluated through two experiments aimed to asses: a) the possible negative effect that phenolic compounds present in WB may exert on the digestive proteases of a marine fish (the seabream *Sparus aurata*) and b) how inclusion of such phenolics within the feed matrix may affect potential bioavailability of protein during the digestion process. This last experiment was developed by *in vitro* assay simulating the digestion in two fish species, the sea bream (*S. aurata*) and the grey mullet (*Mugil cephalus*).

Materials and methods

The WB used in the different experiments (red grape pomace and lees) were obtained from two artisanal wineries placed in Almería and Cádiz, (Spain) respectively. The grape pomace was dried in an oven for 72 h at 60 ºC and subsequently finely grounded until obtaining a fine powder that was used in the assays while the lees were employed in liquid form in all tests. A complete characterization of phenolic compounds and antioxidant capacity was carried out in both WB using specific methods (Brand-Williams et al., 1995; Graça et al., 2005). Two different experiments were developed:

Experiment 1. An inhibition assay was carried out by preincubating digestive enzyme extracts obtained from seabream, with a known protease activity, with variable amounts of grape pomace meal and after measuring the resulting reduction of activity compared to a control sample.

Experiment 2. This experiment was oriented to assess the potential negative effect of WB phenolics on protein bioavailability when the product was included at 10 % (w/w) in a matrix composed by hemoglobin, starch, sunflower oil and carboxy methyl cellulose designed to simulate a compound feed. The assay was developed using a membrane bioreactor described in Gilannejad et al. (2017) adapted to simulate *in vitro* the digestive conditions of two farmed fish species (seabream and mullet). Total amino acids released during the hydrolysis were measured using the o-phtaldialdehyde method (Church et al., 1983) and total phenolics were determined by the method described by Graça et al. (2005).

Results and discussion

The analysis of WB showed a significantly different profile of phenolic compounds (Table 1). The content in all the types of phenolic compounds was always higher in grape pomace than in lees, while the antioxidant capacity measured in the former product was higher. Results obtained in the inhibition assay are detailed in Figure 1. The inhibitory effect was higher on acid than in alkaline protease activity. The curves were used to estimate the expected inhibition on such activities resulting from the intake of a feed containing 10 % WB in a 100 g fish, these accounting by 7 % and 4 % for acid and alkaline proteases, respectively.

(Continued on next page)

Table 1. Values are presented as mean SD. Values in columns not sharing the same letter differ significantly with $p < 0.05$. Comparisons between by-products are indicated with lowercase letters.

By-products	Antioxidant capacity (μmol TEAC/g d.m.)	Total phenolics (mg galic acid/g d.m.)	Flavonoids (mg rutin/g d.m.)	Tannins (mg tannic acid/g d.m.)	Anthocyanins (mg cyanidin-3-glucoside/g d.m.)
Lees	134.44 ± 15.96^a	26.27 ± 1.10^a	15.44 ± 1.71^a	13.58 ± 0.70^a	0.251 ± 0.00^a
Grape pomace	337. 37 ± 14.05^b	65.88 ± 0.85^b	46.49 ± 2.38^b	21.71 ± 1.33^b	0.160 ± 0.01^b

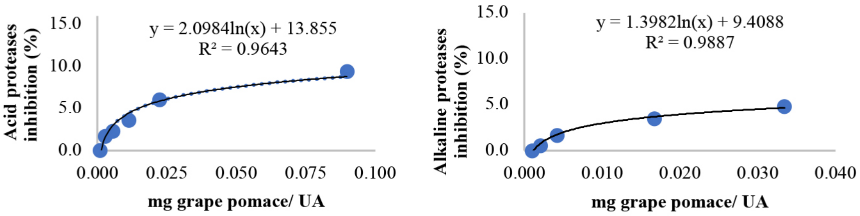

Figure 1. Inhibitory response of seabream digestive proteases (stomach and intestine) after incubation with increasing doses of grape pomace meal.

Table 2. Nutrients released after *in vitro* hydrolysis in Experiment 2. Comparisons between species are indicated with capital letters.

	By-products	mg total phenolics/g by-products	Percentage reduction in amino acid bioavailability
Seabream	Lees	2.87 ± 3.09 A	36.86 ± 2.68 A
	Grape pomace	2.65 ± 3.75	32.04 ± 7.55
Mullet	Lees	12.08 ± 3.04 B	21.94 ± 3.45 B
	Grape pomace	6.36 ± 2.56	16.16 ± 0.70

Data of the release of amino acids and phenolic compounds due to the action of the digestive enzymes of seabream and mullet under conditions simulating the digestion is summarized in Table 2. A significant reduction in the amount of amino acids release, ranging from 16 % to 36 %, was evidenced when any of the two WB were present in the feed mixture when compared to control diet (WB free). In addition, significant differences were obtained between species with a lower reduction in the case of mullet (no acid digestion). No significant differences were observed in results obtained with the two by-products (pomace and lees) within each species. Results suggest that the use of WB as a source of bioactive phenolics can produce negative effects on protein digestion of fish.

Amino acid composition was analyzed in three species of mullets, and, in different commercial raw materials (from animal or plant origin) and new alternative protein sources, in order to evaluate their possible use as ingredients for mullet diets. A total of 45 raw materials were analyzed, being afterwards clustered according to their protein suitability. Commercial plant and marine proteins presented the lowest and highest protein quality, respectively, meanwhile animal proteins showed a high level of a high AAR, but very low of CS. Finally, considering the raw material evaluated the most limited AA for mullet diet formulation was Met, followed by His.

Introduction

Mullets are excellent candidates to promote the aquaculture diversification, due to their omnivorous diet, excellent nutritional and organoleptic quality, and the possibility to produce them in diverse production systems and environments. Among the species of mugilids, the *Liza aurata*, *Chelon labrosus* and the *Mugil cephalus* are some of the species with commercial interest. However, due to its recent attention in its production, the information available on the nutritional needs, as well as, formulation of specific diets for these species is scarced or practically zero. Therefore, the objective of present work was to determine the suitability of different protein sources as potential components in the formulation of feed for these three species of mullets.

Material and Methods

For the present work, 45 protein sources (PS) were evaluated, which differed into: marine, new alternative animal and plant sources and also 10 specimens of each three mullets species (*Liza aurata*, *Chelon labrosus* and *Mugil cephalus)* with an average weight between 2 and 5 grams from extractive fishing. Proximate composition of raw materials and whole body fish were analysed in triplicate according to AOAC (1997). Following the method previously described by Bosch et al. (2006), amino acids (AA) of the samples were determined using a Waters HPLC system. With the AA data obtained, the Amino acid ratio (AAR, %) was calculated as (AAsample)/(AAreference) x 100, where AAsample and AAreference are the amino acid contents in the test sample and whole mullet (in each species), which was taken as reference, being the Chemical Score (CS, %) the minimum value from AARs calculated for essentials amino acids (Arg, His, Ile, Leu, Lys, Met, Phe, Thr, Val). In addition, Oser index was calculated follows the equation (Oser, 1951):

Results and discussion

Figure 1 shows the cluster of raw materials according to their AA adequacy for each mullets species analysed, considering three parameters: AAR, CS and IO. The PS were classified into 4 well-differentiated groups. Plant proteins registered low values for the three parameters (green), therefore, less suitable as protein source. On the contrary, marine proteins reported the most suitable profile with high values in all parameters (in orange). A third group correspond to mainly animal protein showed a high AAR, but very low of CS (in blue), and, finally, a mix of plant and animal protein sources registered a very low of IO (in yellow). On the other hand, when the AA profile of raw materials is compared with the mullets whole body, the most limiting AA for protein synthesis was Met, followed by His. In general, the AAR of animal proteins were rich in Arg and Thr, low in Iso, Leu, and particularly low in Met and Lys AAR, as has been observed in the alternative animal and plant proteins. Nevertheless, alternative protein source exhibited a high percentage in Arg (except fermented rice). This study is essential to select the most appropriate combination of ingredients for mullet diets formulation.

E-mail: arianna.martini@crea.gov.it

Introduction

The need to make food production more sustainable and allow access to high nutritional value food for the entire population is nowadays a firm awareness. Thus, it is of paramount importance to quantify the positive and negative environmental impacts of food supply chains to foster the ecological transition towards those having zero or positive impacts and that might also have a significant role in the mitigation of climate change. Bivalve mollusc aquaculture provides high-quality animal proteins and omega-3 PUFA, and is characterized by one of the lowest carbon footprints in the animal production panorama. Furthermore, it can mitigate the effects of eutrophication and play a role in the storage and cycle of fundamental nutrients in aquatic environments. These ecosystem services of bivalve farming are well established. Differently, carbon sink potential is at the centre of an intense scientific debate. Shell formation occurs through the chemical reaction between calcium ions and dissolved carbon dioxide. The reaction produces calcium carbonate, which is incorporated into the shell, and carbon dioxide, released into seawater. Therefore, why is the biocalcification process often considered a carbon sequestration mechanism? The aim of this work is to stimulate a discussion around this complex and debated topic. Data on the biogenic carbon flows and the carbon sequestration potential of biocalcification in farmed Mediterranean mussel (*Mytilus galloprovincialis*) and Manila clam (*Ruditapes philippinarum*) will be presented, framed in the ecological context of the Northern Adriatic Sea and compared with ecologically different bivalve farming sites. Authors would stress that the evaluation of biocalcification contribution to carbon sequestration requires a site-specific approach, by means of combined *in situ* and remote environmental data collection.

Materials and methods

The carbon flows related to the bivalve biocalcification process were computed using data on the ratio of shell to total fresh weight and calcium carbonate content of mussels and clams specific to the study sites (Sacca di Goro, Emilia-Romagna, and Sacca di Scardovari, Veneto, Italy). The sites chosen are the most representative of bivalve production in Italy. Equation 1 was used for the calculation of CO_2 sequestered by the shell during the biocalcification process: (Eq. 1) CO_2 sequestered = mass $CaCO_{3\,shell}$ × CO_2 molecular mass / $CaCO_3$ molecular mass. Equation 2 was used for the calculation of the CO_2 released by the biocalcification process: (Eq. 2) CO_2 released = shell mass × Ψ × % $CaCO_{3\,Shell}$ × CO_2 molecular mass / $CaCO_3$ molecular mass, where Ψ indicates the ratio of CO_2 released per $CaCO_3$ precipitated as a function of seawater buffering capacity. Ψ for each site were calculated using the *seacarb* R package [1]. Environmental data required for Ψ calculations (site-specific pH, salinity, seawater temperature, and CO_2 partial pressure) and chlorophyll-a concentration for the study sites were retrieved from the AquaX platform (Colombosky, https://gis.aquaexploration.com), which collects data with a spatial resolution of 300 m^2 using Copernicus satellite data. Environmental parameters required for the mussel carbon flows computation were retrieved for two other, very different, farming sites, one located in Vigo (Spain) and one in the Osteerschelde National Park (The Netherlands).

A bibliographic review was conducted to collect supporting and conflicting evidence on the hypothesis that shell formation can represent a carbon sequestration mechanism.

Results and discussion

The environmental parameters at the four farming sites and the shell:total fresh weight ratio and carbon sequestration potential of mussels and clams are outlined in Table 1.

Reviews on the possible contribution of bivalve farming in mitigating the effects of climate change are numerous [2]–[4]. However, the role of biocalcification as a carbon sink is controversial [5]–[7] and this debate arises when the ecological context is not properly considered. Two molecules of dissolved CO_2 (HCO_3^-) are required during shell formation. One precipitates into the shell, and the other is released into the seawater. This process leads to a decrease in Dissolved Inorganic Carbon concentration by one unit and a decrease of Total Alkalinity by two units. Consequently, the biocalcification process, in a closed and isolated system, leads to a lowering of pH and an increase in pCO_2, thus limiting the capacity of seawater to absorb atmospheric CO_2. In this context, the formation of the bivalve shell should not be defined as a carbon sink. However, if the biogenic calcification is framed in a coastal epipelagic and highly productive area, the CO_2 released from the biocalcification process is likely to be promptly taken up by photosynthetic organisms, according to the combined equation: $Ca_2+ + 2HCO_3^-$ □ $CaCO_3 + CH_2O + O_2$ [8]. Therefore, the raise of pCO_2 induced by the biocalcification process should not take place in those environments characterized by high primary production (Table 1). Hence, in this context, biogenic calcification can act as a potential carbon sink [6]–[8]. This conclusion is also supported by [9], who demonstrate the overall carbon sink behaviour of the North Adriatic Sea, although characterized by spatial and temporal variability. From the comparison among different farming sites, where different ecological parameters determined high variation in net CO_2 flow, it is evident the necessity to evaluate the carbon sink potential with a site-specific, local approach.

Introduction

The aquaculture sector has experienced important growth during the past decades to meet the seafood demand that fishing practices cannot always sustain. Shellfish represent more than 50% of the global aquaculture production and, in the past two decades, bivalve production increased by 82%, reaching 17.7 million t in 2020 [1]. Shellfish are an important component of diets all over the world for their high nutritional values. Furthermore, many studies have proved that bivalve aquaculture, if carried out in a sustainable way, could offer important ecosystem services (e.g., nutrients regulation, coastal protection, boosting biodiversity, carbon removal, and food provisioning) [reviewed in 2]. One of the most economically important farmed bivalves in Europe is the Manila clam Ruditapes philippinarum. In 2020, Manila clam aquaculture production in the EU-28 overreached 25,290 t, 96% of which was supplied by Italy [3]. Clam farming consists of the following phases: seed procuring and sowing, management of the farming area and clam density in the seabed, harvesting, and depuration. Clam seed is usually collected in natural nursery areas. However, during the past two decades, a serious decline in wild clam populations, and therefore spat availability, has been observed [4]. The causes behind this reduction are poorly understood, but, likely, they lie in phenomena acting synergistically, such as rising seawater temperature, anoxia, eutrophication, environmental quality degradation, and diseases. To cope with the shortage of natural seed, Italian clam farmers also rely on seed produced in hatchery facilities (most of which is imported from EU countries and the United States), where microalgae production, broodstock conditioning, spawning, and larval rearing (up to 6 mm) take place. Against the context of climate change and its effects, it is likely that, in the future, clam farmers will be more dependent on hatchery-produced seed. The environmental burdens associated with hatchery seed production are expected to be higher than wild seed procuring. This contribution reports the results of the first Life Cycle Assessment model applied to a Manila clam hatchery. The case study applies to the only hatchery present in Italy, which produces about 5 t of seed/year. The environmental impacts of hatchery seed production are quantified, and potential hotspots are identified, to provide useful suggestions to improve the environmental performance of the clam supply chain.

Materials and methods

The case study referred to a Manila clam hatchery (reference year: 2020) located on the North Adriatic Sea coast, Goro (FE, Italy), one of the most productive areas for clam farming. The LCA approach follows the guidelines of [5]. The objective of this study was to assess the environmental performance of the clam hatchery, by analyzing material and energy flows through the system. A cradle-to-gate analysis has been carried out, considering the following processes: 1) microalgae production, 2) broodstock maintenance and conditioning, and 3) larval rearing until the marketable size was reached. The system boundaries included the above processes and all material and energy inputs and outputs to and from the system. The functional unit (FU) chosen was 1 kg of live clam seed. The *Life Cycle Inventory* was based on data provided by the technical personnel of the hatchery through questionnaires and interviews (foreground data). The Ecoinvent 3 database has been used to gather data about the production of electricity and raw materials (background data). The *Life Cycle Impact Assessment* has been carried out using the software SimaPro 9.1.0.7 (PRé Consultants), adopting the ReCiPe 2016 (H) method.

*Table 1 Impact assessment of hatchery seed production– Characterization. Results refer to 1 kilogram of live clam seeds. *The Global Warming impact category does not consider the biogenic carbon flows related to shell formation.*

Midpoint Impact Category	Unit	
Global warming*	kg CO_2 eq	26.432
Terrestrial acidification	kg SO_2 eq	0.097
Freshwater eutrophication	kg P eq	0.009
Marine eutrophication	kg N eq	0.001
Fossil resource scarcity	kg oil eq	8.227
Water consumption	m^3	0.575

(Continued on next page)

Results and conclusions

The environmental performance of the hatchery seed production is reported in Table 1. The main driver of the environmental impacts was electricity consumption, with a contribution larger than 80% for the selected impact categories. Liquid oxygen consumption followed, with a contribution of 3-12% depending on the impact category considered.

It is worth pointing out that this work specifically computes the environmental impacts associated with the hatchery phase for clam seed production. Therefore, the FU chosen is 1 kg of live clam seed, which corresponds to about 20,000 individuals. Considering a minimum survival rate of 60% (data estimated by farmers) and a mean individual weight of 10 g for adult clams, 1 kg of clam seed would produce about 120 kg of commercial-sized clams.

The results confirm that electricity consumption, which partially depends on fossil fuels, is one of the biggest bottlenecks to the environmental sustainability of food supply chains. This agrees with the only other study documenting the environmental performances of an oyster hatchery in the United States [6]. The environmental burdens associated with the production of clam seed could be reduced by switching to alternative technologies to cope with the energy demands of the facility, such for example, investments in photovoltaic and wind energy production systems. The improvement of the clam supply chain's environmental performance should be combined with the development of other clam hatcheries in Italy. This would reduce the environmental costs associated with the import of clam seed from Spain, France, the Netherlands, and the United States.

Introduction

Fish lipids are mainly characterized by polyunsaturated fatty acids (PUFAs), which are extremely sensitive to oxidative decay during storage. Lipid oxidation is one of the main factors responsible for the reduction of fillets' sensory quality (flavour, colour, and texture), both in refrigerated and frozen conditions [1]. Oxidation is also linked to the loss of functional properties and nutritional value of foods [2]. However, its adverse effects may be slowed down by adding several antioxidant compounds. Among them, astaxanthin, one of the most represented carotenoids in aquatic animals, has become of great interest due to its powerful antioxidant activity [3] and its role in increasing the shelf-life of fish fillets [4]. In recent years, innovative and under-exploited ingredients for aquaculture feed formulation have been investigated. In recent studies [5], [6], the meal from whole red swamp crayfish (*Procambarus clarkii* Girard, 1852), an invasive freshwater crustacean rich in lipids, proteins, and astaxanthin [7], has been included as a functional ingredient in diets for rainbow trout, gilthead seabream and red porgy [5], [6], [8] due to its nutritional properties and effects on skin/fillet colour [6], [9]. Given the rapid growth of organic aquaculture [10], demand for natural astaxanthin is rising for certified aquaculture feeds. However, natural astaxanthin sources are scarce, and their real effects are still poorly studied.

This work aimed at evaluating the effects of an organic aquafeed formulation including *P. clarkii* meal, on the shelf life and quality of gilthead seabream (*Sparus aurata*, L. 1758) fillets, previously refrigerated or frozen.

Materials and methods

A two-month feeding trial (July to September 2021) on *S. aurata* was carried out within the CREA permanent experimental device in Capraia Island (Livorno, Italy). The device consists of two commercial-sized mariculture cages, placed inside a local aquaculture facility. In the first phase, for one month, a total of 7,000 fish (3,500 per cage, mean weight of 400 g) were fed with commercial organic feed. During the second phase, the control cage (CTRL) continued to be supplied with the organic commercial diet, while the experimental cage (EXP) shifted to the organic feed including *P. clarkii* meal. The meal was obtained from about 400 kg of *P. clarkii* caught as part of the containment plan of the species (Legislative Decree 230/2017 of the Lazio Region) in the Nazzano Tevere-Farfa Regional Nature Reserve (Rome, Lazio), a wetland of high naturalistic value. After the crayfish were shredded and dried, 1,000 kg of 10% crayfish meal pelleted feed was produced (Nutri-Tech SRL, Mantova, Italy). The two diets were formulated to be isolipidic and isoproteic. At the end of the trial, 200 fish from each cage were collected. EXP and CTRL refrigerated samples (kept at 4°C) were analyzed 1 and 4 days (T1 and T4) after collection; EXP and CTRL frozen samples (kept at -20°C) were analyzed 31 and 34 days (T31 and T34) after collection. The analysis of the antioxidant power of *P. clarkii* meal, diets, and fillets was carried out by measuring the decay time of the radical DPPH (1,1-diphenyl-2-picril-hydrazyl) [11]. To estimate the lipid quality of fillets, the Flesh Lipid Quality (FLQ) index was calculated. The FLQ index correlates the amount of eicosapentaenoic acid (EPA) and docosahexaenoic acid (DHA) with the amount of total fatty acids (FAs) [12]. To verify the aptitude of seafood to increase the risk of cardiovascular diseases related to the quality of lipids, a Thrombogenic Index (TI) was also determined [12]. The fillets' oxidation level was evaluated by measuring the levels of thiols and malondialdehyde (MDA), valuable indicators of meat degradation and oxidative stress [13]the redox balance can be affected by training regimen, dietary macronutrient ratio and their interaction. In this study, we conjointly evaluated the effects of physical activity (by voluntary swimming (VS. Finally, the increase in volatile nitrogen content (used as freshness index), mainly ammonia and trimethylamine (TMA), which are primarily responsible for the repulsive scent of fish, was measured [14].

Results and Discussion

Growth performances between the two cages were not significantly different. Concerning fillets nutritional quality only lipid content was significantly different between the two groups, being more abundant in the CTRL group (4.4% d.w.) than in the EXP group (3.6% d.w.) (ANOVA $p < 0.05$). The EXP fillets showed a fatty acid profile characterized by a low content of saturated (SFAs) and monounsaturated FAs (MUFAs), and high content in PUFAs, notoriously important in the human diet (especially omega 3). PUFAs are highly oxidizable components, causing faster oxidation of the flesh. As a result of the experimental diet, the presence of astaxanthin in the crayfish meal has counteracted this effect. Indeed, in the DPPH analysis, the higher the antioxidant capacity, the greater the scavenging activity [11]: crayfish meal has given excellent results (38.6% of scavenging activity), which are reflected in the EXP feed (34.5% of scavenging activity). CTRL feed showed the lowest values (1.1 % of scavenging activity). As for the fillets, the antioxidant power decreases over time, although the EXP fillets showed, on average, higher values for the entire duration of the storage trial. Significant differences (ANOVA $p < 0.05$) were found between the T1 and the frozen samples (T31, T34), for both CTRL and EXP. The EXP fillets showed a significantly higher FLQ index than CTRL (28.6% and 21.13%, respectively), indicating higher quality of lipids. The TI (which increases with the risk of blood clots [12]), was higher in the CTRL fillets compared to EXP ones, although remained both within the low-risk threshold (< 0.40). High values of thiols indicate less oxidation of the fillet [12]: the EXP fillets showed a significantly higher content of thiols than CTRL. Regarding MDA, EXP fillets showed lower values than CTRL, highlighting lower oxidative stress [12]. For the analysis of the freshness, the seabream fillets for the two treatments at T1 and T4 were evaluated: the analysed samples fell below the value of 9.3 mg / 100g of volatile nitrogen (which identifies very fresh fish), obtaining values of about 6 mg / 100g for the fillets in the two treatments at both storage times. No significant differences were found.

This study highlighted encouraging results regarding the use of red swamp crayfish as a natural and functional ingredient in diets formulated for organic gilthead seabream farming: (1) a growth comparable to the commercial diet, (2) high antioxidant power due to the presence of astaxanthin, (3) a lower sensibility to oxidation, and (4) a high content in PUFAs, especially omega 3.

Introduction

The use of diets with high-lipid levels may lead to an increase in tissue fat deposition and susceptibility to lipid peroxidation, jeopardizing fillet quality, which is of major concern for the final consumer. To mitigate these potential harmful effects, several nutritional strategies have been applied, including the use of functional additives.

Oleic acid (OA) is a monounsaturated fatty acid (FA) that has been receiving special attention as a functional ingredient in mammal diets, due to its beneficial effects on weight gain and fat deposition control by interfering with feed intake (FI). Recent evidence in mammals also suggests that Oleoylethanolamide (OEA), a FA ethanolamide produced in the intestine from food-derived OA, and other N-acylethanolamines (NAEs) (e.g. anandamide, AEA; and palmitoylethanolamide, PEA), could be involved in FI regulation, possibly acting as satiety signal. Beside the impact of NAEs on FI regulation, other biological effects, including anti-inflammatory, analgesic and neuromodulatory effects were also reported (Diep et al., 2011).

In fish, OA dietary supplementation has also been associated with FI regulation (Librán-Pérez et al., 2014). Recently, we have seen in European seabass that supplementation of high-lipid diets with 1 and 2 % of OA reduced FI and enhanced feed efficiency without affecting growth performance (unpublished data). However, the interplay among FI, fat deposition, and lipid metabolism regulation by dietary OA in fish was not yet fully explored. Besides its role in FI regulation, in higher vertebrates, OA has also been described as an antioxidant and anti-inflammatory agent. In fish, however, the role of OA in the oxidative status and anti-inflammatory response is still scarcely studied. Thus, the present study aimed to evaluate in European seabass (*Dicentrarchus labrax*) fed high lipid diets the effect of dietary OA supplementation on fat deposition and its potential as an antioxidant. Taking in mind the growing importance of lipid-derived signals as feeding regulators in mammals and the lack of knowledge on the possible involvement of NAEs on FI regulation in fish, an additional aim of this study was to investigate the link between dietary fat content/OA levels and intestinal/tissue levels of NAEs.

Material and methods

Triplicate groups of 22 European seabass (Initial body weight of 21.4g) were fed six isoproteic diets (45% crude protein) containing two dietary lipids levels (16 and 22%) and supplemented with 0, 1, or 2% of OA (diets 16L:0OA; 16L:1OA; 16L:2OA; 22L:0OA; 22L:1OA; 22L:2OA). Fish were fed these diets twice a day to apparent visual satiation, six days a week, for 10 weeks. At the end of the growth trial, liver, hypothalamus, intestine, and muscle from 3 fish per tank were collected and stored at -80° C until enzymatic assays, and glutathione, OEA, AEA, and PEA quantification. Adipose tissue, muscle, and liver from another 3 fish per tank were sampled to assess fat deposition mechanisms.

(Continued on next page)

Results

At the end of the trial, OA supplementation increased the hepatic G6PDH but decreased malic enzyme activity and decreased mTOR expression. Hepatic Akt, phosphorylated Akt (p-Akt), and p-mTOR expression were not affected by the dietary treatments. The inclusion of OA in the diets did not affect OEA levels in the tissues analyzed but decreased intestinal AEA and PEA levels.

Regarding antioxidant enzymes, GPX, GR, and CAT were not affected by dietary treatments, while dietary lipid levels increased SOD activity in the intestine. The highest antioxidant enzymatic activity was observed in the liver and intestine compared to muscle. Intestinal SOD and GR activities were higher than in the liver and muscle.

Hepatic tGSH and GSH levels were higher than in the intestine and muscle, while GSSG level was higher in the intestine than in the liver and muscle.

Overall, the oxidative status, measured as OSI and LPO, was not affected by dietary treatments but was different in the tissues analyzed, with the highest OSI and LPO levels being observed in the muscle, followed by the intestine and liver.

Conclusions

The present results suggest that OA may affect lipid metabolism and fat deposition by decreasing mTOR expression, without affecting the phosphorylated forms of Akt and mTOR, suggesting that the fatty acid synthesis in the liver was not induced. Moreover, while dietary OA did not affect OEA levels in the tissues, it promoted a decreased AEA and PEA suggesting an enhancement of anti-inflammatory response. Dietary OA supplementation did not affect the oxidative status of European seabass.

Although dietary lipids and specific fatty acid as OA are major nutritional factors regulating OEA production in mammals, the role of dietary lipids/fatty acids in the regulation of European seabass OEA intestinal levels was not clarified as no changes on OEA content were observed. On the other hand, the decrease in AEA and PEA intestinal content of European seabass observed in response to dietary OA intake supports a regulatory role for these NAEs in FI control or other biological roles that need to be further investigated.

Introduction

Intensive fish production in aquaculture is a stressful environment that increases susceptibility to opportunistic pathogens and diseases, ultimately leading to fish death. This implies economic losses for producers and reduces the growth of a sector that is considered one of the major sources of dietary protein for human consumption[1]. To reduce the impact of opportunistic pathogens, rapid methods for the selection of novel anti-inflammatory and immunostimulants are needed to modulate and strengthen fish immunity and prevent/control disease outbreaks.

Zebrafish is a model of excellence to unravel the immune mechanisms and signaling pathways[2], due to its complete sequenced genome and advances in genomic engineering technologies. It has already been used to comprehend inflammatory disorders affecting fish and mammals due to the conservation of immune response mechanisms. In particular, the zebrafish scales have been used as a semi-high-throughput system for drug discovery in a variety of biomedical applications[3]. Moreover, scales have been suggested to be used as a screening platform to reduce the number of animals and as an alternative to *in-vivo* experimentation. Here we show that scales can be used as a powerful model for the study of the immune response to bacterial infections. We observed an increase in the number of macrophage cells (*mpeg1.1*$^+$ cells) responding to lipopolysaccharide stimulation, making scales a suitable and rapid methodology to identify novel inflammatory and immunostimulant molecules.

Materials and methods

Adult zebrafish (*Tg*(*mpeg1.1:eGFP*)^{gl22}, 3-6 months) were maintained in 3.5-L tanks in a 980-L recirculating aquaculture system (ZebTEC®, Tecniplast, Italy) with the following water parameters: temperature - 28 ± 0.5 ºC, conductivity - 750 ± 25 µS/cm, pH – 7.5 ± 0.2 and, photoperiod - 14:10 h light:dark. Water quality was maintained as described in Martins *et al*.[4]. Fish were maintained in a feeding regime using ZEBRAFEED® (400-600µm, Sparos Lda, Portugal).

Scales were plunked from fish anesthetized with MS-222 (Sigma-Aldrich, Spain). Thereafter, scales were washed with sterile PBS and cultured as described in Pasqualetti *et al*.[5]. Briefly, scales were cultured for 72 hours post-exposure (hpe) with L-15 media (Gibco™, Fisher Scientific, Portugal) containing L 10% fetal bovine serum, 1% L-glutamine, and penicillin-streptomycin. *E. coli* lipopolysaccharide (LPS, Sigma-Aldrich, Spain) stocks were prepared at 1 mg/mL, 10 mg/mL and 100 mg/mL, and used for the preparation of media containing 1 µg/mL, 10 µg/mL and 100 µg/mL, respectively. Culture media was replaced every 24 hpe. Scales were photographed at 24, 48 and 72 hpe with Axiocam 305 mono (Zeiss, Germany) coupled to a Zeiss SteREO Lumar V12, and images were processed using ImageJ software where the number of macrophages (*mpeg1.1*$^+$ cells) was counted.

Data were expressed as a box plot with median ± min/max. Normally distributed data (Shapiro-Wilk´s test) were analyzed with an unpaired t-test -Welch's correction ($P \leq 0.05$).

Results

Scales plunked from adult zebrafish (*Tg*(*mpeg1.1:eGFP*)^{gl22}, 3-6 months) and exposed to different concentrations of LPS (i.e., 1 µg/mL, 10 µg/mL, 100 µg/mL) in an *ex-vivo* culture system. We observed a significant increase in the number of macrophages during the first 24 hpe for the higher concentrations tested (10 µg/mL, 100 µg/mL). However, a reduction in the number of macrophages was observed for LPS 100 µg/mL at 48 and 72 hpe, relatively to 24 hpe, but this did not occur for LPS 10 µg/mL (Figure 1).

(Continued on next page)

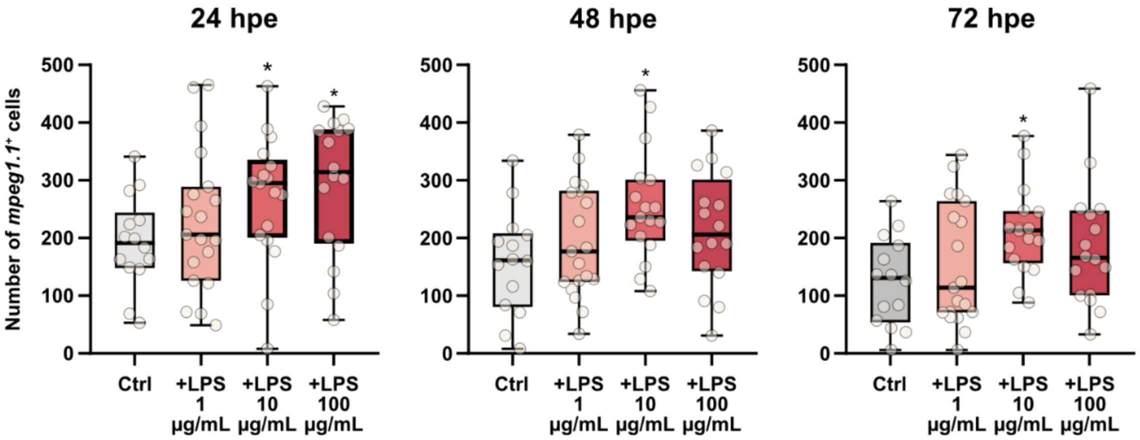

Figure 1. *Ex-vivo* exposure of zebrafish scales to LPS (1 µg/mL, 10 µg/mL, 100 µg/mL) for 72 hours post-exposure (hpe). Asterisks (*) represent significant differences among treatments (unpaired t-test with Welch's correction, $P<0.05$).

Discussion

Zebrafish scales have been used both as *in-vivo* and *ex-vivo* systems, for semi-high-throughput screening of compounds[3], and were addressed as a viable alternative method to the *in-vivo* culture systems. A recent study showed a unique characteristic of scales by their content in phagocytic macrophages (*mpeg1.1*$^+$ *cells)*[6]. However, limited data exist on their suitability as a model to uncover the mechanisms of inflammatory disorders. Our data revealed that occurs an increase in the number of macrophage cells in response to LPS stimulation, where a concentration of 10 μg/mL showed a significant increase in the number of macrophage cells (*mpeg1.1*$^+$ cells) at 24, 48, and 72 hpe compared to the Ctrl group. The *ex-vivo* culture of zebrafish scales can serve as a powerful model for the comprehension of fish immune response to bacterial infections and the search for novel anti-inflammatory molecules to be used for prophylaxis or treatment of infections in fish aquaculture. Its use in research settings allows for the decrease, repurpose, or reuse of animals respecting the 3Rs policy and is an ideal system to overcome the complete elimination of animals for research settings after 2030.

Introduction

Novel foodstuffs demand sustainable ingredients rich in micro and macronutrients and free of any toxic substances that might be in the environment. Seaweed and their derivates are widely used as ingredients in some food products worldwide as additives (alginate salts and carrageenan) or are directly consumed as *Ulva* spp. (Sea lettuce) in some countries. *Ulva* algae is rich in protein and minerals but there is scarce knowledge about their antioxidant activity and phytochemical composition (Vazquez-Rodriguez and Amaya-Guerra, 2016). Some research is actually focused in how the management of light in algae culture tanks might affect the yield and nutritional quality of the crop in IMTA-RAS systems (UlvaPRO Subproject 2). This work presents the preliminary results about the effect of different conditions of light management and preservation processes after harvest in the antioxidant capacity and bioactive compounds in *Ulva onhoi*.

Material and methods

The optimization of *Ulva*'s culture conditions, emphasizing on the management of light, is approached from a multidisciplinary perspective. *Ulva* was cultured in the circular tanks with different stocking densities and incident irradiances. *Ulva* fronds were washed and homogenized. Sample was divided in two portions. One fraction was dried by air at 60±2°C for 48 h, the other one was lyophilized during 48 h until constant weight.

After removing the moisture some parameters were determined: phenolic compounds content (by Folin-ciocalteu method) and antioxidant capacity (by ORAC assay, Cuprac assay and DPPH assay). Dried and lyophilized algae samples will be used directly as an ingredient in energy bars.

Results

The effect of light distribution in culture tank affected drastically the dry matter content of *Ulva onhoi* (Figure 1). Depending on the culture conditions, up to 4 % is found ($p<0.05$).

Results obtained will help to understand how the crop management may have an effect in the bioactive compounds of the algae and, additionally, the potential of the dried/lyophilized biomass as food ingredient.

Acknowledgments: Work funded by Spanish MICIU (RTI2018-095062-A-C22).

Introduction

The integration of fish farms with seaweed in recirculation systems is a promising line of action for the diversification and sustainability of aquaculture, and will contribute to the reduction, use and recovery of waste and by-products. The incident irradiance on the surface of the seaweed cultures, expressed as µmol of photosynthetic photons per square meter and second (μmol m^{-2} s^{-1}), is frequently the determining factor in the growth and photoinhibition processes, and one of the main challenges to increase the productivity and reduce the land surface required for seaweed production in the IMTA-RAS system.

The engineering of these IMTA-RAS systems has been studied (UlvaPRO Subproject 2, https://futur.upc.edu/25161329?locale=en), emphasizing the adequate management of light in algae culture tanks to obtain the best macroalgae production, both from the quantitative and qualitative point of view. Here we presented the main results obtained in an IMTA-RAS system (*S. senegalensis*-*Ulva ohnoi*). The studies conducted included:

-The distribution of light in seaweed tanks in function on irradiance, stocking densities and chlorophyll content of the *Ulva*;
-The effects of light distribution on growth and photoinhibition processes in *Ulva*;
-The effects of light distribution on nutritional quality and food safety of the *Ulva*.

Material and methods

The optimization of *Ulva*'s culture conditions, emphasizing on the management of light, is approached from a multidisciplinary perspective. According to the studies conducted, different experiments were carried out:

-Distribution of light in seaweed tanks:
Three circular tanks (64 cm diameter, 30 cm height) with bottom air injection (8 l min^{-1}) and opaque walls that received the irradiance through the water free surface were used. Different incident irradiances in the surface of the tanks were used with different stocking densities.

For each stocking density and incident irradiance, five PAR measurements were made every 5 cm from the surface to the deepest point of the tank (5, 10, 15, 20,and 25 cm from the tank surface) at three distances from the tank wall (8, 16 and 24 cm). PAR measurements were made with an ULM500 Light Meter & Data Logger connected to a US-SQS/L sensor (Walz, Germany) taking 5 PAR measurements per second during 60 seconds (n=300).

-Effects of light distribution on growth and photoinhibition:
Ulva was cultured in the circular tanks with different stocking densities and incident irradiances. Chlorophyll fluorescence parameters (PAM-2100, Walz, Germany), chlorophyll content (determined with a portable chlorophyll optical meter using the method described by Masaló and Oca (2020)) and specific growth rates were determined along time.

-Effects of light distribution on nutritional quality and food safety:
Initial and final *Ulva* fronds in each combination of stocking density and incident irradiance used to study the effects of light distribution on growth and photoinhibition were washed, dried and homogenized. With these dried samples different parameters were determined: basic nutritional parameters (mineral content, proteins, phosphorus, macro and micronutrients; and also the nitrate content), dietary fiber content (soluble and insoluble), heavy metals and polyphenols.

(Continued on next page)

Results ***(to be updated for the final abstract)***
-Distribution of light in seaweed tanks:

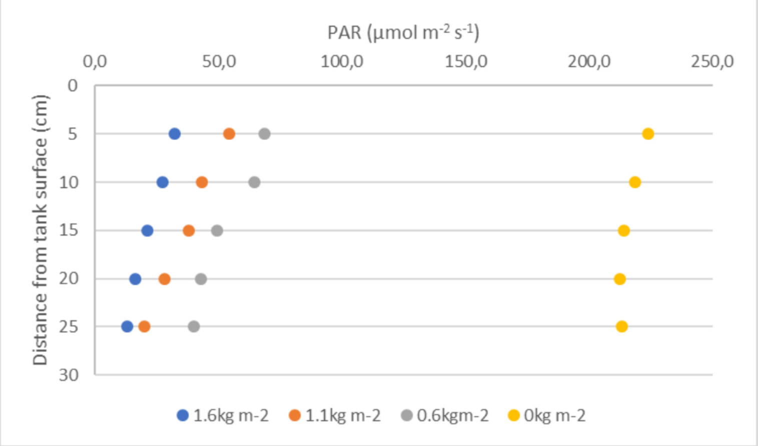

Fig 1. Example of light distribution at 24 cm from the tank wall in a tank with an avarege irradiance at tank surface of 250 µmol m^{-2} s^{-1}. Light measurements were made with different stocking densities (0.6, 1.1 and 1.6 kg m^{-2}).

-Effects of light distribution on growth and photoinhibition:
Experiments are currently carried out; results will be updated for the final abstract.

-Effects of light distribution on nutritional qualitity and food safety:
Ulva fronds are currently being stored for their posterior analysis; results will be updated for the final abstract.

Results obtained will help to identify the best algae management conditions for the most efficient use of light in order to maximize the productivity of the algae.

At the same time, the potential improvement of safety and nutritional quality of the algae produced in these systems will be assessed.

ROAD MAPS TOWARDS COASTAL-RURAL SYNERGY- THE COASTAL KNOWLEDGE EXCHANGE PLATFORM

M. Mata-Lara

Geonardo Environmental Technologies
mariana.mata.lara@geonardo.com

Introduction

The COASTAL project is funded by the H2020 Research and Innovation Programme[1] and aimed at improved coastal-rural synergy. The unique combination of systems modelling and multi-actor approaches with coastal and rural business entrepreneurs, administrations, stakeholders, and natural and social science experts resulted in evidence-based business solutions and policy recommendations, supporting rural and coastal development while preserving the environment. After four years of work with coastal communities, COASTAL is launching the **Knowledge Exchange Platform,** a **toolbox of resources** for boosting the coastal-rural synergy that provides the **space for stakeholders, experts and decision makers to interact, share and co-create new knowledge**.

The main goal of the KEP is to **direct target audiences to the information, data and tools, at a level of detail best suited to their interest.** All information, tools and services will be tailored to the needs of each audience type.

Objectives of the KEP

The specific aims of the KEP are to:

- Create **stakeholder awareness** of the case studies and the project as a whole;
- **Disseminate results**;
- **Utilise synergies** with, or build on, other existing knowledge sharing platforms;
- **Develop networks of practitioners** in relevant sectors;
- Create the basis for a **durable legacy of project outcomes**;
- Disseminate success stories of achievements of COASTAL to **promote the adoption of approaches to sharing knowledge**, add value, lever resources and **promote systemic innovations between experts and stakeholder communities** in the sectors relevant to coastal rural development.

Results

The KEP will provide target audiences tailored pathways for accessing project results and ensure best opportunities for further uptake and exploitation. When accessing it through the address https://h2020-coastal.eu/platform, the user will find a main menu consisting of six paths, providing further different types of content and presented in different formats as specified below.

1. **Best Practices & Policy Guidelines**
    a. Best Practices: It will consist of an interactive EU-wide inventory and qualitative analysis of best practices, business opportunities and innovative solutions related to coastal-rural collaborations.
    b. Policy Guidelines: A downloadable set of recommendations for improving the coastal-rural synergy from a policy perspective both locally and at an EU-level.
2. **Road Maps for Land-Sea Synergy**: interactive roadmaps are the compilation of all work carried out in each Multi-Actor Lab. These provide the context and bring business solutions and policy recommendations for the specific problems studied in each case study area, highlighting the actors involved, key resources need, beneficiaries and potential impacts at short-, mid- and long-term.
3. **Models for evidence-based policy analysis**: We are making available models developed during the project through a System Dynamics Modelling approach, for users to download them and adapt them to their specific conditions.
4. **Scenarios and Visions:** This section will present interactive flipbooks for the general public to read through. With visual content and simple language, we expect these flipbooks will give a good overview of what was done and achieved in each case study.
5. **Repository:** This section will store the Practice Abstracts developed for EPI-AGRI, summarizing in one paragraph each action, as well as all past newsletter issues published.
6. **User Forum:** This will be a space for stakeholders to interact, share knowledge, exchange ideas, discuss and collaborate on improving the synergies between rural and coastal environments. Each COASTAL MAL leader will be in charge of moderating the forum for each region and of boosting the users' participation.

(Continued on next page)

Conclusion

The Knowledge Exchange Platform is a platform for continued knowledge sharing, capacity building and co-creation, aiming at giving coastal and rural operators and planning agencies access to knowledge, solutions, and experiences of other regions and operators facing similar problems around land-sea synergies. The use of its resources would strengthen the opportunities for coastal and rural development and will facilitate land-sea collaboration across Europe.

This project has received funding from the European Union’s Horizon 2020 research and innovation programme under grant agreement N° 773782. https://h2020-coastal.eu

ASSESSMENT OF ENVIRONMENTAL MONITORING METHODS FOR INTEGRATED MANAGEMENT OF AQUACULTURE IN OPEN SEA: A MASS BALANCE MODEL APPROACH

Introduction

Integrated Multi-Trophic Aquaculture (IMTA) appears to be an interesting alternative for the sustainable development of aquaculture activities. Based on the association of different species with trophic interactions, this concept aims to reduce the environmental impact of aquaculture and through this diversification would ensure more stable income for producers. The development of IMTA in coastal areas is promising (Chopin *et al.*, 2012; Buck *et al.*, 2018), but requires detailed documentation on trophic interactions between the various aquaculture activities. A multispecies activity can be defined as IMTA only once trophic interactions has been proven. Therefore, our capacities to describe trophic interactions is crucial and requires qualitative and quantitative methods.

Materials & methods

To address this issue, we have selected relevant tools to describe open sea IMTA. Indirect methods through the application of mass-balance modelling is one of those. By quantifying nutrients exchanges (*i.e.,* nitrogen and phosphorus fluxes) between the aquaculture compartments and with the nearby environment, this modelling approach aims to assess the impact of nutrient inputs coming from salmonid farms toward others aquaculture extractive compartments and may help the management of aquaculture activities. This approach allows also to estimate consequences of increasing the production of one or more aquaculture activities.

We evaluate this approach in the Trieux estuary (Côtes d'Armor, France) where coexist salmonid farms, oyster, mussel, and seaweed productions. In details, survey among professional producers were firstly conducted to collect input data for modelling (*i.e.* period of production, initial and final biomass produced, mortality, quantity of feed provided by fish farmers, etc.). Then, growth and mass balanced models were applied for each aquaculture compartment: the fish compartment (*Oncorhynchus mykiss*), the shellfish compartment (*Crassostrea gigas*) and the seaweed compartment (*Alaria esculenta),* during 8 months, from November 2021 to June 2022, corresponding to the period production of fish and seaweed compartments. Finally, a global mass-balance model including nutrient inputs from the watershed catchment area was produced with and without effluents from the fish compartment.

Results & Discussion

Application of the various mass balance models allowed us to estimate N and P from each compartment. We calculated that trout emitted 55.2 g N/kg and 10 g P/kg of fish, oysters emitted 220 mg N/kg and 70 mg P/kg of oyster meat, and algae absorbed 4.15 g N/kg and 0.68 g P/kg of algae relating to the entire biomass produced over the study period. Still, the most important thing to remember is that over the study period, the fish farming compartment emitted 357 kg N and 79 kg P, while the oyster farming compartment can be considered as a good extractor since it removes 4,636 kg N and 51 kg P, as well as the algal farming compartment, which removes 12 kg N and 2 kg P. The latest is of little importance because of the low tonnage produced. However, the quantity of N and P fixing rate by the oyster farming compartment must be qualified since the quantity of N and P ingested is not known. Then, if we consider only these three compartments that represent an IMTA system, the final N balance is negative, *i.e.*, there is more extraction of nutrients than emission into the environment. This is due to the oyster farming, which extracts a lot of nutrients. This result is in line with the interest in developing IMTA since nutrients are captured and extracted from the ecosystem. The final P balance is positive because the extraction by oysters is not sufficient to capture all the emissions of the fish compartment. However, when we take into consideration the nutrient flows from the watershed, the situation is quite different, the N and P balance is largely positive. Indeed, the watershed provides 99.75% of the N and 97.92% of the P of the estuarine ecosystem. The discharge of the fish farm represents only 0.08% of the N and 0.65% of the P, that goes through the estuary on a yearly basis, which is highly negligible.

(Continued on next page)

To go further, the final objective of such a project would be to integrate spatiotemporal variations in material flows. For this, using a direct method, via the monitoring of different trophic markers such as stable isotopes, fatty acids and/or trout DNA, would allow to validate the hypotheses posed by the mass balances. This is what has been done in the project, sampling of wild and farmed species has been carried out, the analyses are yet to be performed. Concerning the model part, it would be interesting to continue the project by setting up more precise production monitoring while developing other more complex models at different scales (ex. DEB, DEPOMOD, ECOPATH). These models would make it possible to conceptualize in a more exhaustive way all the flows of matter, from the species to the ecosystem by also modelling the flows related to the sedimented particles, and their hydrodynamics. Indeed, the distance between the aquaculture compartments is not considered at all here. However, the distance closely influences the capture of particles since the dispersion is determined by the hydrodynamics of the area. Thus, it is possible that the oyster and algal compartments do not capture, or capture very little, of the particles released by the fish compartment.

To sum up, this preliminary study applied an environmental monitoring methodology but did not allow for the identification of all material flows. The models applied are simplified and do not consider many flows such as flows between compartments, flows related to primary producers, or benthic flows. Moreover, the models do not allow to know if there is recycling of fish farming discharge outside the aquaculture compartments since the biocenosis compartment has not been modelled. Nevertheless, the study allowed us to determine the obstacles and levers that could be used to improve the method and increase the accuracy of the monitoring of material flows in estuarine IMTA systems.

Finally, this project addresses the complexity of the functioning of systems considered as IMTA in open sea, given the hydrodynamics of the environment and the nutrient inputs from the watershed.

Introduction

The clearance rate (CR), defined as the volume of water cleared of particles per unit time, can reflect the physiology status of filter-feeding animals. This is one of the most important ecophysiological parameters for assessing growth, carrying capacity and influence of bivalves on ecosystem dynamics (*e.g.* Yu et al., 2010). CR is strongly dependent on endogenous factors such as: size, weight and reproductive cycles, as well as exogenous factors, which mainly include temperature, salinity, fluid dynamics and seston properties. Interpreting the CR results is crucial to understand how these factors can affect bivalve's filtration and consequently optimizing production systems. The most bivalve CR has been assessed under laboratory conditions, however this estimation does not generally provide a real information of what is found in the field (*e.g.* Clavier & Chauvaud, 2010). It has been found that the biodeposition method can provide continuous recording under field conditions and reflects the physiological status of bivalves more accurately than other methods (Yu et al., 2017). This method is uniquely suited for *in situ* experiments and can provide well founded CR data. In this study, we estimated the CRs of *Magallana gigas* juveniles of a bivalve nursery (Bivalvia), in the Ria Formosa lagoon, south of Portugal, using the *in situ* biodeposition method.

Material and methods

The experiments were carried out during Spring, Summer and Autumn seasons. The juveniles of oysters were acclimated in a suspended tank at a depth of ~0.5 m in the nursery Bivalvia (south of Portugal) for at least 2-3 days prior to the experiment. After acclimation, 500 oysters spat (length – 7±0.8 mm; wet weight – 0.11±0.05 g) were randomly placed in five cylindrical sediment traps for the CR measurements. Also, another five traps holding only oyster's shells were used as a control, to provided references for natural sedimentation. The cylindrical sediment traps were made of PVC, 1.2 cm holding mesh was hung 5.0 cm from the trap top and the top of each trap was then covered with a net of 1 cm mesh size. All sediment traps were randomly fastened to suspended tanks, in the middle of production system, at a depth of ~0.5 m. The environmental parameters (water temperature, pH, dissolved oxygen and salinity) were measured at the experimental depth (0.5 m) at the beginning and the end of the experiment. Triplicate water samples were collected to determine chlorophyll *a*, nutrients, total particulate matter (TPM), particulate inorganic matter (PIM) and particulate organic matter (POM). The individual CR (L ind^{-1} h^{-1}) was estimated using the biodeposition method (*e.g.* Sroczyńska et al., 2012): CR = (W – W0) C N T, where W is the inorganic matter weight from a trap with oyster (mg), W0 is the average inorganic matter weight from the control traps (mg), C is the average PIM concentration in the ambient water during each experimental period (mg L^{-1}), N is the number of oysters in the trap and T is the length of deployment period (h).

Results and discussion

Food availability is one of the limiting factors for the success of shellfish production. The effects of food competition resulting from spatial aggregation and by the high density of bivalve's production have been demonstrated in many situations and for different species. The availability and quality of food is usually the determining factor in growth models used to evaluate the success of a bivalve's production, namely in nursery phase. The CR of the juvenile oyster was higher during the spring trials (19.9 L g^{-1} h^{-1}) and lowest in the winter (11.5 L g^{-1} h^{-1}). This trend was also observed in food availability (chlorophyll *a*) and in TPM. Several studies have shown that the clearance rate increases with seston concentration up to a threshold beyond which this rate begins to decrease. This limit is species specific and for the oyster *M. gigas*, Barillé & Prou, (1994) considered that the CR increases up to a limit of approximately 50 mg L^{-1} of PTM. In the trials carried out in the Bivalvia nursery system, the maximum TPM values were recorded in the summer (25.80±8.77 mg L^{-1}), not exceeding this maximum. A holistic approach of all determined parameters showed that: a clear positive relationship between CR and food availability; seston did not affected the oysters feeding and consequently growth and the physical, chemical and biological characteristic of nursery seawater was not limiting for the good performance of juveniles. The results obtained contribute to the knowledge of the physiological behaviour of *M. gigas* juveniles in a nursery and constitute an important tool for application in energetic models of the species.

Introduction

The sardine (*Sardina pilchardus*) is a multiple spawner of indeterminate fecundity, belonging to the family Clupeidae and distributed throughout the Mediterranean. Sardine has separate sexes and sexual maturity is generally reached at the end of the 1st year at a length of 10 cm. (Ganias et al., 2004). In the Adriatic Sea, the spawning season lasts from fall to spring with a peak in winter. Sardines are among the most ecologically and economically important marine fish species and are subject to high fishing pressure worldwide (Domenella et al., 2016). Overfishing is undoubtedly the greatest threat to marine biodiversity and fish stock conservation. Global fisheries bycatch, the incidental catch of unexploited or unmanaged species, is also a major threat to the world's oceans. Otoliths are traditionally used to obtain information on the species, age, and size of fish (Rodríguez Mendoza, 2006), while histology is routinely used for sex determination, gonadal developmental stage, etc. (Blazer, 2002). Due to the low selectivity of fishing gear, fishermen catch sardines that are at different stages of development. The research proposes the integration of a live fish sorting device that will allow a relevant proportion of undersized fish that currently die during hauling to survive healthy and return to the sea. Adjustment of fishing gear and appropriate sardine catch size selection methods could reduce the proportion of juveniles of these species in the catch.

Material and methods

On a fishing vessel, the diameter of the grid (sea separator) was set (Ø=11 mm) as part of the vacuum pump fishing device (FAIVRE 8, France) used to transfer fish from the purse seine net into isothermal fish boxes. Fishing with the surrounding purse seine net was performed and the percentage of target species of the selected fish (N=100) caught in the central Adriatic Sea in March 2022 was recorded. The selected sardines were stored by freezing (-18°C) and then processed in the laboratory. By macroscopic and microscopic examination of gonads, gametogenesis was determined ICES (2008). Routine histology was used to prepare tissue sections for histological analysis. After fixation in Davidson fixative, tissues were further dehydrated with increasing alcohol concentrations, cleared in xylene, and soaked in paraffin wax using an automated Excelsior AS processor (Thermo Fisher Scientific Inc., USA). Paraffin block sections were cut into 2 µm sections using a Microm HM 355S microtome (Thermo Fisher Scientific Inc., USA). Tissue sections were stained with modified Harris hematoxylin and Young's eosin (Thermo Fisher Scientific Inc., USA) for histopathological evaluation and with periodic acid (Biognost, Croatia) for visualization of mucosal substance. Photomicrographs were taken with Axio Scan.Z1 scanning light microscope (Zeiss, Germany) and processed with image processing software ZEN 2.3. Age was determined by the number of microincrements on the sagittal otoliths (ICES, 2017). The extraction of otoliths (40) was performed in the laboratory. After extraction, the otoliths were cleaned in fresh water and stored dry in vials until age determination. Age determination was performed using a Dino-Lite digital microscope (Dino-Lite Europe, The Netherlands). Otoliths were immersed in 70% alcohol in a black petri dish and illuminated with light.

Results and discussion

The results of histological sections of the gonads of selected sardines indicated fish at different stages of gonadal development. Fig. 1 shows the female at the mature stage and the male at the early mature stage with central spermatogonia lobules (SG) filled with spermatids and spermatozoa (ST /SZ) and surrounded by a basement membrane (arrow). Primary oocytes of the female (PO), yolk vesicle stage oocytes (YV), primary yolk globule stage (PYG), secondary yolk globule stage (SYG), tertiary yolk globule stage, hydrated oocyte stage (HYD) with large oil drop (OD), postovulatory follicle (POF) (marked). The male was in the early maturation stage with central spermatogonia (SG) filled with spermatids and spermatozoa (ST /SZ) and surrounded by basement membrane (arrow).

(Continued on next page)

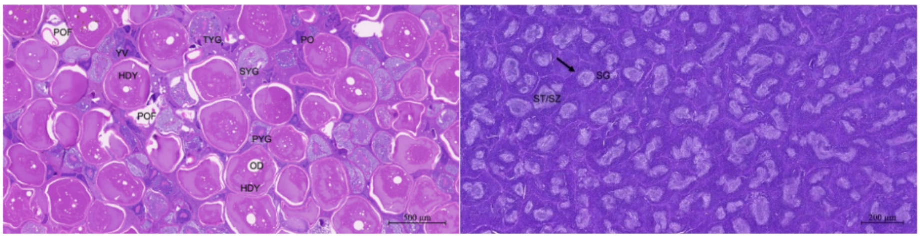

Fig.1. Histological sections of selected sardine ovary (left) and testis (right)

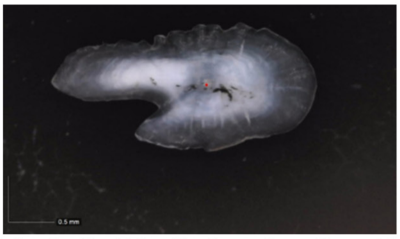

Fig. 2. Otolith of selected sardines (*Sardina pilchardus*)

Following the two-step procedure of counting anullus formation and applying the conventional rule of date of birth, most of the selected sardine samples were assigned to age group 1 (Fig. 2), with the exception of one individual that was assigned to age group 2.

Conclusions

The selected fish were at different stages of gonadal maturity and were assigned to age group 1. It is recommended that the small pelagic fish selector be further developed to improve its performance for even better selection of undersized individuals.

Introduction

From an economic point of view, sturgeonsare of great value as a source of caviar and meat production. Over the years, populations of wild sturgeon have significantly declined due to overfishing and poaching, combined with water pollution and loss of natural habitats. This has led to the current status of the sturgeon family as one of the most endangered species among all animal species [1]. Recirculation aquatic systems (RAS) are considered to be the most environmentally friendly way of producing fish at a commercially profitable level, and sturgeon is one of the species of interest for rearing in RAS conditions [2]. RAS have been already successfully used in fish farms designed for sturgeon breeding (e.g. Russian sturgeon (*Acipenser gueldenstaedtii*), Baltic sturgeon (*Acipenser sturio* L.), sterlet (*Acipenser ruthenus*), beluga (*Huso huso*) for reproduction both in Ukraine and Lithuania. The rearing of sturgeon fish in RAS is accompanied by a number of problems caused by the intensification of the process. As a consequence, a decrease in nonspecific immunoresistance entails a number of illnesses caused by opportunistic microflora. Sturgeon juveniles are particularly sensitive to stress during periods of metabolic restructuring, which is clearly visible in the digestive system. It is known that in the early larval stages, there is a change in the secretion of digestive enzymes during the staged development of the digestive tract. P. Budington has identified three critical stages in the development of the digestive system of sturgeons, when they are particularly sensitive to unfavourable rearing conditions: The first stage (from 3 to 14 days after hatching) is the beginning of endogenous nutrition of pre-larvae (yolk sac) stage, the second (from 7 to 14 days after hatching) is the active nutrition stage, and the third stage (from 24 to 30 days after hatching) is metamorphosis, when the larval digestive system acquires functions typical of adults [3]. The transition to each stage is accompanied by increased mortality of sturgeon larvae. Probiotic preparations are often used to prevent this [4, 5].

The aim of our work was to study the effect of a complex probiotic preparation produced in Ukraine - “Emprobio” – on the survival of juvenile sturgeons during their rearing in closed systems.

Materials and methods

The experiments were carried out in RAS on small sterlet fry larvae, immediately after their transition to exogenous nutrition and lasted for 28 days at a temperature of 18°C. During the experiment a probiotic “Emprobio” was used, whichenriched feed organisms (*Artemia salina* L.). The duration of enrichment was 6 hours at a temperature of 5°C. The sterlet larvae were divided into three groups: 1000 specimens in each group according to the amount of probiotic in the feed : -0.4 cm^3/dm^3 -4 cc/dm^3 and a control group of sterlets received nauplii, probiotic. The fish were fed 6 times a day at a regular intervals. Food rationing was carried out taking into account daily requirement in live feed for sterlet larvae and fry which is 60 – 70% of fish body weight. Probiotic “Emprobio” is non-spore, liquid veterinary probiotic, it contains mixture of various live cultures, including bacterial cells *Lactobacillus casei*, *Lactobacillus plantarum*, *Lactobacillus lactis*, *Lactobacillus acidophilus*, *Saccharomyces cerevisiae*. Number of live microbial cells in $1cm^3$ of probiotic is at least 10^6-10^8. Bacterial inoculations were carried out using standard microbiological methods followed by bacterial identification using biochemical methods.

Results

Feeding with probiotic-enriched *Artemia* improves the growth processes which become visible after fourteen days of feeding. The average mass of the larvae in the experiments is 25.9 and 27.9% higher compared to the control group, respectively. At the same time, it is shown that there is no significant difference between the weights of fish which were enriched with different concentrations of microorganisms in the incubation mixture. Apparently, 0.4 ml of probiotic ($4x10^8$ cells/g live nauplia) is sufficient to induce a maximum release of microorganisms in the intestines, which provides a positive effect of beneficial microflora. During microbiological examinations of the intestines of juvenile sturgeons the opportunistic bacteria of the genus *Aeromonas*, *Pseudomonas* as well as enterobacteria were detected and identified. The positive effect of the probiotic “Emprobio” application is noticeable on the overall survival rate of fish already after the

(Continued on next page)

first day of use of the probiotic, when in the control group of fish 24,1 % of individuals died due to intestinal bloating. The survival rate after seven days of feeding with the probiotic in the experimental group No 1 was higher compared to the experimental group No 2 by 5 % with a probability 0.05. During the next fourteen days of the experiment the cumulative survival rate of fish in both experimental groups did not change, while in the control group gradually decreased to 51 %. The results of bacterial seeding of intestinal contents of sterlet juveniles from experimental and control groups confirmed the efficiency of the transfer. Thus, all lactic acid bacteria contained in the probiotic were isolated in the intestines of the experimental groups in the amount of 1×10^5 cells/g, as well as yeasts *Saccharomyces cerevisiae* in the amount of 3.2×10^2 cells/g. In the control group, there were only isolated colonies of lactic acid bacteria.

Conclusions

The rearing of larvae and their transition to artificial feed, as well as the rearing of early fry are the most complex stages in the technological cycle of sturgeon rearing in RAS. Survival, growth rate of commercial fish, feed utilization efficiency, and, consequently, the efficiency of the entire production depends on the quality of the produced juveniles. The search for and development of ways to apply new, safe and effective preparations that have a positive effects on the survival of juvenile sturgeon are one of the promising areas of research, and our work will have its continuation and application to other species of sturgeon in the future.

E-mail: alkistibatzina@gmail.com

Introduction

Within the scope of the SaltBox project, i.e. the design and manufacture of a fish size/biomass estimator for gilthead seabream, it is necessary to establish accurate weight-morphometrics relationships, through which the image captured by the estimator can be "translated" to actual body weight. The aim of the present study is to report these relationships for gilthead seabream.

Materials and Methods

A total of 3312 specimens were individually weighed and photographed with embedded ruler. Targeted body weight ranged from 50 to 1000 g and special attention was paid to obtain at least 75-100 observations in a range of 25 g weight classes. Photographs were analyzed by digital image analyses and several morphometric traits were obtained. Pearson product-moment correlations were calculated, regression analysis was performed, and several models were applied to identify the most accurate one predicting weight from one or more of the morphometrics traits.

Results

The strongest correlation was obtained between weight and body monolateral area, followed by body lengths (i.e. total, fork, standards length, body height). The best model to describe weight (W)-morphometric traits (MT) relationships was of the type: W = aMTb, with the exception of W-eye diameter and W-eye area relationships, which were neither strong nor well fitted. Multiple or polynomial regression also produced inferior estimations. Also, when data were analyzed separately for body weight ranges of 50-100 g, 100-500 g and 500-1000 g, relationships obtained were weaker and did not offer any advantage over those of the full body weight range examined.

Conclusion

Results obtained indicate that body monolateral area can be best used to accurately estimate actual body weight. The size/ biomass estimator resulting from the SaltBox project can be tuned towards the precise estimation of this morphometric trait.

Aknowledgements

The project is co-funded by the European Maritime and Fisheries Fund and the Greek government.

EXTRUSION PROCESSING OF FISH FEED PELLETS: INFLUENCE OF SILICA AND OIL CONTENT ON THE PRODUCT PROPERTIES

M. Mayser*[1], J. Wiertz[1], C. Schillinger*[2], C. Bader[3], V. Stohl[3], I. Huismann[3]

[3] Hochschule Fulda, Leipziger Straße 123, 36037 Fulda, Germany

Introduction

Aquaculture is a fast growing market and there is a large demand for high fat fish feed especially for species like salmon and trout. The current production process for fish feed cannot introduce enough oil into the extrusion process because of the negative effect on the extrusion process, pellet stability, fat retention and nutritional quality (Huber, 2000). Therefore the standard production process includes a coating step after extrusion to increase the fat content which increases the production costs. This project aims to increase the fat content during the extrusion process by the addition of silica to the fish feed formulation.

Materials and methods

A fish feed formulation consisting of soy protein concentrate, wheat flour, fishmeal, and canola oil was processed in a lab-scale twin-screw extruder (TwinLab F 20/40; Brabender GmbH & Co. KG, Germany). The formulation without and with the addition of 1% of different silica grades (Aerosil® 200 F, ZeoFree® 600, Sipernat® 50, Evonik Operations GmbH) was feed into the 0D opening. Water was added at 10D and canola oil was added at 20D to the extrusion process to increase the fat content up to 37% (Fig. 1). The resulting fish feed pellets were analyzed for abrasion resistance and fat loss.

A stable extrusion process for fish feed pellets was established with fat contents of 22, 27, 32 and 37 percent. 1 % of silica in the formulation reduces the lubricating effect induced by the addition of oil (Fig. 2). It also reduced the viscosity and thereby the thermo-mechanical energy input resulting in enhanced product quality. Depending on the silica grade the resulting pellets showed a 40 to 70 % higher resistance to abrasion compared to the pellets without silica (Fig. 3). It also reduce fat leakage of the pellets by 10 to 50 percent compared to samples without silica.

Conclusions

With the addition of silica it was possible add a high amount of oil and to establish a stable extrusion process without the need for an additional coating step after extrusion. The addition of silica reduces the lubricating effect of the addition of oil in the extrusion process and generates fish feed pellets with higher abrasion resistance and lower fat leakage.

Introduction

Seasonal forecasts and climate projections are used in a wide range of sectors and applications, from tourism to energy generation and food production. They provide opportunities for evidence-based long-term planning and early warning of unusual conditions, supporting an ecosystem-based management approach and helping in the design and implementation of nature-based solutions. Predictions of the ocean state, particularly at this time scale, have the potential to aid management of marine resources and to ensure effective protection of our marine environment.

Materials & Methods

The Centro Euro-Mediterraneo sui Cambiamenti Climatici (CMCC) produces a range of ocean-based products, including seasonal forecasts and longer-term climate projections. As an operational seasonal forecasting centre, we provide freely-available 6-month forecasts of physical atmospheric and oceanic variables via the Copernicus Climate Change Service. Here, we highlight the skill of our system to detect surface and subsurface marine heat waves (MHWs) and cold spells (CSs) in European seas.

Results

In collaboration with ISPRA (Italian Institute for Environmental Protection and Research), we have identified examples of mass-mortality events which have affected the aquaculture industry. For instance, there was mass mortality of farmed mussels in the Gulf of Taranto in summer 2015 due to several weeks of marine heat wave conditions. Forecasts of ocean conditions during these events are encouraging (Figure 1), and collaborative efforts with aquaculture stakeholders are necessary to fully understand the reliability and use of forecasts. As a result, we are actively looking for collaborations to co-develop useful marine indicators based on our products. To help us understand aquaculture stakeholder needs, attendees are invited to fill in our survey *“Climate projections and seasonal forecasting for aquaculture”* (see link in poster).

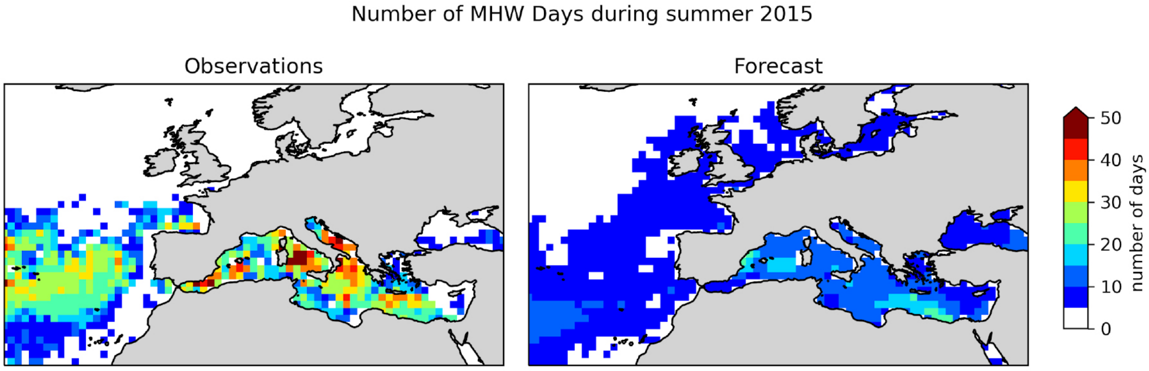

Figure 1: Number of days of marine heat waves between mid-May and September in 2015. Marine heat waves are defined as extreme anomalies in the sea surface temperature which last longer than 5 days. EARLY DEVELOPMENTAL EXPOSURE TO HEAT SHOCK IN RAINBOW TROUT (*Oncorhynchus mykiss*) DOES NOT AFFECT THE RESPONSE TO THE BACTERIAL PATHOGEN *Yersinia ruckeri* IN LATER LIFE BUT ALTERS THE RESPONSE TO PHYSICAL STRESSORS

Email: rjm235@exeter.ac.uk

Introduction

Despite advancements in treatment and prevention, disease remains a major issue in aquaculture with implications for sustainability, welfare and food security. Genetic selection, often bolstered by genomic analyses, has proved successful at combating diseases in several cases, but manipulation of the epigenome in the context of disease prevention has seldom been explored. The propensity for vertebrate epigenomes to be manipulated by environmental stimuli, especially during critical windows of development, provides a potential opportunity for phenotypic selection by modifying epigenetic regulation of transcription. In a preliminary study, we have observed elevated heat shock protein transcriptional response to temperature stress in rainbow trout alevins previously exposed to heat shock during embryo development but not in naïve alevins. Here, we hypothesise that exposure to heat shock during critical windows of early embryo development may have the potential to alter disease susceptibility by modifying responsiveness to a pathogen via the manipulation of the epigenome.

Methods

To test this hypothesis, rainbow trout (*Oncorhynchus mykiss*) embryos were exposed to a 1 hour temperature shock during early development and then maintained under control conditions for the remainder of the study. Non-shocked (naïve) embryos were kept in parallel. At 106 days post hatch, these fish were infected with bacterial pathogen *Yersinia ruckeri*, the causative agent of enteric redmouth disease (ERM), via bath exposure. Control fish underwent a mock bath exposure to phosphate buffered saline (PBS) in which the bacteria were suspended for the disease exposure. Survival was monitored for 16 days, and liver samples were taken at 0, 19 and 43 hours post infection (hpi) for transcriptomic analysis.

Results

Yersinia ruckeri exposure led to rapid and substantial mortality in all infected groups, reaching 80% after 16 days in both heat shocked and naïve fish. Comparisons between heat shocked and naïve fish revealed that developmental exposure to heat shock had no significant effect on survival of fish exposed to *Y.ruckeri*.

Infection resulted in large changes in transcription with 4630 and 4145 differentially expressed genes identified at 19hpi and 43hpi, respectively (fold change > 2, $P < 0.01$), but few differences were identified between the responses of heat shocked and naïve fish. Interestingly, despite the apparent lack of influence of the heat shock pre-exposure on the response to disease, a differential response to the handling stress associated with the infection procedures was detected, suggesting that pre-exposure to heat shock has a modulatory effect on the response to subsequent physical stressors.

Conclusions

The data suggest that the developmental treatment applied here does not cause long term alterations relevant to disease susceptibility. However, different responses to handling stress during the disease challenge suggest that epigenetic manipulation may have occurred and may be affecting other stress response pathways.

EXPOSURE TO TEMPERATURE STRESS DURING EARLY EMBRYO DEVELOPMENT RESULTS IN GREATER HEAT SHOCK PROTEIN 70 INDUCTION IN RAINBOW TROUT (*Oncorhynchus mykiss*) LARVAE UPON RE-EXPOSURE

Introduction

Aquaculture species are exposed to a wide array of stressors that limit production by impacting growth and survival. Despite genetic selection for traits improving growth or disease resistance, little attention has been afforded to selecting for robustness to the common stressors encountered during production. The propensity for the epigenome to be manipulated by environmental stimuli provides another potential platform for improvement of phenotypic traits in cultured species. However, whether intentional exposure to a stimulus can induce epigenetic alterations that result in beneficial changes in transcription and phenotype is unknown.

The present study aims to investigate the potential to intentionally induce epigenetic modifications and explore whether they result in altered responses to future stressors in an important aquaculture model species, the rainbow trout (*Oncorhynchus mykiss*). We hypothesise that exposure of rainbow trout embryos to temperature stress will result in significant alterations in transcriptional responsiveness upon re-exposure to temperature stress in later life, due to alterations in epigenetic patterns.

Methods

Our hypothesis was tested by exposing rainbow trout embryos to temperature stress during different developmental windows in the first week of development, while a control group was maintained in parallel. Post hatch, half of each group were either re-exposed to temperature stress for 24 hours or maintained in control conditions, and then sampled immediately. Real-time qPCR analysis of heat shock protein gene transcription (*hsp70a* and *hsp70b*) was used as a biomarker for responsiveness to temperature stress upon re-exposure.

Results and Discussion

Our findings revealed a greater responsiveness to temperature stress in fish that had been pre-exposed during embryo development. Furthermore, the developmental pre-exposure periods resulting in greater effects coincided with those overlapping with the putative epigenetic reprogramming period for fish species. These results suggest that it is possible to induce a greater ability to respond to temperature stress in rainbow trout by pre-exposing them during sensitive periods of embryo development. We are now investigating the epigenetic mechanisms accounting for these effects using reduced representation bisulfite sequencing. Our data highlights the potential for lasting memory of previous exposures to occur and for this to be used to induce altered phenotypic characteristics in cultured animals.

MACROALGAE AS A SOURCE OF SUSTAINABLE BIOPRESERVATIVES FOR FOOD SAFETY

Ailbhe McGurrin*[1], Julie Maguire[2], Rahel Suchintita Das[1], Brijesh K. Tiwari[3], Marco Garcia-Vaquero[1]

[1] section of Food and Nutrition, School of Agriculture and Food Science, University College Dublin
Belfield, Dublin 4, Ireland

[3] TEAGASC, Food Research Centre, Ashtown, Dublin 15, Ireland
E-mail: ailbhe.mcgurrin@ucdconnect.ie

1. Introduction

With over 10,000 species identified to date, macroalgae experience incredible diversity; minerals can represent 7-36% biomass, lipids 1-5%, polysaccharides 15-76%, protein 5-47% (Cabral, Oliveira, et al., 2021). Macroalgae are exposed to extreme conditions, i.e. large variations in nutrients, temperature, pH, oxygen, and pathogens, leading to the production of secondary metabolites to increase their survival rate (Silva, Silva, Lourenco-Lopes, et al., 2020). These compounds have attracted the interest of the research community as they possess a wide variety of health properties (antioxidant, antimicrobial, anti-inflammatory, anticancer, anticoagulant amongst others), relevant for multiple biotechnological applications (Figure 1). Polysaccharides from macroalgae such as fucoidan, ulvan, galactan, and laminarin have been associated with antibacterial effects, most likely due to interactions with the bacterial cell wall, resulting in membrane leakage (Liu et al., 2017). These antimicrobial properties of macroalgae could play a valuable role as biopreservatives for multiple applications, including food (Cabral, Oliveira, et al., 2021).

With the rise in awareness of antimicrobial resistance in recent years, significant research has focused on alternative sources of antimicrobial compounds such as natural products (Quinto et al., 2019). Concurrent with the rise in focus towards alternative antimicrobials is the significant change in consumer food preferences, associated with concerns that chemically synthesised food preservatives pose dangers for human health, as well as concerns about the sustainability of their production. This has led to an increased interest by the research community in biopreservatives or natural compounds with antimicrobial activity which can be used as effective preservatives to improve food safety (Silva, Silva, Lourenco-Lopes, et al., 2020). This study aims to assess the antimicrobial activity of extracts of the macroalgae *Alaria esculenta* against microorganisms relevant for food safety.

2. Aim

The main aim of this study is to evaluate the antimicrobial activity against foodborne microorganisms of extracts of the macroalgae *Alaria esculenta*.

3. Methodology

Alaria esculenta was extracted using either ultrasound (US), microwave (MW), or ultrasound-microwave-assisted (UM) methods. Total phenolic content (TPC) and total soluble sugars (TSS) were determined via Folin-Ciocalteu reagent methods and phenol-sulfuric acid methods, respectively. Antimicrobial analyses included determining minimum inhibitory concentrations (MIC) and growth curves against microorganisms relevant for food safety and gentamycin as control following broth microdilution methods.

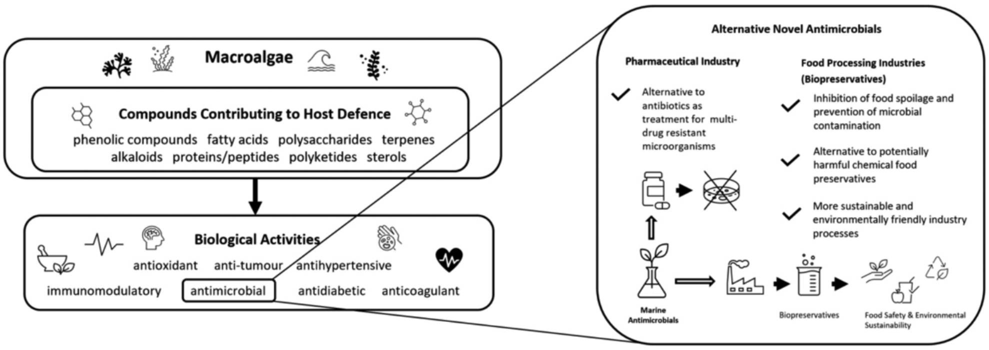

Figure 1. Schematic summarising secondary metabolites produced by macroalgae, their biological activities, and applications in pharmaceutical and food processing industries.

(Continued on next page)

4. Results and Discussion

Overall, the extracts evaluated contained low and similar levels of TPC (ranging from 1.27 to 1.64 mg gallic acid equivalents (GAE)/100 mg dried extract (DE) macroalgae) and protein (ranging from 4.64 to 9.93 mg/100 mg DE). The main differences in composition were appreciated in their contents of TSS, being 18.84, 19.14 and 32.68 mg glucose equivalents (GE)/100 mg DE. Antimicrobial activity was observed against *E.coli,* with MIC of 6.25 mg/ml in extracts prepared by US (TSS=32.68 mg GE/100 mg DE; TPC=1.27 mg GAE/100 mg DE), while the worst performing extracts with MIC of 12.5 mg/ml were achieved by those extracts generated by MW (TSS=18.84 mg GE/100 mg DE; TPC=1.5 mg GAE/100 mg DE).

5. Conclusions

This study indicates the potential of macroalgal polysaccharides generated using green extraction technologies as alternative antimicrobial agents against *E. coli*. Future research should focus on incorporating extracts in real food matrices to assess biopreservative potential.

WWF’S GLOBAL AQUACULTURE STRATEGY

Aaron A. McNevin, Ph.D

WWF
aaron.mcnevin@wwfus.org

Resource scarcity is upon us, and as we emerge from the global COVID-19 pandemic we are recognizing the razor’s edge we walk between supply chain function and collapse. Our contingencies for a sustainable food system are sparse, and the impacts of climate change are being observed, not theorized. But the importance of aquaculture continues to grow as a protein production system and as a mechanism for income generation. Aquaculture’s role in off-setting fishing pressures and creating a lower footprint protein are being questioned. Yet there remains great optimism that aquaculture can meet the expectations of creating a step-change in net food availability, beyond that of other proteins.

Considering the role of aquaculture in the future of food and importance of getting this right, WWF has embarked on a global network strategy to mitigate the negative impacts of aquaculture and amplify the beneficial factors. This first of its kind strategy seeks to increase the role of aquaculture as a livelihoods component, shift the research and development and demand from top-order predators to lower trophic species, halt forest and habitat conversion and increase the resource efficiency of production.

Discussion will focus on draft milestones and targets for aquaculture and the WWF Network approach to realizing the critical role of aquaculture in the broader food system.

EFFECT OF PERSONAL CARE PRODUCT (BUTHYLPARABEN, METHYLPARABEN AND PROPYLPARABEN) ON EMBRYONIC STAGES OF TENCH (*Tinca tinca*)

Introduction

Personal care products (PCPs) are used daily by people around the world. Their entry into environment raises concerns about the potential threat to non-target organisms. Recently, there has been a growing interest in studying the properties of these pollutants. This is mainly due to their properties, which include, for example, the ability to bioaccumulate and also due to potential adverse effects on human health such as substances with mutagenic, carcinogenic and estrogenic activity (Brausch et al., 2010). Since these substances are constantly entering the aquatic environment, more attention must be paid to reveal their ecotoxicological potential. Moreover, it is known that fish are the most sensitive to aquatic contaminants between the period of hatching and onset eating exogenous food (Medkova et al., 2022). Therefore, it is necessary to know their toxicological properties on the early-life stages and their potential to affect health and welfare of aquatic organisms. The aim of this study was to determine the effect of PCPs (buthylparaben, methylparaben and propylparaben) on early life stages of tench (*Tinca tinca*), which is a fish commonly found in central Europe.

Materials and methods

The experiment was performed according to the Guideline for Test No. 236: Fish Embryo Acute Toxicity (FET) (OECD 2013) for the period of 96 hours with five different concentrations and control groups (ISO water and ISO water with solved ethanol). Tested concentration of methylparaben were 0.5, 50, 500, 5 000 and 100 000 µg/L, propylparaben and buthylparaben were tested at 0.1, 10,100, 1 000 and 100 000 μg/L. Fertilized eggs of tench (*T. tinca*) were selected using binocular microscope and distributed into 24 microwell plates. For each concentration plus control and control with solvent, 24 embryos were used. Tench (*T. tinca*) eggs were obtained from commercial farm Rybníkářství Pohořelice a.s. (Czech Republic). Tested substances were dissolved in water prepared according to ISO 7346 (ISO, 1996) with addition of ethanol (solvent). During the test the temperature was 24°C and the photoperiod was 12 hours light/12 hours dark. The solutions were changed every 24 hours and indicators of toxicity were recorded. We observed mortality, malformation rate, hatching and the heartbeat. At the end of the experiment, the samples of embryos were taken (8 replicates from each group) in order to study the effects of tested substances on selected genes expression using qPCR. For qPCR, only the lowest tested concentrations and their thousandfold were used. Statistical analysis was conducted using Unistat 5.6 for Excel (Czech Republic).

Results and discussion

Buthylparaben, propylparaben and methylparaben had a statistically significant negative effect on tench (*T. tinca*) mortality. Buthylparaben and propylparaben caused 100% mortality after 48 hours post fertilization (hpf) at the highest tested concentration. Also, at concentrations of 100 and 1000 µg/L the mortality reached 21% of embryos exposed to these concentrations of butylparaben. Similarly, Merola et al. (2020) described high mortality of zebrafish (*Danio rerio*) after 48h long exposure to buthylparaben. Concerning methylparaben, concentration of 100 000 μg/L caused mortality of 45% specimen. Moreover, concentration 5 000 μg/L caused 21% mortality and concentration 500 μg/L caused mortality of 25%

(Continued on next page)

embryos. On top of that a 96hours exposure to methylparaben revealed increased malformation rate. At the concentrations 5 000 and 100 000 µg/L of methylparaben malformation rate of 25% was observed. The most common malformations were underdeveloped head, heart oedemas, and deformations of tail and spine. Similarly, Dambal et al. (2017) observed malformations such as pericardial oedema, bent spine and blood cell accumulation on embryos of zebrafish (*D. rerio*) that were exposed to buthylparaben. Buthylparaben and propylparaben did not have any effects on the occurrence of malformations. None of the tested substances had any significant effect on the time of hatching. Embryos were hatched at all concentration and all tested substances at 72 hpf. Both butylparaben and propylparaben influenced the expression of the gene *hsp70*, whose expression is known to be markedly induced in response to environmental stresses. Also, methylparaben and propylparaben altered the exposure of *cyp1,* which is used as biomarker of aquatic pollution.

Conclusion

Based on the results of this study, buthylparaben, propylparaben and have at certain concentrations the ability to negatively affect development and welfare of non-target fish and other water organisms.

MEALWORM (*Tenebrio molitor*) IN DIETS FOR RAINBOW TROUT (*Oncorhynchus mykiss*): A STRATEGY TO FACE THE OMEGA-3 PROBLEM OF INSECT-FED FISH

Melenchón F.[1*], Fabrikov D.[2], Galafat A.[2], Alarcón F.J.[2], Pula H.J.[3], Morales A.E.[3], Tomás-Almenar C.[1]

Introduction

The use of insects shows an interesting potential as an alternative to fishmeal in aquafeeds, but tends to diminish the omega-3 (ω-3) fatty acid content in fish fillets (De Haro *et al.*, 2015; Fabrikov *et al.*, 2021; Jeong *et al.*, 2022). Some experiences have attempted to counter this drawback through different strategies (Sealey *et al.*, 2011; Jeong *et al.*, 2021). The present work tested one of them by using an ω-3 enriched oil at different dietary inclusion levels in rainbow trout, and also analysed if that strategy could have other side effects on fish physiology.

Material and Methods

Four isoproteic (45.5%) and isolipidic (17%) diets were tested: one control (C) based on fishmeal as main source of protein, and three with a 50% replacement of fishmeal (18% feed inclusion) with *Tenebrio molitor* meal and an increasing level (0%, T50; 3.1%, TV1; and 7.2%, TV2) of an experimental algal oil rich in ω-3 (EPA and DHA) that partially replaced fish oil. 400 rainbow trout specimens (*Oncorhynchus mykiss*; 4 tanks per diet, 25 fish per tank) with an initial body weight of ~46 g were fed the experimental diets in a recirculating aquaculture system in optimal and controlled conditions during 89 days, until they reached a final body weight of ~415 g. At the end of the growth trial, fillet fatty acids profile, liver redox status, and liver histomorphology were analysed.

Table 1. Effects of experimental diets on fillet and liver of rainbow trout

Fatty acid profile (%/total)	**C**	**T50**	**TV1**	**TV2**	**SEM**
Eicosapentaenoic acid (EPA)	3.29^{c}	2.34^{d}	4.09^{b}	5.33^{a}	0.17
Docosahexaenoic acid (DHA)	18.95^{a}	15.22^{b}	17.51^{ab}	19.94^{a}	0.74
Total omega-3 (ω-3)	24.95^{ab}	19.65^{c}	24.71^{b}	28.65^{a}	0.92
Liver redox status	**C**	**T50**	**TV1**	**TV2**	**SEM**
Superoxide dismutase (U/mg protein)	282.36	271.14	299.62	277.21	10.5
Catalase (U/mg protein)	325.45	342.72	378.66	368.94	20.26
Glutathione peroxidase (mU/mg protein)	16.53^{a}	13.1^{b}	10.41^{b}	10.26^{b}	0.68
Glutathione reductase (mU/mg protein)	7.73	6.3	6.29	6.65	0.52
Glucose-6-phosphate dehydrogenase (mU/mg protein)	57.74	50.21	44.28	44.08	7.37
Malondialdehyde (nmol/g tissue)	65.06^{b}	65.06^{b}	99.54^{a}	111.32^{a}	7.40
Liver histomorphology	**C**	**T50**	**TV1**	**TV2**	**SEM**
Hepatocyte nuclei width (µm)	2.05	2.04	2.09	2.1	0.04
Hepatocyte cytoplasm width (µm)	4.45	4.42	4.59	4.62	0.05
Lipidic accumulation in hepatocytes	+	+	++	++	-

C: Control diet (no fishmeal replacement); T50: 50% fishmeal replacement with *Tenebrio molitor*; TV1 and TV2: 50% fishmeal replacement with *Tenebrio molitor*, and supplemented with 3.1 and 7.2% (respectively) of experimental algal oil. $^{a, b, c, d}$ indicate significant differences ($p<0.05$) between diets. Data are expressed as mean ± standard error of the mean (SEM).

(Continued on next page)

Results and discussion

Growth performance (not included) did not show significant differences among experimental groups, which followed the tendency of a previous study in this species (Melenchón *et al*., 2022). Fillets of fish fed with T50 showed an overall decrease in ω-3 fatty acid content, while TV1 and TV2 had this decrease corrected or reversed, showing even higher levels than C diet in some cases. Interestingly, TV1 and TV2 showed increased lipid accumulation within hepatocytes, which has already been described in other insect-fed fish trials (Randazzo *et al*., 2021). Due to this lipid storage, a situation of oxidative stress occurred in the liver of TV1 and TV2, represented by an increase in malondialdehyde levels linked to a decrease in glutathione peroxidase activity. Perhaps, additional supplementation of these diets with antioxidants would have been necessary.

Introduction

The use of insects shows an interesting potential as an alternative to fishmeal in aquafeeds. Since the intestine is the main organ involved in the absorption of nutrients, gut health plays an important role in fish growth. Also, the study of intestinal microbiota shows potential on this matter, because different microorganisms can influence the processing of nutrients (Semova *et al*., 2012; Wu *et al*., 2012). The present work evaluated the microbiota of rainbow trout distal intestine after a feeding period with one whole insect meal, and a partially defatted version of the same insect, yellow mealworm (*Tenebrio molitor*).

Material and Methods

Three isoproteic (45.5%) and isolipidic (17%) diets were tested: one control (C diet) based on fishmeal as a main source of protein, and two with a 50% replacement of fishmeal (18% feed inclusion) with *Tenebrio molitor* meal, one whole (T diet), and one partially defatted (TD diet). 300 rainbow trout specimens (*Oncorhynchus mykiss*; 4 tanks per diet, 25 fish per tank) with an initial body weight of ~46 g were fed the experimental diets in a recirculating aquaculture system in optimal and controlled conditions during 89 days, until they reached a final body weight of ~415 g. At the end of the growth trial, samples of intestinal digesta were taken for microbiota analyses.

Table 1. Effects of experimental diets on the microbiota of intestinal digesta samples of rainbow trout

Microbiota (% OTU/total)		**Experimental diets**			
Family level	**Genus level**	**C**	**T**	**TD**	**SEM**

(Continued on next page)

Results and discussion

Growth performance (not included) did not show significant differences among experimental groups, which followed the tendency of a previous study in this species when fed yellow mealworm (Melenchón *et al*., 2022). Several changes in microbiota composition are described in Table 1. Among them, a significant increase in *Bacillus sp*., *Brevibacillus sp*. and *Enterococcus sp*. was highlighted for T diet. Lactic-acid bacteria (such as *Enterococcus*) and bacteria from the *Bacillus* genera are known for having probiotic properties in fish (Chang and Liu, 2002; Capkin and Altinok, 2009), which is positive from an applicative point of view. Similar results have been found in other experiences with insect-fed fish (Józefiak *et al*., 2019; Gaudioso *et al*., 2021), but since our experiment described this increase only for T diet, it is possible that insect fat is more relevant for the growth of these bacteria than other insect components like chitin. In this vein, there was also an increase in amino acid fermentative bacteria (*Peptostreptococcaceae* and *Peptoniphilaceae*) and a decrease in *Nostoc sp*. in TD diet, showing the relevance of the nature of the fat in the microbiota profile.

THE USE OF DIET ENCAPSULATION AS A VALUABLE TOOL TO IDENTIFY THE POTENTIAL OF NOVEL FISH DIETS

Rodrigo Mendes*, Luís E.C. Conceição, Francisco J. Sánchez Vázquez

SPAROS Lda., Olhão (Portugal)
*Email: rodrigomendes@sparos.pt

Introduction

Fish can choose their diets and regulate feed intake through “nutritional wisdom”, which is controlled by behaviour, learning and physiological processes, such as the evaluation of the palatability, oral sensation and sensory properties of feed. In aquaculture research, normally, the effects of new diets are performed using growth trials, mainly based on physiological mechanisms. Although this methodology is efficient, it does not consider fish preferences. Moreover, the gustative and olfactory properties of traditional extruded or pelleted diets (texture, taste, odour and flavour) can have functional effects to inhibit or stimulate feed intake. Therefore, to provide a more complete perspective on the potential of novel diets, growth trials may be complemented with other methods.

Self-selection methods have the potential to become valuable tools for the design and ingredient selection of new diets. These methods allow fish to choose which feed most suits their nutritional needs. Diet encapsulation has been used as a promising approach focused only on the nutritional content of feeds, as it packages diets inside eatable gelatine capsules, with the same orosensory characteristics, which masks the organoleptic properties of feeds. Thus, encapsulation allows fish to express their natural behaviour, without the effect of chemosensitivity.

The main objective of this work was to understand the behaviour response and feed preference of Nile tilapia (*Oreochromis niloticus*), using the self-selection method of diet encapsulation, towards the acceptability of innovative sustainable feed ingredients, spirulina (*Arthrospira platensis*) and quinoa (*Chenopodium quinoa*).

Methods

Three experimental diets were formulated and produced at the University of Murcia with distinct proximal compositions. Diet A had casein and dextrin (34% and 30%, respectively) as main ingredients and served as a proxy for a purified diet. Diet B was mainly composed of spirulina (58%), while Diet C had different doses of spirulina and quinoa (46% and 20%, respectively). Diets were given as multi-coloured capsules to 7 individual fish (*O. niloticus*) of 331.88 g ± 31.39 g (mean ± S.D.) for 35 days. To determine daily intake, the total number of uneaten capsules corresponding to each diet was counted for every fish and subtracted from the total number of capsules given. After a determined diet exhibited statistically significant differences (means compared using SPSS version 23.0 by one-way ANOVA, followed by a Tukey’s post-hoc) over the others, feeds were switched between capsule’ colours to reduce the possible preference for a specific colour.

Results

After 10 days of relatively similar diet preferences, fish progressively increased their intake and selection of capsules containing diet C, while simultaneously decreasing that of diets A and B (remained at an average level of 30% and 31%, respectively) (Fig. 1). When the preference for diet C reached values (maximum of 44%) that showed statistically significant differences ($p < 0.05$) for several days (day 11 – 16), the colour of the capsules associated with each diet rotated. Initially, this change decreased the ingestion of diet C, while conversely increasing diet A and B. Until day 29, the preference of fish towards the diets remained at a steady state, until a clear consistency and preference for diet C was once again achieved (between 40.4% and 47.2%; $p < 0.05$).

During days with statistically significant differences between feeds, diet C (1.63 capsules/100g BW; $p < 0.05$) was ingested around 46.8% and 44.2% more than diet A (1.13 capsules/100g BW) and B (1.11 capsules/100g BW), respectively (Fig. 2).

Conclusions

Diet C (with spirulina and quinoa) leads to a better feed intake than diet B (only with spirulina), while the purified diet A (with casein and dextrin) resulted in the lowest intake. Nile tilapia was able to select one of the given feeds based only on post-ingestion and absorption signals. Diet encapsulation trials allow fish to express their behaviour, thus these methods may be considered in the initial screening of potential new aquaculture feeds.

(Continued on next page)

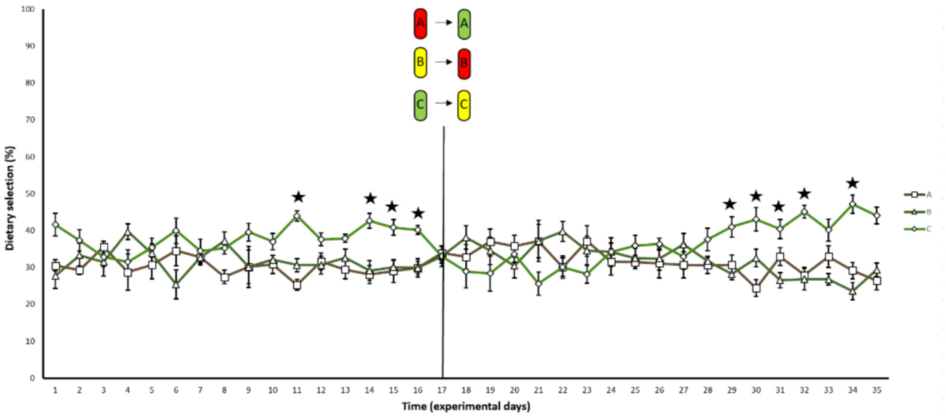

Figure 1 – Evolution of average daily intake of three diets (Diet A, B and C) by Nile tilapia, expressed in percentage of the total number of capsules ingested for 35 days. The content of the capsules changed on day 17. Values represent the mean ± S.E.M. of 7 individual fish. Stars represent significantly different values (ANOVA, $p < 0.05$).

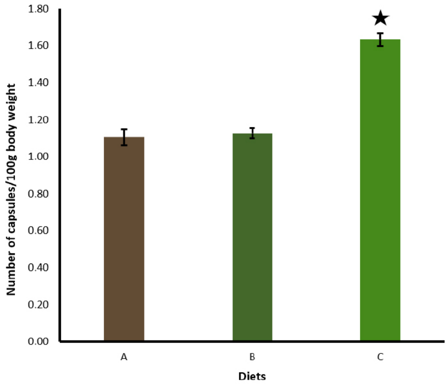

Figure 2 – Average daily intake of three diets (Diet A, B and C) by Nile tilapia, represented by the number of capsules ingested per 100g of body weight during days with statistically significant differences between diets. Values represent the mean ± S.E.M. of 7 individual fish. The star represents significantly different values (ANOVA, $p < 0.05$).

lidia.paredes@uvic.cat

Introduction

The SEA2LAND EU project (2021-2024) aims to provide solutions to help overcome challenges related to food production, climate change and waste reuse. This project will meet this challenge by improving and adapting technologies for nutrient recovery to produce bio-based fertilisers (BBFs) and Tailor Made fertilisers (TMFs) from fishery and aquaculture by-products generated in Europe. Therefore, SEA2LAND will contribute to independence and secure the supply of nutrients to European agricultural systems and will promote the production of large-scale fertilizers (from non-imported raw materials), based on the circular economy model to transform by-products into nutrients for crops. Particularly, CAVIAR PIRINEA together with some research partners are mading available extended catalogue of sidestreams charaterization, which are routinely sold to waste managing companies with no valorisation income derived. The technological approaches developed herein by BETA are revealing that within a private aquaculture production scenario of 3.100T fish/year (i.e., rainbow trout (*O. mykiss*) and sturgeon (*Arcipenser sp.))* and 1.902T of fresh processed products/year (i.e., fish, roe and caviar) => 69m^3 fish sludge, 96T fish víscera and 200T of non-conforming fish/year could respectively be valuated through some of the current research techniques in progress. Likewise, the project could show that every increased productivity as derived from intensification in aquaculture and/or fish processing practices will not only lead to a subsequent huge, but also economically recoverable production of agro innovative byproducts. The solutions developed are expected to reduce the soil nutrient imbalance in Europe.

Material and Methods

An innovative technological approach is being evaluated within WP4 for the valorization of aquaculture by-products (fish sludge and dead fishes). The **SLUDGE** is separated into solid and liquid fractions. Solid fraction valorization is conducted by applying biodrying processes, aiming to reduce the water content and obtain a nutrient-rich biodried product to be used as an organic amendment. The combustion of this product to recover phosphorus from the ashes to produce **phosphoric acid** is also expected. The feasibility of recovering the volatilized ammonia during the biodrying to produce **ammonium salt** is also under current evaluation within the project. The liquid fraction from sludge is being valorized by using several concentration processes. The method consists of an ultrafiltration (UF) system to separate solid particles present in the liquid fraction. The permeate produced by UF passes through the reverse osmosis (RO) system to concentrate the nutrients. The RO concentrate generated is subsequently processed in a Freeze Concentration (FC) unit, where the water is crystallized, and the **nutrients** are recovered in a nutrient-rich concentrate product. Moreover, a high-quality RO permeate with potential to be reused in the aquaculture industry facilities is also produced.

Results

Sludge produced from freshwater aquaculture systems can be successfully valorized by a portfolio of technologies to recover nutrients on a dry basis, as follows for example: (i.) Solid fraction of freshwater sludge: 7.0% TKN, 0.4% TP, and 0.1% K. and (ii.) Liquid fraction of freshwater sludge: 0.33 g N/L, 0.02 g TP/L, and 0.02 g K/L. Dead fish is being valorized as a co-substrate during the treatment of the solid fraction from freshwater aquaculture sludge. The specific use of trout as a co-substrate is showing to be very potential because it presents high organic matter content and valuable and recoverable nutrients as N (4.4% TKN) and P (0.4% TP) on a dry basis.

Likewise, 26 private and public stakeholders involved in 8 technical work-packages and with expertise in the fields of agriculture, aquaculture, fisheries and fish processing from all over Europe, will continue developing through the end of 2024, comprehensive data sets relating to (i.) agriculture and fertilization; (ii.) side-streams characterization and technology development; (iii.) food waste and circular economy; (iv.) environmental performances and constraints; (v.) sustainability assessment and business models.

(Continued on next page)

Conclusions

The physicochemical characterizations herein are making evident the **feasibility of recovering nutrients from dead fish and sludge produced in aquaculture companies** and it could represent a promising option for the production of bio-based fertilizers (BBF) from aquaculture by-products (further details on freshwater vs. marine, in progress).

Furthermore, the potential application of **these BBF could reduce the costs associated with sludge management**, bringing both cost reduction a new market opportunity, for the aquaculture sector.

CAVIAR PIRINEA and BETA Research Centre (University of Vic, Catalonia) will continue working on **nutrients recovering and pilot valorisation activities**, for both aquaculture and trout processing activities.

Introduction

Hydrogen sulphide (H_2S) has been suspected as a potential cause for sudden, unexplained mass mortalities in RAS producing Atlantic salmon postsmolts (Hjeltnes et al., 2019). Marine or brackish RAS are often rich in organic matter, creating ideal conditions for heterotrophic, sulphate-reducing bacteria. In the presence of nitrate and absence of O_2, organic matter should be preferentially used in denitrification, where nitrate is reduced to inert N_2 gas. In the absence of nitrate and oxygen, biodegradable organic matter can be respired with sulphate from sea water, creating highly toxic H_2S. Therefore, maintaining high concentrations of nitrate in RAS is commonly considered as mitigation strategy to reduce the risk for H_2S-events (Højgaard, 2017). However, it is currently not clear how much nitrate is required to prevent the formation of H_2S in sludge. In this study, we have investigated the total potential of H_2S production of sludge collected in RAS with Atlantic salmon in continuously stirred batch reactors. The aim was to investigate the stoichiometric relationship of biodegradable organic matter and nitrate on reaction rates and the total potential for H_2S-generation in RAS.

Material & methods

Sludge was collected as a compound sample from swirl separators connected to the bottom outlet of three RAS tanks from the same system, stocked with Atlantic salmon post smolts of approximately 280 g and operated with brackish water (12 ppt). The sludge was then homogenized and divided between respirometric cBOD assays (41 days, 20°C) and continuously stirred batch reactors to investigate H_2S production of sludge in presence of nitrate. After deoxygenating brackish water (12 ppt) with N_2 gas, 12 batch reactors were prepared with a fixed sludge dose (1% V/V sludge, 0.93 g DM/L, 1.17 g COD/L), and adjusted to variable nitrate concentrations (0, 30, 60 ,120 mg NO_3N/L) in triplicate . The airtight batch reactors (V = ~2 L) were then incubated at 12.4 °C ± 0.2 over 90 days. H_2S production was measured with the "Sulfulla" wet-chemical method previously published by Letelier-Gordo et al. (2020).

Results & discussion

Respirometric assays indicated that about 82% ± 1.7% (n = 4) of the COD in sludge was biodegradable, resulting in cBOD/N ratios of 30.9, 15.5 and 7.8 g cBOD/g N in our treatments with initial nitrate concentrations of 31, 62 and 123 mg NO_3N/L, respectively (COD/N 37.7, 18.9, 9.5). We found that nitrate did not only delay the initial H_2S response in our reactors (5 days for 0 and 30 mg/L NO_3N vs. 7 and 9 days for 60 and 120 mg/L NO_3N, respectively), but also reduced the overall amount of S^{2-} at the end of the experiment (38 g S^{2-}/L sludge and 24.4 g S^{2-}/L sludge for 0 and 120 mg NO_3N/L, respectively). Nitrate depletion in the treatments was confirmed after 3 days for 30 and 60 mg NO_3N/L and 5 days for the 120 mg NO_3N/L treatment, initial S^{2-} production rates were relatively similar between treatments (~0.6 g S^{2-}/L sludge/d, or 6.2 g S^{2-}/kg cBOD/d).

Taking the cBOD/COD ratio of 0.82 into account, we can account for close to 100% of the organic matter supplied to our reactors. Using a stoichiometric ratio of 2.86 g cBOD/g NO_3N for denitrification (Metcalf & Eddy, 2004), we calculated that about 30% of the biodegradable COD was used for denitrification in the 120 mg NO_3N/L treatments after 60-90 days (Fig. 1). Consequently, 2.67 ± 0.161 g of biodegradable COD was used to generate 1 g S^{2-} in our reactors, which closely matches the theoretical stoichiometric ratio of 2.67 g COD/ g S^{2-} for sulphate reduction of Tchobanoglous et al. (2004).

Conclusions

The presented results confirm that nitrate does delay and reduce H_2S production in continuously mixed batch reactors, showing a delay of 2-5 days in H_2S response of sludge collected from Atlantic salmon in RAS after the depletion of an alternative electron acceptors (O_2, NO_3) to sulphate at 12 °C. Furthermore, we highlighted the importance of carbon bioavailability in sludge for assessing H_2S risks in RAS by confirming the basic stoichiometric assumptions underlying organic matter degradation. Although nitrate can delay and reduce the H_2S response in mixed systems, more research is required to understand H_2S production dynamics in sediments and biofilms typical for RAS where diffusion could be a rate-limiting factor.

Introduction

Francisellosis induced by *Francisella noatunensis* subsp. *orientalis* (FNO), is a major threat to the global tilapia industry. There are no licensed vaccines currently available against the disease in tilapia. This study pretended to evaluate the efficacy of a newly developed inactivated autogenous vaccine against francisellosis.

Materials and methods

Nile tilapia fingerlings (1.7 g) free of FNO were recruited for the study. Group A (n=65) and B (n=65) were vaccinated by immersion with autogenous whole-cell inactivated and adjuvanted mono and tri valent FNO vaccines; these were prepared with FNO strains respectively homologous and heterologous to the challenge strain. Group C (n=43) and D (n=22) were vaccinated by immersion with a sterile physiological solution. Group A-D were infected with FNO ($3x10^7$ CFU) by intragastric route 25 days after vaccination and previous anaesthesia. During the 21 days following the infection (dpi) the animals were maintained at 22ºC and the health outcome was monitored twice a day. The number of clinical signs observed in each tank per 100 fishes throughout the study was used to calculate the Area Under the Curve. The efficacy of the vaccine was calculated as Relative Percentage Survival (RPS).

Results

The infection of group C produced mortality (65.12%) and clinical sign commonly observed in francisellosis. Results showed groups A-B showed reduced the mortality and thus achieved RPS of 71.65% and 55.11%. Moreover, the AUC of clinical signs was proportionally reduced compared to group C about 77.49% and 83.92%.

Conclusions

Previous authors demonstrated that immersion whole-cell inactivated vaccines can achieve about 50% of RPS when administered in fingerings and challenged with FNO by intraperitoneal route [1].

The gastrointestinal route is a natural getaway for bacterial infection. This study demonstrate it can be used to test the vaccine efficacy. The tested immersion vaccines reduced the mortality as well as the clinical signs produced by the FNO infection in fingerlings and achieved RPS which can be higher than 50%.

Therefore, the tested vaccine demonstrated to be a promising solution to control francisiellois in nile tilapia.

Introduction

Salmonids are very efficient in using lipids and proteins as energy source[1]. Dietary protein in excess to what is needed for growth and maintenance, is used as an energy source[2]. Protein is the more expensive part of a salmon diet while lipids are a comparatively cheaper ingredient. Replacing the energy resulting from an excess of protein in the diet by energy generated from lipids, while maintaining the same growth is known as the protein sparing effect of lipids[3]. However high levels of vegetable oil inclusion have shown to increase lipid accumulation in the liver[4] and cause issues such as altered immune response and disease resistance. In addition, the cost of vegetable oil has increased during last few years and thereby high energy diets increase the feed cost. Reducing the energy content of feed can improve profitability of a salmon farm and can help to overcome liver health issues. However, this would impact the overall growth performance. In this study, a nutrient absorption enhancer was used in low energy diets to enhance the performance and liver health in Atlantic salmon (*Salmo salar*) pre-smolt.

Materials and methods

The positive control diet was formulated to contain 49% protein, 26% lipids and a gross energy of 24 MJ/Kg. The negative control diet the was formulated to contain 49% protein, 20.5% lipids and a gross energy of 23 MJ/Kg. For the test diets, negative control diet was supplemented with 1kg/ton of an additive containing lysophospholipids and butyrate (Aquatria^{TM}) or with 1kg/ton bile acid. The study was conducted at the Experimental Aquaculture Unit, Catholic University of Temuco. Atlantic salmon pre-smolt of approximately 20g were stocked in 100-liter tanks, 34 fish per tank, 3 tanks per treatment. The fish were fed 3% of the biomass twice per day during the test period of 81 days. At the end of the study, the fishes were weighed to evaluate growth performance, and calculate weight gain, specific growth rate (SGR) and protein efficiency ratio (PER). Feed intake was recorded on a daily basis and feed conversion ratio (FCR) was calculated.

Livers of 3 fish of each tank were processed for histopathological evaluation of the degree of lipidosis. The classification described by Bernet *et al*.[4] and modified by Rosenthal *et al*.[5] was used, which defines five degrees of hepatic lipidosis ranging from grade 0 to grade 4.

Results

Growth results are summarized in Table 1.

Discussion and conclusion

Reducing the lipid and energy content of the positive control diet resulted in a decrease in specific growth rate and protein efficiency ratio and an increase in feed conversion ratio. Supplementation of the negative control diet with 1000 ppm of Aquatria reverted the negative impact of the reformulation. These results demonstrate that this additive offers the possibility to reduce the level of vegetable oil in a salmon diet without affecting the growth.

In addition, the improvement in liver condition that is observed with the fish fed the reduced energy diet, was further augmented by the addition of this additive.

INVESTIGATING THE USE OF DEFATTED *Desmodesmus* IN ATLANTIC SALMON FEEDS DURING THE GROW-OUT PHASE IN SEA

Introduction

The salmon farming industry requires sustainably produced feed ingredients of good nutritional value. Microalgae are excellent candidates for salmon feed ingredients as the algae industry is finding ways to commercially produce them in huge volumes and their nutritional profile is expected to favour the growth and welfare of Atlantic salmon. The major drawback linked to microalgae is the high production cost and hence, the produced biomass should also be diverted to manufacture high-priced pharmaceutical and cosmetic products for human use. Thus, effective utilization of the biomass and improvements in the production methods will progressively reduce the price of algae to a point where the cost will not be a deterrent for their utilisation in animal feeds. It is important that every microalgal fraction left as waste from the production of well-established, commercial products is used up to contribute to a circular economy.

In the present study, we explored the inclusion of defatted *Desmodesmus* in salmon feeds, a biorefinery co-product which is rich in proteins, carbohydrates, minerals and vitamins. In the experiment, performed at Langholmen, Norway (GIFAS), we investigated whether this ingredient has any effect on Altantic salmon key performance indicators (KPIs), flesh quality and composition, and fillet oxidative stability during cold storage.

Materials and methods

Six net pens (5 x 5 x 5 m) in sea were stocked with 80 salmon each (mean weight 1,8 kg), and the trial was run in triplicate pens. Two isoproteic and isolipidic feeds were fed to Atlantic salmon, *Salmo salar*: CTRL (control) and DX (feed containing 7.5% defatted *Desmodesmus* sp.). Daily feeding was carried out by hand and to satiation. Uneaten pellets were collected after every meal, using an underwater funnel and vacuum pump and quantified for accurate assessment of feed consumption.

At the trial start (November 2019), bulk weighing was performed to understand the total biomass in each pen. Each experimental fish was weighed when the trial was terminated in June 2020; i.e., once the size of the fish was more than double the initial size. The fat content and colour of the fillet was measured photometrically using PhotoFish (AkvaGroup AS, Norway). Intestinal morphology was evaluated by histology. Whole body was collected for assessing the proximate composition and energy content. Finally, the oxidative stability of the flesh was assessed during cold storage for the duration of 6 days (Dey, 2020).

Results

The feeding study was run for 197 days, with fish of initial weight 1,83 kg ± 0,02. The average weight of the fish at the end of the feeding period was 4,16 kg ± 0,17. The growth indicators SGR and TGC were not significantly different across dietary treatments. However, the FCR was significantly better in CTRL (1,13) than in DX (1,20). The K factor was also slightly but significantly higher in CTRL fish (1,32) compared to DX fish (1,26), indicative that CTRL fish had a more round (fat) shape.

Colour (in terms of both astaxanthin concentration and SalmoFan) and fat content in the fillet were not significantly different across the diet groups. Furthermore, whole body proximate composition did not show significant differences across dietary treatments.

Significant differences were noted in the fatty acid composition of the fillets from the two groups; the EPA level was lower in the DX group. However, the level of polyunsaturated fatty acids (PUFAs) was not significantly different between the 2 groups; including the DHA level.

(Continued on next page)

Finally, intestinal health was analysed by histological methods. The intestinal fold height and villus width were significantly higher in the DX group, indicating superior gut health. The width of the lamina propria was significantly lower suggesting the absence of inflammation.

The oxidative stability of fillet on cold storage indicated that although the primary oxidation product was higher in DX group on the 6th day, the secondary oxidation product did not show such a trend.

Conclusions

Results from this trial have revealed that defatted microalgae are suitable ingredients for salmon feeds. Differences in fatty acid composition across diets suggest that, even though the microalgal ingredient was defatted, it might still contain some lipids to justify these variations. Importantly, the microalgal diet DX gave superior gut health parameters than the CTRL feed. The observation on the fillet oxidative stability needs to be explored further.

THE OPTIMUM HARVEST TIME FOR CULTIVATED KELP SPECIES (*Saccharina latissima* AND *Alaria esculenta*) DEPENDS ON THEIR INTENDED APPLICATION

Michalek K*, Macleod AK, Ross M, Abell R, Stanley MS

The Scottish Association for Marine Science (SAMS), PA37 1QA Oban, Scotland, UK
Email: kati.michalek@sams.ac.uk

Interest and demand in cultivating seaweeds has been growing rapidly in Western Europe, driven by developing expertise and markets for food and non-food (cosmetics, pharmaceuticals, biofuel, etc.) applications. Kelp species such as the sugar kelp *Saccharina latissima* are most suited and prioritized for commercial culture due to their high growth potential and content of valuable compounds. Thus, they are favoured by research efforts informing the industry, answering questions such as the best time for harvest whilst often using biomass yield alone as the decisive factor.

We cultivated two kelp species (*Saccharina latissima* and *Alaria esculenta*) at our experimental seaweed farm on the West coast of Scotland and performed biweekly consecutive harvests throughout the harvest season (early March to July 2020; $n = 9$ harvest timepoints). Seaweed appearance (blade length and –width, fouling index), biomass yield, nutritional profile (%DW proteins, lipids, etc.) and composition (trace minerals, heavy metals, iodine) were followed over time and in conjunction with prevailing environmental conditions (seawater temperature, light, nutrient, and chlorophyll-a concentrations).

Overall seaweed appearance, quantity, and quality differed across species and harvest times. Maximum biomass yields were reached by mid-June for *Alaria esculenta* (5.46 ± 0.36 kg m^{-1}) and early July for *Saccharina latissima* (5.50 ± 0.65 kg m^{-1}), although yield estimates, blade appearance, but also some compositional parameters such as calcium levels were increasingly affected by heavy biofouling, progressing from epiphytic filamentous algae to calcareous epifauna (e.g. bryozoans, barnacles) during the study. For either species, harvest times of maximum yield coincided with low moisture, high cellulose but also highest iodine contents.

Our data highlight the dramatic variability in kelp performance, considering both biomass yield and -quality, throughout the harvest season as well as the complex relationship with key environmental cultivation conditions. In addition, our findings clearly show that there is no single optimum time for seaweed harvest but rather that this highly depends on the intended application of the product. As such, we recommend harvesting early in the season for food applications (low biofouling pressure and accumulation of heavy metals and iodine, but lower biomass yield) whilst the cultivation cycle can be extended, and harvest performed late in the season to maximise biomass yields and carbohydrate contents for e.g. biofuel production.

Introduction

EU-CONEXUS is a transnational European higher education and research institution that covers the smart urban sustainable coastal development from a global point of view. It was created in the framework of the European universities' initiative (2019) including six Partners: La Rochelle Université (FR), Universidad Católica de Valencia (ES), University of Zadar (HR), Agricultural University of Athens (GR), Technical University of Civil Engineering of Bucharest (RO) and Klaipeda University (LT). European Commission selected EU-CONEXUS Plus among other 20 European University alliances, under the 2022 Erasmus+ call, supporting the rollout of the European Universities initiative for 4 more years. In this further development of EU-CONEXUS, three new partners were integrated: South East Technological University (IE), University of Rostock (DE) and Frederick University (CY). The 9 partners from all European marine regions, develop education, research and innovation projects that include the totality of social, economic, technical and environmental problems and opportunities that the coastlines are facing today. Recent EU-CONEXUS activities related to aquaculture are presented.

Materials and Methods

EU-CONEXUS offers comprehensive, joint and flexible educational activities at all levels, trying to reach out to a larger and more diverse student and staff population and foster mobility (physical, virtual or blended), multilingualism and automatic recognition of academic qualifications. Work towards the European Student Card initiative is promoted, in an effort to strengthen European identity. The Alliance implements student-centered and challenge-based approaches to education, which relies on the active engagement of students in all activities of this European University, orchestrated by the Student Board. Joint educational actions have already been developed by creating two joint Minor programmes at the Bachelor's level, as well as joint study programmes for the Master and PhD cycle. Joint actions are also regularly organized for high schools in order to raise awareness on Smart Urban Coastal Sustainability (SmUCS). EU-CONEXUS is developing a Smart Campus, a virtual pedagogical environment to help students and teaching staff of each partner institution, to share information and work together remotely, offer virtual classes and set-up an EU-Career Center. Several tools and activities have also been developed to promote EU-CONEXUS Joint Research Area and the submission of joint research projects to international calls for proposals.

Results

The EU-CONEXUS European University, launched (2021) its first joint educational offer: the "Minor in Coastal Development and Sustainable Maritime Tourism" and the "Minor in Blue Economy and Growth". Each Minor programme consists of 5 sectors; each one of them offers several courses that each student is able to select. The first graduates were awarded a Minor Certificate (30 ECTS from minimum 2 sectors, 3 different EU-CONEXUS universities, 5 courses included in the Diploma Supplement). Certain courses are provided in both semesters by different partners and teaching collaboration is promoted. For example, the course "Aquaculture" is offered to students in autumn semester by AUA and in spring semester by UCV with a similar content and certain common lectures. The Joint Master Programme in Marine Biotechnology (JMPMB), starting in September 2022, is considered as the most ambitious project activity of the Alliance. EU-CONEXUS JMPMB has been selected by the Erasmus+ programme Erasmus Mundus Joint Masters (2022-2027, Project ID: 101050597) and will be able to offer more than 20 scholarships yearly to the best applicants in 2022, 2023, 2024, 2025. JMPMB is a 2-years full time study programme, taught in English with the following structure: (a) 1st semester: core courses in Marine Biotechnology (UCV, Spain), (b) 2nd semester: core courses in Marine Biotechnology (LRUniv,

(Continued on next page)

France) and internship (at any company in any country), (c) 3rd semester: a specialisation (optional courses taught online) from 4 tracks (Innovative Bioproducts for Future; Blue Biomass; Marine Biorefinery; Aquaculture Biotechnology) and "Academic Research Integration" course where groups of students from different tracks will work together on transversal research projects (in any partner university according to the chosen track by the student), and (d) 4th semester: Master Thesis in any partner. During the 1st week of May, UCV organised several activities within the framework of European Maritime Day. A Conference was held (Valencia, 3-4 May 2022) with presentations by professors and experts from universities of the EU-CONEXUS Consortium and companies dedicated to aquaculture (AVRAMAR and CROMARIS). Students of the Aquaculture course in the Minor Programmes have been invited to UCV, to have an 'Aquaculture Week' of physical training, and carry out the blended mobility (incoming students from Greece, Lithuania and Ireland). The students attended classes and laboratory practices together and also visited the fish cages of the AVRAMAR company for learning first-hand how the fish farms operate and more about the Mediterranean aquaculture. For High Schools, the 1st EU-CONEXUS Workshop (31 March 2022) was offered virtually (in English) to Greek students (16-18 years old). Experts of two EU-CONEXUS institutions (UCV and AUA) presented and had an interactive discussion with students on topics related to SmUCS such as: (a) Coastal risk, (b) Introduction and familiarization with Fisheries and Aquaculture sectors, (c) Career in Blue Economy: Opportunities and Challenges.

The 1st physical Research Workshop of EU-CONEXUS was held in AUA (Athens, 1-2 May 2022) organized by the Research Council. The perspectives in Smart Urban Coastal Sustainability Research Workshop brought together researchers from the 9 EU-CONEXUS Universities. Vice-Rectors of Research or their delegates, presented the institutional research profiles, with more than 90 researchers attending the four parallel sessions based on the thematic areas of the Joint Research Institutes (JRIs): Coastal Engineering, Environmental Science & Biodiversity, Life Science & Biotechnology, and Social, Cultural & Human Sciences. The (AUA) as an interconnectivity portal, where users have access on researchers and staff involved in EU-CONEXUS, their affiliations, scientific interests, past and ongoing projects, research infrastructures and research teams. In order to develop EU-CONEXUS Joint Research Area, partners have started to harmonize their research protocols and processes. As a result, Multilingual Laboratory Manuals (MLMs) are being produced by EU-CONEXUS. Several protocols on analyses related to aquaculture, biotechnology and other disciplines related to marine environment have already been developed and uploaded on EU-CONEXUS Protocol Portal. External services related to aquaculture are also offered by labs, of which several are accredited or are going to be in the near future, promoting excellence and quality in research.

Conclusions

EU-CONEXUS implement challenge-based and interdisciplinary approaches to education and R&I, deepening the link with the ecosystems related to SMUCS and the broader society to tackle societal challenges, foster entrepreneurial skills and societal engagement. Research in interdisciplinary issues is promoted within JRIs, as well as networking of researchers by the EU-CONEXUS Research Portal. This European University can help the production of knowledge for the sustainable future of European coastal areas and is constantly building new bridges with the society. EU-CONEXUS offers opportunities for synergies with industry and public authorities with smart solutions on Urban Coastal Sustainability, including responsible Aquaculture. Sustainable use of marine resources, fish nutrition, carbon footprint, environmental control, consumers' perception and professional profiles are important topics for cooperation with aquaculture industry. Educating students, even from high school, about the quality of aquaculture products, eco-friendly aquaculture, ecosystem services and the social dimension of aquaculture, is a significant benefit to the fish farming value chain.

WWF CREATING ACCOUNTABILITY IN GLOBAL FEED SUPPLY CHAINS

Danny Miller, M.Sc.

World Wildlife Fund
daniel.miller@wwfus.org

WWF's progress towards removing habitat degradation from the global food system is hampered by the lack of accountability in the animal protein and feed sector which drives deforestation and conversion. We seek to gain this accountability through the development of a feed ingredient decision support tool (DST) that is fueled by a global hub of information to evaluate environmental, social and governance (ESG) risks of ingredients as well as those that supply them.

Animal protein production is the largest driver of habitat change. Habitat degradation and the over-exploitation of natural resources also are linked to human rights abuse and worker mistreatment. Thus, the production of animal protein and food creates enormous stress on both people and the planet. WWF is currently in the early stages of a global movement to eliminate habitat degradation from food supply chains. While there is progress on the slowing of habitat conversion for the rearing of farmed animals (cows, chickens, fish and swine), the habitat conversion for animal feed ingredients continues to grow because of a lack of transparency, traceability and accountability in supply chains.

The challenge of producing more food with fewer resources will require intensification of the animal protein production sector. Intensification creates a greater reliance on formulated feeds and those feeds, and the ingredients used to make them, are not under the control of producers, yet producers are held responsible for liabilities and risks that may affect their customers (retail/food service), their investors or consumers. Retailers are increasing their attention on feed related issues (see Costco and Tesco letters of support), but investors are as well (see FAIRR letter of support) because their investments in food companies may become "stranded assets" if the risk in these supply chains is not transparent. Thus, it is not only WWF that is concerned about the sustainability of feed ingredients, forward thinking animal protein producers are spotting the trends that have landed major retail chains in court.

For animal protein producers to increase production in a responsible manner, they must be equipped with the knowledge and information that allows them to identify risks – in real time - in feed ingredient supply chains as well as changing market preferences and demands. The purpose of this project is to shine the light on where, how and who produces the ingredients used in feeds for animal protein production beginning with salmon aquaculture in order to begin the transformation of the animal feed sector. We are starting with salmon because the sector has worked together to achieve common goals already. This goal is to create an ESG risk-based DST that is powered by an AI-enhanced global information hub on current impacts of ingredient production such that the most accurate and current knowledge of the current science as well as environmental, social and governance impacts of ingredient production can be shared publicly and catalyze ingredient decisions that are based on current science and values aided by transparency which disrupt the status quo. The DST will allow animal protein producers to avoid ingredients and ingredient suppliers that create the greatest impact and pose the greatest reputational and financial risks to downstream supply chain actors.

Once released, the tool will have direct application to avoiding ingredients produced by the clearing of natural habitat (legal or illegal) for row crops (Brazil, Russia, USA, etc.). The tool will also provide information on the stock status of fisheries to avoid species that are over-exploited (Chile, Norway, USA, Peru, Europe (north Atlantic fisheries). Additionally, the safeguards that are desired for workers will be on display through the transparency of policies around labor and working conditions that occur in specific countries as well as specific locales. Utilizing the human risks component of the tool will raise greater awareness on how production of ingredients can occur while providing the necessities for human well-being of workers. Fundamentally, we are seeking to have global application of the tool and create a race to the top in terms of performance such that the right actors are being rewarded for the specific attributes we expect from those who were underperformers in the past.

This project builds on existing research on protein demand changes in the developing and least developed regions of the world, as well as the patterns of climate and habitat change that will shift supply chains to different regions of the world. WWF will also merge our current efforts to decouple habitat degradation from commodity supply chains with this project to provide greater consensus around the real and perceived impacts of feed and feed ingredient production.

(Continued on next page)

The work to create greater transparency and accountability in the animal feed sector is paramount for the sustainability of food systems. Without this accountability, feed ingredients will remain in the shadows and continue to consume a tremendous amount of the planet's resources. To our knowledge, this is the first effort to truly confront these issues with a lens to promote greater stewardship in resources used through the production of animal feed. The sustainability of animal feed is one of the greatest challenges for our food system with direct implications for the emissions that contribute to climate change, the conversion of our natural ecosystems that buffer humans from climate change and zoonotic diseases and the protection of the biodiversity in habitats threatened by conversion.

COMPARING OPPORTUNITIES AND CHALLENGES IN PRODUCTION SYSTEMS FOR SALMON AQUACULTURE

A. Misund*, T. Thorvaldsen, M. Thakur, A.V. Strand, R. Tiller

SINTEF Ocean, Postboks 4762 Torgarden, NO-7465 Trondheim, Norway
E-mail: Andreas.Misund@sintef.no

Introduction

Norway is a leading producer of Atlantic Salmon (*Salmo salar*) on a global scale. However, growth in production in conventional sea-based fish farming is curbed by challenges such as salmon lice and escape of fish. The industry is eager to innovate to solve these challenges. Policies to develop new concepts for aquaculture has also been initiated by the government (Føre et al. 2022). Currently, the Norwegian salmon aquaculture industry is characterized by rapid development, establishment and operation of new production systems including land-based, floating closed and semi-closed and open ocean aquaculture systems.

Regulation and localisation of new production systems requires knowledge about the systems. Applying a comparative perspective, the objective of this study is to provide knowledge of industry actors perceptions of challenges and opportunities related to new aquaculture production systems in Norway. This knowledge is valuable for a sustainable development and regulation of the industry.

The project “Compareit” is financed by the Research Council of Norway (grant number 319647). It is a *collaborative project to meet societal and industry-related challenges* conducted in close collaboration with key industry actors in the Norwegian aquaculture industry.

Materials and methods

To explore perceptions of industry actors, interviews, workshops, and document studies have been key methods. Interviews and workshops related to the following research questions: What are considered key challenges and opportunities within each production system? What are considered key challenges related to regulation of new concepts?

Results

For all new systems, the opportunity of production growth is seen as a key motivation. For the different systems, certain aspects are highlighted to obtain this in a sustainable manner. Land-based systems are designed to increase bio security (less patogens and contamination), and farmers aim to collect and utilize the organic material to create circular economy. Still, the industry required to process waste needs to be established to reach this ambition. Looking at challenges, disinfection of the water and formation of hydrogen sulphide are mentioned. The technology is considered complex, and energy use is potentially high.

Semi-closed and closed systems in the sea also require more energy than conventional sea-based fish farms to pump water into the systems, but these systems allow for using areas that are not suitable for conventional open net pens that are more sheltered in fjords etc. Furthermore, the opportunity to prevent sea lice and escapes are important drivers for this technology.

For open ocean aquaculture systems, key opportunities include utilizing new areas, better water quality, stable temperatures, and water exchange. Industry actors state that there is a need to acquire more knowledge about the challenges related to fish health and welfare in open ocean locations.

For new production systems, regulators must handle new issues and industry actors express that some of the processes are time-consuming and unpredictable. In the case of open ocean aquaculture for instance, the areas in question fall outside the responsibility of the municipalities, and the government are currently working on a new regulatory regime that aims to facilitate for production in new areas.

Conclusion

This study shows that both opportunities and challenges exist in different production systems for Atlantic Salmon in Norway. What the industry may look in the future depends on solving these challenges and establishing regulation that contributes to sustainable production for all production systems.

Literature

Føre, HM., Thorvaldsen, T., Osmundsen, TC., Asche, F., Tveterås, R., Fagertun, JT., Bjelland, HV. (2022) Technological innovations promoting sustainable salmon (Salmo salar) aquaculture in Norway, Aquaculture Reports 24

COST EXPLOSION IN SALMON AQUACULTURE: THE IMPACT OF DISEASES, PARASITE INFESTATIONS AND REGULATIONS

Bård Misund

Professor, University of Stavanger Business School, N-4036 Stavanger, Norway
Email: bard.misund@uis.no

Since the inception in the early 1970s, salmon aquaculture production has exhibited very high growth rates. However, in the last decade growth rates have fallen dramatically. Authorities' concerns with negative externalities from salmon farming arising from the impact of sea lice, diseases and escapees on wild salmon have led to stricter environmental regulation and reduced production growth. While numerous studies have examined the impact of sea lice and diseases on wild salmonids, very few studies have addressed the private costs of sea lice and diseases. The same environmental factors affecting wild salmon also have a negative impact on cost and fish welfare for farmed salmon. Over the last 15 years, production costs have increased by nearly 150 percent, and 40 percent just over the last 5 years. Using firm level data, we analyze the impact on cost variation from diseases, parasite infestations and regulations. Our results show that since 2012, cost heterogeneity has increased dramatically, and can empirically be attributed to increased private costs of sea lice infestations, suggesting that stricter regulation has resulted in an internalization of externalities from salmon aquaculture.

THE EFFECTS OF GARLIC (*Allium sativum*) AND HENNA (*Lawsonia inermis*) EXTRACT ON REDUCING THE FUNGAL LOAD OF FERTILIZED AND EYED EGGS OF RAINBOW TROUT (*Oncorhynchus mykiss*)

Alireza Mobarhan*, Ali Azimian

Department of Fisheries, Sanandaj Islamic Azad University, Iran
Email: dr.mobarhan@gmail.com

Green malachite is one of the aniline-colored products and is known to be mutagenic and carcinogenic. The use of this chemical compound in fish intended for human consumption has not been approved by the US Food and Drug Administration. Following the application of restrictions on the use of green malachite due to its very adverse environmental effects and the complete safety of garlic and henna plant extracts, this material was investigated as an alternative to green malachite.

This research was done in a completely practical way and in environmental conditions. In this method, five trays were selected, three trays with plant extract and two trays as control with green malachite and pure water with temperature conditions of 13 degrees Celsius with pH 5.7 and oxygen solubility of 6 mg/liter for 17 days.

From the green stage to the emergence of the egg with concentrations of 25, 50 and 70 mg/liter in the treatments with the extract and 3, 5 and 10 mg/liter in the green malachite treatment each with 3 repetitions by daily washing method for 1 hour was tested.

The results showed that the combined use of two extracts of garlic and henna with a concentration of 70 mg/liter had 70% survival in the egg hatching stage and based on statistical data, it had a significant difference with the samples and concentrations of the control treatments. It can be a suitable substitute for chemical disinfectants such as green malachite.

IDENTIFICATION OF THE MICROFLORA OF THE GASTROINTESTINAL SYSTEM OF RAINBOW TROUT (*Oncorhynchus mykiss*) AND THEIR POSSIBLE IMPORTANCE IN TERMS OF PROBIOTICS

Alireza Mobarhan*, Ali Azimian

Department of Fisheries, Sanandaj Islamic Azad University, Iran
Email: dr.mobarhan@gmail.com

Today, the role of the microflora of the digestive system in maintaining the health and comfort of animals is undeniable. The present study was carried out with the aim of identifying the microflora of the digestive system of rainbow trout and their possible importance in terms of probiotics. For this purpose, 20 rainbow trout fry weighing 2 grams were prepared and provided to the project, and during the growth period, disinfectants and antibiotics were not used. After the fish reached the desired weight, they were transferred to the laboratory and biometrically measured, and they were in the range of weight between 3010 grams and total length of 8 to 12 cm. After disinfection of fish with 70% alcohol and dissection with sterile tools, external intestine and preliminary and differential microbial culture including culture with Nutrient Agar, MacConkey Agar, TSI, TSA, SIM, MR-VP, Urease Test Broth, E.M.B, Starch media. Agar was done. Gram staining was used to identify bacteria. Also, biochemical tests and reagents including methyl red, Vojsprosquare-barite reagent, Coax reagent, oxidase-catalase test, sugar dough test in OF environment, gelatin decomposition test and starch hydrolysis test were used for definitive diagnosis of bacteria.

The results of this research indicate that the bacterial flora and their percentage in rainbow trout include *Edwardsillate sp.* (8%), *Cirobracer sp.* (10%), *Shewanella sp.* (30%), *Hawmophilus sp.* (2%), *Plesiomonas sp.* (25%), *Aeromonas sp.* (25%). Predominant flora with probiotic potential includes *Shewanella sp.*, *Plesiomonas sp.* and *Aeromonas sp.*

THE GROWTH POTENTIAL AND QUALITY OF MEAGRE (*Argyrosomus regius*) AT WARMER TEMPERATURES, A CASE STUDY FROM THE RED SEA

Introduction

Meagre is a widely diffused species that thrives in the Mediterranean but also in the Atlantic Ocean, from north Europe to equatorial Africa. The optimal texture and taste as well as its fast growth and environmental adaptability makes it an ideal candidate for aquaculture exploitation. The production of meagre, which occurs mainly in the southern part of the Mediterranean Sea, outlines how better growth performances can be achieved in warmer temperatures and in areas with milder winters. The scope of this research was to determine the growth potential, feed response and the body characteristics of meagre reared in warmer seawater, such as the Red Sea environment.

Materials and Methods

Two different trials involving juveniles of 115 g (Run 1) and pre-adults of 568 g (Run 2) were carried out in order to assess the growth potential of *Argyrosomus regius* at different growth stages. The fish in both trials were stocked in 1.1 m^3 tanks, with 41 juveniles stocked in triplicates per tank (4 kg m^{-3}) while pre-adult were stocked in number of 16 individuals (8 kg m^{-3}). Fish were fed twice a day for a period of 74 days. Four locally available commercial diets were used, with values of crude proteins and crude fat (CP/CF) for juveniles as follows: 47/14 (Diet 1), 46/13 (Diet 2), 47/12 (Diet 3) and 42/20 (Diet 4). For pre-adults the CP/CF values were similar to the juvenile trial, with the only exception of Diet 2, whose CP/CF was 48/14.

The water salinity in both trials was 41-42 g L^{-1}, while temperature was 25.32 ± 1.21 °C in Run 1, and 27.34 ± 0.7 °C in Run 2.

Fish data was analyzed using one-way ANOVA followed by Fisher Least Significant Difference (LSD) test to compare significant differences between treatments.

Results

The juvenile fish grew between 130 to 209 g during the 74 days of feeding. Final body weight was statistically higher in Diet 1 (324g) than in the other ones (range 295-246 g). Specific growth rate (SGR) resulted highest in Diet 1 with 1.4 ($P < 0.05$), medium in Diet 4 (1.25) and lowest in Diets 2 and 3 (1.00 and 1.04 respectively). The FCR was higher in Diets 1 and 4 (1.09 and 1.18) than Diet 2 and 3 (1.52 and 1.41).

The final body weights of pre-adult fish resulted highest in Diets 1 and 2 (770 g and 733g). Similarly SGR for the same diets were respectively 0.40 and 0.37, higher than Diets 3 and 4 (0.17 and 0.14). The FCR was not statistically different in Diets 1 and 2 (1.61 and 1.85).

The protein efficiency ratio in juveniles was statistically higher in Diet 1 and 4 (1.82 and 2.17 respectively), and in Diets 1 and 2 for pre-adult (1.33 and 1.08).

Proximate composition of the body of pre-adult fish showed no differences in crude protein % but showed higher level of crude fat % in Diets 2 and 4.

(Continued on next page)

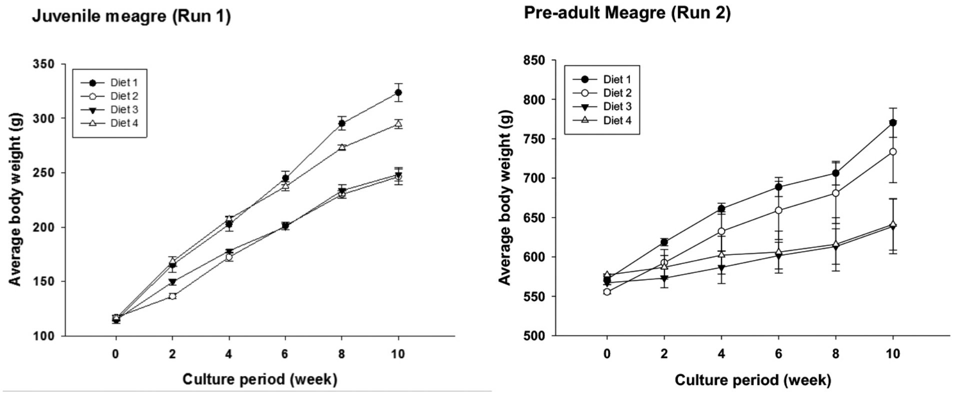

Fig. 1. Average body weight of juvenile and pre-adult meagre fed the different commercial diets. Values represent means ± S.E.M. (n=3)

Discussion

The current study showed that the growth performances of meagre were comparable to other researches carried out at lower temperatures or salinities. In Run 1 the performances were comparable to the FCR of 1.2 obtained by Martínez-Llorens et al., (2011) using 47% CP and 20% CF. In juveniles the SGRs were similar or higher than the values found in the literature. In pre-adults the FCR showed similar or even better results than most of the papers with same body weights. However SGRs were slightly lower than the 0.57 obtained by Gültepe et al. (2016) or the 1.77 obtained by Velazco Vargas (2014). The proximate concentration of the carcass of the fishes showed higher percentages of proteins compared to the 15.8-16.7 % of Carvalho et al. (2018).

Conclusions

Meagre tested in the Red Sea conditions proved comparable growth with all the scientific researches carried out in the Mediterranean Sea, particularly for juvenile fish. Some suboptimal performances in pre-adult fish could be motivated by the higher temperatures, the small size of the pellets as well as some nutritional flaws determined by the use of commercial feeds not specifically formulated for meagre.

DIFFERENT METHODS OF OVULIN HORMONE INJECTTION ON STREES INDICIES (GLUCOSE AND CORTISOL) OF CASPIAN CARP (*Cyprinus carpio*)

Majid Mohammad Nejad*, Hajimohammad Shirmohammadli, Khadijeh Eslami

Department of Fishery, Bandar Gaz Branch, Islamic Azad University, Bandar Gaz, Iran. P. O. Box: 48715-119
E-mail: majid_m_sh@bandargaziau.ac.ir

Introduction

Glucose and cortisol are important indicators in assessing the level of stress in living organisms. Blood glucose is the most variable index that is greatly affected by handling, transportation, environmental stress, seasonal changes, nutritional status and maturity (Hosseini Fard et al., 2013). Cortisol in bony fish affects reproductive function and gamete growth. Cortisol, an important corticosteroid produced during the spawning season, can suppress fish immunity (Odhiambo et al., 2020). Inducing sexual maturation in fish can be stressful and can have an adverse effect on fish reproduction. Hormone injections into fish for the purpose of inducing reproduction, in addition to affecting the levels of sex steroids, can cause changes in fish's blood stress indices (Falahatkar et al., 2016). Therefore, it is important to use a method that puts the least stress on the fish. In this study, different methods of injecting the Ovulin hormone on glucose and cortisol of Caspian carp were studied.

Materials and Methods

12 Caspian carp were injected in three methods in one time: injection under the pectoral fin, injection under the dorsal fin and injection under the ventral fin at a dose of 0.6 ml / kg of Ovulin hormone. Blood samples were taken from male and female broodstocks with 5 cc syringes and from fish tail arteries in two stages (before hormone injection and 12 hours after hormone injection). In the hematology laboratory and after centrifugation at 5000 rpm, serum was isolated from blood cells for 5 minutes and glucose and cortisol levels were measured by automated devices. All statistical analyzes were performed using SPSS software version 26. Shapiro-Wilk test was used to investigate the normal distribution of data in groups and for all variables. One-way analysis of variance (Oneway ANOVA) was used for statistical comparison between groups, and after performing the Test of Homogeneity of Variances and Duncan test was used to compare groups with each other (Mohammad Nejad, 2022).

Results and Discussion

The results of glucose and cortisol analysis in male and female broodstocks of Caspian carp showed that in both sexes and in all three injection methods, its amount increased after hormone injection (Tables 1 and 2).

The amount of stress increase due to hormone injection in both male and female broodstocks in the method of pectoral fin and dorsal fin was more than the method of injection under the ventral fin. The comparison between the two broodstocks also showed that the increase in stress in the female broodstocks was more than the male broodstocks. These results were consistent with the study of changes in stress indices of *Cyprinus carpio* in different stages of artificial reproduction (Mohammad Nejad, 2022). The results of this study show that hormone injection is effective in increasing stress in Caspian carp. Consistent with the results of this study, injection of various hormones in artificial reproduction increased glucose and cortisol levels in some fish (Mohammad Nejad, 2022). Almost any type of stress (physical and neurological) causes an immediate and pronounced increase in ACTH secretion and within minutes leads to a sharp increase in cortisol secretion from the cortical part of the adrenal glands. One of the many effects of cortisol is to increase the body's resistance to stress by reducing glucose uptake, so as cortisol increases, blood glucose levels also increase rapidly (Saha et al., 2003), which was also proven in the current study. Due to the injection of Ovulin hormone in male and female broodstocks, the amount of cortisol increased due to stress and then the absorption of glucose from the blood decreased and as a result, the amount of glucose in the blood serum increased.

However, the relationship between stress and reproductive hormones of Caspian carp was not investigated in the present study but, the relationship between stress and its indicators with sex hormones in fish has been proven. The effect of cortisol on reducing estradiol and testosterone has been reported in some fish (Falahatkar et al., 2016). Therefore, using a method that can put the least stress on the fish during the breeding process is important and necessary. The results of the present study show that hormone injection by injection method under the dorsal fin can cause less stress to the Caspian carp, so it is recommended compared to the other two methods in the reproduction of this fish.

(Continued on next page)

Table 1: Stress indices of female broodstocks of caspian carp in different methods of Ovulin hormone injection

Stress index	Injection area	Before injection	After injection
Glucose	Pectoral fin	79.5 ± 5.5^{a}	$125 \pm 4^{a*}$
	Dorsal fin	72.5 ± 4.5^{a}	$113.5 \pm 4.5^{a*}$
	Ventral fin	68 ± 6^{a}	$108.5 \pm 5.20^{a*}$
Cortisol	Pectoral fin	8.84 ± 0.43^{a}	$114.5 \pm 7.5^{a*}$
	Dorsal fin	7.88 ± 0.47^{a}	$21.25 \pm 1.15^{b*}$
	Ventral fin	9.39 ± 3.84^{a}	$108 \pm 4^{a*}$

Non-common Latin letters for each index in each column indicate the difference between the injection methods and the * in the row indicates a statistically significant difference before and after the injection ($p < 0.05$).

Table 2: Stress indices of male broodstocks of caspian carp in different methods of Ovulin hormone injection

Stress index	Injection area	Before injection	After injection
Glucose	Pectoral fin	49.5 ± 3.5^{a}	$91 \pm 3^{ab*}$
	Dorsal fin	55.5 ± 4.5^{a}	$121 \pm 5^{a*}$
	Ventral fin	48.5 ± 6.5^{a}	$83.5 \pm 10.5^{b*}$
Cortisol	Pectoral fin	16.15 ± 0.75^{a}	$27.7 \pm 0.5^{a*}$
	Dorsal fin	13.55 ± 0.77^{a}	17.95 ± 3.25^{b}
	Ventral fin	9.03 ± 0.89^{b}	$28.8 \pm 1.4^{a*}$

Non-common Latin letters for each index in each column indicate the difference between the injection methods and the * in the row indicates a statistically significant difference before and after the injection ($p < 0.05$).

Introduction

With the continuous growth of the human population and the increase in per capita fish consumption (FAO, 2022), aquaculture represents a great opportunity as a global food source, being a solution to mitigate overfishing. One of the problems in the aquaculture industry is the use of fish meal and fish oil as sources of proteins and lipids for feeds, especially in carnivorous species such as greater amberjack (*S. dumerili*). Therefore, it is necessary to look for alternative ingredients to make their farming more sustainable and, perhaps, more profitable. Considering that feed in the aquaculture industry accounts for around 60% of production costs (APROMAR, 2022), the use of plant sources as raw materials is not only interesting from sustainability, but also from profitability. However, in carnivorous species, the use of plant sources can have adverse effects due to lower digestibility, so a solution could be the use of biotechnological treatments to increase the bioavailability of their nutrients, as has been demonstrated with microalgae (Agboola et al., 2019; Molina-Roque et al., 2022). Furthermore, the benefit of including nutraceutical compounds in the diet has been demonstrated on numerous studies (Dawood et al., 2015; Kader et al. 2013; Perera et al., 2020), so the addition of this type of ingredient in the diet of carnivorous species could mitigate the possible adverse effects of using plant sources.

Material and Methods

A total of 225 individuals (initial body mass, ~ 6 g) were distributed in 9 tanks of 400 L, which constituted the 3 experimental groups (in triplicate): i) Control, fed with standard formulation; ii) PP, feed with 50% protein from plant sources enzymatically treated to increase their bioavailability; iii) PP-LB, similar to the PP diet, but with the inclusion of 3% nutraceutical compounds. After 69 days of *ad libitum*-feeding trial, a final biometric sampling was performed, and samples from plasma, liver and intestine were taken. Somatic and zootechnical indices were calculated, and samples from each tissue (plasma and liver metabolites, circulating cortisol levels and intestinal resistance as a measure of intestinal integrity) were analysed.

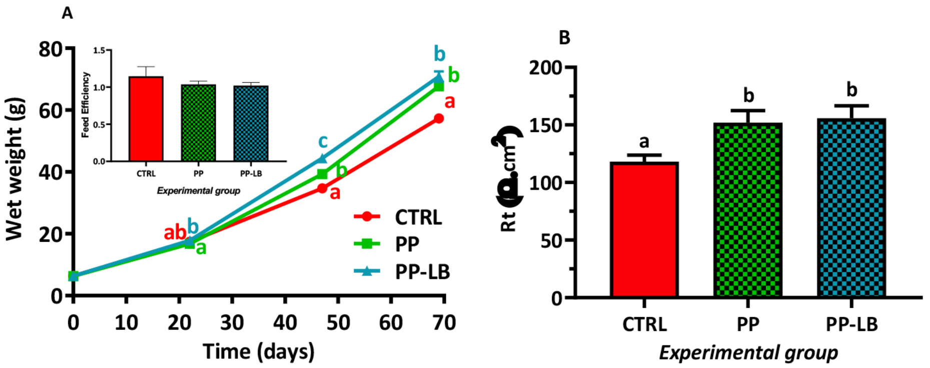

Fig. 1. Evolution of the wet weight and feed efficiency (**A**), and intestinal epithelial resistance (**B**) of *S. dumerili* juveniles fed with the three diets. The results are expressed as the average ± SEM (n = 12 fish). Different letters represent statistically significant differences at a p-value<0.05 resulting from the one-way ANOVA analysis.

(Continued on next page)

Results and Discussion

The results indicated an increase in growth performance with the two experimental diets (PP and PP-LB) associated with a stimulation of fed intake, gut elongation and favourable metabolic orchestration, despite a slight increase in circulating cortisol levels. In fact, the moderate presence of cortisol stimulates the production of neuropeptide Y (NPY), which promotes feed intake (Bernier et al., 2004) and increases absolute metabolic scope (Pfalzgraff et al., 2022), which would support the results observed about growth performance with the two experimental diets. Furthermore, with the use of electrophysiological analysis of the intestine, a significant increase in epithelial resistance has been observed, resulting in increased selectivity and integrity of the intestine in the specimens fed with the two experimental diets, and demonstrating a good intestinal health.

All these results demonstrate an improvement in nutrient assimilation and utilisation, which leads to a higher energy investment for somatic growth, indicating that the use of pre-treated plant-based raw materials is optimal in a high-growing carnivorous species.

IMPROVED FERTILIZER MANAGEMENT FOR SMALL TO MEDIUM SIZED COMMERCIAL DECOUPLED AQUAPONIC SYSTEMS

Hendrik Monsees[a], Rebecca John[a], Gösta Baganz[a], Georg Staaks[a], Werner Kloas[a], Daniela Baganz[a]

a Leibniz-Institute of Freshwater Biology and Inland Fisheries, Müggelseedamm 310, 12587 Berlin, Germany
*E-mail: h.monsees@igb-berlin.de

Introduction

The potential of becoming one of the most effective sustainable production systems for the combined production of animal protein and plant crops is attributed to decoupled aquaponic systems (Kloas et al. 2015, Monsees et al. 2017). Here, recirculating aquaculture systems for fish production are combined with hydroponic systems for soilless plant production allowing individual management of each single compartment thereby recycling dissolved nutrients derived from metabolism of the fish. Nevertheless, professional adjustment of selective micro- and macro-nutrients can be very expensive, especially for small to medium aquaponic operations (e.g. complete lab analysis of RAS-derived water). Therefore, (i) one of the aims of this study is to provide cost effective strategies for nutrient management in aquaponics systems. In order to meet specific plant requirements, the knowledge on nutrient concentrations as well as predictable patterns and trends in the RAS water is pertinent for correct fertilizer addition. Consequently, further aims are to (ii) identify the origins of macro- and micro-nutrient and to find accumulation patters, as well as the attempt to predict their general trends, and nutrient dynamics (N,P,K), (iii) to meet plant needs as close as possible according to a professional fertilizer management in hydroponic production units.

Material & methods

Literature values from RAS and aquaponic applications were collected with regard to predefined boundary conditions. Additionally, water samples were collected from different research or commercial RAS or corresponding aquaponic facilities. Micro- and macro-nutrients were analyzed using continuous flow analysis (CFA) and inductively coupled plasma-optical emission spectrometry (ICP-OES). Models were tested in a first trial with two different treatments against a hydroponic control (n = 3, 10 lettuce plants per replicate).

Results

General nutrient patters for RAS and aquaponic facilities were identified and used for the development of models. The first results of the model testing in a hydroponic setup revealed that lettuce can be effectively produced in an aquaponic setup without the need for detailed nutrient analyses. The lettuce growth was comparable between both aquaponic applications, but significantly reduced by 10 % compared to the hydroponic control (Fig. 1).

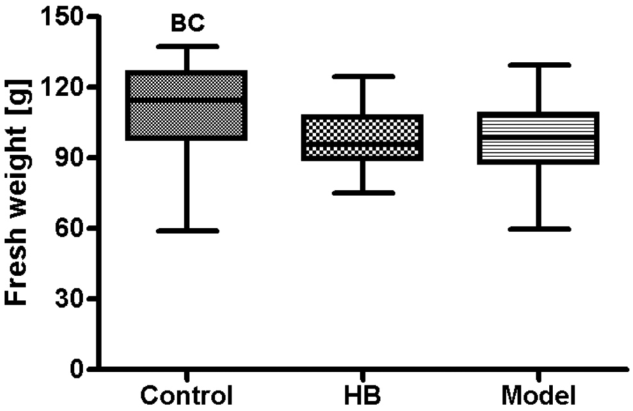

Fig. 1. Lettuce growth in three different hydroponic treatments. C = control, tab water based nutrient solution; HB - aquaponics, fish water based nutrient solution with supplemented nutrients after detailed nutrient analyses; Model - like HB, but without detailed nutrient analyses prior to nutrient supplementation. The three different treatments were applied in triplicates, each with ten individual lettuce plants.

(Continued on next page)

Discussion

The potential of identifying and using nutrient patterns in RAS and aquaponics for a combined production of fish and plants in a decoupled aquaponic approach were clearly shown in this study. By applying this easy approach, professional nutrient management can be simplified for small and medium aquaponic producers. The first results are very promising, showing that overall aquaponic yield is not affected with respect to the type of nutrient management. The post adjustment of the nutrient profile using fish water for professional hydroponic application was more challenging as in conventional hydroponics (with rain water or tap water) but it was demonstrated that for most nutrients the set points were reasonably close to the recommended nutrient concentrations as it was also shown in other studies (Suhl et al. 2016, Monsees et al 2019).

Additionally, the authors are very optimistic that with ongoing professionalization and standardization of practices in decoupled aquaponic technology, more farmers will adapt towards professional management approaches and that comparable yields to conventional hydroponic production can be expected, as it was already show e.g. in Monsees et al. 2019.

Introduction

Among the impacts produced by the aquaculture industry, fish escapes are considered one of the most harmful in terms of wild population unbalances. Developing reliable traceability tools becomes essential to assess escape events extent and ecological consequences. Bio-morphological analysis have been extensively used to differentiate geographically separated populations as well as wild stocks from aquaculture counterparts. Former studies made use of body shape and solid structures such as scales and otoliths to determine fish origin [**1**]. Somatic growth patterns are reflected in these structures by means of mineral layer depositions, which are known to be related to life phases, seasons, and habitat transgressions. Nonetheless, little is known about how they adjust their morphology through feralisation processes, meaning a potential bias for stock identifications. Considering the solid background of otolith growth rings and microchemistry as traceability markers, the present study explores differences between wild, farmed and escaped fishes according to otolith external macro and microstructure.

Material and Methods

We collected 131 sea breams (*Sparus aurata*), 135 sea basses (*Dicentrarchus labrax*) and 76 meagres (*Argyrosomus regius*) from fish markets located in the Spanish East Coast (C. Valenciana and Murcia regions). Based on body shape analyses [**1**], fish distribution by origin was established (Fig.1-A). After labelling, weighting, and taking biometrics, we performed dissections and extracted otolith larger fractions (pair of *sagittae*). Once clean and dry, we took bird-eye pictures of the left *sagittae* piece, placing the *sulcus acusticus* (groove) face upwards (Fig.1-B). We enhanced otolith shape by increasing the contrast with reflected light. Resulting pictures were processed in two diverse ways: 1) univariate morphological descriptors (uMDs) measurement (area, perimeter, roundness, circularity, axis length and aspect ratio); and 2) Fourier analysis based on Elliptic Fourier Descriptors (EFDs) [**2**]. Briefly, it decomposes two-dimensional closed silhouettes into a set of ellipses or EFDs. Using applied software such as SHAPE, EFDs can be transformed into numerical coefficients (a, b, c, d) that, in turn, can be used to compare the shape of two or more sets of figures.

Prior to statistical analysis, we removed allometry effect over data from uMDs by Burnaby vs Standard normalization. Regarding EFDs normalization, we prevented any figure orientation or rotation angle effect over the analysis by subtracting the first 3 coefficients from the first EFD of each sample. To check normalization effectiveness, we used a data resemblance matrix by Euclidean distance and performed PERMANOVA analysis with length (TL) as covariable ($p < 0.05$; perm: 9999).

Searching for morphological divergence between otoliths from origin groups (Wild (W), Farmed (F) and Escaped (E)), we conducted several statistical tests: 1) Principal Component Analysis and 2) Discriminant Function Analysis based on uMDs and 3) Principal Component Analysis using EFDs coefficients.

Results

Principal component analyses allowed us to visually separate origin groups in different data clouds, enclosed within 3 ellipses (Fig.1-C). Both, uMDs-based and EFD coefficients-based, displayed the same tendency: the three ellipses overlapped to a greater or lesser extent. However, farmed and escaped groups showed a more similar data dispersion range compared to wild. Otoliths from wild individuals tend to reflect a lower diversity regarding shape, especially in *S. aurata*. Focusing on microstructure, PCAs link *S. aurata* otoliths morphological variations to changes in ostium opening, post-cauda angle and overall roundness. *D. labrax* otoliths mainly differ in post-cauda and rostrum angle. *A. regius* displays slight differences in post-ventral margin roundness and lateral irregularities. DFA displayed precision rates from 50 to 77%, a low accuracy.

(Continued on next page)

	Wild	Farmed	Escaped
S. aurata	91	20	20
D. labrax	30	27	78
A. regius	*	17	59

Fig. 1. A: Sample distribution by species/origin. *No evidence of wild *A. regius* populations in the studied area; B: Sea bream otolith regions/structure; C: PCA based on Elliptical Fourier Descriptors for wild, farmed and escaped groups.

Discussion

Overall, there were no significant differences between wild, farmed and escaped fishes in regard to otolith external morphometry. Supporting former literature [**1**], otolith shape should only reinforce scales or body morphometrics. However, data dispersion and overlapping degree among groups provided insightful information. On their journey to the wildness, escapees are subjected to stressors such as lack of resources or shifts in social and physical conditions. Success or fail depends on a balance between phenotypical plasticity and selective pressure. By contrast, aquaculture farms ensure survivability by granting abundant/constant food resources, lack of predators, disease control... favouring wider otolith shape diversity. Moreover, otolith macro- structure appears to be resilient trough feralisation over extended periods. Last, we have identified species-specific regions susceptible to suffer microstructural changes. We are currently balancing our data and exploring fish origin effects on otolith long-term development.

REPLACING FISH OIL BY SUSTAINABLE MARINE LIPID SOURCES IN DIETS FOR TURBOT (*Scophthalmus maximus*): EFFECTS ON GROWTH PERFORMANCE, NUTRIENT BALANCE AND MUSCLE FATTY ACID COMPOSITION

M. Monteiro[1], A. Marques[1], F. Piloto[3], M.A. Salgado[1,3], C. Castro[4], F. Soares[2], L. Conceição[2], L.M.P. Valente[1,3]

Introduction

Fish oil (FO) is the ideal lipid source for carnivorous marine fish diets due to its high digestibility and high essential fatty acids content, particularly long-chain polyunsaturated fatty acids (LC-PUFA) such as eicosapentaenoic acid (EPA) and docosahexaenoic acid (DHA). Given FO limited supply, sustainability issues, and increasing costs, alternative lipid sources must be found. Replacing FO is not a simple task as often the alternative sources modify tissue fatty acid (FA) composition and may compromise the nutritional benefits associated with fish human consumption. Thus, in the present study, the potential of sustainable marine lipid sources was evaluated in turbot (*Scophthalmus maximus*) focusing on the dietary effects on growth performance, nutrient balance, and body FA composition.

Materials and methods

Six extruded isoproteic (60% dry matter - DM), and isoenergetic (22 kJg^{-1} DM) diets were formulated (Table 1). The control diet (CTRL) included FO (sardine oil) and rapeseed oil as the main lipids sources and was formulated to include 2.7% EPA+DHA. The other five diets included different marine lipid sources to partially and totally replace FO and fortify turbot muscle in omega-3 LC-PUFA, without major increase in production costs: algae oil (ALGASARDINE), salmon oil (a co-product from the salmon industry) and a blend of microalgae (ALGAESSENCE). A FO-based diet was also included as a positive control (SARDINE). In ALT1 and ALT2 diets, FO was totally replaced by salmon oil and algae oil and fishmeal was replaced at 30% by *Tenebrio molitor* meal and a protein concentrate from *Corynebacterium glutamicum*. Fish (150 g) were reared in a commercial farm (~15 °C) and fed twice a day at apparent satiation. After 75 days, growth performance, feed efficiency and total lipids and FA profiles in whole body and muscle were determined.

Results

All groups of fish almost doubled their initial body weight and there were no differences in growth performance and feed utilization amongst dietary treatments. FO replacement had a clear effect on FA muscle deposition. EPA gain was highest in fish fed CTRL, SARDINE and ALGAESSENCE diets, while docosahexaenoic acid (DHA) gain was highest in the ALT1 group. No significant differences were observed in EPA+DHA retention. All experimental groups presented low muscle lipid levels (< 1%) and similar EPA+DHA levels. Fish fed ALGAESSENCE were the only ones able to surpass EFSA recommended EPA+DHA levels for human consumption (275.5 mg 100g^{-1}); ALT2 group exhibited values equivalent to SARDINE (~ 230 mg 100g^{-1}) and for the remaining dietary treatments values of 215 mg 100g^{-1} were obtained.

Table 1 – Protein, lipid sources, expected EPA+DHA and estimated cost of the experimental diets

	CTRL	**SARDINE**	**ALGASARDINE**	**ALGAESSENCE**	**ALT1**	**ALT2**
Ingredients (%)						
Fishmeal LT70	55.0	55.0	55.0	55.0	38.5	38.5
Tenebrio meal	-	-	-	-	7.0	7.0
C. glutamicum	-	-	-	-	2.5	2.5
Sardine oil	7.0	10.7	5.4	9.5	-	-
Salmon oil	-	-	-	0.7	8.0	6.0
Algae oil	-	-	2.7	-	2.9	4.9
Rapeseed oil	3.8	-	2.7	-	-	-
Blend of algae	-	-	-	2.0	-	-
EPA+DHA	**2.7**	**3.7**	**3.7**	**3.7**	**2.7**	**3.7**

(Continued on next page)

Discussion and conclusions

Replacing up to 100% of fish oil with the alternative lipid sources did not significantly affect fish growth performance or feed utilization in *S. maximus*. All fish presented similar muscle EPA+DHA values, but only the ALGAESSENCE fed group reached values above EFSA recommendation (275.5 mg $100g^{-1}$) for preventing cardiovascular diseases. This suggests that the combination of alternative sources of lipids, and particularly the inclusion of an algae blend (ALGAESSENCE) may be a viable alternative for replacing FO in turbot diets.

This trial was carried out in juveniles under commercial conditions often variable and difficult to control. In order to carry out further evaluation of the impact of diets with different fatty acid compositions, the use of an energy-protein flux model coupled with a fatty acid dilution sub-model is envisaged, which will allow us to predict fish growth and muscle LC-PUFA deposition for different scenarios. This tool will help defining best strategies and finishing diets adapted to a particular farm.

Introduction

The aquaculture industry and scientific community have been trying to shift to a lower usage of marine-harvested resources, such as fish meal, in aquafeed production. Low trophic marine species, like Polychaeta, can contribute to practices able to support a sustainable blue economy. They are potential candidates for bioremediation of aquaculture waste and may be a viable alternative protein source to fish meal due to its high protein content and high levels of ω3 LC-PUFA. They are also rich sources of bioactive compounds able to modulate fish immunological system and/or stress response.

The overall aim of this study was to assess the potential of Polychaeta meal to replace fish meal in European seabass diets assessing growth performance, nutrient utilization, whole-body composition, muscle fatty acid profile, and liver lipid metabolism.

Materials and Methods

A growth trial with European sea bass (*Dicentrarchus labrax*) juveniles (14.5 g) was performed using four isoenergetic (22% dry matter, DM), isoproteic (51% DM), and isolipidic (17% DM) diets. A fish meal-based diet (FM, control) was compared with three experimental diets including 2.5% (PM2.5), 5% (PM5) and 10% (PM10) of spray dried Polychaeta meal (PM, *Alitta virens*), to replace 10%, 20% and 40% of FM, respectively. All experimental diets were extruded by Nofima (Norway). Triplicate homogeneous groups of fish per treatment were divided by twelve 160 L fiberglass tanks and fed by to satiety using temporized automatic feeders, three times a day (9h, 12h, and 16h), for 93 days. The fish were subjected to a 12-h light/12-h dark photoperiod regime and kept in a recirculating saltwater system (salinity 35‰, 22 ± 1 ºC).

At the end of the growth trial, all fish were individually weighed and measured. Five fish per tank were sampled for whole-body composition; other 6 fish were sampled to collect dorsal muscle for total lipid and fatty acids analysis and liver samples for analysis of lipogenic enzymatic activity. The remaining fish were used for a digestibility trial to evaluate the apparent digestibility of crude protein, crude fat, and gross energy in the diets using yttrium oxide as an inert marker.

Table 1 – Growth performance and feed intake of European sea bass fed the experimental diets for 93 days. Values represent the mean ± standard deviation.

	Diets			
	FM	PM10	PM20	PM40
IBW	14.47 ± 0.03	14.52 ± 0.01	14.49 ± 0.02	14.52 ± 0.01
FBW	76.67 ± 0.23	78.07 ± 1.60	79.10 ± 3.80	77.77 ± 3.01
K	1.17 ± 0.03	1.21 ± 0.01	1.19 ± 0.04	1.19 ± 0.01

PER	1.84 ± 0.07	1.89 ± 0.03	1.87 ± 0.02	1.90 ± 0.06

IBW– initial body weight (g); FBW – final body weight (g); K – final condition factor; DGI – daily growth index; VFI – voluntary feed intake; FCR – feed conversion ratio; PER – protein efficiency ratio.

(Continued on next page)

Results

All fish accepted very well all experimental diets. Replacement of FM by PM had no effect on the voluntary feed intake, daily growth index (2.0), or feed conversion ratio (1.0) of the fish (Table 1). Hepatosomatic and viscerosomatic indexes also remained similar among treatments. Nutrient retention and gain, flesh fatty acid profile, and liver lipid metabolism results will be further analyzed and discussed.

Discussion and Conclusion

The present results indicate that PM can successfully replace FM up to 40%, without impairing feed intake, growth performance, and nutrient utilization. Thus, this invertebrate marine biomass seems a viable new ingredient for sea bass diets, replacing fish meal and contributing to food security. However, the functionality of Polychaeta meal remains to be explored.

SALINE WASTEWATER FROM FISH AND OYSTERS TO GROW DIFFERENT SPECIES OF HALOPHYTES IN GREENHOUSE

Ivo Monteiro[1*], Maria João Rodrigues[2], Viana Castañeda-Loaiza[2], Hugo Ferreira[1], Morgana Angelo[1],
Florbela Soares[1], Pedro Pousão-Ferreira[1] and Luísa Custódio[2]

[1]IPMA, Aquaculture Research Station, Olhão, Portugal
[2]Centre of Marine Sciences, University of Algarve, Faculty of Sciences and Technology
Ed. 7, Campus of Gambelas, Faro, Portugal
E-mail: ivo.monteiro@ipma.pt

The rapid growth of the aquaculture production over recent years has led to a significant increase in marine wastewater being discharged to natural ecosystems following the use of seawater in fish production. This waste effluent contains high concentrations of nitrogen, phosphate and nitrate and organic compounds, resulting in a serious environmental problem. Recent studies have demonstrated a strong positive relationship between biochemical oxygen demand (BOD), nutrient loading of discharged wastewater, and the emergence of eutrophic conditions (Anh *et al.* 2021). Therefore, treatment prior to discharge to meet environmental regulation, which are becoming more stringent, and protect the environment, are required for these purposes. Physical-chemical treatment methods typical have higher infrastructure and operational costs associated than the implementation of a multi-trophic aquaculture (IMTA) approach, which contribute to the reduction of the environmental impacts while adding further income by producing crops with commercial food and/or medicinal uses. However, salinity represents a significant inhibitor to most of the crops, based in glycophyte plants (Duan *et al.* 2022). Even with transgenic or genetic approaches, it has been proven difficult to bread salt tolerant cultivars, due to the complex physiology of salt tolerance mechanisms in plants. So, in this context, the utilization of salt tolerant species (halophytes) is imperative.

Halophytes are able to complete their life cycles at hypersaline (at least 300 NaCl), highly UV radiation and extremely fluctuating temperatures environments, for successive generations (Rodrigues *et al.* 2021). Evolved to live in those stressful conditions allowed these plants to deal with production of free radicals and occurrence of oxidative stress by developing anatomical and biochemical strategies that leads to a production of different metabolites, as phenolic acids vitamins or sterols, many with interest for human use. These adaptations can be a valuable source of biocompounds with antioxidant, anti-inflammatory and antitumor proprieties, that can be used for different commercial proposes. Despite being perfectly adapted to these conditions and all biochemical richness, halophytes only represent about 1% of all plants, and their potential uses are still relative underdeveloped from a meta perspective. Therefore, it is necessary to screen for halophytes with potential to be a valuable asset as feedstock to nutrition, pharmaceutical, ornamental industries and develop their uses (Duan *et al.* 2022).

Based on years of research in halophytes (XtremeBio - CCMAR) and aquaculture (EPPO - IPMA), this line of research, halophytes production with wastewater from marine aquaculture, born to answer the necessity of treat the aquaculture effluents and develop valuable crops with any potential to be used. In our work, we created a system at Pilot Research Station in the southern city of Olhão, Portugal (Fig1), were the wastewater from fish and oyster production is picked up in the decantation tank and led to the greenhouse by pumps and pipes. In the greenhouse, this water is used to cultivate different halophytes that become part of different projects as XtemeAquaCrops and SaltyCrops that already produced a lot of scientific work (Rodrigues *et al.* 2021, Rodrigues *et al.* 2020, Rodrigues *et al.* 2019a and Rodrigues *et al.* 2019b) with different species, sea lavender (*Limonium algarvense* Erben), *Polygnom maritimun* or *Sarcocornia* spp.

Our findings are contributing to the feasibility of contamination-free aquaculture and characterization of halophytes that can be used by different industries.

Introduction

Proficiency can be improved and ecological impact of aquaculture reduced through two key actions a) the use of sustainable ingredients to replace fish meal and fish oil (FM/FO) in the feeds and (b) a successful breeding program addressed to improve growth, feed utilization and fish health. The main objective of the project AQUAIMPACT is to assess possible interactions between fish genotype and nutritive utilization of non-conventional feed ingredients by evaluating a wide range of biological and productive parameters. Among these, total activity and secretion patterns of digestive enzymes offer a highly valuable information on how different factors, linked either to species-specific features or to food composition, may determine the net availability of nutrients. In the present work the aforementioned points were assessed through an experimental design aimed to evaluate a) changes in the levels of activity of different digestive enzymes present in two populations (slow- or fast-growing) seabream (*Sparus aurata*) with different growth trajectories over the production cycle, and b) the effect of different types of protein ingredients on the digestive enzyme profile in both populations of fish.

Materials and methods

Two groups of gilthead sea bream juveniles (288 days after hatching) belonging to two different genotypes (High Growth, HG, from the National Breeding Program PROGENSA® and RF – unselected used as a reference population) were fed for 30 days (3 times a day/6 days a week; 25 fish per tank, 4 tanks/genotype/dietary group) with: (i) a low content of FM/FO control diet based in current commercial formulation (C); (ii) a "future" diet including poultry meal as partial replacer of FM (50%) (F); (iii) a diet using insect meal as partial replacer of FM (33%) (I) and (iv) a diet using single cell proteins from bacterial origin as partial replacer of FM (66%) (CL). Diets F, I and CL replaced totally FO by a combination of poultry oil and DHA oil. Afterwards, fish were used for determination of variations in the pattern of secretion of several digestive enzymes. After receiving the first daily meal, the fish were sequentially sampled at 0, 1, 3, 6 and 9 hours post feeding (5 fish/sample, 45 fish/diet). After separate dissection of stomach and the rest of intestine, crude extracts were obtained by mechanical homogenization of both the tissue and gut contents, followed by centrifugation. Different enzymes (pepsin, trypsin, chymotrypsin, amylase, lipase, leucine aminopeptidase and alkaline phosphatase) were determined using routine protocols. The effect of genotype and diet on total enzyme production, as well as the effect of sampling moment and diet on the time pattern of enzyme production within each genotype, were evaluated by a two-way ANOVA followed by Bonferroni *post-hoc* test when significant differences were found at $p<0.05$. In addition, the differences in values of each enzyme activity obtained at different sampling moments for a given diet were evaluated by one-way ANOVA followed by Bonferroni *post-hoc* test.

Results

Significantly higher ($p<0.05$) values of pepsin and chymotrypsin were obtained in HG fish compared to RF. The effect of the diet was only significant in the case of aminopeptidase, with higher ($p<0.05$) values measured in fish fed the CL diet when compared to fish fed the rest of the dietary treatments and irrespective of the fish genotype. In contrast, the effect of diet was evidenced when the two genotypes were evaluated separately and showed a significant effect on the secretion of pepsin, amylase and aminopeptidase in fish belonging to the HG group, but no effect on those of the RF group. The effect of time after ingestion of a meal was significant ($p<0.05$) for all the enzymes in the HG group, with the exception of lipase and phosphatase and similarly significantly influenced the activity of all the enzymes, with the exception of pepsin, in the RF group.

(Continued on next page)

Time secretion patterns of enzymes in fish fed on different diets were more evident in the HG group, with significant differences ($p<0.05$) for pepsin, amylase and aminopeptidase. In contrast, with the exception of amylase, no significant differences related to diet type were observed in the pattern of enzyme secretion within RF group. Three types of patterns were identified in response to feeding classified as: (a) *Quick response*; characterized by a sharp increase of values measured 1 h after meal supply followed by a steady decrease and maintenance of values for the rest of sampling time; (b) *Delayed response;* characterized by greater variations and peaks observed from 3 to 6 hours after feed intake and (c) *No variation;* characterized by the absence of variations in enzyme activity as a response to meal supply.

HG fish presented a quick response for pepsin in fish fed on diets CL, F and I compared to fish fed C diet, which did not present variations in the activity of pepsin during the experiment. In the case of RF fish, the quick response for pepsin activity was detected in fish fed CL, F and C, whereas fish fed I diet did not present variations. HG fish presented a delayed response for trypsin, chymotrypsin, alkaline phosphatase and to a lesser extent in amylase and aminopeptidase, being more evident in fish fed CL and I diet than in fish fed C and F diets. In RF fish trypsin, chymotrypsin and amylase presented a delayed response pattern, however the maximum levels of enzyme production were generally observed much earlier that in the HG group, around 3 h post feeding. HG fish presented almost no variation in lipase activity along the response pattern, and for RF fish presented a similar pattern for lipase, aminopeptidase and alkaline phosphatase activities.

As a resume, the above detailed results suggest the existence of significant differences between both fish genotypes in terms of total production of several digestive enzymes as well as in the patterns of their secretion after feeding. In addition, the composition of the diets also influenced both parameters; higher enzyme production was observed in fish of the HG group receiving diet CL, but lower in those fed on diets F and C, and a similar response was observed in fish in the RF group. These results may partly explain the differences in growth and feed efficiency observed between both genotypes when fed on the different diets.

ASSESSING THE IMPACT OF DIFFERENT EXPERIMENTAL DIETS ON BALLAN WRASSE (*Labrus bergylta*) LARVAE GROWTH PERFORMANCE

Maria Morais[1], João Henriques[1], Luís Conceição[1] and Eduardo Jiménez-Fernández[2]

Introduction

Ballan Wrasse became an important eco-friendly alternative for the biological control of sea lice on farmed Atlantic salmon (Kvenseth 1996 and Skiftesvik *et al*. 2013). Despite the improvements on hatchery production over the last years, there are still some bottlenecks, especially at the early larval development stages. In particular, the weaning stage can be characterized by low survival and growth rates, and incidence of deformities (Kousoulaki *et al*. 2015). The aim of this study is to assess the effect of various diets with different protein sources on the growth performance of ballan wrasse larvae.

Material and methods

The Ballan wrasse (*Labrus bergylta)* larvae trial was performed at Otter Ferry Seafish facilities following the commercial husbandry and feeding protocols. It lasted for 44 days, from 31-75 Days After Hatch (DAH), at a temperature of 12 ± 0.8 °C. Larvae had an initial weight of 0.001±0.1g. Four diets were tested in quadruplicate: two commercial controls (1 and 2) and two experimental diets (A and B) with different sources of protein, both produced at SPAROS. Experimental diet A (60% of crude protein) had krill, squid and shrimp meals as main protein sources whereas diet B (58% of crude protein) had krill and squid meals as main protein sources. Both diets had 15% of crude fat with similar levels of n-3 HUFAs.

Results

Ballan wrasse larvae fed diet B showed significantly higher Dry Weight (DW) at 50 DAH ($P<0.05$) (Fig.1). At 75 DAH, Total Length (TL) was significantly higher in fish fed diet B ($P<0.05$).

Discussion and Conclusion

Different dietary protein sources had an impact on Ballan wrasse larvae growth. It was observed that larvae fed with a mixture of krill and squid meals as main protein sources (Experimental diet B) showed a tendency for higher growth performance when compared to fish fed the other diets. Overall, results support the fact that the use of different marine raw materials in microfeeds for Ballan wrasse larvae may influence weaning success (Kousoulaki et al. 2015). It also supports the need of tailored microfeeds for different fish larval species (Navarro-Guillén et al. 2019).

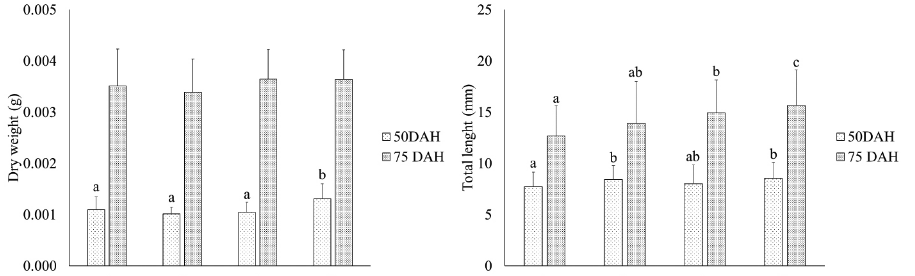

Figure 1.
Dry Weight (DW) and Total Length (TL) of Ballan wrasse larvae fed commercial diets (1 and 2) and experimental diets A and B at: 50 DAH, n=3 for DW and n=25 for TL; and 75 DAH, *n*=3 for DW and n=30 for TL. Results are expressed as means ± standard deviation. Different lowercase letters indicate significant differences between the dietary treatments ($P<0.05$).

Introduction

Taste receptors (TRs) are classically associated to the perception of gustatory sensations in oral tissues. However, many TRs are also found in different body tissues including the gastrointestinal tract (GIT), where they perform important roles (Finger and Kinnamon, 2011). In the GIT, the presence of TRs in specialized cells (enteroendocrine cells: EECs) regulates digestive, absorptive and metabolic functions through gut sensing mechanisms (Alpers, 2010). Functional actions of TRs are associated to their co-expression with gut peptides, including ghrelin (GHR), cholecystokinin (CCK), glucagon-like peptide-1 (GLP-1) or peptide YY (PYY), to cite a few. Once a TR is activated, an intracellular signaling cascade is initiated, terminating with peptide secretion in the EEC basolateral side, which can signal neighboring (paracrine action) or remote (endocrine action) cells, or activate afferent neurons (neural action). The taste receptor type 1 (T1R) family is one of the TR types that is commonly expressed in EECs, acting as heterodimeric sensors of nutrients in the mammalian gut: T1R1/T1R3 responding to umami compounds such as amino acids, and T1R2/T1R3 to sweet substances. We previously showed the expression of the *Sparus aurata* (*sa*) T1R gene repertoire in oropharyngeal, GIT and brain tissues. However, this does not necessarily imply a conserved role in gut sensing. Furthermore, expression in GIT was observed in early larval stages but no expression was found in oropharyngeal tissues up to 12 days post-hatching (dph), which was puzzling.

The present study aimed to provide direct evidence for mRNAs co-expression of *sa*T1R genes (mostly *t1r3*, as the common element of both receptors) with EEC-type peptides such as *ghr*, *cck*, *pyy* and proglucagon (*pg*), to establish a morphological link indicating possible roles of T1R in gut nutrient-sensing mechanisms and in the regulation of fish digestive processes. A second objective was to extend the period of investigation during larval ontogeny to establish the temporal pattern of expression in GIT and oral tissues for the entire *sa*T1R gene repertoire in relation to first-feeding.

Materials and methods

Whole-mount in situ hybridization (WISH) techniques were used to localize *sa*T1Rs mRNA expression in whole larvae in five selected stages, including yolk-sac nourishment (5 dph) and exogenously feeding (on rotifers) larvae at four stages (11, 14, 17 and 21 dph), up to the appearance of a mature digestive system in this species.

Chromogenic in situ hybridization (CISH) and dual fluorescent ISH (FISH) methods were used to localize and co-localize the mRNA expression of selected *sa*T1Rs (*t1r3*, *t1r1* and *t1r2b*), taste signaling molecules (*giα1* and *giα2*), gut peptides (*ghr*, *cck*, *pyy* and *pg*), and a specific marker of undifferentiated and mature EECs (neurod1: *nd1*), in the different areas of the GIT from stomach to posterior intestine, in adult seabream.

Results and discussion

In pre-feeding larvae, mRNAs for the seven *sa*T1Rs were found in the stomach and foregut, and expression in posterior intestine was also observed for *t1r2b*. At 11 dph, expression patterns remained essentially the same in the developing GIT, and even though exogenous feeding had already started, *sa*T1R expression was not detected in oral taste tissues (lips, tongue, oral cavity epithelium). During post-feeding stages, mRNAs became gradually detected in the oral cavity epithelium and/or tongue and pharynx, while overall maintaining a strong expression in the stomach and intestine.

In adult fish tissues, presumptive EECs were firstly identified in different positions of the GIT mucosa using *nd1* as a specific marker. Then, it was demonstrated that *sa*T1R genes are mostly expressed in cells that are consistent with mature EECs, co-localizing with taste signaling molecules (*giα1* and *giα2*), and that heterodimerization is a conserved mode of TR coupling in fish tissues, although single expression is also found (as in mammals). Finally, some cases of co-localization between *t1r3* and *ghr*, *cck*, *pyy* and *pg* genes in different regions of the GIT were identified, as well as independent and non-overlapping expression domains, as described also in mammals.

(Continued on next page)

Table 1. Summary of gut *vs* oral sites of *sa*T1R(s) expression throughout ontogenesis.

T1R(s)	5 dph	11 dph	14 dph	17 dph	21 dph
t1r1	Gut	Gut	Gut	Gut/Oral	Gut/Oral
t1r3	Gut	Gut	Gut	Gut/Oral	Gut/Oral
t1r2a	Gut	Gut	Gut	Gut	Gut/Oral
t1r2b	Gut	Gut	Gut/Oral	Gut/Oral	Gut/Oral
t1r2d	Gut	Gut	Gut	Gut/Oral	Gut/Oral
t1r2e	Gut	Gut	Gut	Gut	Gut/Oral
t1r2f	Gut	Gut	Gut	Gut	Gut

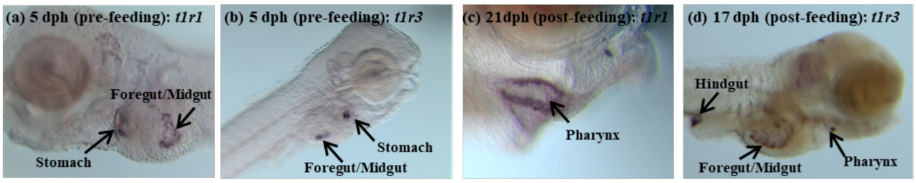

Fig. 1. Exemplificative WISH images obtained for larval *t1r1* (a, c) and *t1r3* (b, d) expression prior to (a, b) or after (c, d) the start of exogenous feeding.

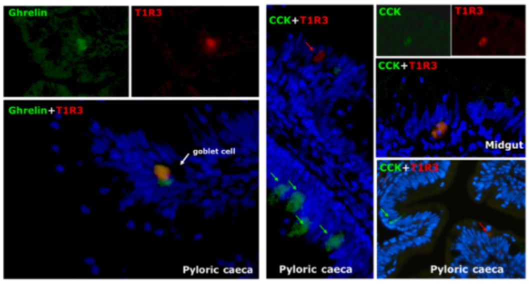

Fig. 2. Exemplificative dual FISH images from adult tissues showing both single and co-expression of T1R (*t1r3*) and gut peptides (*ghr*, *cck*) mRNAs in pyloric caeca.

In conclusion, the co-localization of *sa*T1Rs with neuroendocrine gut peptides has been clearly documented in cells with EEC-like morphology, along the GIT. This provides important evidence supporting their plausible implication in the modulation of gut hormone secretion, which had not been clearly established so far in a fish species. Furthermore, the confirmed expression of all *sa*T1R genes in the larval gut before first feeding, even prior to oral tissue expression, suggests their involvement in important GIT physiological processes, and that the onset of gene expression is not induced by food but rather genetically programmed.

Introduction

Maintaining a good feed intake is crucial for aquaculture productivity, to guarantee an adequate intake of energy and nutrients in growing animals. However, fish feeding can be affected by many factors, including poor palatability of dietary ingredients (failing to provide attractive sensory cues), changes in the diet to which the animal is accustomed, or other factors that affect the animal's motivation to feed, including stress, poor health or sub-optimal environmental conditions. Fish species, and salmonids in particular, have highly sensitive olfaction and gustation. These sensory systems are key to detect and identify food items (mainly olfaction) and promote selective food intake (mainly gustation). Therefore, by modifying the organoleptic qualities and enhancing attractive chemical cues of aquaculture feeds, it is possible to optimize feed intake in farmed fish.

In the present study, an experimental protocol developed for testing the palatability of feeds and feed intake under dietary changing conditions (i.e., with a challenge of diet "novelty") was used to assess the efficacy of palatability enhancers (PE) designed to improve feed intake of low palatability diets for rainbow trout (*Oncorhynchus mykiss*) and Atlantic salmon (*Salmo salar*).

Materials and methods

Two trials were performed in 60 L cylindroconical tanks equipped with an INRA automated feces collection system, originally developed for digestibility studies but adapted as an experimental tool to quantify feed intake. The tanks were operated as an open-flow freshwater system in which the tank outlet water is sieved by moving grids, and all suspended residues are separated from the water and projected into a metallic tray. This allows a full recovery of all uneaten pellets (Figure 1). Trial 1 was performed with 20 rainbow trout per tank, with mean body weight (BW) of 74 ± 6 g and at an average temperature of 14.3ºC. Trial 2 was done with 20 Atlantic salmon per tank with BW of 18 ± 1.7 g and at an average temperature of 12.6ºC.

Each trial tested a positive control (PC) diet of high palatability (with very high contents of marine ingredients; Table 1), a negative control (NC) diet of reduced palatability (low level of marine ingredients and high in plant protein and oil sources; Table 1), and experimental diets with the same basal formulation as the NC but supplemented with various test additives at 0.1%. All test additives form stable oil suspensions and were blended in oils and applied post-extrusion by coating. Each tank was fed on a diet during one week and each week a new experimental feed was introduced, until each diet had been tested in 4 different tanks (i.e., without the repetition of a given diet in the same tank). Therefore, a total of 4 replicates (tanks) were used per treatment, each replicate representing the average feed intake during one week.

Fish were fed twice a day (at 10.00 and 15.00h), in excess of the maximum feed intake estimated by feeding all tanks on the PC diet for one week before starting the trial (WK0). Every day, during 20 minutes after each meal, the uneaten feed pellets from each tank were recovered, dried overnight in a convention oven, and quantified in a dry basis. Feed intake was calculated as a % of fish biomass, by subtracting the uneaten dry feed from the distributed dry feed.

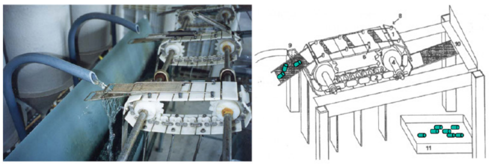

Fig. 1. INRA feces collection system used for the collection of uneaten pellets.

(Continued on next page)

Table 1. Main ingredients (>2%) in experimental basal formulations.

	Trial 1 (Trout)		Trial 2 (Salmon)	
Ingredients (% of feed)	PC	NC	PC	NC
Fishmeal LT70	22.75	12.75	30.00	7.50
Fish protein hydrolysate	5.50		5.00	
Squid meal	5.50			
Krill meal	15.00		5.50	
Soy protein concentrate		17.50	9.00	20.50
Pea protein concentrate				15.00
Wheat gluten		7.65	7.00	15.00
Corn gluten meal		8.00	5.00	5.00
Soybean meal 48		10.00		
Wheat meal	28.15	15.50	15.50	10.10
Faba beans (low tannins)	5.00	5.00	5.00	5.00
Fish oil	16.90	1.20	16.80	4.00
Soybean oil		9.50		
Rapeseed oil		9.50		14.40

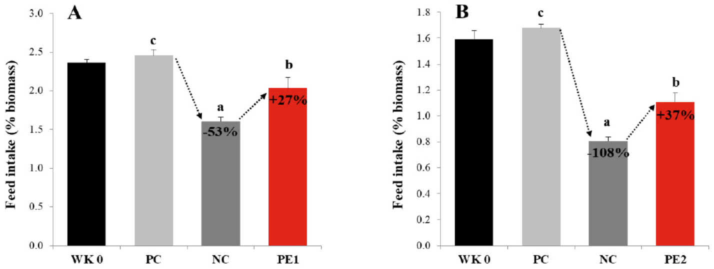

Fig. 1. Feed intake (% biomass) in trial 1 (A) and trial 2 (B). PE1 and PE2 are different palatability enhancer additives. Columns are means of n=4 tanks (1 week duration) ± standard deviation. Letters indicate P<0.05 (one-way ANOVA).

Results and discussion

The palatability trials enabled screening different PE additives and identifying those with the highest phagostimulant effect in both salmonid species (Figure 2, showing the most effective test additive in each trial). Results show that the intake of the PC diet remained high and constant during the duration of the trials, and similar to the maximal level assessed for all tanks on the pre-trial week (WK0). Feed intake was highly and significantly reduced on the NC treatment, compared to the PC – 53.3% less in rainbow trout and 107.9% less in Atlantic salmon. However, the palatability of the NC diet could be significantly improved by supplementing with 0.1% of PE1 in rainbow trout (+26.9% feed intake) or with 0.1% of PE2 in Atlantic salmon (+37.2% feed intake).

In conclusion, the results confirm that the experimental protocol enables a precise measurement of feed intake in juvenile fish, presenting a good methodology to identify palatability enhancers for fish feeds. Furthermore, it is noteworthy that despite being closely related, the most effective PE differed among the two species, supporting that fish have remarkable species-specificity in taste preferences (Morais, 2017).

MODULATION OF PHYSIOLOGICAL RESPONSES IN ATLANTIC SALMON EXPOSED TO STRESSOR CONDITIONS: HYDROLYZED *Debaryomyces hansenii* IN FUNCTIONAL FEEDS CAN IMPROVE FISH HEALTH AND WELFARE

Introduction

The salmon farming industry faces biological challenges related to multi-stressor conditions (e.g., physical, infectious and environmental problems) that impact fish health and welfare, and cause economic losses (1). To address these problems, the use of microbial ingredients (MI) in functional feeds to improve overall fish health is gaining interest (2). Yeast as MI contain a wide range of Microbe-Associated Molecular Patterns (MAMPs) such as β-glucans, α-mannans and nucleic acids, which act on host pattern-recognition receptors (e.g., Toll-like receptors and C-type lectin receptors). This can induce both local and systemic physiological effects by modulating cytokines and effector molecules that also regulates the stress response, as well as coordinating the antigen presentation process (1, 3-5).

A promising MI for aquafeeds is *Debaryomyces hansenii*. It has already been described in different vertebrates that selected inactivated fractions (e.g., cell wall components and polyamines) from this non-Saccharomyces yeast species have been able to modulate the expression of immune-related biomarkers (NFϰB, IL-1β, and TNFα) and to increase phagocytic ability and the production of reactive nitrogen species in leukocytes (6, 7).

In our study, we have focused on the use of two distinct hydrolyzed *D. hansenii*-based products (LAN4 and LAN6 from Lallemand SAS), to evaluate their effects on immune-related biomarkers of Atlantic salmon exposure to short-term hypoxia stress or to stress associated with seawater transfer. This knowledge will facilitate the inclusion of bioactive components based on *D. hansenii* in functional feeds for salmonids, with the potential to modulate physiological responses in fish exposed to challenging conditions.

Materials and Methods

A fish trial was conducted for 13 weeks (7 weeks in freshwater and 6 weeks in seawater) with vaccinated Atlantic salmon fed a commercial-like control diet (CD) or CD containing 0.1% LAN4 (marine origin) or 0.1% LAN6 (dairy origin) in triplicate (Figure 1). At the end of freshwater phase, fish from each dietary group were transferred to seawater, while those that remained in freshwater were subjected to an acute stress challenge (1 min hypoxia; 8). For hypoxia stress test, plasma, gills and distal intestine samples were collected before stress (pre-stress), immediately after (0-h post-stress), 1, 3, 6, 12 and 24-h post stress. Regarding the fish transferred to seawater, a natural outbreak of *Moritella viscosa* was detected after 5 weeks (week 12) and a week later (week 13), plasma, gills, distal intestine and liver samples were taken from all fish. We combined transcriptomic strategies with detection of specific phenotypic biomarkers by carrying out RNAseq, ELISA and morphometric analysis in the samples.

Results

Compared to the control diet (Figure 1) and following acute hypoxia, fish fed LAN4 were able to prevent the secretion of plasma cortisol and IL-10, which are both biomarkers associated with immunosuppression. Moreover, gills showed differentiated gene expression of metabolic pathways associated with stress tolerance and oxidative regulation, and in the intestine, goblet cells maintained higher levels of mucins, that are proteins involved in the protection of the intestinal tract. Interestingly, while plasma total IgM levels after the *M. viscosa* outbreak in seawater showed no difference between dietary groups, there was (in fish fed LAN6) a 14% increase of specific IgM against *M. viscosa*, in addition to an upregulation of genes related to humoral immune response and complement activation in liver.

Conclusions and perspectives

Functional feeds containing a specific strains of hydrolyzed *D. hansenii* yeast have the potential to differentially modulate health parameters and stress response, hence can contribute to improve welfare in intensive aquaculture. We are thus currently evaluating the ability of *D. hansenii* yeast to induce trained immunity and support the capacity to withstand multi-stressor conditions in order to build-up a more resilient Atlantic salmon.

Introduction

Aquaculture is one the fastest growing food sectors worldwide requiring increased levels of industrialization and intensification. A vital aspect of sustainable aquaculture is to safeguard the welfare of the animals, a practice benefiting not just the farmed fish, but also the farmers and consumers, as it improves the quality and cost-efficiency of the product. The recent development, miniaturization and greater accessibility to biosensing technologies (*e.g*., data storage tags) have allowed for their increasingly widespread adoption in animal research, which may pave the way for their routine implementation in aquaculture settings to monitor for early warning indicators of poor welfare (Brijs et al., 2021; Føre et al., 2018). Still, to test the validity of these sensor data as welfare indicators, further analyses establishing correlations between the sensor values and blood parameters are required. Towards this goal, we investigated how well parameters measured using data storage tags such as heart rate and swimming activity at different conditions (*i.e*., rest, elevated swimming speeds, stress and recovery) correlate with blood parameters often used as indicators of acute stress and poor welfare.

Materials and methods

Atlantic salmon (*Salmo salar*, n = 13, body mass = 1207.2 ± 65.1 g) were simultaneously implanted with an intravascular venous catheter for blood sampling and a data storage tag capable of measuring ECG and activity (via 3D accelerometer). The fish were then transferred to a swim respirometer, where oxygen consumption was measured overnight at a swimming speed of 0.5 body lengths s^{-1} (BL s^{-1}). After the overnight recovery period, swimming speed was increased in 0.5 BL s^{-1} steps to 1.5 BL s^{-1}, following which the fish were netted out of the respirometer, thus eliciting stress, and transported to a holding tank, where they were allowed to recover for 24 hours. Throughout the protocol, blood samples were obtained *via* the catheter at six timepoints: at rest (0.5 BL s^{-1}), 1.0 BL s^{-1}, 1.5 BL s^{-1}, immediately post stress, 1 hour post-stress and 24 hours post-stress. Blood parameters measured include cortisol levels, venous oxygen partial pressure, pH, lactate levels, osmolality, hematocrit, hemoglobin concentration, blood ion composition and glucose concentration. Additionally, we videorecorded the fish during the swim trial, allowing us to measure ventilation rate and tail beat frequency.

Results and discussion

Preliminary results are provided in Figure 1, although further blood analyses are currently being performed. Heart rate, activity and oxygen consumption rate increased with swimming velocity, while partial pressure of oxygen and pH decreased. pH was lowest following stress, although it was restored to resting levels 1 hour post-stress. Lactate concentration increased at 1.5 BL s^{-1}, indicating increase in anaerobic metabolism, and peaked 1 hour post-stress. Pearson correlation analysis of the available data showed that heart rate was significantly positively correlated to activity and, both heart rate and activity were correlated to oxygen consumption rate. Heart rate was negatively correlated to lactate concentration, while activity was negatively correlated to pH and venous partial pressure of O_2. In conclusion, these preliminary results indicate that heart rate and activity correlate with oxygen consumption rate and other stress-driven cascades of physiological events that can be measured in the blood, providing further evidence that biosensors can be used as a tool to estimate stress in aquaculture. This can be used to facilitate the correction of harmful husbandry practices that lead to exacerbated stress, thus reducing the likelihood of long-term negative consequences to the welfare of the fish.

SCALING KELP FARMING AS A NATURE-BASED SOLUTION

Bailey Moritz

WWF- US, Aquaculture
1250 24th St NW, Washington, DC 20037
bailey.moritz@wwfus.org

Research continues to bolster widely recognized ecosystem services of kelp farming activities, including uptake of excess nutrients, mitigation of ocean acidification, and habitat creation. Not only do farms contribute to carbon sequestration, but the harvested biomass can be used in value chains that offset global resource use. Kelp farms also improve coastal community resilience through new economic opportunity. Their benefit to both people and nature make kelp farms an important nature-based solution in many regions.

In order to unlock the potential for kelp farming as a nature-based solution, barriers to growth must be addressed. WWF-US is two years into implementation of a strategy reducing barriers for the responsible expansion of the seaweed industry in underdeveloped seaweed farming regions, namely the North Atlantic and Eastern Pacific. Barriers include access to capital for farmers and companies, developing market demand, and achieving social license to operate more farms in coastal areas. Environmental NGOs recognizing the contribution of kelp farming to effectively restore ecosystems and address societal challenges as a nature-based solution have a key role to play in improving public buy-in for the industry, allowing production to scale up.

This presentation will explore how, in conversation with local communities, there is room for farms to increase, a necessary step to achieving meaningful impacts on climate and ecosystems, and function as a nature-based solution.

THE EFFECT OF POLYPROPYLENE MICROPLASTICS AND CHEMICAL POLLUTANTS ON EUROPEAN SEA BASS (*Dicentrarchus labrax*) GUT MICROBIOTA

Introduction

It is generally accepted that plastics, consisting mainly of micro-sized (1 µm–1 mm) and nano-sized (<1 µm) particles, have become a serious threat to marine ecosystems, not only because they can physically damage the organisms, but also due to the toxicity of the associated chemical pollutants (Jambeck et al., 2015). Microplastics (MPs), which are consumed by marine organisms that confuse them with food sources, can causes various adverse effects. In fish, environmental chemicals can effectively induce changes in gut microbiota. Therefore, a dysbiosis might develop in the host's intestine after consuming MPs due to the ingestion of foreign and potentially pathogenic bacteria or to chemicals that make up or adhere to MPs (Fackelmann and Sommer, 2019). The consequences of exposure to MPs and the combined effects of MPs and adsorbed pollutants, on the microbiota community has not been exhaustively investigated. Accordingly, we exposed European sea bass juveniles to chemical pollutants and to MPs contaminated or not with a blend of chemical pollutants (dichlorodiphenyldichloroethylene (p,p'-DDE), chlorpyrifos (CPF), and benzophenone-3 (BP-3)), by adding them to the fish diet. The aim of the study was to determine the individual and combined effects of dietary MPs and chemical pollutants on the fish gut microbiota population.

Materials and Methods

The feeding trial was set in a flow-through marine water system with three hundred European sea bass (80.91 ± 13.28 g), randomly distributed in twelve tanks (500 l). Four different diets were formulated. Commercial diet with no additives was considered as the control diet, whereas diet MP, diet P and diet P+MP were manufactured adding to the commercial diet: MPs alone, or a mix of three chemical pollutants, or MPs contaminated by the same mix of chemical pollutants, respectively. The level of inclusion of MPs in the diets was 10% (w/w), while, for diets P and P+MP the blend of the three chemical pollutants was composed by p,p'-DDE, CPF, and BP-3 in concentration of 1000, 100, and 300 ng/g, respectively. At the end of the trial, two fish per replicate tank (6 fish/diet) were sacrificed to collect the fecal matter and the autochthonous intestinal bacteria for gut microbiome analysis. The sequencing was carried out using Illumina MiSeq platform and processed using QIIME™ 2 (v. 2018.4) then, the representative sequences from each operational taxonomic units (OTUs) were aligned to Greengenes database v. 13.8 down to genus taxonomical level.

Results and Discussion

In line with previous studies (Wan et al., 2019), the present metagenomic analysis showed an alteration in sea bass gut microbiome composition and in bacterial species richness following the ingestion of pollutants or polluted MPs. Furthermore, the PCoA analysis revealed that pollutant treatments significantly altered gut microbiome community structures that clearly separated them from the control group. Irrespective of the diet, the gut microbiota of European sea bass was dominated by Firmicutes, Proteobacteria, and Actinobacteria phyla, as already reported in previous microbiome studies in this species (Rimoldi et al., 2020). However, their relative abundances were significantly changed by ingesting pollutants. In particular, compared to the control group, although the dietary inclusion of virgin MPs did not cause relevant changes in microbiome, the polluted diets increased the abundance of the phylum Proteobacteria, widely considered a microbial signature of gut inflammation (Shin et al., 2015), while reduced the Firmicutes content, which instead are generally considered beneficial and associated with a healthy intestine. These bacteria in fact, are known for having anti-inflammatory potential and a crucial role in regulating the host immune system (Terova et al., 2016). These results are in line with those reported for yellow croaker (*Larimichthys crocea*) and adult zebrafish (*Danio rerio*) exposed to PS-MPs (Jin et al., 2018). In agreement with the reduction in beneficial bacterial taxa belonging to Fimicutes phylum, PICRUSt analysis predicted a decrease in starch and carbohydrate metabolism as well as in cysteine, methionine, and purine metabolism. On the contrary the two-component and secretion system pathways were instead greatly upregulated. This would agree with the gut inflammatory signs and microbiome profiles observed in fish fed diets containing chemical pollutants. Likewise, an increase in lipopolysaccharide biosynthesis could be related to the inflammatory status of intestine and to dysbiosis.

(Continued on next page)

Conclusion

In summary, our results clearly demonstrate a significant perturbation in gut microbial communities, including the reduction in beneficial bacteria genera and the increase in potentially pathogenic microorganisms. The results obtained in this study provide, therefore, new insights into the potential risks of ingesting MPs as pollutant carriers in marine fish.

Introduction

In recent years, insects have emerged as a more sustainable alternative ingredient for aquafeeds. Although the potential of insect meals as protein replacement has already been established, very limited information is available regarding the inclusion of insect lipids. Black soldier fly (*Hermetia illucens*) larvae, one of the most promising insect species, are rich in fat (25-35%), with a fatty acid profile mainly composed of medium-chain fatty acids (MCFA), mainly lauric acid (C12:0) [1,2] These MCFA are rapidly catabolized and preferably used as an energy source rather than deposition as an energy reserve, thus making insect oil an interesting ingredient for use in aquafeeds. Therefore, this study aimed to evaluate the inclusion of *Hermetia illucens* larvae oil (HIO) as a replacement for vegetable oils (VO) in diets for gilthead seabream (*Sparus aurata*) juveniles.

Materials and methods

A control diet (HIO0) was formulated to include 3% fish oil and 10% VO mix (50% linseed, 30% palm, and 20% rapeseed oils). Three other diets were formulated to include HIO at increasing levels (4, 8, and 10%), replacing 33, 66, and 100% of the VO mix (diets HIO33, HIO66, and HIO100, respectively). All diets were tested in triplicate in a growth trial with gilthead seabream juveniles (60g) hand-fed to apparent visual satiation for 10 weeks. At the end of the trial, the fish intestine was collected to assess the dietary effects on the activity of digestive enzymes. A digestibility trial was also conducted to determine the apparent digestibility coefficients (ADC) of the diets.

Table 1: Apparent digestibility coefficients (ADCs) of gilthead seabream juveniles fed the experimental diets.

							Polynomial contrasts	
	HIO0	HIO33	HIO66	HIO100	SEM	ANOVA P-value	Linear P-value	Quadratic P-value
Dry matter	53.3	50.5	48.5	57.7	2.37	0.238	0.118	0.155
Protein	90.1	88.7	88.7	91.2	0.52	0.068	**0.046**	0.056
Lipids	85.3	84.7	82.9	86.7	0.55	0.068	0.064	0.038
Energy	70.1^{b}	67.3^{b}	72.0^{ab}	76.2^{a}	1.37	**0.004**	**0.002**	0.079

Means of n=4. SEM: standard error of the mean. Different superscript letters indicate significant differences between treatments (one-way ANOVA, p<0.05).

Table 2: Activity of digestive enzymes of gilthead seabream juveniles fed the experimental diets.

							Polynomial contrasts	
	HIO0	HIO33	HIO66	HIO100	SEM	ANOVA P-value	Linear P-value	Quadratic P-value
Trypsin	77.9	83.0	79.8	72.7	4.38	0.877	0.647	0.505
Total Proteases	1.03	1.25	1.27	1.04	0.05	0.159	0.925	**0.025**
Lipase	3.55	3.29	3.13	3.21	0.13	0.732	0.345	0.531
Amylase	206.5	159.1	158.1	131.4	10.3	0.181	**0.038**	0.788

Trypsin, Lipase, and amylase activity: nmol mg protein^{-1}; Total proteases activity: nmol mg protein^{-1} min^{-1}. Values are presented as a mean of n=9. SEM: standard error of the mean. The absence of superscript letters indicates no significant differences between treatments (one-way ANOVA, p> 0.05).

(Continued on next page)

Results and Conclusion

Results indicate that the dietary inclusion of HIO increased the diet's energy digestibility (Table 1). The ADC of dry matter and lipid were not affected, while the ADC of protein showed a positive linear trend. While no significant effects were observed in the digestive enzyme activity (Table 2), a decreasing trend was observed in amylase activity.

Overall, these results suggest that gilthead seabream juveniles can effectively utilize *Hermetia illucens* larvae oil without detrimental effects on nutrient digestibility and activity of digestive enzymes. Further studies are required to understand the impact of HIO on lipid metabolism, oxidative stress response, and immune status of gilthead seabream and also the implications on fillet quality traits.

Introduction

Black soldier fly (*Hermetia illucens*) larvae have already been established as one of the most promising insect species to be included in aquafeeds. They have a high protein content, a balanced amino acid profile, and are also able to convert low-quality waste materials into high-valuable ingredients. Most of the research has been focused on its protein portion and so, limited information is available on the use of *H. illucens* larvae oil (HIO) in fish feeds. *H. illucens* larvae are rich in lipids (25-35%), mostly composed of medium-chain fatty acids (MCFA), namely lauric acid (C12:0), with great potential to be used as an energy source (1) and have also been reported to exhibit antioxidant, antimicrobial, and immune-modulating properties in animals (2,3). Therefore, this study aimed to evaluate the effects of the dietary inclusion of *H. illucens* larvae oil (HIO) on the hepatic and intestinal antioxidant response of gilthead seabream (*Sparus aurata*) juveniles.

Materials and methods

Four experimental diets (3% fish oil) were formulated to replace a vegetable oil mix (containing 50% linseed, 30% palm, and 20% rapeseed oils) with HIO at increasing levels: 0, 33, 66, and 100%, corresponding an inclusion level of 0, 4, 8, and 10% (diets HIO0, HIO33, HIO66, and HIO100, respectively). These diets were tested in triplicate groups of gilthead seabream juveniles that were hand-fed to apparent visual satiation for 10 weeks. At the end of the trial, the liver and intestine of 9 fish per dietary treatment (3 fish/tank) were collected to assess the effects on lipid peroxidation and the activity of selected antioxidant enzymes: glutathione reductase (GR), glucose-6-phosphate dehydrogenase (G6PDH), and catalase.

Table 1: Lipid peroxidation and activity of selected antioxidant enzymes of gilthead seabream fed the experimental diets

[1]LPO – Lipid peroxidation (MDA/g tissue); [2]GR - glutathione reductase (mU/mg protein): [3]G6PDH: glucose-6-phosphate dehydrogenase (mU/mg protein); [4]CAT: catalase (mU/mg protein).
SEM: Standard error of the mean

(Continued on next page)

Results and conclusion

Present results indicate that the dietary inclusion of HIO had no effects on the activity of intestinal antioxidant enzymes, while lipid peroxidation was significantly reduced when compared to the control diet. Liver lipid peroxidation was also not affected by the experimental diets, but an increase in GR and G6PDH activity was observed, being the highest at the highest inclusion level of HIO. Catalase activity also linearly increased with the inclusion of HIO.

These findings suggest that *H. illucens* larvae oil can reduce intestinal lipid peroxidation while increasing the antioxidant response in the liver of gilthead seabream juveniles.

Introduction

Fish farming is a rapidly developing industry globally. However, the current stagnation of fish meal and fish oil production from wild fisheries hinders future growth of aquaculture. The most apparent alternatives are plant products, which have been long used in animals to minimize aquaculture's dependency on marine fisheries resources (Perera et al., 2019). Plant-derived oil and protein, on the other hand, have been shown to have deleterious impacts on the metabolism and physiology of fish due to their high non-digestible carbohydrate content and the presence of anti-nutritional elements. This gains additional importance in breeding programs to avoid compromising selection for a high growth rate in commercial environments, where several factors interact and affect growth (Xu et al., 2019). In this study, we examine the early response of blood biochemical indicators to plant-based diets in gilthead sea bream across different genetic backgrounds. The overall objective is the identification of non-invasive markers indicative of the nutritional status of gilthead sea bream.

Materials and methods

One thousand gilthead sea bream from 20 families (50 individuals per family) were tagged with an intraperitoneal chip and randomly divided into two cages, in a commercial farm of AVRAMAR SA, Greece, where they were acclimatized on a high marine-protein diet from July to September. At the beginning of the experiment in September, fish were weighed and one cage switched to a high plant-protein diet. Blood samplings were performed 15 and 30 days after diet shift. Blood was sampled by caudal puncture into heparinized syringes, transferred into tubes, and centrifuged to isolate the plasma that was stored at -80^{o}C until the quantification of cholesterol and triglycerides concentrations through colorimetric methods, and transthyretin (TTR) by novel sandwich ELISA method developed for the purpose. Thereafter, fish were weighed bimonthly until the end of production cycle in August, when the fat content was also determined.

Results and Discussion

The response to diet-shift was family-dependent. SGR differentiated with diet in certain families and only between September and November. Diet did not affect significantly fat content in any family.

Thirty days after diet shift, total plasma protein content was higher in all families feeding on the plant-rich diet and in 18/20 families it was significantly higher than in feeding on marine-rich diet. Diet significantly affected cholesterol in 9/20 families whereas 10/20 families feeding on plant-rich diet exhibited significantly higher triglyceride content 30 days after diet shift. This might be an indication of a lack of energy resources and a physiological need to access fat deposits in order to balance daily energy needs (Ibarz et al., 2007).

TTR levels were more responsive to diet and a high differentiation was observed on day 15 after diet shift. These early TTR levels were significantly correlated with the total SGR to the end of the rearing period in fish fed on the marine-rich diet as well as with the TTR levels 30 days following the diet shift. This is in agreement with earlier findings that TTR may be a potential marker of protein-energy malnutrition in gilthead sea bream (Morgado et al., 2007), and it is further reinforced with its correlation with growth performance.

In fish fed on the plant-rich diet, the total SGR to the end of the rearing period was significantly correlated with cholesterol levels 30 days following the diet shift. Also, in the same fish, a strong significant correlation between total plasma protein and cholesterol content was recorded in both sampling days. Total protein and cholesterol on day 30 were significantly correlated with SGR between September and November in marine- and plant-diet fed fish, respectively. Strong correlation among cholesterol, plasma protein and growth rate could render them representative biochemical candidates given that significant changes of them have been also reported in other diet regimes (Sitjà-Bobadilla et al., 2005).

(Continued on next page)

Conclusion

A strong interaction between genetic background and diet composition was recorded in investigating candidate non-invasive markers. Total plasma protein, TTR and cholesterol appeared indicative of the growth potential under different feeding regime. However, their response was not consistent across feeds, which calls for cautious interpretation. In any case, non-invasive biochemical markers can highlight physiological changes that occur in fish when they transition to a plant-based diet.

Introduction

Modern fish farming integrates genomics in breeding programs to guide broodstock selection and genetically select for improved offspring (Houston et al., 2020). Across-genome genetic data, such as SNPs, can be associated with a specific trait and, through parental selection, this trait can prevail in a population. European sea bass (Dicentrarchus labrax) and gilthead sea bream (Sparus aurata) are the emblematic fish species farmed in the Mediterranean (FEAP, 2021). GWAS and whole genome sequencing have led to extensive SNP discovery in the last decade (Peñaloza et al., 2021). **Improving** the shelf life of the final product is paramount to modern aquaculture towards reducing losses and total production costs. However, fresh fish is highly perishable and decay faster than other types of meat due to accelerated metabolic or structural (e.g., myofibrillar and extracellular matrix modifications) post-mortem alterations induced by endogenous proteases. In this study, we identified SNPs in genes encoding for these endogenous proteases associated with muscle deterioration and we used MassArray technology to screen commercial fish and successfully associate enzymatic activity as a trait with genetic polymorphism.

Materials and methods

A total of 161 gilthead sea bream and 186 European seabass were sampled from two commercial fish farms in Western and Central Greece, respectively. Fish were of commercial size (300-500g). White muscle samples were collected on harvest day and stored in dry ice for DNA extraction and determining enzyme activity. DNA extraction was performed using the PureLink™ Genomic DNA Mini kit according to manufacturers' instructions. DNA quality and quantity was assessed and then samples were properly diluted and sent to Inqaba Biotechnical Industries (Pty) Ltd for genotyping using the MassArray system. Whole genome sequencing was performed in pooled samples with a mean sequencing coverage of 30X on both species using the HiSeq 3000 Illumina platform. A customized bioinformatics pipeline for the analysis of FASTQ files was performed and Variant Calling Files (VCF) were generated. The activity of major proteases, namely Calpain, Collagenase and Cathepsins, responsible for white muscle degradation was measured following a protocol previously described (Ntzimani et al., 2021).

Table 1. Number of variants genotyped in European seabass and gilthead seabream. The allele frequency (%) and the difference in enzymatic activity when the allele of interest is present is also showed.

Results and Discussion

Thirty-two genes in total were identified in the genome of sea bream and sea bass encoding for calpains, cathepsins and collagenases. In total, 6,800 (*S.aurata*) and 2,608 (*D.labrax*) SNPs, were detected in those 32 genes. A filtering step was performed, selecting missense variants in genes that are expressed in the white muscle and those mapped in the catalytic/regulatory domains of the enzymes were selected. Based on these criteria, 57 and 47 missense SNPs were selected for genotyping for seabream and seabass, respectively. The association analysis revealed 6 and 9 SNPs for seabream and seabass, respectively, to be statistically significantly associated with the enzymatic activity of calpains, collagenases and cathepsins (Table 1). These SNPs combine differently in each individual, and each combination detected appears to affect enzymatic activity levels differently. These findings provide a tool for parental selection in breeding programs for extending the shelf-life of the final product.

Conclusion

MassArray can be a cost-effective tool in breeding for a specific trait. The combination of the variants arising from the current study can be used towards extending the freshness and shelf-life of these emblematic Mediterranean fish.

Introduction

Greater amberjack *(Seriola dumerili)* is a very promising candidate for the diversification of the Mediterranean aquaculture due to high growth rates, consumer appreciation and commercial value. Although hormonally induced spawning is well progressed, there are still many limiting factors for further expansion of greater amberjack farming [1]. High growth dispersion at hatchery stages and unsynchronized development is a major drawback in intensifying juvenile production. Temperature is a key factor in promoting fish development and growth with strong epigenetic effects [2]. Feeding at early stages is another challenging factor given the lack of a fully functioning digestive system. Rotifers and copepods are the main live feed alternatives for the early larval stages. Species of both have a great variety of amino acid and fatty acids composition, although copepods have a richer amino acid profile [3]. In this study, we investigated the influence of different rearing temperatures and different live feeds, on the process and variation of myogenesis at early development in greater amberjack.

Materials and methods

Greater amberjack eggs from a hormone-induced spawn of captive breeders were subjected to a 2X2 rearing experiment; two different rearing temperatures (20 °C vs 24 °C) were combined with two different types of live feeds [copepods (C) vs rotifers (R)] to form four experimental groups (20C, 20R, 24C, 24R). Larvae samples were collected at three developmental stages; notochord flexion (FL), end of larva rearing (ELR) and middle metamorphosis (MM). For histological analysis, larvae were fixed in cold Serra's solution and were then classified by total length (TL) by group age before chosen at random for embedding. Serial microsections (6μm) were prepared, and stained with H&E stain. Stained sections of 10 individuals per age group were examined, and images were processed using ImageJ software. The total cross-sectional area (TCSA) of white muscle in one epaxial quadrant was measured in each specimen [4]. For gene expression analysis, eight individuals per stage per condition combination (food X temperature) were sampled and stored in RNA*later* at -20 °C until RNA was isolated and cDNA synthesis was performed. The expression of 3 genes; *mylpfa* (myosin light chain 2a, hypertrophy), *mylpfb* (myosin light chain 2b, hyperplasia), *myog* (myogenin, coordination of myogenesis) were quantified by real-time PCR and normalized against two reference genes (*rps18*, *rpl13a*). Significant differences between the expression level of each gene at different conditions were analyzed using Wilcoxon signed-rank test.

Results and Discussion

Total length (TL) was almost linear after hatching and the TCSA of dorsal white muscle increased continuously between stages. The combined effect of temperature X live feed significantly affected larval growth ($p=0.037$), whereas TCSA was strongly affected by the type of live feed ($p= 0.039$). At MM, the largest dorsal epaxial quadrant was observed in the larvae reared at 24°C eating copepods (24C) ($p<0.05$). TCSA increased at different pace in the four groups with 24C exhibiting the smallest TCSA at ELR and ending with the largest at MM. Interestingly, 24C group had overall the shortest TL. Group 24R on the other hand exhibited high axial growth throughout the rearing phase. Overall, rearing at 24°C appeared to favor axial and white muscle growth.

The expression levels of *mylpfa* gene were affected neither from the temperature nor from the type of live feed. Significant differences were identified in the expression of *mylpfb* and *myog* genes between the four groups at the stages of FL and ELR. At FL, expression of *myog* that drives muscle cell differentiation and of *mylpfb* that signifies hyperplasia, was higher in larvae reared at 24°C. By ELR, group 24R exhibited the highest *myog* and *mylpfb* expression. At MM, *mylpfb* expression was highly dispersed in larvae reared at 24°C, regardless the type of live feed. The shift from larvae to juveniles is dependent on the proper deployment of hyperplastic and hypertrophic processes during the early phases of muscle development. This

(Continued on next page)

can be attributed to both temperature and diet, as the rate of hyperplastic and hypertrophic development is known to be strongly influenced by temperature during incubation and larval rearing [3]. Based on *mylpfa*/*mylpfb* expression levels, it appears that hyperplasia dominates the white muscle development up to metamorphosis and it is strongly affected by rearing temperature.

Conclusions

Both rearing temperature and feed type influenced white muscle development in greater amberjack larvae. The combined results from histological and gene expression analyses indicate that temperature is the major factor with 24ºC favoring a higher pace of white muscle development in comparison with 20ºC. Within 24ºC, the type of live feed used resulted in different phenotypes at MM with rotifers supporting longer larvae with smaller TCSA as compared with copepods. A higher development pace was accompanied by a higher variation in gene expression levels that were not accompanied by higher variation in phenotypic traits, i.e. TL and TCSA.

OCCURRENCE OF MYCOTOXIN IN AQUA FEED SAMPLES AND RAW MATERIAL IN 2022

A. Mueller*, U. Hofstetter and B. Standen.

DSM Austria, Erber Campus 1, Getzersdorf, Austria

anneliese.mueller@dsm.com

Mycotoxins are secondary fungal metabolites which can affect health and performance of aquatic specues and are frequently found in various feedstuffs. Mycotoxin occurrence and contamination levels in fish and shrimp feed were monitored in this study. Due to the natural co-occurrence of mycotoxins, the toxicity of contaminated feed cannot be accurately estimated by determining the concentration of one only. The following study represents an effort to further broaden the knowledge on mycotoxin occurrence and co-occurrence in feed.

A total of 110 fish and shrimp feed and feed raw materials samples were analyzed using Liquid Chromatography Mass Spectrometry/Mass Spectrometry (LC-MS/MS) for six major mycotoxin groups: aflatoxins, type A trichothecenes (DON, NIV, ..), type B trichothecenes (T-2, HT-2, ..), fumonisins (FUM), zearalenone (ZEN), and ochratoxin A.

One of the most common fungal metabolites detected was deoxynivalenol (detected in 55% of samples, with an average concentration of positive samples of 239ppb and a maximum concentration of 710ppb). Other common mycotoxins included fumonisins (50% of samples, mean 379 ppb, max 3837 ppb) and zearalenoe (38% of samples, mean 31 ppb, max 208 ppb). 23% of samples showed DON and ZEN co-occurrence whereas 28% showed co-occurrence of DON and FUM, all 3 mycotoxins are produced on the field by *Fusarium* species.

Thanks to the increased sensitivity of mycotoxin analysis a greater number of mycotoxins and fungal metabolites have been reported. The potential for multi-mycotoxin contamination validates use of multiple mitigation strategies to properly address animal health and performance concerns.

All Regions - Table of Mycotoxins Detected including Risk Threshold

Total Risk Level: 45%	**Afla**	**ZEN**	**DON**	**T-2**	**FUM**	**OTA**
Number of samples tested	110	108	110	76	110	76
% with mycotoxin detected	24%	38%	55%	4%	50%	28%
% above health risk threshold	12%	6%	29%	0%	11%	3%
Average of positive (ppb)	98	31	239	25	379	5
Median of positive (ppb)	2	22	211	21	235	3
Maximum (ppb)	2194	208	710	48	3837	38
Recommended max threshold (ppb)	2	50	150	50	500	10

Introduction

The development of pikeperch (*Sander lucioperca*) production has accelerated over the last 20 years, thanks to significant R&D efforts. In addition to traditional pond production, the growth of intensive farming is also striking. The first step is the development of the controlled and programmed reproduction. At present, hatchery breeding using *in vitro* fertilisation (collection and dry fertilisation of the gametes) is the most researched area. In our previous studies, we demonstrated that sperm injected into the ovaries of externally fertilized fish retains its fertilizing ability several hours before induced ovulation. This method can be successfully used in combination with (Müller et al. 2018, 2020) or without hormonal treatment (Gazsi et al. 2021) in case of several species. The aim of our study was to investigate the efficiency of sperm ovarian lavage in case of pikeperch induced spawning in the absence of male. Additionally, in order to assess the appropriate moment for the lavage, we monitored the effect of carp pituary (CP) suspension on final oocyte maturation and ovulation.

Materials and methods

The pikeperch broodstock was transported from the Nagyatád V95 LtD fish farm (Nagyatád, Hungary) to the Laboratory of MATE Kaposvár Campus. The fish were sorted by sex (10 females, 4 males) and individual females were separated in 250 l tanks, while male specimens were placed in pairs into two 300 l tanks. The tanks were in same water circuit and the water temperature was maintained between 13.2-14.7°C. Hormone treatment of singular injection of 7 mg/kg CP was administrated intraperitoneally. The maturation stages of oocytes (Zarski et al., 2012) were assessed following biopsy sampling of all females at three different moments - at the same time as hormone treatment (0 h), at 48 h and 70 h post-injection. Clarified oocytes were photographed and oocyte stage was evaluated. Artificial nest substrate (60×70 cm) was inserted for spawning, straight after sperm ovarian lavage. The method of sperm injection was as described by Müller et al. (2020). Briefly, 1 ml sperm per kg of female's body weight was equally divided into two ovarian lobes 75 h after hormone treatment. The timing of sperm injection was determined based on the oocyte stage and previous studies so that the "ovarian storage time" would not exceed 40 h, the time when spermatozoa fertility greatly reduces (Müller et al., 2020).

Results

In total nine fish ovulated and released their eggs. The maturation dynamics of the 9 females showed large individual differences, visible in latency time being at 83h (n=1), 88h (n=1), 95h (n=5), 99h (n=1), 154 h (n=1). Several fish did not ovulate on the artificial substrate but disposed the eggs next to it (n=4). Fertility values measured at 72 h post-fertilisation showed large individual differences in total range 0-84%. There was no correlation between the fertilisation rate and ovulation time (sperm storage time).

Discussion

The ovarian lavage method was successfully used with different siluriform and cypriniform species (Müller et al., 2018, 2020; Gazsi et al, 2021). To the best of our knowledge, this is the first report on the application of this fertilisation method in pikeperch. The outcome of the technique appears to be rather variable, nevertheless, such variability was already described in pikeperch on different issues (Ljubobratović et al., 2017, Zarski et al., 2019; Colchen et al., 2020). Therefore, future studies are required to adapt this method to pikeperch and other perciforms respecting the biology of their gonads.

MAXIMISING BIOMASS GAIN AND FEED CONVERSION EFFICIENCY IN RECIRCULATING AQUACULTURE SYSTEMS USING A NEW REAL-TIME NITRITE AND NITRATE MONITOR

M. Grau-Butinyac[1], J. Downes[2] and E. Murray[1*]

1. Research & Development, Aquamonitrix Ltd., Carlow, Ireland
2. Marine Institute Catchment Research Facility, Furnace, Newport, Mayo, Ireland
E-mail: emurray@aquamonitrix.ie

Introduction

Recirculating aquaculture systems (RAS) have the potential to reduce fish stress and improve welfare by controlling a range of parameters including feed rates and water quality [1]. RAS has been employed in freshwater phase of Atlantic salmon production with ongoing investigations to produce larger pre-smolts to reduce the required length of time of the marine grow-out phase [2]. To ensure successful production, nutrient balance and biofilter performance in RAS systems is key. Monitoring of nitrite (NO_2^-) and nitrate (NO_3^-) aims to maximise biomass gain and feed conversion efficiency in RAS. Current methods for nitrite analysis include spectrophotometry, however this methodology consists of time-consuming sample preparation and uses hazardous reagents. Instead, the use of Aquamonitrix real-time nitrite and nitrate analyser can overcome these drawbacks while allowing to monitor the correct operation of the biofilter; manage water quality and optimise feed conversion efficiency.

The aim of this case study was to identify optimal feed rates and water quality and achieve maximum feed conversion efficiencies. Aquamonitrix nitrite and nitrate monitor was used. At the start of the case study, monitoring of nitrite and nitrate levels ensured bacterial communities in biofilter had established and ammonia was oxidised to nitrite and then nitrate. Real-time results provided by Aquamonitrix informed of water quality in the RAS system.

Methods

The case study was carried out in the RAS facility of the Atlantic West coast of Ireland (operated by the Marine Institute). The system has eight 5.5 m^3 tanks with a total 44,000 L capacity and production capacity of 12,000 Atlantic salmon pre-smolts in the freshwater phase. Feeding was daily, starting at 8.30 am, with 20.4 grams added to the system every 90 seconds for 12 hours.

In-situ monitoring was carried out using Aquamonitrix nitrite and nitrate analyser. The analyser incorporates rapid ion separation in combination with novel UV LED based detection for selective and sensitive detection of nitrite and nitrate in waters [3]. Real-time nitrite and nitrate concentrations were remotely accessible and reported via the proprietary Datamonitrix IoT portal which allows users to remotely access continuous concentration information generated by the analyser deployed within the RAS facility.

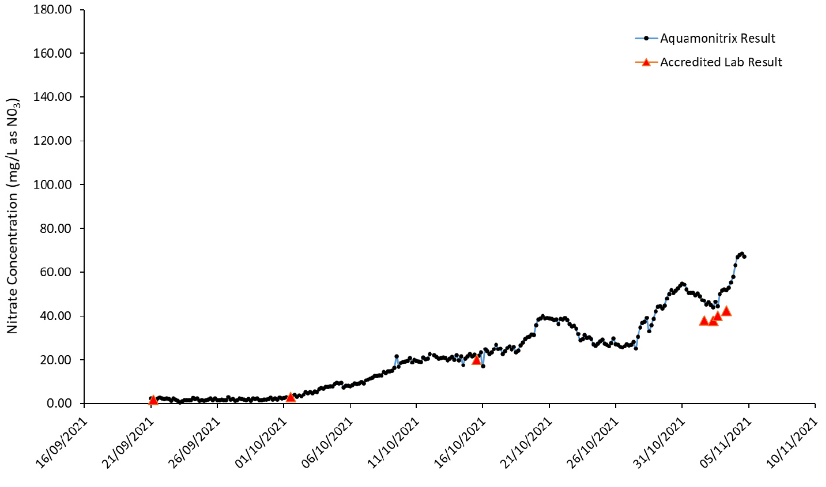

Figure 1: Nitrate accumulation in the system overtime. Aquamonitrix results were compared to accredited laboratory results to demonstrate accuracy of the unit on the monitoring of nutrients.

(Continued on next page)

Results

Temporal resolution of results provided by Aquamonitrix allowed the observation of fluctuations of nitrite levels in relation to feed input through the day. Nitrite build-up started after the feeding started and continued during the day. This nitrite build-up was then reduced overnight as bacteria broke it down to nitrate.

Nitrate accumulation was also detected in the system overtime (Figure 1). Nitrate increased along with increasing fish biomass. Biomass gain and total feed input were closely correlated with a linear increase of these factors.

Discussion

Results obtained from this case study using Aquamonitrix for the monitoring of nitrite and nitrate in a RAS system showed the importance of specific and accurate nutrient monitoring with high temporal resolution. The observed nitrite fluctuations aligning with feeding cycles within a single day highlight the speed at which real-time results can be obtained. The monitoring of these nutrients also provides the correct operation of the biofilters, in this case observed by the decrease of nitrite overnight which is being oxidised by bacteria present in the biofilter. Correlations between nutrients and fish biomass allow to determine water exchange rates and track water quality in the system. It was concluded that efficient feed conversion occurred in the RAS system, emphasising the environment in which the fish were present was of high-water quality. The operation strategy of the RAS system to achieve the optimal environment of efficient feed conversion was obtained through the high temporal and accurate monitoring nitrite and nitrate using Aquamonitrix analyser.

AQUACULTURE STEWARDSHIP COUNCIL (ASC) CERTIFICATION: EVALUATION OF NICHE SPECIES (I.E. PERCH AND CAT FISH) FOR THE DEVELOPMENT AND IDENTIFICATION OF SPECIES AND SYSTEM-SPECIFIC CERTIFICATION METRICS

Fabiola Mustafaj*, Katherine Dolmage, Kathrin Steinberg

Daalseplein 101
3511 SX Utrecht
The Netherlands
Fabiola.Mustafaj@asc-aqua.org

The Aquaculture Stewardship Council is the world's leading certification scheme for farmed seafood. The ASC uses market-based approaches to incentivise famers to achieve strict standards regarding environmental and social performance. Currently, the ASC standards cover 17 species groups under 11 standards, plus a joint ASC-MSC standard for seaweed. Standards development to date have been multi-year dialogue processes involving many stakeholders from academia, producers, ENGOs, and others. While these processes have resulted in robust standards, they are lengthy and do not allow for a quick response to new or emerging species in the market. To respond to requests more quickly for new species standards, the ASC has developed a niche species process.

Developing alongside our Farm Standard process, the niche species project recognizes that many impacts of aquaculture are based on the production system, rather than only being species dependent. The Farm Standard will include a core set of indicators and will monitor ecosystem impact consistently across species and regions and set species-specific limits where necessary (e.g., mortality levels, feed conversion, etc.). Therefore, this is the perfect time to create a process to add species and framework more easily for developing metrics.

The niche species development itself begins with an analysis of market demand and emerging species in aquaculture production. Priority species are then entered into a risk matrix, which identifies areas of environmental or social concern. For example, species that are highly invasive, require wild caught broodstock, or which present concerns from a human welfare perspective will be flagged. While not necessarily meant to eliminate these species from consideration, the risk matrix will highlight areas which may require further investigation or consultation. A list of potential species for inclusion will then be reviewed by the ASC Supervisory Board, who provide the final decision on which species shall be developed.

The ASC is currently partnering with catfish and pikeperch producers in Europe to gather data and develop metric limits for these species. Pilots will be conducted with these farms to test the process, after which a formal methodology can be released.

The combination of the Farm Standard and niche species project will improve the ASC in several ways. First, the volume of aquaculture production able to be certified will increase with each additional species added. Second, a consistent set of standards across species will allow for us to better determine impact. The development of improved reporting templates outlining metrics requirements across species will allow for trend analysis and robust impact reporting.

EFFECT OF PROCESSED (BIOSECURE) MACROALGAE ON GROWTH AND HEALTH OF ABALONE *Haliotis midae*

Introduction

The provision of microbiological safe diets is a crucial aspect in any intensive culture condition. This reduces the risk of introduction of potential pathogens to the stock which could lead to infections and disease outbreaks. In the abalone industry, macroalgae is often harvested from the sea or grown in abalone farms in the integrated multi-trophic aquaculture (IMTA) systems then fed directly to the farmed abalone stocks or incorporated into formulated abalone diets. Despite the benefits of macroalgae inclusion on abalone growth, microbial hazards linked to the use of fresh macroalgae have been reported (Kua et al. 2011, Banach et al. 2020, Barberi et al. 2020). Application of biosecurity processing treatments to render the macroalgae safe is recommended as a necessary step for their effective utilization. However, there is limited information regarding the effect of processed macroalgae on the fed abalone stocks. In this study, three macroalgae *Ecklonia maxima*, *Ulva lactuca* and *Gracilaria gracilis* were subjected to a combination of different biosecurity processing treatments: disinfection with povidone-iodine solution, oven drying and UV-C treatment before being incorporated into formulated abalone diet. The effect of the biosecure macroalgae meal on the growth performance and health of abalone was assessed.

Materials and methods

Seven experimental diets were formulated and fed to sub-adult abalone for a period of five months. Three diets contained biosecure macroalgae kelp, gracilaria and ulva respectively, other three contained the same macroalgae but were not subjected to any biosecurity treatment, the remaining diet was the control and did not contain macroalgae. Diet formulations were conducted according to standard commercial diet formulation. The seven diet treatments were fed to baskets of abalone in four replicates using a randomized-block design with each treatment represented once in each tank to ensure standardized conditions. Feeding was carried out using standard farm feeding procedures of 0.3-0.4% of body weight per day. Sampling was done at the start of the experiment, after one month, at month four and end of the experiment. Total weight of the abalone baskets was taken using an electronic balance after draining off the excess water. Sub-samples of thirty abalone were then taken randomly from each basket, blotted dry to remove excess water then individual shell length and weight taken. Weight was recorded to the nearest 0.01 g using a balance while shell length was measured along the longest axis to the nearest 0.01 mm using Vernier callipers. To assess the health indicators, two whole abalones were taken from each replicate basket at the end of the experiment for histopathology analysis.

Table 1: Mean (± se) wet weights and growth rates of abalone *Haliotis midae fed with different diets containing biosecure and non-biosecure macroalgae: Abfeed* (AB) biosecure gracilaria (BG), non-biosecure gracilaria (NBG), biosecure ulva (BU), non-biosecure ulva (NBU), biosecure kelp (BK) and non-biosecure kelp (NBK). (preliminary data)

Diet Treatments	Mean Initial Weight (g ± se)	Mean Final Weight (g ± se)	Growth Rate (g day^{-1})
AB (control)	37.54 ± 0.48	53.04 ± 1.02	0.101
BG	37.98 ± 0.48	56.55 ± 0.8	0.121
NBG	37.64 ± 0.51	57.41 ± 0.81	0.134
BU	37.92 ± 0.53	56.99 ± 0.81	0.127
NBU	37.65 ± 0.46	59 ± 0.87	0.139
BK	37.8 ± 0.43	57.58 ± 0.96	0.129
NBK	37.46 ± 0.48	55.27 ± 0.74	0.116

(Continued on next page)

Results

Preliminary results indicate that, overall, the macroalgae containing diets produced significantly higher growth compared to the control. Diet containing non-biosecure ulva (NBU)recorded the highest growth followed by non-biosecure gracilaria diet (NBG) (table 1). There was a significant difference between treatments in terms of final abalone weights ($p<0.05$). Analysis to determine the effect of the biosecure diets on health of abalone is ongoing.

The findings of this study are expected to contribute towards improved growth and health of farmed abalone stocks, and a reduction in the risk associated with diseases and pathogens that could potentially be introduced to abalone stock through feeding practices.

ARE FISH LARVAE FULLY IMMUNOCOMPETENT AT EARLY STAGES?

Introduction

Early development is a critical stage since the highest mortality of fish occurs in this period (Garrido et al., 2015)the relation between the size-at-hatch and early survival was assessed using laboratory experiments and on field-caught larvae of the European sardine (Sardina pilchardus. The high vulnerability of fish to disease and stressors during larval stages compared to post-larval stages raises a question about the immune capacity of fish larvae before and after the larval - juvenile transition. Overall, the immune repertoire of teleosts and presumably the immune response is more complex than in other vertebrates because of the acquisition and retention of additional gene copies during evolution of immune-related genes as exemplified by the complement genes (Najafpour et al., 2020)factor H (Cfh. Studies of immune-related molecules during larval development tend to take a candidate gene approach, but little information is available about the acquisition of full immune capacities in fish. For example, in the Atlantic cod until 8–10 weeks post-hatching IgM was absent (Schrøder et al., 1998), which suggests the immune repertoire and immune response may be different in early developmental stages. Wang et al. (2008) studied the differential expression of several complement genes, C3, C1r/s, C4, C6, Bf, MBL and MASP in zebrafish (*Danio rerio*) and proposed the alternative pathway is active and responded to LPS in larval stages. Gilthead sea bream (*Sparus aurata*) is an important commercial marine species, and disease management and production of high-quality larvae of this species remains a challenge for the aquaculture industry (Muniesa et al., 2020)risk analysis and biosecurity systems. Mediterranean marine fish farming, as any aquaculture production, is affected by various infectious diseases. However, seabass and seabream, the main produced species, are not listed as susceptible host species for the notifiable pathogens listed in the current EU legislation, which generates a lack of systematic reporting. The results presented in this study come from a survey directly to fish farms (50 hatchery and on-growing units from 10 Mediterranean countries. In the present study, the goal was to use high-throughput sequencing (RNA-seq) of sea bream larvae during flexion and at mid-metamorphosis to prospect the potential immune capacity of fish larvae during very early life stages.

Material and methods

Total RNAs (tRNA) of the whole larvae in flexion and mid-metamorphosis stages were extracted using an E.Z.N.A. Total RNA Kit I (VWR, USA) according to the manufacturer's instructions. Initially pools composed of 3 sea bream larvae at flexion and 1-2 larvae at mid-metamorphosis were homogenized in lysis buffer using mechanical disruption with two iron beads (5 mm) and a Tissue lyser II (Qiagen, Germany) for 3 cycles (30 Hz) of 30 seconds at room temperature. Paired-end RNA-seq sequencing libraries (2 × 150bp read length) were produced using an Illumina HiSeq xten platform (Novogene, Shanghai, China). After quality control filtering, the reads were mapped to the seabream reference genome (https://www.ncbi.nlm.nih.gov, RefSeq assembly accession: GCF_900880675.1) using the bioconductor package Rsubread (Liao et al., 2013). Analysis of differentially expressed (DE) genes was performed using normalized read counts and by computing moderated t-statistics of differential expression by empirical Bayes moderation of the standard errors in the limma package (Ritchie et al., 2015)limma has been a popular choice for gene discovery through differential expression analyses of microarray and high-throughput PCR data. The package contains particularly strong facilities for reading, normalizing and exploring such data. Recently, the capabilities of limma have been significantly expanded in two important directions. First, the package can now perform both differential expression and differential splicing analyses of RNA sequencing (RNA-seq.

Results

The expression profile of the immune genes involved in both innate and adaptive immunity was analyzed in sea bream at flexion and mid-metamorphosis. Transcriptome comparisons of the two stages of sea bream larvae identified 150 immune-associated gene transcripts that were significantly changed between flexion and mid-metamorphosis. Overall, most of the immune-associated genes involved in innate and adaptive immunity were down-regulated in younger larvae at the flexion stage (≅ 24 dph) compared to the bigger larvae at mid-metamorphosis (≅ 50 dph). Several genes associated with the adaptive immune response such as C1q (e.g., *c1qa*, *c1qb*, *c1qc*) and MHC (e.g., several *mr1*) were down-regulated in the flexion stage. Gene ontology of the DE genes in 24 dph sea bream larvae (compared to 51 dph) showed enrichment of "*Abnormality of complement system*" (HP:0005339) and "*Complement deficiency*" (HP:0004431) terms based on the human phenotype ontology (HPO). Many immune-associated genes were expressed in both flexion and mid-metamorphosis larval

(Continued on next page)

stages while some immune gene transcripts such as MHC (e.g., major histocompatibility complex class I-related gene protein-like, XM_030411748), C1q (e.g., complement C1q-like protein 4, XM_030431421) and lectin (e.g., galactose-specific lectin nattectin-like, XM_030422915) were absent at the flexion stage (≅ 24 dph) compared to mid-metamorphosis (≅ 50 dph).

Discussion and conclusion

The significant change in many immune-related gene transcripts between larvae at flexion and mid-metamorphosis suggests that the immune capacity of sea bream larvae changes during development. The clear down-regulation of most of the immune-associated gene transcripts in larvae at flexion is indicative of a very low immune capacity in very early stages of sea bream. This is coherent with the observed increase in a suite of immune-associated genes (C3, C1r/s, C4, Bf, MBL and MASP) in zebrafish larvae after hatching (Wang et al., 2008). The lack of immune competence in early life stages leading to severe mortality was also proposed for the Indian major carp, *Labeo rohita*, which had low mean antibody levels up to 3-weeks post-hatch (Swain et al., 2006)Labeo rohita (Ham.. Most innate immune genes showed an increase in transcription around hatching and first feeding in Atlantic cod, *Gadus morhua* (Seppola et al., 2009). Taking into consideration the results about complement in our transcriptome study of sea bream larvae and the study of the zebrafish complement response where the competency of the alternative pathway was suggested (Wang et al., 2008), it seems likely that activation of complement by the classical and lectin pathways does not occur in early development. The absence of gene transcripts related to the adaptive response at flexion in sea bream and their upregulation at mid-metamorphosis (≅ 50 dph) suggests the adaptive response emerges later in the development of sea bream larvae. Overall, the transcriptome data suggests that although many gene transcripts related to the immune system are present in the flexion stage, levels are very low and the larvae are unlikely to be immunocompetent. The levels of immune-related gene expression increased during development and achieved significantly higher expression at mid-metamorphosis. The results of this study about the immune status of sea bream larvae as revealed by their transcriptome will contribute to improve the management and efficacy of immunostimulants and vaccines.

Introduction

Nucleotides (NT) and nucleic acids (NA) are considered promising additives in aquafeed formulation. Dietary NT and NA have been shown to enhance growth, improve disease resistance, modulate immune functions and positively affect the gut microbiota of many fish species (Hossain et al., 2020). NT and NA could be beneficial in-feed additives for fast grower carnivores fish species such as European seabass (Dicentrarchus labrax). Moreover, NT and NA may enhance the expression of certain genes which are important for non-specific defences (e.g. cytokines) as well as increasing the resistance to a variety of stressors. The objective of this study was to evaluate the effects of dietary nucleotides and nucleic acids on growth of European sea bass juveniles fed different fish meal level.

Material and Method

Six isoproteic and isoenergetic experimental diets formulated to contain two different fish meal (FM) levels (FM10, 10 % and FM20, 20%) were added with 500 ppm of NT or 500 ppm of NA (FM10, FM10NT, FM10NA, FM20, FM20NT, FM20NA). Diets were tested on triplicate fish groups of 60 individuals (initial weight: 14.33 g) over a period of 88 days. During the trial, feed was provided to apparent satiation, temperature was kept at 23.0 ± 1.0 °C and oxygen above 7.5 mg L^{-1}. At the end of the trial, fish were exposed to suboptimal conditions by increasing temperature to 30.0 ± 0.5°C and decreasing oxygen to 4.5 mg L^{-1} for 8 days while keeping the same feeding conditions. Final body weight, specific growth rate (SGR), feed intake (FI) and feed conversion rate (FCR) were calculated. Intestine and liver cytokine gene expression, as well as gut microbiome were performed before and after the exposure to suboptimal rearing conditions. Differences among treatments were considered significant at $P < 0.05$.

Results

At the end of the trial fish fed diets with NT and NA inclusion presented significantly higher body weight. Fish fed FM20NA presented the highest body weight and SGR and the lowest FCR. FI has given significant difference. Feed with NT and NA inclusion gave higher palatability. Concerning somatometric indices, no differences occurred among groups. On proximate composition, fish fed FM10, FM10NA and FM20 displayed most elevated water body retention. Higher crude lipid retention occurred in FM20NT group. On nutritional indices, FM20NA diet showed the most elevated protein and lipid efficiency (PER, LER, GLE, GPE). All cytokines tested (IL-1 β; TNF-α; IL-10; TGF-β) showed a significant effect on treatments. Comparison between groups at the end of the feeding trial (T1; Fig. 1) showed that the gene of the pro-inflammatory IL-1β cytokine was significantly more expressed ($p = 0.0260$) in fish with FM10NA compared to fish with FM20NT. IL-1β was significantly higher in fish with FM10NA ($p = 0.0260$) or FM10NT ($p = 0.0043$) compared to fish fed with FM20NA and FM20NT. Conversely, the gene expression of the regulatory TGF-β cytokine was significantly higher in groups with FM20NA ($p = 0.0043$) or FM20NT ($p = 0.0043$) compared to group fed with FM10NA and FM10NT. No significant effects were detected in fish fed with FM10/FM20. After the suboptimal rearing condition period (T2; Fig. 1) there was a significant difference ($p = 0.0411$) in the gene expression of the pro-inflammatory cytokine TNF-α. The FM20NA group showed the highest TGF-β expression with values significantly higher than FM10NA ($p = 0.0303$) and FM20NT ($p = 0.0411$).

Discussion and conclusion

This study provided novel insight on the effects of NT/NA inclusions for European seabass juveniles fed different FM-FO levels. It improved voluntary feed intake by 10.7% at FM10 and 9.4% at FM20. An increase in SGR was observed with each inclusion of NT/NA in the diet compared to the only FM diet. Notably, fish fed with NT/NA inclusions in the FM20 diet showed a marked improvement in lipid and protein absorption. NT/NA inclusions in the FM20 diet have had a positive impact on the intestinal mucosa by increasing the anti-inflammatory TGF-**β**. Thanks to the increase in TGF-**β** they had a better nutritional absorption resulting in improved growth performance. In conclusion, results on growth performance, nutritional indices and cytokines gene expression suggest the addition of NT and NA in the diet of European sea bass (*Dicentrarchus labrax*) juveniles.

(Continued on next page)

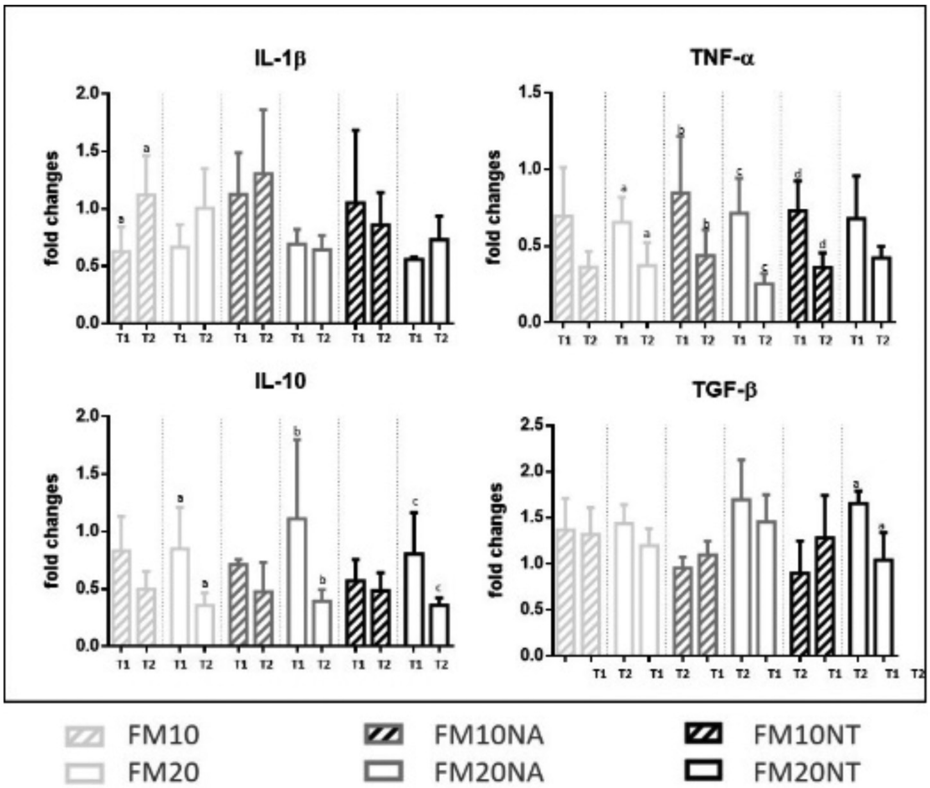

Figure 1. Gene expression analysis at the end of the feeding trial (T1) and after the suboptimal rearing condition period (T2). Comparison between different time points (T1 *vs* T2): same superscript letter means a significant difference ($p \leq 0.05$).

Introduction

In the current context of rapid growth, marine aquaculture faces a major challenge for sustainable expansion given its economic and environmental dependence on the limited availability of marine-derived meals and oils used in feed formulation. This linear model is unsustainable and therefore, the current aquaculture of marine species is based on the use of replacement feed with high levels of inclusion of plant components whose nutritional profiles are far from those of marine ingredients. Specifically, the use of vegetable oils entails a drastic reduction in n-3 long-chain polyunsaturated fatty acids (n-3 LC-PUFA), absent in vegetable oils, and a concomitant increase in other shorter (up to 18 carbons) polyunsaturated fatty acids (PUFA) (Naylor et al., 2009), including linoleic (18:2n-6) and linolenic acids (18:3n-3). Certain aquatic invertebrates have the capacity for the endogenous production (biosynthesis) of n-3 LC-PUFA. This feature became apparent following a study (Kabeya et al., 2018) that revealed that a particular type of enzymes ("ωx desaturases"), historically believed to be absent in animals, exist in multiple invertebrates. The presence of omega desaturases gives these invertebrates the potential to biosynthesize n-3 LC-PUFA, just like the primary producers. Such metabolic capacity, together with their detritivorous feeding habit, make some aquatic invertebrates ideal candidates to apply the principles of the Circular Economy, through the recycling of waste materials of low nutritional value from bioindustries, to produce a highly nutritious biomass. This can represent a new sustainable source of n-3 products in high demand by rapidly expanding sectors such as aquaculture, and can contribute to transform the aforementioned linear model into a circular one. In this context, different national and international projects (IMPROMEGA, SIDESTREAM, BIOCYCLES) are being developed to delve into these aspects, using polychaete annelids, and gammarid and copepod crustaceans. The ultimate objectives pursued include: 1) to investigate the in *vitro* and *in vivo* capacity for the biosynthesis of n-3 LC-PUFAs; 2) to evaluate the regulation of the n-3 LC-PUFAs biosynthesis through dietary lipids; 3) to study the regulation of the enzymes involved in the biosynthesis of n-3 LC-PUFAs through environmental factors.

Materials and Methods

The generic approach to address the objectives consists of the selection of species, followed by the molecular and functional characterization of the enzymes involved in the biosynthesis of fatty acids, basically elongases and desaturases. Molecular characterization is based on the search for sequences in both public (e.g. NCBI, Ensembl) and non-public genomic and transcriptomic databases accessible through collaborations. The sequences are then used for the design of degenerated primers to obtain the complete sequences of the genes of interest by means of PCR. The functional characterization is based on the heterologous expression of the genes in a yeast system (*Saccharomyces cerevisiae*). The species that so far have been studied are the polychaetes *Hediste diversicolor* and *Platynereis dumerilii*, the gamarid crustaceans *Echinogammarus marinus* and *Gammarus locusta*, and the copepods *Tigriopus californicus*, *Apocyclops panamensis* and *Platychelipus littoralis*.

Results and Discussion

Polychaetes have **ω**x desaturases and a complete enzymatic set that theoretically allows them to carry out the *de novo* synthesis of LC-PUFAs, mainly eicosapentaenoic (20:5n-3) and arachidonic (20:4n-6) acids, but also docosahexaenoic acid (22:6n-3), although the latter to a lesser extent (Kabeya et al., 2020). As for the gammarids elongases, but not desaturases have been found. This limits their theoretical capacity for LC-PUFAs synthesis, although recent studies show their potential to be cultured from agriculture and other bioindustries residues while maintaining moderate levels of LC-PUFAs (Ribes-

(Continued on next page)

Navarro et al., 2021, 2022). In copepods, the enzymatic capacity seems to be phylogenetically driven, being complete or near-complete in the Harpacticoids, intermediate in the Cyclopoids and limited in the Calanoids. Species such as *T. californicus* can be net generators of LC-PUFAs like the primary producers (phytoplankton and other microorganisms) (Kabeya et al., 2021). The real enzymatic capacity of invertebrates for the biosynthesis of n-3 LC-PUFAs should be investigated through feeding experiments designed to provide complementary data to those already obtained *in vitro* and that will allow to individually characterise the expression and function of enzymes involved in the n3 LC-PUFAs biosynthesis. This is underway in our laboratories, and is a fundamental step to understand how the use of metabolic precursors contained in waste materials (sidestreams) used as food, can be optimized by manipulating culture conditions, and thus study how diets with poor lipid profiles similar to those of the sidestreams of bioindustries such as aquaculture and agriculture, can modulate the biosynthetic capacity of n-3 LC-PUFAs (nutritional regulation). Apart from the diet and its lipid composition, environmental factors such as temperature and salinity are implicated in the regulation of the genes involved in the biosynthesis of n-3 LC-PUFAs, which offers the opportunity to develop culture protocols aimed at a greater production of these compounds and avoiding or, where appropriate, minimizing genetic manipulation.

Introduction

Aquaculture is considered a hotspot for the emergence and spread of antimicrobial resistance (AMR) because the coexistence of fish, bacteria and antibiotics in the aquatic environment provides the ideal conditions (Cabello et al, 2013). However, little is known on AMR in aquaculture compared to terrestrial farming. In particular, studies on the occurrence of AMR in recirculating aquaculture systems (RAS) are very scarce, in spite of being the fish farming system of the future. The objectives of this study are 1) to describe the dynamics of selected indicator bacteria within a RAS (i.e. sources, persistence and diffusion) and 2) to compare their AMR profiles to those from clinically important isolates in human medicine.

Materials and methods

This project is being performed at the RAS based at the vet school Oniris, Nantes, over six months (February-July 2022). Rainbow trout is farmed year-long at this experimental station that uses domestic water and follows a thorough water treatment: sand filtration, biological filtration and UV. The dynamics of AMR within this RAS are being studied with a longitudinal study design, by tracking a selection of indicator bacteria in all compartments (water, sediment, fish, feed and biofilm). On a monthly basis, the following samples are collected: 7 water samples from different parts of the recirculating system (including each water treatment step, see Table 1), 1 sediment from water reservoir, 5 biofilms and 5 fecal samples from fish tanks. Each batch of fish feed distributed during the study period is sampled once. Dead fish are opportunistically sampled. All the samples are tested for the presence of *Escherichia coli*, *Pseudomonas* and *Aeromonas*. *E. coli* is an indicator of fecal contamination from mammals and birds, whereas *Aeromonas* and *Pseudomonas* are ubiquitous aquatic bacteria. All three bacterial groups are good indicators of AMR in the environment as they are prone to accumulate and exchange AMR genes. Samples are plated on Glutamate Starch Phenol Red agar (Merck, Germany) for detecting *Aeromonas* and *Pseudomonas* and on Eosin Methylene Blue agar for detecting *E. coli* (Biokar, France), then incubated at 37° C for 24-48 hours.

MALDI-TOF will be used to confirm and identify isolates at species level. Confirmed isolates will be tested by the broth micro-dilution method to determine their Minimum Inibitory Concentration. The antibiotics used in this antimicrobial susceptibility test include Sulfamethoxazole, Trimethoprim, Ciprofloxacin, Tetracycline, Meropenem, Azithromycin, Nalidixic Acid, Cefotaxime, Chloramphenicol, Tigecycline, Ceftazidime, Colistin, Ampicillin, Gentamycin and Amikacine. For each of the bacterial groups studied (*E. coli, Aeromonas, Pseudomonas*), 20 isolates from human clinical infections have been retrieved from the collection of the University Hospital (CHU Nantes) for comparison of AMR profiles.

Results and discussion

44 samples have been tested so far in two sampling events. *Aeromonas* is presumptively the most prevalent bacteria, being found in all compartments of the RAS and almost all the samples. *Pseudomonas* on the other hand seems less prevalent, especially in fish feces. No *E. coli* was found, but coliforms were isolated from water, sediment, biofilm and feed. Further analyses are needed to know whether coliform contamination from feed does persist in this RAS.

With regards to water, only domestic water is presumptively free of *Aeromonas* and *Pseudomonas*, meaning that water is the cleanest at the arrival to the station (Table 1). Fish and feed would be the main sources of these bacteria, which are likely to persist in this RAS. Interestingly, biofilm seems the most dynamic compartment of this system, presumptively shifting from being mainly *Aeromonas*-positive to being mainly *Pseudomonas*-positive, as water temperature rose from 14°C to 16°C.

Introduction

Antimicrobial resistance (AMR) is a threat for human and animal health, and for the production of safe food including aquaculture products. A One Health approach is needed to solve this global challenge, but studies that explore the link between AMR from animals, humans and the environment are very scarce. The objectives of this study were to assess the presence of antibiotic-resistant *Escherichia coli* in the rainbow trout farm environment, and to explore the similarity with antibiotic-resistant *E. coli* from farmers and farm employees. *E. coli* was selected for this study because it is an indicator bacteria of fecal pollution from mammals and birds, and an indicator of AMR in the environment.

Materials and Methods

Two farms located in Brittany (NW France) were enrolled in this longitudinal study. Both farms grew rainbow trout (grow-out phase mainly) in continuous flow systems with raceways. Farms A and B were located on different watersheds and represented different risk scenarios with regards to upstream microbial pollution from aquaculture, livestock and humans. Farm A was located downstream from two fish farms and several cattle and swine farms. The closest wastewater treatment plant was 10 km upstream. On the opposite, Farm B reported that no livestock or fish farm was operating upstream. However, a wastewater treatment plant was located closer to farm B (5 km upstream). Farmers reported the use of thrimethoprim-sulfadimethoxine (farm A) and florfenicol (farm B) in the year prior to the beginning of the study.

Two raceways per farm were selected for the monthly monitoring of *E. coli* in water, biofilm and fish. A total of six sampling events took place at each farm, from February to August 2020. At each farm and sampling event, twenty samples per raceway were collected: 10 water samples (100 ml each), one biofilm sample and 9 fishes (feces and internal organs). In total, 240 samples per farm were processed for the isolation of *E. coli*. Farmers and farm employees from both sites were asked to send their fecal samples to the lab for the isolation of *E. coli*. Eight human fecal samples were received in total, five from farm A and three from farm B.

All samples were plated on EMB agar and incubated at 37°C for 48 h. Presumptive *E. coli* colonies were confirmed by MALDI-TOF. Antimicrobial susceptibility was tested by the broth microdilution method against the following antimicrobial agents: enrofloxacin, oxytetracyclin, thrimethoprim-sulfadimethoxine, flumequine, oxolinic acid, colistin and florfenicol. Epidemiological cut-off values were used to classify an isolate as susceptible or resistant, preferentially those determined by the EUCAST. When not available, cut-off values were either inferred from the literature or calculated with the Normalized Resistance Interpretation (NRI) method. The automatic Excel programmes were made available through courtesy of P. Smith, W. Finnegan, and G. Kronvall. Table 1 shows the cut-off values used in this study.

Results

Sixty-seven *Escherichia coli* isolates were obtained during the study period: 42% from farm A and 58% from farm B. In particular, 36 isolates were obtained from water, 28 from fish farmers and three from fish. On farm A, *E. coli* was found in water, fish and fish farmers. On farm B, only water and fish farmers were positive for *E. coli*. This bacterium was not isolated from biofilm samples from any of the farms.

25 out of the 67 *E. coli* isolates did not show phenotypic resistance to any of the antibiotics tested (11 from farm A and 14 from farm B). On the opposite, none of the three isolates from fish (farm A) were pansusceptible. Table 1 shows the percentage of isolates that were resistant to each of the antibiotics tested, and the sample type of origin. The majority of resistant isolates (25 out of 42) showed resistance to only one of the antibiotics tested. Interestingly, all isolates showing resistance to three or more agents (6) were found in water and farmers from site B.

(Continued on next page)

Table1. Cut-off values used for each antibiotic tested, percentage of resistant isolates and samples of origin

Antibiotic	Cut-off value	% of resistant isolates	Sample type
Enrofloxacin	0.125 mg/l	17.9% (12/67)	water and farmers
Oxytetracycline*	8 mg/l	29.9% (20/67)	water, farmers and fish (sole resistance found in fish gastrointestinal tract)
Thrimethoprim-sulfadimethoxine*	1 mg/l – 19 mg/l	20.9% (14/67)	water and farmers
Flumequine*	16 mg/L	6% (4/67)	water and farmers, only farm B
Colistin	1 mg/l	25.4% (17/67)	water (mostly) and farmers
Florfenicol*	32 ml/l	0% (0/67)	-
Oxolinic acid*	1 mg/l	10.4% (7/67)	water, farmers and fish

*antibiotic authorized for its use in aquaculture in France, only under veterinary prescription

Discussion

In spite of the two enrolled farms being different risk scenarios with regards to upstream pollution from livestock and humans, the overall occurrence of *E. coli* is very similar in both sites. *E. coli* in rainbow trout farms is mainly found in water and farmers, whereas fish are unlikely carriers. The three fish that were positive for this bacterium were in fact diseased animals (furunculosis), thus there may be a link between poor health condition and the colonization of the gastrointestinal tract by *E. coli*. Our results also suggest that biofilms found in freshwater fish farms do not act as a reservoir of *E. coli*.

With regards to AMR, similar phenotypes are found in water and farmers. Resistance to oxytetracycline for example is the phenotype most frequently found in *E. coli* in this study setting, and it is also found in all sample types but biofilm: water, farmers and fish. Oxytetracycline is one of the antibiotics used in aquaculture in France, thus this result is not surprising. However, this finding in *E. coli* from fish farmers may be due to the widely spread resistance against tetracycline in *E. coli* from humans rather than to the use of oxytetracycline in aquaculture. Interestingly, the second most frequent resistance phenotype in this study is resistance to colistin, which is not primarily used in aquaculture in France and is of critical importance for human medicine, according to the WHO. Resistance to colistin was mainly found in *E. coli* from water samples, suggesting they originate from upstream pollution. This antibiotic is mainly used in poultry and pig farms in France, thus we were expecting to find more colistin-resistant *E. coli* in samples from farm A. The fact that farm B is closer to a wastewater treatment plant may explain the similar occurrence of colistin-resistant *E. coli* in both farms.

INTERACTION OF DIET, HOST GENETICS AND GUT MICROBIOTA DURING THE PRODUCTION CYCLE OF GILTHEAD SEA BREAM

Introduction

The AquaIMPACT H2020 EU project aims to integrate selective breeding and nutrition for producing more sustainable marine fish with a higher phenotypic plasticity to deal with environmental challenges. At this interplay between diet and genetics, gut microbiota emerge as a reliable criterion to assess the selection practices. However, the influence of the host genome on the composition and activity of gut microbiota is still scarcely investigated in gilthead sea bream (Piazzon et al., 2020). Thus, the aim of this study was to unravel the main effects of alternative diet formulations along the production cycle of gilthead sea bream selected for high growth (HG) compared to reference (REF) fish, establishing correlations between intestinal gene expression and gut microbiota abundance.

Methods

HG and REF gilthead sea bream were fed CTRL (15% FM; 6-8% FO) and FUTURE (7.5% FM; 12% poultry sub-products and 3% DHA-rich algae oil) diets during 12 months at the experimental facilities of ECOAQUA, at ULPGC, under natural photoperiod and temperature conditions. Initial (t_0; Nov-19; 10 g body weight; 18 fish), intermediate (Jul-20; t_1; 200 g; 36 fish) and final (Nov-20; t_2; 350 g; 40 fish) sampling points were established to assess the dynamics of anterior intestine (AI) mucosal adherent microbiota composition across the production cycle. As the most prominent differences in gut microbiota among groups were found in t_1, fish of this sampling point were selected for RNA-sequencing. V3-V4 region of the 16S rRNA of each sample was amplified and sequenced by Illumina MiSeq, and taxonomy was assigned using the RDP database. RNA-seq libraries were sequenced by Illumina NovaSeq6000. Good-quality reads were mapped against CSIC gilthead sea bream genome and differential expressed transcripts (DET) were retrieved using DESeq2 (FDR < 0.05). Over-representation analyses of GO and KEGG terms were implemented in goseq and protein-protein association networks were retrieved using STRING (FDR < 0.05). DET expression and OTUs abundances of the equivalent fish of t_1 were correlated using Spearman correlation tests ($P < 0.001$).

Results

Illumina sequencing and taxonomic assignment of the 94 samples allowed the identification of 1,897 OTUs at 97% identity threshold along the gilthead sea bream production cycle. Taking into account the entire population, Chao1 richness index progressively decreased with age, whereas the α-diversity Simpson index was significantly higher in t_1 and t_2 than in t_0. Proteobacteria was the most abundant phylum (64-78%) in all the sampling times, followed by Firmicutes (13-15%), Actinobacteria (6-12%), and Bacteroidetes (~2%). The core microbiota of gilthead sea bream along the production cycle was constituted by 25 OTUs (>1% in at least one of the three sampling times). A validated PLS-DA (Figure 1A) rendered the separation of the three experimental time points. The FUTURE diet induced a shift in the gut microbiota composition of REF fish, validated by PLS-DA, but not in HG fish. The influence of the genetic background was already evidenced at t_0, when discriminant analyses separated HG from REF fish. The magnitude of this separation and the number of discriminant taxa persisted along time, but progressively decreased in t_1 and t_2 in fish were fed CTRL diet. By contrast, HG and REF fish microbiota was not distinguished when fed the FUTURE diet. In t_1, RNA-seq mapped reads were associated to 41,582 AI transcripts, with 1,429 DET (1,218 unique descriptions). Group comparisons displayed 1,057 and 459 DET differentially regulated between HG-CTRL and REF-CTRL fish, and between HG-FUTURE and HG-CTRL, respectively. A total of 1,025 significant associations were established between the abundance of 96 OTUs and the expression of 476 DET. A total of 35 correlations between 20 abundant (>1%) OTUs and 25 DET were stablished (Figure 1B). The 60% of the correlated OTUs were associated to DET related with immune system, with a clear presence of Bacilli linked to anti-inflammatory responses. The microbiota-independent list of DET (953) showed the over-representation of transcripts involved in β-oxidative processes of very long chain fatty acids (up-regulated in HG-CTRL) and smooth muscle contraction (up-regulated in HG-FUTURE).

(Continued on next page)

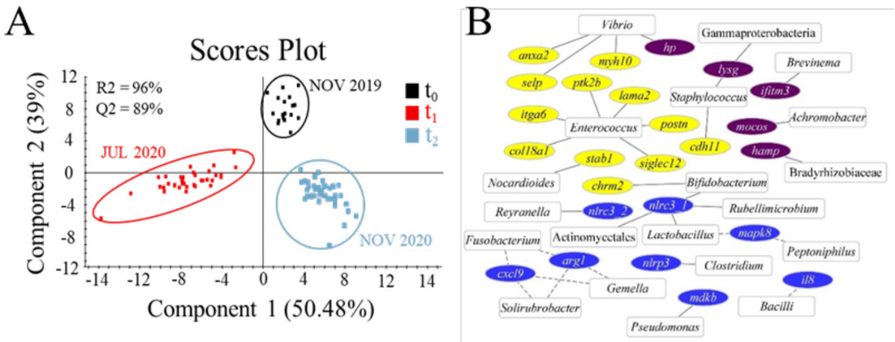

Figure 1. (A) PLS-DA score plots of gut microbiota separating the three sampling points along gilthead sea bream production cycle. (B) Correlation network showing significant correlations (Spearman, $P < 0.001$) between OTUs (white) and DET (yellow, blue, purple) in the anterior intestine.

Conclusions

These results highlight the plasticity of gilthead sea bream gut microbiota along its production cycle, showing the effects of size and season. As in previous studies (Naya-Català et al., 2022), the genetic background strongly influenced the gut microbial composition and the intestinal response of this species, as selected fish exhibited a more plastic microbiota and more changes at the transcriptomic level, when facing dietary changes. Genes related with cell membrane fluency were up-regulated in HG-CTRL fish, whereas FUTURE diet boosted genes involved in intestinal motility in both fish groups. Correlation studies denoted the close link between immune system genes and the intestinal microbiota. Altogether, these results show how diet and genetics can affect the microbiota and the digestive process, and highlight that certain taxa could be interacting with the gilthead sea bream transcriptome.

REGENERATIVE CELLULOSE FIBERS: POTENTIAL USE OF LYOCELL TEXTILES IN SHELLFISH AQUACULTURE

Xaver Neitemeier-Duventester[1], Patrick Unger[1], Manuela Fritzsch[2], Harry W. Palm[1]

[1]Aquaculture and Sea-Ranching, Faculty of Agricultural and Environmental Sciences, University of Rostock, Justus-von-Liebig-Weg 6, 18059 Rostock, Germany
[2]Saxonian textile research institute, Annaberger Str. 240, 09125 Chemnitz

Introduction

The purpose of the presented study was to test alternatives for plastic gear in aquaculture application. Microplastics are a major threat to the oceans and their inhabitants, causing increasing problems in all parts of the world. Microplastic contamination and enrichment has been detected in shellfish as well as in several fish meals in different countries.

Therefore, Lyocell (CLY, Lenzing AG) was tested as blue mussel spat collector band. Lyocell origins from cellulose, made of sustainably grown wood, is produced in a closed cycle and is biodegradable (certified with OK biobased certificate, Vincotte certificate). In general, significantly less water is needed for production of Lyocell than for other synthetical as well as natural fibers such as cotton.

Material and Methods

Cellulose fiber bands are tested for their use in blue mussel cultivation in the German Baltic Sea. Therefore, settlement of spat and durability of the cellulose material were tested in field trails within 2022 and compared with commercial Polypropylen (PP) bands. Samples were deployed at May 2nd 2022 before spat fall. Lyocell collector ropes were woven in the STFI and were tested in field for blue mussel spat collection (see Fig. 1a. and b.). Practical work was carried out in Kiel Bay, Baltic Sea in cooperation with the *Kieler Meeresfarm*, Kiel, Germany. Material durability and traction measurement was tested in the Laboratory of the STFI.

The number of mussels per sector of 15 cm was determined and the largest 35 mussels were measured and weighed. The data obtained was compared for statistical variance and significance between the two types of mussel collectors using SPSS.

Results

At sampling date (Aug, 08th 2022) attachment of blue mussel was comparable between Lyocell and PP bands. Mean mussel size was 14,1±0,9 mm and av. 895 individuals per sector for lyocell, and 13,0±2,7 mm with av. 772 mussels per sector for PP. Mussel settling and growth was significantly higher on Lyocell collectors ($p<0.001$).

Discussion

Microplastics are of major concern for the ecosystem and in particular are dangerous in mussel aquaculture, causing disorders of protein metabolism in mussels. Replacement of plastic collectors was tested and initial results indicate suitability of Lyocell textiles for spat collection, as attachment of spat, number of mussels and size of them was significantly higher on Lyocell than on plastic collectors. After three months under water, Lyocell still had enough strength and no ropes or collector bands broke.

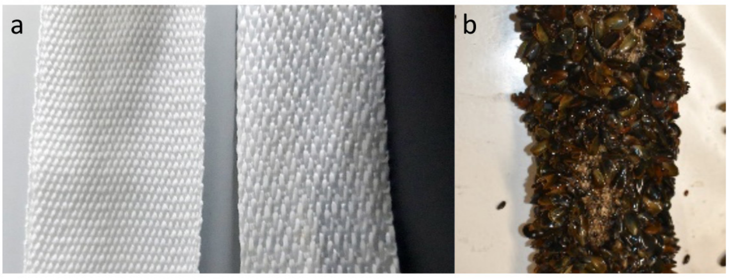

Figure 1a: Lyocell collector band (Lenzing AG) and original sample used, made of polypropylene side by side. 1b: Lyocell band, after three months with on grown mussels.

AN UPSTREAM-DOWNSTREAM EXTERNALITY RELATED TO WATER QUALITY: THE CASE OF THE PORONG RIVER IN INDONESIA

Rasmus Nielsen[a*] Frank Jensen[a], Venticia Hukom[a], and Max Nielsen[a]

Department of Food and Resource Economics, University of Copenhagen
Rolighedsvej 25, 1958 Frederiksberg C. Denmark
Email: RN@IFRO.KU.DK

Introduction:

In this paper, we discuss an upstream-downstream externality related to water quality (level of ammonia) in a river by distinguishing between a non-cooperative and cooperative case. For empirical case, we use the Porong River, which is located in the East Java province of Indonesia. In this river, aquaculture farmers are located downstream while the industrial firms are placed upstream. Using production economic modeling, we find the following interesting results. In the non-cooperative case, we find that the optimal profit by a polyculture is higher than the optimal profit for an industrial firm, and this result is robust to variations in relevant parameter values. Furthermore, by comparing the non-cooperative and cooperative cases, we find that the optimal gain of moving to joint management is reasonably high, and when varying relevant parameter values, this gain remains almost unchanged.

Results:

For the Porong River, we obtain two main results: 1) In the non-cooperative case, the profit for the polyculture farmer is higher than the profit for the industrial firm and, 2) The gain of moving to joint management (or the damage cost of the upstream-downstream externality related to water quality) is reasonably high. Due to uncertainty about the estimated parameter values, we also con-ducted sensitivity analysis by varying each relevant parameter value by +/- 50 % separately. For all parameter variations, we find that the profit is higher for the polyculture farmer than it is for the industrial firm and that the variation in the gain of moving to joint management is very low.

Conclusion:

Finally, in this paper, we have identified the gain of moving to joint management for the Porong River in Indonesia using production economic modelling. We also show that when moving from a non-cooperative case to a coop-erative case, the upstream industrial firm will loss profit while the downstream polyculture farmer will gain profit. An important issue is how to ensure that the cooperative solution is achieved.

CAPTURING AN APHRODISIAC: IMPROVING THE CATCH EFFICIENCY OF OYSTER SPAT (*Crassostrea gigas* & *Ostrea edulis*) IN THE DUTCH SOUTHWESTERN DELTA

Lotte Niemeijer*, Eva Hartog, Tony van der Hiele, Lotte-Julia Bouwman, Demian Zwaan & Jasper van Houcke

HZ University of Applied Sciences, Edisonweg 4, 4382NW, Vlissingen, The Netherlands
*email: s.c.niemeijer@hz.nl

The oyster cultivation sector in the Netherlands has been struggling for several years with a sharp decline in oyster production as a result of variable spawning rates, and mortality in oyster spat (<1 year). The high mortality is partially due to the oyster herpes virus (Ostreid herpesvirus 1; OsHV-1) and predation by the Japanese oyster drill (*Ocinebrellus inornatus*). In order to improve the oyster production volumes in the Netherlands a project was started aimed to increase the catch efficiency of both Pacific oyster spat (*Crassostrea gigas*) and European flat oyster spat (*Ostrea edulis*).

The conventional method of collecting natural oyster spat in the Netherlands is by seeding empty mussel shells on bottom plots. In the Oosterschelde this is mainly done on intertidal plots whereas in Lake Grevelingen this is only possible on subtidal plots.

As a new method, different types of substrates were used in order to collect oyster spat on both intertidal and subtidal plots: loose mussel shells on bottom plots; coupels; and mussel shells in plastic and biodegradable (PLA) nets. Furthermore, in the first year, half of the experimental units were covered with a calcium layer while the other half were not. On intertidal locations, mussel shells were placed in open cages to prevent them from flushing away due to tidal cycles. The coupels and netted mussel shells were mounted on iron A-frames and placed on the bottom in such a way that the substrates were hanging in the water column.

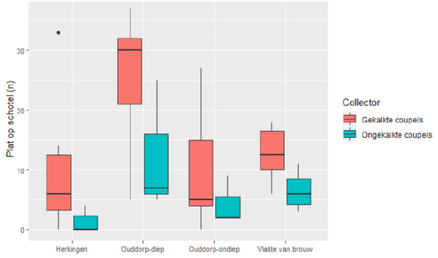

Fig. 1 European flat oyster spat collected in 2020 on coupels with calcium layer (red) and without a calcium layer (blue) on subtidal locations in Lake Grevelingen expressed in number of spat per coupel.

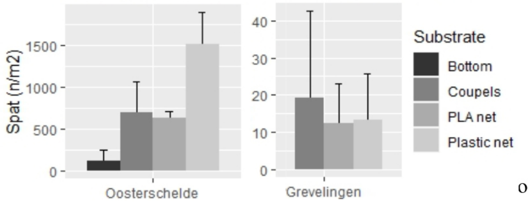

] on

Grevelingen (b) expressed in number of spat per m^2. Note that the y-axis differ.

To determine the seasonal larval peak, water samples were taken weekly at various locations within the research area and analyzed for the presence of larvae of both oyster species. The substrates were deployed in the field during the larval peak in July, e.g. before the settlement of the spat. Monitoring of the oyster spat took place in November, after the settlement of the spat. The monitoring was carried out by means of destructive sampling, whereby a fixed amount of substrate material from the various test locations was collected and oyster spat was counted.

The first year of experimentations was focused on assessing the best substrates. Only coupels with a calcium layer in Lake Grevelingen resulted in higher catch efficiency of spat (Fig. 1).

The second-year was used to deploy the best substrates on a larger scale. So far, the results of the second year show us that in the Oosterschelde (a), the netted mussel shells seem to collect more spat per surface area compared to coupels. However, for Lake Grevelingen (b) this is the opposite.

Data analysis of the second year of the project is currently ongoing and the results of both years will be discussed during the presentation.

Introduction

Whiteleg shrimp *Litopenaeus vannamei* is the most aquacultured crustacean species and the market demand is growing. In addition to traditional pond aquaculture, new indoor technologies like bio-floc systems or recirculating aquaculture systems (RAS) are being developed, but they may pose additional technological, energetic sustainability, animal welfare challenges. It was noticed, that indoor operation and animal handling procedures in RAS often cause substantial stress for shrimp with different negative consequences, even death. The aim of this study was to evaluate the handling stress-related mortality of whiteleg shrimp in a recirculating aquaculture system by comparing standard open and the new type of completely isolated shrimp tank, developed at Klaipeda University.

Materials and methods

Handling mortality was evaluated for three different experimental cycles of whiteleg shrimp from ~1 to ~25 g individuals, cultivated in RAS, located in the Business Incubator of Klaipeda University. Handling is considered as measurements and sorting procedures for experimental purposes. During or shortly after these procedures, the acute mortality rate of handled animals were monitored. In 2021, more elaborated study on growth performance and mortality was conducted, comparing an innovative, completely isolated shrimp tower tank, and 6 standard open 2.8 m^2 tanks – three as a control and three with different handling treatments. There was no additional stress in the control group other than the necessary unavoidable procedures, while handling stress group had different intensity treatment. Additionaly, stress levels in experimental animals were assessed by the concentration of glucose in the hemolymph.

Results and discussion

The significant acute mortality, caused by standard handling procedures during experimental cultivation, was found for whiteleg shrimp in all three cycles, reaching 20-25 %. However, significantly higher mortality rate suffered handled shrimps grown under complete isolation conditions (41.6±12.6 %). The mortality rate were related to the age (or size) of animals, when the highest procedural mortality rate was recorded during the second-third month or at 5-15 g of individual weight. When evaluating the hemolymph glucose concentration as a marker of stress response, no clear patterns were observed. Although glucose concentration is one of the standard markers of stress in crustaceans, it may not reflect the level of procedural stress in shrimp and the resulting acute mortality in this study.

EFFECTS OF HIGH TEMPERATURE EXPOSURE ON SEX DETERMINATION AND GONADAL TRANSCRIPTOMES AND METHYLOMES IN GENETIC FEMALE (XX) AND MALE (XY) NILE TILAPIA (*Oreochromis niloticus*)

Introduction

Reproduction is an essential biological function through which living beings perpetuate themselves. This biological process consists in the production of new offspring from breeders involving the reproductive system. Sex determination (SD) corresponds to any factor initiating sexual destiny towards one or the other path of sexual differentiation (male or female), while sex differentiation corresponds to the underlying mechanisms responsible for the development of functional female (ovaries) or male (testicles) gonads (Hayes 1998). SD can result either from genetic factors and is defined at fertilization (Genetic Sex Determination, GSD), or from environmental factors and is defined after fertilization (Environmental Sex Determination, ESD) (Piferrer et al., 2012). Between these two extremes, some species have a SD depending on both genetic and environmental factors in different proportions. In these species, SD is referred as GSD + ESD.

Environment, through the perception of various abiotic (temperature, pH, photoperiod) and biotic (population density, social structure) factors, can modify the sexual development leading to phenotypic sexual differentiation in a pathway opposite to that genitically defined at fertilization (Devlin et al. 2002)and the mechanisms involved in primary sex determination are now beginning to be defined. A range of gonadal differentiation types have been described for fish, including gonochoristic species possessing purely ovarian or testicular tissues, as well as hermaphroditic species that can initially mature either as males (protandrous. This lability in sex determination and differentiation mechanisms is widespread among fish.

Effect of temperature on SD was reported for 60 teleost fish species (Ospina-Álvarez and Piferrer 2008). However, the underlying genetic mechanisms are poorly understood. Exposure to high or low temperatures during the thermosensitive period for SD can have different effects on the sex ratio of a population. Generally, the most common sex reversal profile is a masculinization effect induced by temperatures higher than the thermal optimum observed for the species (Ospina-Álvarez and Piferrer 2008).

Nile tilapia, *Oreochromis niloticus*, is a gonochoristic tropical fish species with a high commercial interest. This species has a complex sexual determinism involving several factors (Baroiller et al. 2009). Genetic factors are involved with a homomorphic and male heterogametic sex chromosomes system (XX|XY). The effect of minor genetic factors is also reported and temperature can influence sex determination with masculinization observed at temperatures above 32°C producing XX males (Baroiller et al. 2009).

In this context, the aims of our study was to investigate the molecular mechanisms involved in the masculinization process induced by high temperature in genotypic XX female Nile tilapia, and the effects of high temperatures on genetically male (XY) individuals.

Material and methods

Monosex XX and XY tilapia progenies were exposed to a temperature of 36,5°C from 10 to 30 dpf. Gonad transcriptome was analysed at the beginning (15 dpf) and after (40 dpf) the high temperature exposure. In parallel, we characterized the gonad methylome to evaluate the role of epigenetic control on the differentially expressed target genes. Sex ratio of the different progenies was analysed at 90 dpf.

Results and discussion

High temperature treatment induced different effects on sex ratio according to genotypes. In XX progenies, masculinization rate ranged from 20 to almost 100%.

(Continued on next page)

Surprisingly, an opposite effect was observed in XY genotype, with feminization of some progenies. Sex reversal incidence and rate were lower compared to XX masculinization with only 50% of sensitive progenies and reversal rate ranging from 6 to 52%. To our knowledge, this is the first report of such a SD thermosensitivity profile in a vertebrate species.

Our study introduces for the first time a correlation between gene expression and observed inversion rate (masculinization or feminization). Differential expression analysis allowed to identify more specifically genes directly involved in high temperature sex reversal process in *Oreochromis niloticus*. Feminization and masculinization have different characteristics in genes expression pattern. Indeed, during masculinization we observe an induction of known male pathways coupled with a repression of known female pathways. Conversely, during feminization we observe an induction of the known female pathways but the male pathways seem to persist.

We identified *foxl2* gene, known to be widely involved in the female determination and differentiation pathway in vertebrates and tilapia. In our study, *foxl2* presents a particularly interesting expression profile. Indeed, as we have shown, during masculinization it presents an onset of repression at 15 dpf, which is a function of the rate of inversion observed, and at 40 dpf is clearly under-expressed. In a symmetrically opposite way, we identify an induction of its expression already at 15 dpf during feminization and also at 40 dpf. Among the other sex determinism genes identified, we interestingly observe a constant induction of the *gsdf* gene following the heat treatment regardless of the stage and the genotype.

Our study highlighted difference in expression of genes related to metabolism. Indeed, we have demonstrated a repression of the expression of pathways involved in metabolism during masculinization and an induction of these during feminization.

Differences in methylation patterns according to masculinization or feminization were also highlighted. The study of the methylation difference also shows methylation modifications at the level of genes involved in metabolism with opposite profiles between masculinization and feminization.

Introduction

Interest is growing for aquaponics as a way to reduce environmental negative impact of running aquaculture and hydroponics systems separately. The PERCIPONIE project (Interreg GR) aims to develop percid fish culture in aquaponic systems. Intensive pikeperch (*Sander lucioperca*) aquaculture is still in its infancy. Moreover, this specie is considered as a good prospect for the European market due to its fast growth rate and economical expectation. Those characteristics made it a perfect candidate for the « Perciponie » project. The main risk of an aquaponic system regarding water quality and fish welfare is the accumulation of high concentration of nutrients (particularly nitrate) into the system in order to support the best growth of the plants.

The aim of the work was to assess the welfare and production performances (growth and survival) of pikeperch in aquaponic water quality conditions.

The study was performed in two steps : first we experimentally test the effect of different nitrate concentrations on growth performances, survival rate and welfare of pikeperch. Secondly, we evaluate these parameters in a coupled aquaponics pilot system in pikeperch monoculture and pikeperch/sturgeon polyculture

Material and Methods

First, we exposed pikeperch to increasing concentrations of nitrates (354 mg/L to 2655 mg/L NO_3^-) and measured growth indicators such as weight gain, specific growth rate and feed conversion ratio. 20 juveniles (194,3±28.3 g) were randomly distributed in 250l aquarium with an individual filtration system. Nitrate solutions were added to the water with a peristaltic pump to maintain nitrate concentrations at 6 different experimental values. Fish were fed at 1% of biomass/day. Fish growth and survival were measured and welfare was evaluated at the end of the experimental period (60 days) on 5 fish by measuring plasma cortisol, brain serotonin and dopamine levels by ELISA assays.

Secondly, pikeperch was reared in real aquaponic conditions to assess the productivity of the system. The aquaponics facility surface: 100 m², total volume: 18 m³) allows to assess the productivity in real production conditions. Pikeperch were reared at 23°C.Average pH and oxygen levels were 6,9 and 8,2 mg/L respectively. Stoking densities varied between 30 to 88 kg/m³ depending on the size of fish.

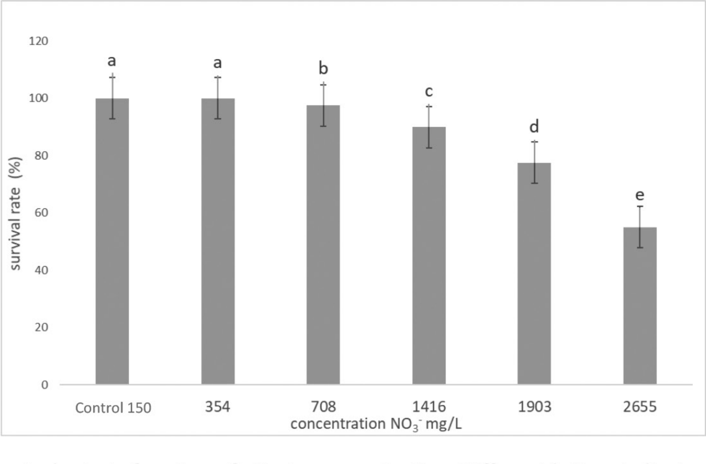

Figure 1. Survival rate in function of nitrate concentration. Different letters indicate a statistical différence (p < 0,05).

(Continued on next page)

Initially, the aquaponic pilot was exclusively stocked with pikeperch and the vegetal production consisted solely in lettuce. In a second time, a polyculture approach was tested withpikeperch and sturgeon (*Acipenser ruthenus*). Fish and vegetable productivity was assessed on a 74-day experimental period. Pikeperch welfare was evaluated by measuring cortisol, serotonin and dopamine levels.

Results and discussion

Pikeperch exposed to increasing nitrate concentrations showed a decrease in survival rate above 354 mg/L NO_3^- (Figure 1). This indicates that the toxicity threshold value is between 354 mg/L and 708 mg/L. Survival rate was close to 100% and similar between 150 mg/L, 354 mg/L NO_3^- and the control. Growth indicators tend to decrease with the increase in nitrate concentrations. However, only the highest concentration (2655 mg/L NO_3^-) led to a statistical reduction in growth compared to control. Plasma cortisol levels were similar in all groups. Dopamine and serotonin analysis are in progress..

First productivity results of pikeperch monoculture in real aquaponic conditions were assessed during 74 days. Mean nitrate concentration in the system during the experimental period was 321 mg/L, which is under the toxicity threshold previously assessed for growth and survival. Pikeperch annual production reached 160 kg with a mortality rate of 7,8%. Lettuce mean weight reached 267,2 g ± 54,6 g. Seven weeks are needed to fully grow a lettuce, 1 week of germination on rockwool followed by 6 weeks of deep water culture on hydroponics rafts. Based on those data, we estimated an annual production of 1282 kg/an. Welfare analysis and comparison with pikeperch-sturgeon polyculture are still in progress.

Final results will be very helpful to guarantee pikeperch welfare and support the development of pikeperch culture in aquaponics.

INVESTIGATION OF HIGH-PRESSURE PROCESSING ON THE EXTRACTION OF FREE AMINO ACIDS FROM DUCKWEED (*Lemna minor*)

Introduction

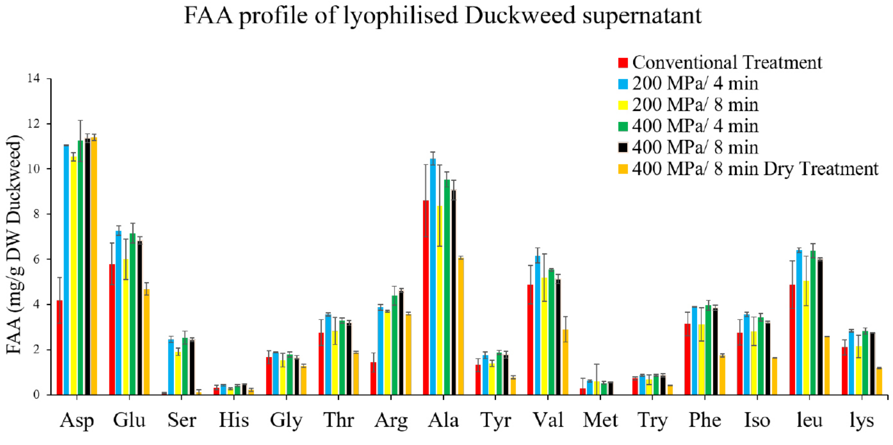
Over the years, there has been a strong interest in the downstream processing of aquatic plants to extract proteins, as it is instrumental in fulfilling the nutritional demand of the emerging population. Duckweed (*Lemna minor*) of the *Lemnaceae* family is widely known as the smallest, fastest-growing flowering plant. Due to rich essential (39.20%), non-essential (53.64%), and non-proteinogenic (7.13%) amino acids, it is considered a "water lentils" for human consumption (Chakrabarti et al., 2018; de Beukelaar et al., 2019; Pagliuso et al., 2022). Several conventional extraction strategies are employed to recover amino acids from duckweed; however, these methods are exorbitantly expensive and time-consuming. Therefore, in the present study, high-pressure processing (HPP) and conventional assisted extraction (CAE) were employed to recover flavour-active free amino acids (FAAs) from Duckweed, and the objective was to investigate the effects of HPP and CAE on the aqueous extraction of FAAs from its dry biomass.

Material and methods

The lyophilised duckweed powder was used for this work. Initially, seven extraction strategies (i.e., HPP (n=5), and CAE (n=2) were investigated. Based on the yield of total soluble solids post-HPP and CAE treatment, samples were subjected to FAA profiling, which was carried out using a UHPLC-FLD method. About sixteen FAAs were found in the extracts, including all nine essential amino acids. Comparison between the matrices of FAAs composition was also carried out using principal component analysis (PCA) on the results of the extracts.

Results

Results showed that the primary amino acids extracted are aspartic, glutamic, threonine, alanine, valine, leucine, and arginine. Overall, the highest concentration of FAAs was found in samples treated with 200 and 400 MPa for 4 min treatment time (Figure 1). This study demonstrated the highest extraction of umami flavor (aspartic and glutamic acids) using these novel extraction technologies from *Lemna minor*. Additionally, HPP treatment reflected significantly higher extraction of FAAs compared to conventional treatment.



FAA profile of lyophilised Duckweed supernatant

Figure 1. Illustrates FAA profile of Duckweed extracts treated with HPP and CAE

Introduction

Vibriosis caused by pathogenic *Vibrio* species is one of the major constraining factors for the sustainable production of farmed shrimps. The immune system of shrimps consists of only the innate immune system, which is believed to lack adaptive features i.e., specificity and long-lasting memory. However, studies carried out in the past on invertebrates (e.g., insects, honey bees, oysters) suggested that their innate immune system could be trained to mount enhanced and long-lasting protective immune responses against both related and unrelated pathogens (Salminen & Vale 2020; Kangale et al. 2021). This capacity of innate immunity to respond adaptively to secondary challenges represents a memory-like characteristic of innate immunity (Norouzitallab et al. 2019). The emerging view that innate immunity could be trained for having long lasting memory has generated immense interest in the shrimp research community to carry out extensive research focusing on this area. We conducted a series of transgenerational studies using the brine shrimp *Artemia* as a model for shrimps to study innate immune memory and the transfer of this trained immunity from parents to offspring. We also focused on possible mechanisms associated with it. The specific aim of carrying out such studies is to develop a robust, cost-effective, and more sustainable disease-control strategy. We used the brine shrimp *Artemia* as a model for farmed shrimps to study the impact of primary exposure of the parental generation to *Vibrio* spp. on the resistance of the progenies against homologous or heterologous challenge. The results suggested that training the immune system, induced by exposure of the parental population of *Artemia* at their early life stages to variouse species of *Vibrio* (relevant to aquaculture species) caused a significant increase in the resistance of the three successive generation progenies (of which none was exposed to the parental stressor) against subsequent challenge with a homologous or heterologous *Vibrio* strain. Protection in the infected offspring was more pronounced when they were infected with the homologous *Vibrio* strain. Interestingly, this transgenerational inheritance of acquired vibrio-resistant phenotype was associated with elevated levels of the signaling molecules such as heat shock protein 70 (*hsp70*) and high mobility group box 1 (*hmgb1*), alteration in the expression of selected innate immunity-related genes, and modifications of the selected epigenetics marks, such as global acetylation level of H4 and tri-methylation level of H3K4, in the progenies whose ancestors were trained by *Vibrio* exposure (Norouzitallab et al. 2016; Roy et al., 2022). These pioneering studies were the first to provide evidence for the occurrence of innate immune memmory in a crustacean species, and to provide some insight into the mechanisms involved. Building upon these findings, recently, several other studies were conducted both by our group as well as others to examine in a comprehensive manner the occurrence of immune memory in shrimps and other farmed crustaceans, and the molecular mechanisms behind such possible phenomena. In this review, we aim to bring this information together to address the question whether the shrimp's innate immunity could be trained to protect them against pathogenic vibrios. We believe that the knowledge generated from these types of research studies will revolutionize our understanding of the defense systems not only in farmed shrimps but also in commercially important farmed invertebrates (like crayfish, lobsters, mussels, honeybees). The findings of this study can be useful for the development of prophylactics, such as vaccines relevant to these species.

Introduction

The effect of re-feeding after fasting on the compensatory growth of aquatic animals has always been an interesting topic in aquaculture and fish nutritional physiology. Feed deprivation and re-feeding can significantly affect proximate composition of fish (Qiu *et al*., 2017). The primary goal of the present study was to investigate how different fish sizes as an individual variable (small vs big) can affect the growth performance when European seabass *Dicentrarchus labrax* individuals are subjected to feed deprivation. Secondary goal was to examine the effects of a specific feeding strategy on proximate and fatty acid composition at different sizes of *D. labrax*, which is a fish species of great economic importance in the Mediterranean industry.

Materials and Methods

The experiment was carried out in a Recirculating Aquaculture System (RAS) at the CARUS research facility of Wageningen University and Research in the Netherlands. Fish with an initial weight of 87.5±16.2g were randomly allocated in 6 tanks (90 fish/tank), supplied with artificial seawater. Fish were distributed into two groups and each treatment was tested in triplicate. The control group was fed daily (twice) *ad libitum* with commercial pellets (Altech Coppens, The Netherlands) whereas the second group was fed for 8 days and deprived for 2 days. This sequence was replicated for 40 days. Throughout the experimental procedure water temperature and pH were maintained at 17.2±2.4°C and at 7.37±0.23, respectively. At the end of the experiment, fish from each treatment (fed and fasted) were classified as fast (FG) and slow growers (SG) according to their final weight and 9 fish from each group were randomly captured and sampled. Crude protein content was analyzed using the Kjeldahl method. Lipid content was measured using the Soxhlet method and ash content was obtained after combustion at 600 °C for 5 h. Energy content was determined using an IKA oxygen bomb calorimeter (C5000, IKA Werke, Staufen, Germany). To determine fatty acids' profiles Folch extraction method was used, followed by esterification and separation using a capillary column in an Agilent GC (6890). One-way analysis of variance (ANOVA) followed by Tukey post-hoc test, was used for each treatment. Main effects and interactions among experimental groups were identified using two-way ANOVA. Mean differences were considered significant at $P < 0.05$.

Results

All fish adapted well to the feeding regimes, and no mortalities were recorded throughout the experimental period. At the end of the experiment, both fast growing (FG) and slow growing (SG) groups of fed and fasted fish increased their weights. Within the FG and SG groups, the experimental feeding treatment did not significantly affect final body weight. Furthermore, the intraperitoneal fat ratio (IFR) for both FG and SG groups, was not affected by dietary status ($P > 0.05$) and the highest IFR values were observed for the fasted ones. In addition, significant differences ($P < 0.05$) were observed among the groups for moisture, dry matter, proteins, ash and gross energy, but no significant changes were found in lipid content ($P > 0.05$). Fed experimental group exhibited significantly higher EPA (20:5n-3) and DHA (22:6n-3) than their fasted counterparts. Except for DHA, no interaction between nutritional status and growth was observed. The lipids of SG contained significantly lower proportions of 18:1n-9, 18:2n-6, Σn-6 and 18:3n-3 and higher proportions of 14:0, 18:4n-3, 20:1n-9, 22:1n-11, EPA and DHA, compared to the FG.

(Continued on next page)

Discussion

The proximate and fatty composition of different sized seabass individuals were evaluated. In the present study, the final weight between the FG and SG groups were not significantly affected by the short-term food deprivation period. Furthermore, this period did not have a substantial effect on IFR. On the contrary, Caruso *et al*. (2011) have mentioned a decline in growth under a short-term starvation period on European seabass and blackspot seabream. The need for the development of a suitable feeding strategy during production in aquaculture, is urgently required. Therefore, the specific feeding schedule concerning starvation and re-feeding cycles could be a likely feed management choice for the culture of this species. Also, no considerable changes occurred in carcass lipid content, between fed and fasted groups, nevertheless it was measured higher protein content in SG compared with the FG, only for the fed fish. On the contrary Yılmaz & Eroldogan (2011) measured higher protein content in fish from the control group. Bigger fish usually have higher lipid and protein status, compared with the smaller ones, as they accumulate more energy stores. As a result, larger fish usually evolve better adapted mechanisms to control food deprivation period and are less sensitive to mortality. Different feeding regimes may affect fatty acid contents (Ambrosio *et al*., 2008). In this study, high levels of saturates, especially 14:0 and 16:0 were observed in fed SG compared to the fasted SG. It is evident that most of the aforementioned fatty acids were affected not only by the short-term food restriction but also by the fish size. Such feeding protocol could be helpful for aquaculture through controlling survival and growth and optimizing the feeding costs.

Introduction

Fish farming in cages in Lake Victoria has been rapidly increasing following the decline of catch rates of wild stocks. However, of recent, massive fish kills have been witnessed in some cage sites. Preliminary studies have attributed the fish mortalities to localized upwelling events that lead to depletion of dissolved oxygen due to release of decomposing matter into the water column. We developed ROMS model to be used to predict such events and ultimately play a critical role in cage culture site selection.

Methodology

We modelled these dynamics using a Regional Oceanographic Model System (ROMS) as from January 1st, 2000. Using the bulk flux technique, the model is based on real bathymetry, river runoff, and atmospheric forcing data.

(Continued on next page)

Results

Annual cycles of thermo-stratification (September–May) and mixing (June–August) are observed in the water column, according to simulations. Surface water currents have several forms, ranging from a lake-wide northward flow to gyres of various sizes and numbers. Upwelling and downwelling zones arise as a result of an underflow. The lake's center and western inshore waters have the highest current velocities, implying that water circulation is better there. However, water exchange between the major gulfs (especially Nyanza) and the open lake is minimal, which could explain the water quality discrepancies found in those areas.

The findings of this study add to our knowledge of the physical processes (temperature and currents) that influence diel, seasonal, and annual variations in stratification, vertical mixing, inshore—offshore exchanges, and nutrient fluxes, all of which have an impact on biotic distribution and trophic structure. Information from this study on upwelling areas/timing and vertical mixing, for example, will help anticipate high primary production and, eventually, fisheries productivity in Lake Victoria, as well as optimal cage culture sites.

ATLANTIC INTEGRATED MULTI-TROPHIC AQUACULTURE – THE ASTRAL PROJECT

Introduction

ASTRAL is a European Union Horizon 2020 collaborative project that focuses on integrated multi-trophic aquaculture (IMTA). The aims of the project include defining, supporting, and promoting sustainable IMTA production across the Atlantic.

Integrated Multi-Trophic Aquaculture (IMTA) is developing as an innovative option for further enhancing the sustainability of aquaculture. Aquaculture faces many challenges in the future due to emerging threats such as the growing risk of harmful algae blooms (HABs) and disease linked with climate change; production and infrastructure losses from extreme events; fluctuations in water temperature and oxygen levels; ocean acidification, and increased demand for resources (Lafferty, 2015). By culturing a combination of lower trophic and higher trophic species together, the co-products of one crop (fed animals) are converted into fertilizer, food and energy for the other crops (extractive seaweeds and animals). This IMTA practice is shown to increase circularity and reduce waste from fed species and lower the nutrient load in the water (FAO, 2018). ASTRAL (EU H2020) focuses on IMTA production in the Atlantic region to address these challenges. IMTA systems can reduce environmental impacts, diversify and increase production, lower investment risks, create jobs, increase consumers' trust, as well as support sustainable aquaculture and the circular bioeconomy (Chopin, 2015). The aim of ASTRAL is to boost IMTA with the implementation of innovative and resilient production, while assessing environmental stressors and pollutants occurrences with new technology developments.

Methodology

ASTRAL is engaged with five IMTA research/production sites in the Atlantic basin to assess production methods, management systems, biosecurity, food safety and profitability, these are known as IMTA labs. ASTRAL is assessing IMTA circularity of each of the IMTA lab systems to allow the development of a zero-waste strategies. The IMTA labs are assessing the presence of microplastics and microbial communities to inform biosecurity and health measures for the chosen IMTA systems. Life cycle assessments (LCA) are comparing the environmental impacts of IMTA to those of traditional aquaculture. Affordable sensors and new technologies are being developed to enhance monitoring capabilities for the aquaculture industry.

IMTA lab Brazil is a biofloc system. During intensive shrimp production without water renewal, there is an accumulation of nutrients excretion/feed degradation and organic matter (biofloc) that are removed mechanically and biologically. The integration of IMTA species consuming biofloc (tilapia and oysters) and dissolved nutrients (seaweeds and halophytes) has been investigated as an alternative to monoculture to maintain the water quality in the closed production system.

IMTA lab South Africa incorporates a commercial farm (Buffeljags Abalone) that integrates the cultivation of abalone, in land-based raceway tanks, with the green alga, *Ulva*, grown in adjacent interconnected paddle raceways using abalone effluent. *Ulva* serves as a biofilter allowing for increased water re-circulation in the system and *Ulva* is used as a supplementary feed for the abalone. IMTA lab SA is also developing an IMTA land-based system for other high-value aquaculture species - sea urchins.

(Continued on next page)

IMTA lab Scotland operates an IMTA open-water system to optimise cultivation techniques of macroalgae and shellfish and demonstrate an improved economic case for the co-cultivation of kelps and native oysters. This lab is undertaking environmental monitoring to improve the cultivation system performance (yield and composition, stocking density and biosecurity). The development of new cultivation systems is exploring options to minimise cultivation wastes through improved system design and reducing, reusing, and recycling polymer-based cultivation materials.

IMTA lab Ireland is developing and validating cost-effective IMTA processes in an open-water system. This IMTA system is exploring the feasibility of the cultivation of Atlantic salmon, lumpfish, European lobster, native oysters, scallops, seaweeds and spiny sea urchins. Production technologies are being assessed and optimised to enhance profitability and to mitigate environmental impact. This lab seeks to establish best practice for the cultivation of these species by monitoring and assessing animal welfare, biosecurity and health management.

Prospective IMTA lab Argentina is gaining knowledge from the other IMTA labs. Feasibility studies are being carried out to assess local species (fish, crustacean, mollusc and echinoderm) and to identify appropriate sites within the Beagle Channel to facilitate IMTA development.

Results

ASTRAL is examining the potential of these IMTA value chains throughout the growing seasons to establish criteria for optimal production conditions. Monitoring continues to establish baseline data for better yield and profitability, reduction of environmental impacts and lessening of waste.

Introduction

The World Bank said already in 2013 that "*Feeding an expected global population of 9 billion by 2050 is a daunting challenge that is engaging researchers, technical experts, and leaders the world over*"(World Bank 2013). The impressive growth of the aquaculture industry in the past decades has resulted in more food being produced, keeping the prices of fish down and making it more accessible to consumers around the world – giving us hope that the daunting challenge in fact is possible to overcome.

Globally, Norway is a leading producer of Atlantic Salmon. During the last 10 years, the Norwegian aquaculture industry has experienced an incredible development, with a total revenue growth of more than 200%. Despite the growing demand of salmon, the growth in production volume is currently at a halt due to the environmental challenges faced by the industry. Challenges include salmon lice and escapees, (Thorvaldsen, Holmen et al. 2015, Misund 2019). These challenges have resulted in negative media attention and decreasing social acceptance for the industry (Tiller, Brekken et al. 2012), resulting in a lack of growth of the industry. Consequently, the industry needs to be innovative and improve its sustainability and reputation. Current challenges and opportunities pertaining to regulations of the production systems needs to be identified and assessed to enable innovation and sustainable growth of the industry. And who doesn't love a good board game. For the purposes of this article, Serious Games are defined as games with a purpose beyond that of purely entertainment and enjoyment (though we love that too). Serious games have a long and rich past, having been used in military and educational training for decades. Serious games have increasingly been used to raise awareness about environmental issues and sustainability (Stenros 2017) – but not aquaculture directly in Norway. In this study, we chose to use serious games as a method to collect data about challenges and opportunities related to regulating the different aquaculture production systems in Norway, to gain input and suggestions for sustainable development of the industry and while also allowing us to increase ocean literary among future generations.

Methods

In this study, Serious Games served a dual purpose as a method for harvesting data related to stakeholders' perceptions of the challenges and opportunities, and for increasing societal understanding and awareness about them. Set in the context of the United Nations Sustainable Development Goals (SDGs) and the United Nations decade of ocean science, we developed "The serious(ly) fishy game". The game is developed based on discussions and information gathered in workshops with stakeholders and in collaboration with representatives from the aquaculture industry. The game, which is contextually placed in Norway, was played in three different sessions with experts from the industry as well as with high school students in Norway. To contribute to the sustainable development of the industry, the aim was to collect qualitative expert data in an informal gaming setting on the challenges and opportunities pertaining to regulating new production systems in the Norwegian aquaculture industry. This would be a more engaging method for finding new solutions that we may not have thought of before.

The game starts out with the participants getting general information about the SDGs and being forced to pick three out of four SDGs given to them and rank them according to their perception of their importance. The reason behind limiting the numbers of SDGs for the game was to get a more focused discussion and to save time while playing the game. After having ranked the SDGs, the participants were then presented with information about the aquaculture industry (e.g. export value and challenges related to regulations. Based on this new information, the participants are asked to discuss whether they wanted to change the prioritized order of the SDGs.

(Continued on next page)

Following the SDGs section, the game had five phases. The first four were directly related to the four specific production systems at hand: land-based, floating closed, floating semi-closed and open ocean aquaculture systems. The participants were presented information about the systems, such as its history, benefits and challenges. Then the participants were given a scenario related to each system that they must first discuss, and then rate the social, economic, and environmental impacts of. After having rated the consequences, the participants are given three countermeasures for each scenario that they had to choose from and rank in terms of social, economic and environmental consequences. The countermeasures had different focus where A was social, B more economic and C more environmental focused. This is something participants were not made aware of until the wrap-up session at the end of the game. The fifth phase contained scenarios that addressed challenges faced by all the production systems. This included sustainable regulations, the use of land produced food for the fish and security threats. The scenarios presented throughout the game were meant to provoke discussions, but at the same time they had to be realistic enough to create a real discussion. The scenarios and the countermeasures were created based on the discussions in the stakeholder workshops. They were further tested, adapted and validated by industry representatives.

The game finish up with a ‘wrap-up’ section where the participants were asked to discuss the decisions they made throughout the game and discuss whether they had focused more on social, economic or environmental impacts when choosing countermeasures. Further, they are asked to discuss how the decisions they made relate to how they prioritized the SDGs in the beginning of the game.

Results

Results from the first round of playing the game shows that the expert participants representing both research and industry see both challenges and opportunities related to the different production systems used in the Norwegian aquaculture industry and that these varies based on what sector they are representing (research or industry) and their age. In this first round of playing the game there was three groups. Two groups ranked the SDGs the same, having SDG 14 as the most important, SDG 12 as the second most important and SDG 8 as the number three. Thereby choosing to get rid of SDG 9. The final group on the other hand ranked SDG 9 as the one with the highest priority and choosing to get rid of SDG 12. Another interesting result was that the two groups that ranked SDG 14 as the most important one, did not choose any of the countermeasures most focused on the environment, but rather countermeasures with an economic or social focus.

Introduction

Biofouling is the growth of organisms such as algae, mussels and hydroids on submerged marine structures. In the sea-based aquaculture industry, biofouling is a challenge as it causes reduced oxygen flow through the fish cages, net deformation, and increased wear and tear on the nets and mooring systems due to occlusion of the nets. Underwater robots utilizing pressure cleaners are often employed to remove the biofouling. This poses a risk to fish health, as harmful cleaning waste is released into the water. An alternative to pressure cleaning is to use brush-based grooming robots that gently disturb the net at regular intervals and hence prevent the biofouling from establishing [1]. Net inspection and monitoring of the environment is also of importance to the fish farmers. The project Netclean 24/7 (RCN 296392) has for the last 3 years developed the autonomous underwater robot 'Remora' for net cleaning and monitoring. This work presents the results of the Netclean 24/7 project and includes an analysis of the robots' functions, modelling of the robot dynamics, autonomous control functions, and a docking station design for permanently resident aquaculture robots.

Materials and methods

Before the development of the robot and its autonomous functions could begin, a thorough analysis of the requirements of the robot was performed. The SEATONOMOY method [2] was used for this purpose. This iterative method aims to define all the required operations the robot must be able to perform, then breaks these operations down into smaller sub-tasks. Once completed, the SEATONOMY method provides the designers with a comprehensive overview of the requirements for all software and hardware necessary to complete the robot [1].

Developing autonomous functions for a robotic system is deemed easier if one has a mathematical model of the robots' dynamics, and the environment it operates in. As such, a model was developed for the Remora robot moving on a dynamically changing fish cage [3].

The autonomous functions of the robot were developed through a series of simulation experiments utilizing the mentioned model. The robot required algorithms that could ensure path following and obstacle avoidance. Based on the investigation of several such algorithms [4, 5], the Elastic Band Method (EBM) was chosen. This method conceptualizes the robot's path as a rubber band between a start point and an end point. If an obstacle appears, the path wraps around the obstacle, much like an elastic rubber band would do in the same situation. To ensure that the robot maintains a safe distance to obstacles, a series of bubbles are placed along the path. The bubbles radii are chosen such that the inside of a bubble is considered a collision free area.

To realize fully autonomous and resident robotic systems in aquaculture a subsea docking station suited for aquaculture sites is required. An extensive study on existing subsea docking stations for autonomous underwater vehicles (AUVs), as well as a concept design for aquaculture use, were performed as part of the Netclean 24/7 project [6].

Results

The results of the Netclean 24/7 project include an extensive analysis of the requirements and specifications for an autonomous, resident biofouling prevention robot. Further, a mathematical model has been developed to describe the dynamics of crawling robots. Advanced motion planning and obstacle avoidance algorithms has been developed and extensively tested, both in simulations [7], and laboratory experiments. A concept for a subsea docking station for aquaculture robots has been designed based on identified requirements from subsea docking stations used in other domains. Figure 1 shows a simulation of the motion planning and obstacle avoidance utilizing the mathematical model. The model captures the interactions between the robot, the net structure, and the ocean currents, while the motion planner is able to re-calculate the path to avoid obstacles. Figure 2 shows the results from the laboratory trials. The robot was able to avoid both static and dynamic obstacles in a controlled environment. Figure 3 shows the subsea docking station concept for residential aquaculture robots. The concept is based on wireless charging and data transfer.

Conclusion and future work

The Netclean 24/7 project consists of project owner Remora Robotics and partners SINTEF Ocean, Nordlaks AS, Xylem Aanderaa AS, and NTNU. The Remora robot is currently operational at several active fish farming locations in Norway and field trials implementing the results of the Netclean 24/7 project are planned in 2022.

Introduction

Genomic selection can improve the selection accuracy and reduce the generation interval. However, pedigree selection has been utilized for growth and body weight in commercial aquaculture breeding programs because of the increased cost of genotyping. Thus, in the present study an effort was made to develop a reduced, low-cost SNP panel to be utilized for genomic selection purposes for production traits (i.e., growth, body weight) and disease/parasite resistance (i.e., parasite count). The aim of the study is to compare the pedigree and genomic predictions using the 30K MedFISH array (Peñaloza et al., 2020) and selected low-density SNP panels for body weight in European seabass (*Dicentrarchus labrax*).

Materials and Methods

For this purpose, a selected sub-sample of 985 fish, from the total of 1,576 fish, infested with *Lernanthropus kroyeri*, was genotyped using the MedFISH array. Two GWAS were performed, one for growth in the sea cage and the other one for the final weight at the end of the experimental period (Oikonomou et al. 2022a, in press) and from these the significantly associated SNPs with the trait of interest (p-value<0.05) were selected. Further, a multitrait GWAS using different growth at different periods in the sea cage was performed and significantly associated SNPs (p-value<0.01) were selected. Based on the above criteria, 1,715 SNPs related to growth were finally selected.

Furthermore, a GWAS was performed for resistance to *Lernanthropus kroyeri* (parasite count, PC) (Oikonomou et al. 2022a, in press). Two low-density panels (SNP–panel 1 and SNP–panel 2) were constructed using two selected groups of SNPs as criteria, according to their p-value from the GWAS (p-value<0.01 and <0.05, respectively). Then, 245 and 1,192 SNPs associated to parasite resistance (GWAS for parasite resistance), were included in the SNP-panel 1 and SNP-panel 2, respectively. *T*hose SNP panels were enriched with the 1,715 SNPs related to growth. Thus, two reduced density SNP – panels, which included 1,960 SNPs (named as SNP-panel 1) and 2,907 SNPs (named as SNP – panel 2) were constructed.

Estimated Breeding Values (EBVs) for the final body weight were calculated using Best Linear Unbiased Prediction (BLUP) and Genomic Estimated Breeding Values (GEBVs) for the final body weight were assessed using Genomic-BLUP (GBLUP) for the three SNP panels (30K MedFISH array, SNP–panel 1 & 2), using BLUPF90. Each time, 20% of the population was selected randomly and its phenotypes were masked (216 fish), thus, the breeding values (EBVs or GEBVs) were estimated using the information from 80% of the total fish. This process was performed 20 times and the correlation between the predicted values for the final body weight and phenotypes was calculated in the validation group. A one-way ANOVA with repeated measurements was performed among the four groups (SNP–panel 1, SNP–panel 2, 30K MedFISH array and pedigree).

Results

In the validation group, the use of pedigree showed the lowest correlation coefficient (0.38) followed by the 30K MedFISH array (0.41), while the use of SNP–panel 1 (1,960 SNPs) provided the highest prediction (0.70) followed by the SNP–panel 2 (2,907 SNPs) in which the estimate was 0.66 (Figure 1). Moreover, a statistically significant difference (p-value<0.01) among the four genetic evaluation procedures was found. The post-hoc analyses with a Bonferroni adjustment were performed and revealed that there was a statistically significant difference between each pair.

(Continued on next page)

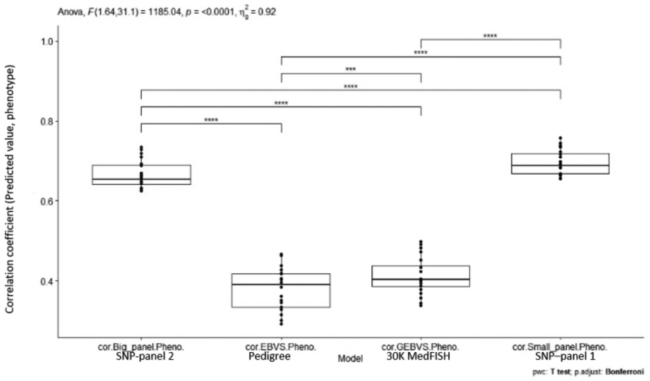

Figure 1. Boxplot for the correlation coefficient between predicted value and final body weight and results from the one-way ANOVA with repeated measurements among the four groups.

Discussion

When, selecting for disease resistance (parasite count) instead of body weight, the SNP – panel 2 provided the highest estimate (0.81) followed by the SNP – panel 1 (0.75) (Oikonomou et al. 2022b) while selecting for body weight the SNP-panel 1 provided the highest estimation (0.70). Regardless of the selection trait (disease resistance or body weight), higher correlation coefficient was established using small, selected SNP panels compared to the 30K MedFISH array.

Furthermore, higher correlation coefficient was found when using genomic information (30K MedFISH array and SNP-panel 1& 2) than when using pedigree relationship matrix. These findings indicate that small and cleverly selected SNP panels, such as SNP – panel 1 and 2 could potentially be utilized in cases of multi-trait genomic evaluation, and in some cases, can provide better predictions especially when parts of phenotypic information is missing.

Introduction

Morpho-anatomical abnormalities is a critical issue in terms of unpredictability, product quality and animal welfare that requires continuous awareness in fish production (Koumoundouros 2010). Anomalies could be developed due to unfavorable abiotic conditions, inappropriate nutrition, and genetic factors (Boglione et al., 2013). Hence, their early detection is long ago considered of immense importance and selective breeding is widely recognized as a key factor for the development of resource efficient, sustainable, and economically profitable aquaculture productions (FAO 1995). Recently, Fragkoulis et al. (2018) studied the genetic parameters of the upper-jaw abnormalities in gilthead seabream and showed a low range of heritability (0.01-0.22), especially the heritability of the Inwards bending (bMa) and Fusion (FMaPm) of the jaw, were 0.04 and 0.22, respectively. In the present study a preliminary analysis was performed to identify microsatellite markers, from two linkage groups, affecting the Inwards bending (bMa) and Fusion (FMaPm) of the jaw.

Materials and methods

Genomic DNA from 498 offspring was extracted using a selective genotyping strategy based on the total length and /or their high phenotypic variation of the deformities. The selected offspring belonged to 153 full sib families, from 53 dams and 45 sires. All fish were genotyped using the microsatellite loci in LG1 and LG21 which were described by Loukovitis et al. (2016). Alleles were sized and individuals were genotyped using the software STRand 2.4.110 (http://www.vgl.ucdavis.edu/informatics/STRand). Offspring at the age of 39 Days Post Hatching, were examined for Inwards bending (bMa) and Fusion (FMaPm) deformations, as described by Fragkoulis et al. (2018). The phenotypes were analyzed as binary data (1: Absent of deformation, 2: Presents of Deformation). For the Inwards bending (bMa) and Fusion (FMaPm), 28.7% and 26.31% of the offspring showed deformation, respectively. A de novo linkage analysis was performed using the options “prepare”, “build” and finally the “flipsn” of CRI-MAP v3.0 software (Green et al., 1990). The linkage distances were estimated assuming the Kosambi’s mapping function. Furthermore, Quantitative Trait Loci (QTL) analysis was performed in QXPAK 5.0 software (Pérez-Enciso and Misztal, 2011), using a maximum likelihood Variance Component Analysis with the presence of a polygenic component (pedigree-based animal model) and the QTL effect.

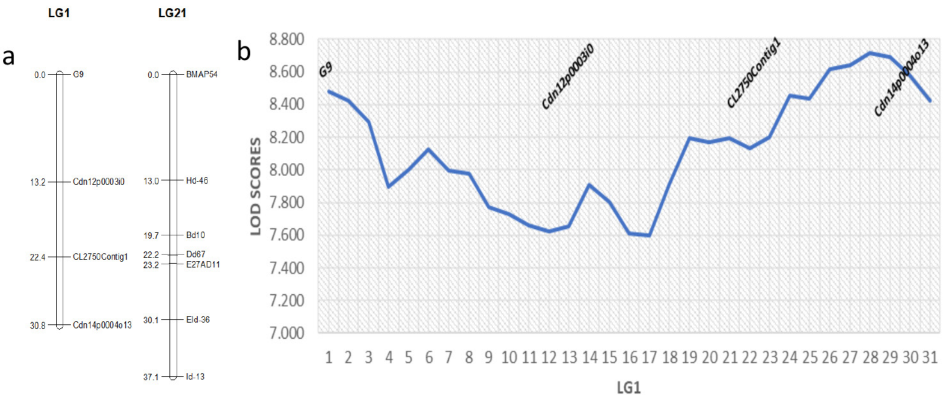

Fig 1 (a) Linkage groups 1 and 21 named according to Loukovitis et al. 2016 (b) Quantitative trait loci (QTL) analysis of bMa in LG1

(Continued on next page)

Results and Discussion

The markers were distributed into two linkage groups (LG1, LG21) named according to Loukovitis et al. (2016). The constructed map showed small differences between Loukovitis et al. (2016) and Tsiggenopoulos et al. (2014). In our study, the length of the LG1 and LG21 were 30.8cM and 37.1cM while in Loukovitis et al. (2016) were 23.5cM and 17.2cM respectively. Focusing on QTL analysis, no QTL related to the Fusion (FMaPm) was found on neither of the linkage groups studied, even though, Fragoulis et al. (2018) estimated an inheritance of the trait equal to 0.22 using an animal model. On the other hand, a QTL related to Inwards bending (bMa) was detected on LG1 linked to *Cdn14p0004o13* and its heritability was 0.11. For the Inwards bending (bMa) the related QTL must be investigated deeply, in order to examine its presence and clarify its effect, using a higher sample size before it can be used in Marker Assisted Selection.

Funding

This study was financially supported by national (Greek) funds (NSRF 2014-2020, call «Novelty in Aquaculture», Project No. 5010952) of the Ministry of Rural Development and Food, Greece.

In the last decade, the intensification of aquaculture practices, increasing number of facilities, number of species produced and rearing densities, have led to environmental stress, reduction of water quality, increase of chronic stress, growth impairment and health problems, all indicators of the reduction of the welfare of farmed fish (Saraiva *et al*., 2019). Recently, one of the tools that has been recommended to guarantee or improve the welfare of captive fish is the application of environmental enrichment (EE) (Brydges & Braithwaite, 2021). Structural, sensory, social, nutritional, or occupational EE aim to provide an adequate breeding environment, reduce stress to a minimum and meet the behavioural needs of individuals, promoting good welfare (Näslund & Johnsson, 2016).

For instance, structural enrichment improved survival rates and the physiological stress response, reduced stereotypical behaviour and aggressiveness, and enhanced cognition, exploratory behaviour, and brain physiological functions, among other positive effects on fish welfare (Neto & Giaquinto, 2020; Arechavala-Lopez *et al*., 2019, 2020; Räihä *et al*., 2019). However, most of these studies are focused on early-life fish stages or on-growing phases and there is still a lack of knowledge particularly on the broodstock. In this study, we measured behavioural and physiological indicators to assess the effects of structural environmental enrichment on the welfare of gilthead seabream broodstock.

Over the course of 5 months, 60 adult seabreams, distributed in six 3,000 L cylindrical tanks, were filmed regularly before, during and after feeding, cleaning, and sampling procedures. Three of the tanks were enriched with nine hanging organic ropes on 1 m^2 floating structures, while the other three tanks had no enrichment (control). Operational welfare indicators (OWIs) recently developed for farmed seabream were used and adapted to build an ethogram for the broodstock behaviour analysis.

Overall, fish in enriched tanks present a darker colour and perform more aggressive displays (erect fins, chases and flight behaviours, $p<0.001$). The enrichment structures also influence the swimming activity in the tank, since fish in enriched tanks behave more independently and vigorously ($p<0.001$ and $p=0.045$, respectively), and forage more actively ($p=0.014$), while fish in control tanks seem to school more ($p<0.001$). Moreover, fish on enriched tanks presented a significantly higher final weight ($p=0.049$) than fish from control tanks. The feeding event also had an effect on behaviour, especially on the spatial distribution of the fish in the tanks ($p=0.045$ for horizontal distribution; $p=0.013$ and $p=0.011$ for vertical distribution, respectively). Physiological analysis of cortisol are in process, which will allow us to check the effects of structural enrichment on stress hormones of seabream broodstocks.

It should be highlighted that this is the first study carried out on seabream broodstock, where we demonstrate that simple structural enrichment can induce positive changes on fish behaviour and welfare without major changes in rearing protocols, and therefore, they might be implemented at larger scale.

Introduction

Rising levels of atmospheric carbon dioxide are driving ocean warming and acidification, which may negatively affect the nutritional quality and physiological performance of marine species, with great economic importance to both fisheries and aquaculture sectors (Anacleto et al., 2018; Lah et al., 2018; Camacho et al., 2020). Yet, the impacts and interactions of both environmental stressors on nutritional properties, as well as on physiological (metabolic) responses, of most fish species remain unclear and still require further understanding. In this context, the aim of this work was to evaluate the effect of ocean acidification (i.e., ΔpH=−0.3 units equivalent to $\Delta p\mathrm{CO}_2$~+600 µatm) and warming (i.e., ΔT=+ 4 °C) (combined or not) on the chemical composition, fitness and energy budget of juvenile Senegalese sole (*Solea senegalensis*), a farmed species with high commercial value.

Materials and methods

Juvenile Senegalese sole (25.2±5.1 g total weight; 12.7±1.3 cm total length) were distributed and maintained in 12 tanks (4 treatments x 3 replicate tanks; n=4 individuals per tank) with independent recirculation aquaculture systems. The specimens were acclimated for one month and exposed to four scenarios during 75 days to understand the potential impacts under current and future expected conditions, according to projections of the Intergovernmental Panel on Climate Change (RCP 8.5 scenario; IPCC, 2021): i) Control (CTR) - seawater temperature set at 19 °C and pH at 8.0 ($p\mathrm{CO}_2$~400 µatm) (current conditions in Iberian Peninsula Senegalese sole farms); ii) Ocean acidification (OA) - seawater temperature set at 19 °C and pH at 7.7 ($p\mathrm{CO}_2$ ~1000 µatm); iii) Ocean warming (OW) - seawater temperature set at 23 °C and pH at 8.0 ($p\mathrm{CO}_2$ ~400 µatm); and iv) Ocean acidification and warming (OAW) - seawater temperature set at 23 °C and pH at 7.7 ($p\mathrm{CO}_2$ ~1000 µatm). Throughout the experimental period, fish were daily fed with 2% of their average body weight (divided by two meals). At the end of the trial, the ammonia-N, oxygen consumption rates (OCR) and biometric data were assessed. Then, fish were dissected to weight viscera and also to collect faeces (for energy determination). Moisture, ash, free fat, crude protein and gross energy were determined (at the beginning and end of the assays) in the whole fish body. Different calculations were performed to assess animal fitness, growth performance and energy budget.

Results and conclusions

Generally, the chemical composition, survival rate, fulton's condition factor and hepatosomatic and viscerosomatic indexes were not significantly affected by acidification and warming (acting alone or in combination), neither by sampling time. On the other hand, the total weight and total length (TL) significantly increased in all scenarios after 75 days. Weight gain of fish subjected to OA, OW and OAW was significantly higher than that obtained in fish exposed to CTR conditions. Furthermore, the highest relative growth rates (RGR) and specific growth rates in terms of wet weight (SGRw) and protein (SGRp) were observed in fish exposed to OW and OAW. In addition, the RGR and SGRp found in OAW were also significantly higher than those observed in OA. The TL was similar in the four treatments at the end of the experiment. Moreover, fish exposed to CTR conditions had significantly higher ammonia excretion rate (AER) compared to those exposed to OA, OW and

(Continued on next page)

OAW. However, all values found were very low (≤ 0.020 mg g^{-1} L^{-1} h^{-1}). Additionally, the maximum and standard metabolic rates (MMRs and SMRs), as well as energy intake (C), were generally significantly higher in fish subjected to OA, OW and OAW than in fish exposed to CTR conditions. Regarding energy distribution, the highest fraction was generally allocated to growth (48-63%), followed by excretion through faeces (36-51%), respiration (approximately 1%) and finally ammonia excretion (0.1-0.2%) in all treatments.

The results obtained clearly show that i) the juvenile Senegalese sole is resilient under seawater acidification and/or warming conditions; ii) changes in seawater pH and temperature values do not seem to have direct consequences on chemical composition, TL and animal fitness; iii) the acidification and warming (acting alone or in combination) have significant effects on growth (in terms of weight, RGR, SGRw and SGRp; more evident for OAW), AER, OCR and energy budget of juvenile Senegalese sole after 75 days of exposure. Thus, the impact of higher temperature and pH values (i.e., above the tolerance of this valuable commercial fish species produced in Europe) on its nutritional quality and physiological performance should be tested in coming studies.

Introduction

The development of new functional diets for Meagre (*Argyrosomus regius*) that promote both growth and health is an important step towards the increase of this species' production and has been the focus of various studies. However, analyses of fish welfare can be complex and either require animal sacrifice or end up causing additional stress for the fish. Therefore, it becomes important not only to find proper techniques and biomarkers that allow a better measurement of the effects of new diets on fish but also to find non-lethal biomarkers that will reduce the need for animal stress and sacrifice. The aim of this study was to obtain reference values and potential non-lethal biomarkers from blood samples of fish that will help assess fish nutritional status.

Methods

A nutritional challenge was performed for 7 weeks with groups juvenile meagre fish. Diets were tested in triplicate: an optimum diet (55.1 % of fish meal, FM) that was used as control (CTRL) and two other diets, a challenging diet (15% FM, CD) and an extremely challenging diet (5% FM, ED), partially devoid of fisheries-derived ingredients. At the end of the trial, 18 fish from each tank were collected. Blood samples were analysed using a Siemens epoc® Blood Analysis System to obtain biochemical parameters. Blood was also used for two different dilutions of HBSS and heparin (20U) solution (1:20 and 1:200) and immediately applied in a Neubauer chamber under x40 optic microscope ampliation for red blood cell (RBC) and total white blood cell (WBC) counts. The remaining blood was used to collect plasma following centrifugation (10,000×g, 5 min, room temperature). Plasma anti-protease and peroxidase activities, and total immunoglobulins and plasma protein were determined as described in Guardiola *et al*. (2018). Results were analysed using IBM SPSS statistics 27.0.1 software package (SPSS® IBM, Chicago, IL, USA). All data was analyzed by one-way ANOVA and Tukey's multiple range test was used for identifying differences between means. The probability level of 0.05 was used for the rejection of null hypothesis.

Results

Final weight, weight gain, feed intake, daily growth index, and feed efficiency decreased significantly with the increase of the diet's challenge level (Table 1). Blood parameters and plasma immunological and biochemical parameters showed significant differences between fish fed different diets, except for peroxidase and immunoglobulin levels, which showed no significant differences between fish fed different diets (Table 1).

Conclusion

Growth parameters were greatly affected by the reduction of diet quality, serving as good indicators of possible health issues in the fish and making samples collected from this trial ideal for the establishment of potential biomarkers. Results obtained from the analysis of the samples showed that blood parameters were affected by the challenging diets. This way, several of the parameters measured in fish blood at the end of the nutritional challenge showed potential as non-lethal biomarkers and seem to accurately indicate differences in fish fed lower quality diets. It is important to highlight parameters such as glucose, lactate and creatinine levels as parameters that we can easily connect to other physiological parameters of the fish and use collectively as biomarkers. These biomarkers can provide an initial view of the physiological status of the fish and can be later connected to other confirming biomarkers from fish samples.

Introduction

In recent years the development of new diets for aquaculture fish species aimed to avoid the inclusion of high amounts of fisheries by-products, focusing on the use of alternative ingredients that will provide growth, health, environmental and economic benefits. The effects of such diets on Meagre (*Argyrosomus regius*) have been the focus of various studies though it is often difficult to observe long-term effects on fish health and detect them in zootechnical performance. Consequently, it is essential to establish biomarkers that are precise and more practical to measure, allowing easier observation of the effects of diets on fish. The aim of this study was to obtain reliable biomarkers from histological analysis of fish intestine, with focus on objective measures that do not require an extensive background in intestinal histology, that will assess fish health in response to diets. For this, a semi-quantitative analysis was combined with a quantitative analysis and machine learning methods to mine for more precise analytical methods that will facilitate the histological analysis for future research.

Methods

Nutritional challenge

A nutritional challenge was performed for 7 weeks with juvenile meagre. Diets were tested in triplicate: an optimum diet with fish meal (55.1 % of fish meal, FM) used as control (CTRL) and two other diets, a challenging diet (15% FM, CD) and an extremely challenging diet (5% FM, ED) partially devoid of fisheries-derived ingredients. At the end of the trial, 18 fish from each tank were sampled and the intestine was removed and divided into anterior, intermediate and distal intestine for further histological analysis.

Histological analysis

The three intestinal sections were processed and sectioned using standard histological techniques. Sections were stained with hematoxylin and eosin. Both quantitative and semi-quantitative analysis were performed with ZEISS software ZEN 3.5 (blue edition).

Statistical analysis

Results were analyzed using IBM SPSS statistics 27.0.1 software package (SPSS® IBM, Chicago, IL, USA). Quantitative data was analyzed by one-way ANOVA tests and Tukey's multiple range test was used for identifying differences between means. Semi-quantitative data was analysed by a nonparametric Kruskal–Wallis test followed by multiple comparisons. Probability level of 0.05 was used for rejection of null hypothesis.

Nutritional status classification using Decision Trees and K Nearest Neighbours classifiers

Supervised machine learning classification algorithms (Decision Trees, DT and K-Nearest Neighbours, KNN) were trained to predict the nutritional status of fish based on a vector of 18 intestinal histological features of semi-quantitative or quantitative nature. Briefly, data was split 70:30 into training:test datasets, respectively. DT was plotted with 10 depth levels, 10 features and using entropy as criterion for the best split (decision tree parameters were decided after cross-validation). KNN was performed after data normalization, with K=4 neighbours. All analysis were run with Python 3 using pandas, numpy, seaborn, matplotlib and slkearn libraries.

(Continued on next page)

Results

Semi-quantitative

In the anterior intestine the parameters presence and vacuole size, number of goblet cells, lymphocytes in the epithelium (p=0.000) and granulocyte localization (p=0.046) showed significant differences between fish fed different diets, the parameters of villi fusion (p=0.940), lamina propria size (p=0.647) and submucosa inflammation (p=0.131) did not present significant differences between groups. For the intermediate intestine the parameters that showed significant differences were: villi fusion(p=0.15), granulocyte localization (p=0.006), lamina propria size, submucosa inflammation, presence and vacuole size, number of goblet cells and lymphocytes in the epithelium (p=0.000). Finally, in the distal intestine section, all previously mentioned parameters showed significant differences between fish fed different diets (p=0.000).

Quantitative

In the anterior intestine quantitative parameters that showed significant differences between fish fed different diets were: villi number (p=0.001), lumen area (p=0.039), total area, maximum total diameter, villi area and villi density (p=0.000). Maximum lumen diameter did not present significant differences between groups (p=0.059). In the intermediate intestine all previously mentioned parameters showed significant differences between groups (p=0.000) and the same was observed in the distal intestine section with p=0.000 in all parameters except villi number (p=0.028), total area and total maximum diameter (p=0.001).

Nutritional status classification

DT algorithm was able to predict with 64% accuracy the nutritional status of the fish. Fish subjected to the extreme treatments (optimum diet and extreme diet) were more precisely identified (66% and 69% precision, respectively). KNN returned an accuracy of 57% with the extreme diet being the one classified with higher precision (65%). Both methods used a combination of quantitative and semi-quantitative histological features, but DT performed better compared to KNN.

Conclusion:

Combining semi-quantitative histological features with quantitative measures of intestinal structure can be regarded as an important biomarker to predict fish nutritional status. Preliminary data analysis showed an interesting level of accuracy, but far from optimal. Based on our preliminary data, histology biomarkers should be combined with other analysis to fully discriminate fish nutritional status. Further data analysis between intestinal sections and within type of analysis (quantitative vs semi-quantitative) will be performed with the goal of establishing histological biomarkers of nutritional status that are simple, reliable and do not require extensive experience in histological analysis to identify sub-optimal nutritional status.

Introduction

Morden aquaculture has been decoupled from using fish meal as one of the major ingredients for aquafeeds. Many aquafeed producers now use soy and corn-based proteins, often associated with sub-optimal growth and feed efficiency, increased land and water use, and aquaculture carbon-foot print. These non-local resources have generated new ecological and socio-economic issues [1].

Macroalgae are a readily available resource with moderate protein and high fiber, minerals, antioxidants, and vitamin content. Production of macroalgae does not rely on land and freshwater use and may also be harvested from coastal regions with minimal environmental impact. Several authors have studied the inclusion of macroalgae in diets, concluding that high (>10%) dietary incorporation of macroalgae negatively affected growth and feed utilization parameters. Authors support that disruption of the macroalgae cell wall may increase nutrient bioaccessibility and access to the digestive enzymes, favoring nutrient absorption efficiency and fish growth. Adequate physical, chemical, enzymatic, and/or fermentation treatments may be required to disrupt the macroalgae extracellular polysaccharides matrix [2,3].

Codium tomentosum natural distribution included Europe and North Africa. It has also been successfully produced as an extractive species in integrated multi-trophic aquaculture systems (IMTA), including in Portugal. *Codium tomentosum* has a relatively higher protein level, circa 20-25%, but its potential as an aquafeed ingredient has been little studied. The present work aims to investigate the potential of alkaline hydrothermal pre-treatment of *Codium tomentosum* to increase its viability as an ingredient in diets for European seabass.

Material and Methods

Treatment of macroalgae

Samples of *Codium tomentosum* were provided from AlgaPlus, Aveiro, Portugal. *Codium tomentosum* was mixed with water (control) or NaOH (0.5N and 1N; solid-liquid ratio of 4:3) and autoclaved (121ºC) for 30 and 60 min. All the samples were analyzed for neutral detergent fiber (NDF), acid detergent fiber (ADF), crude protein, soluble protein, and phenols.

Growth trial

Four experimental diets were formulated to be isoproteic (48% dry matter basis) and isolipid (18% dry matter basis). A practical diet was used as a control diet (D1), and three other diets were formulated to include 7.5% *Codium tomentosum* at the expense of a mixture of soybean and wheat meal, namely non-treated *Codium* (D2), autoclaved for 30 min with 1N NaOH (D3), and autoclaved for 60 min with 1N NaOH (D4). The growth trial was conducted in a RAS system equipped with 12 tanks of 500 L water capacity, thermoregulated to 22 ºC. 192 acclimatized European seabass juveniles (IBW of 38 g) were divided into 12 groups and fed each experimental diet in triplicate, twice a day until satiation, 6 days a week, for 11 weeks.

Results

Irrespective of autoclave time exposure, *Codium tomentosum* soluble protein, and phenols content were significantly increased, while crude protein, NDF, and ADF significantly decreased when mixed with NaOH 1N than with NaOH 0.5N. These results suggested that the combined alkaline (NaOH 1N) with hydrothermal treatment (for 30 or 60 min) disrupted the cell wall of macroalgae being chosen to be incorporated as an ingredient in diets for European seabass.

(Continued on next page)

At the growth trial, it was observed that all the diets were well accepted by the fish, and mortality was low and not influenced by the diets. Dietary inclusion of 7.5% of untreated *Codium tomentosum* did not affect overall growth performance, feed intake, and feed utilization efficiency. However, relative to the control diet, the dietary inclusion of 7.5% *Codium tomentosum* treated with NaOH 1N and autoclaved for 30 min significantly increased growth performance and feed and protein efficiency ratio. In contrast, the *Codium tomentosum* treated with NaOH 1N and autoclaved for 60 min resulted in similar growth performance and feed utilization efficiency to the control diet, which was significantly lower than that obtained for the *Codium tomentosum* treated with NaOH 1N and autoclaved for 30.

In conclusion, the pre-treatment of *Codium tomentosum* with NaOH 1N and autoclaved for 30min significantly improved the potential of *Codium tomentosum* as a local and complementary feed ingredient for carnivorous fish species.

Introduction

The quality of nutrients in broodstock diet represents one of the major factors influencing fish reproductive success and offspring quality/survival. Especially for mature female fish, reproduction is one of the most metabolic demanding activities and relies on the proper administration of dietary protein and lipids, especially fatty acids. Specifically, polyunsaturated fatty acids (PUFA) are drained from storage sites (mainly muscle and liver) to the ovary where can be involved in follicle maturation or incorporated into the eggs as the main nutritional source for the embryo while guaranteeing proper hatching and early larval development. For that reason, over the last years, great attention has been given to the role of specific dietary nutrients, such as PUFA, in the reproductive processes of teleosts. However, in cultured fish, several stressors, including malnutrition, can potentially interfere with oogenesis and induce atresia of ovarian follicles. For this reason, investigating whether a diet is able to correctly sustain fish reproduction is of primary importance, especially when alternatives to conventional ingredients are tested. On this regard, insects gained great attention within aquafeeds formulation thanks to their eco-friendly and cost-effective rearing and their promising nutritional values. In particular, the Black Soldier Fly (*Hermetia illucens*; BSF) is characterized by a balanced essential amino acid profile comparable to fish meal and represents a valuable protein source for fish diets. However, the BSF fatty acids profile, rich in saturated fatty acids (SFA) and poor in PUFA is not always ideal for fish, especially when considering fish lipid requirements during the critical life-cycle stages of oocyte maturation and reproduction. The present study was aimed to test the effects of two different dietary inclusion levels (25 and 50 %) of full-fat BSF prepupae meal respect to fish meal on reproductive performances of adult zebrafish females through a multidisciplinary approach.

Zebrafish (*Danio rerio*) is a well-established experimental model for studies on reproduction since it is easily reared in laboratory conditions and, if compared to other teleosts species, it reaches sexual maturity in a relatively short time. On this regard, zebrafish represents an ideal organism to better understand the link between broodstock nutrition and female reproductive success, generalizing how several biological processes take place in model organisms and thus providing useful information for finfish production. The well-consolidated knowledge about zebrafish oocyte development and maturation is essential to better understand the dietary effects of new diets.

Materials and Methods

A control diet containing fish meal, wheat gluten meal, wheat flour, pea protein concentrates and FO as major ingredients, was prepared according to a commercially available standard diet for zebrafish (Zebrafeed, Sparos ltd, Portugal). BSF-based diets were prepared by including 25 and 50 % of full-fat BSF prepupae meal respect to FM (referred as BSF25 and BSF50, respectively) in the control diet formulation. All the experimental diets were iso-nitrogenous (40%), iso-lipidic (17%) and iso-energetics (22%). Zebrafish were fed the experimental diets for 12 months (form larvae to adult) and the reproductive performances of mature females were assessed through a multidisciplinary approach including: (i) evaluation of growth, gonadosomatic index, spawning and hatching rates: (ii) gas-chromatographic analyses for fatty acids composition of adult females carcasses and fertilized egg; (iii) histological analysis on the ovary to assess oocyte maturation stages and the oil droplet percentage in class IV oocytes; (iv) spectroscopic analysis by Fourier Transform Infrared Microspectroscopy (FTIRM) to analyse the macromolecular composition of class IV oocytes; (v) molecular analyses on liver samples to evaluate the expression of genes involved in PUFA biosynthesis (*elovl2*, *elovl5*, and *fads2*).

Results and Discussion

The inclusion of BSF prepupae resulted in a dietary PUFA reduction and a parallel increase in SFA. This unbalanced dietary lipid profile also characterized the fatty acid composition of females' carcasses but did not affect their growth and gonadosomatic index. Differently, considering class IV oocytes and fertilized eggs, a higher SFA and lower PUFA content were only detected in BSF50 group by both gas chromatographic and spectroscopic analyses. Accordingly, in this study, fish fed BSF diets (particularly BSF50) showed a higher expression of genes involved in PUFA biosynthesis able to convert

(Continued on next page)

shorter-chain precursors (moved from storage sites like muscle and liver) to highly unsaturated ones. The different trend in PUFA content between the fish carcasses and the spawned eggs or class IV oocytes represents a very interesting result, which underlines a significant investment of female zebrafish in the reproductive event, strongly suggesting the selective accumulation of these fatty acids in the eggs. Adult female zebrafish were perfectly able to cope with the lower (25%) dietary BSF prepupae meal inclusion level respect to fish meal, resulting in similar reproductive performances compared to Control. Conversely, the BSF50 group showed a general decrease in spawned eggs, possibly due to a delay in oocyte maturation (greater abundance of previtellogenic oocytes detected by histological analyses) caused by (i) the necessity of a longer ex novo PUFA biosynthesis by the fish and subsequent oocyte accumulation or (ii) the activation of atretic processes. This last hypothesis is supported by the increase in atretic oocytes and by a reduction of postovulatory follicles in BSF50 with respect to BSF25 and Control. However, the BSF50 group showed a comparable hatching rate to that observed in Control and BSF25 ones. This is one more evidence of the extraordinary effort that female fish put in the reproductive event, choosing for quality rather than quantity by activating specific processes to select those oocytes that should be ovulated or reabsorbed.

In conclusion, the results obtained in this study showed that the dietary substitution of FM with a full-fat BSF prepupae meal up to 25% did not affect reproductive performances of female zebrafish, while a higher substitution (50% with respect to FM) resulted in reproductive impairments, specifically in terms of number of spawned eggs.

ALTANET – THE ATLANTIC LOW TROPHIC AQUACULTURE NETWORK

P. Olsen[1]*

[1] Nofima, PO Box 6122 Langnes, NO-9291 Tromsø, Norway
E-mail: petter.olsen@nofima.no

Introduction

Low trophic aquaculture is growing in importance, and the number of industry actors, species, products, projects, events, and publications is increasing. The goal of the Atlantic Low Trophic Aquaculture Network (ALTANet) is to create and maintain an overview of LTA-related news stories, events, projects, calls, tenders, reports, publications, training materials, and websites. The main output from the network is the altanet.info dynamic website which contains links to content relating to aquaculture involving macroalgae, echinoderms, molluscs, and crustaceans, as well as Integrated Multi-Trophic Aquaculture (IMTA) in general.

Manual updates and machine learning algorithms for dynamically generated LTA-related content

The EU-projects AquaVitae and ASTRAL, with supporting funding from the Norwegian Research Council, initiated the ALTANet network and in particular created the altanet.info website. The website has two component parts; one based on manual updates and one based on dynamically generated content created by a machine learning algorithm. The manual updates are done by correspondents, and relate to existing and upcoming events, projects, reports, publications, videos, and webinars. Anyone interested in adding information about a LTA-related resource can do so (or ask a correspondent to do so) and based on this input searchable and sortable ordered lists are created where the content is accessible through filters and free text search. The dynamic content is generated by a machine learning algorithm that runs every night to trawl the internet for LTA-related news stories. An initial set of LTA-related keywords and rules were defined which yielded around 10 candidate news stories per day, of which around 5 were actually relevant. After manual classification of more than 1000 news stories (into relevant / not relevant) the accuracy of the algorithm increased (it compares candidate news stories with those known to be relevant) and it is now around 93%. The algorithm now runs without the manual classification step, which means that around 5 LTA-related news stories are added to the altanet.info website every day.

Discussion and conclusion

The altanet.info website can be useful for anyone interested in low trophic aquaculture in the following ways:

- As a communication channel used to highlight existing and upcoming events, projects, reports, publications, videos, and webinars, and to make sure that the LTA community knows about them
- As an openly available resource for searching for and finding out about existing and upcoming events, projects, reports, publications, videos, and webinars
- As a daily and dynamic provider of online LTA-related news from all over the world

All content on the altanet.info website is classified by species or production type, and the pre-defined species / production types are macroalgae / seaweed, echinoderms / sea urchins / sea cucumbers, molluscs / oysters / mussels, crustaceans, and Integrated Multi-Trophic Aquaculture (IMTA). All website content can be searched, selected, and filtered by species / production type, which means that anyone only interested only in one particular species can filter out all other content if desired.

INCREASED PRODUCTION AND SOCIETAL EXPECTATIONS: THE IMPORTANCE OF SOCIAL ANCHORING IN NORWEGIAN SALMON AQUACULTURE INDUSTRY

M. S. Olsen*, T. C. Osmundsen

NTNU Social Research, 7491 Trondheim, Norway.
*E-mail: marit.olsen@samforsk.no

Introduction

The salmon aquaculture industry has attracted considerable controversy, and in later years, social and ecological challenges have caused limitations to industry growth in several salmon producing countries, including Norway (Young et al., 2019). Both industry and government share a vision of 5-fold increase in production within the next 30 years, however, this vision is also met with skepticism, especially concerning a potential increase in environmental challenges.

Recent regulatory measures and governmental instruments are largely focusing on solving environmental challenges as a way to improve the industry's sustainability. Environmental sustainability is (from the governmental perspective) described as something that is bearable by both nature and society, or in other words, acceptable for society. We therefore argue that this is closely related to public perception of the industry and its production, and thus, also including social and economic dimensions of sustainability. Public acceptance is an important element for the Norwegian salmon aquaculture industry and can be viewed as a form of social anchoring, on local and national level. Having public support for the industry is crucial in order to gain access to good production sites and for an increase in production, and in satisfying consumers in local and global markets.

From its beginning, the Norwegian salmon aquaculture industry has been regulated by various policy instruments and in line with important political objects, which has especially focused on increasing business activity in rural coastal communities. The last decade, however, we have seen a change in aquaculture policy moving away from specific political objectives and towards an industry policy relying to a greater extent on market forces. At the same time there has been an exceptional high profitability in the industry. So when public policies have been changing from a local to a more national priority in distributing industry benefits, local communities are less content with their share of value creation. Previous research on public attitudes, public acceptance, and social license is ambiguous on the various factors important for shaping public opinion, and thus, how to improve attitudes towards the salmon aquaculture industry on both a national and local level (Krøvel et al., 2019).

This paper investigates how public regulation and it's pertaining tools, incorporate measures that secures a social anchoring of the aquaculture industry. It takes as a departure point, the different schemes for production licenses, and how these schemes were interpreted by the public, as in specific stakeholders. We are examining to what extent these schemes appear to include elements that may (potentially) improve the social dimension of sustainability, in other words, specific measures to improve a social anchoring of industry activity on local and national level. The research questions of this paper is: What elements does the public consider important for the social sustainability of the aquaculture industry? And to what extent, does proposed schemes for increased production incorporate measures that respond to such concerns? And finally, are these topics brought forward in the consultation responses from different stakeholders?

Materials and methods

The empirical data for this paper is a combination of quantitative data; results from a nationwide survey (N = 1183), and qualitative data; document analysis. The survey was conducted in 2020 and asked people about their opinion on salmon aquaculture production and the industry presence in their local community. The qualitative analysis is based on publicly available material related to Norwegian aquaculture regulation in general, and documents concerning the development licenses, eco-technology licenses, and licenses for offshore aquaculture (not finalized until May 2nd) in particular, e.g. white papers, green paper, responses to consultation rounds for the three different licenses schemes.

(Continued on next page)

Results and discussion

This paper combines findings from social acceptance literature and a recent study of public attitudes towards the Norwegian salmon aquaculture with the current policy development which focuses on technology development for improving the industry's environmental sustainability. The survey results show that the general impression of the Norwegian salmon aquaculture industry is fairly good, however; people are reluctant to increase industry production, and it is reported that the industry is to a larger extent behaving in accordance with the expectations from the authorities rather than the expectations from the industry. Benefits like job creation, increases business activity, creating robust communities, and food production is emphasized as important contributions, but these does not outweigh the negative consequences sufficient for wanting production growth. In addition, previous studies and ongoing debates have also shown how expectations from coastal communities are concerned with the distribution of economic benefits. Findings from the survey suggest that people are not satisfied with the distribution of economic benefits, especially on a municipal level.

With the establishment of an Aquaculture Fund in 2016, higher governmental income when enabling growth (through the traffic light system), and a new production fee introduced in 2021, the coastal communities have increased their economic benefits from the industry. This is an important step for improving the social anchoring of industry on a local level. However, with the newly proposed license schemes, the focus on social and economic benefits for coastal communities seem to be displaced by the focus on development of technological innovations to solve environmental challenges.

The data collection for the new licensing schemes (analysis of hearing responses) is on-going through May-June 2022; preliminary results suggests that new governmental policies to a large extent focuses on improving environmental sustainability, and this have potential direct and indirect impacts also for the social and economic dimensions of sustainability. For example, the proposal for offshore aquaculture licenses mainly view economic and social revenues as beneficial for the national level. We find that an implication of these licenses is that with production moving out of the municipal sea area, this also distances the production and benefits from the local community. Revenues to coastal communities hosting aquaculture production might decrease, due to value added and employment being moved to more central regions. On the other hand, the development of the new technological solutions could lead to an increase in value and job creation in the supplier industry (ripple effects), although these may be localized elsewhere and without proximity to aquaculture companies and the coastal communities voicing their expectations about the industry presence.

INTEGRATED MULTITROPHIC AQUACULTURE OF ABALONE *Haliotis midae* AND SEA CUCUMBER *Neostichopus grammatus*: AN EFFICIENT AND SUSTAINABLE METHOD TO REDUCE ASSOCIATED TANK CLEANING COST AND LABOUR INVOLVED IN ABALONE FARMING

Abigail John Onomu*, Matthew James Slater and Niall Gordon Vine

[a]Department of Zoology and Entomology, University of Fort Hare, Alice, 5700, South Africa
[b]Alfred-Wegener-Institute, Helmholtz Center for Polar and Marine Research, Bremerhaven, 27570, Germany
Email: abigailjohn90@gmail.com

Abalone farming produces nutrient-rich sludge, and the frequent cleaning and removal of sludge from abalone tanks is labour and capital-intensive. This study aimed to assess the feasibility of abalone (*Haliotis midae*) and the warty sea cucumber (*Neostichopus grammatus*) in an IMTA system and the effect of reducing abalone tank cleaning frequency on abalone growth, water quality, and sludge content and volume.

The study was conducted for 16 weeks. Four treatments namely, abalone cocultured with sea cucumber with tanks cleaned once weekly (AS1); abalone cocultured with sea cucumber with tanks cleaned twice weekly (AS2); abalone only with tanks cleaned once weekly (A1); abalone only with tank cleaned twice weekly (A2) were used. Abalone were maintained under commercial stocking conditions and were fed Abfeed™ and seaweed (*Ulva lacinulata* and *Gracillaria gracilis*) while the sea cucumbers fed on the abalone faeces and left-over feed, which settled at the abalone tank's bottom (sludge). The coculture of abalone and sea cucumber is feasible with a 99±0.43% survival of abalone. There was a significant interaction between the type of culture and the frequency of cleaning ($F_{(1,476)} = 12.41$, $p<0.001$). Abalone in the A2 treatment group showed better growth ($p = 0.006$) than those of the A1 treatment group, while abalone in AS1 had significantly better growth ($p<0.001$) than those in the AS2 treatment group. Also, abalone in AS1 showed better growth ($p = 0.026$) than abalone in the A1 treatment. However, abalone in AS1 had similar growth ($p = 0.53$) with those in A2. This study shows that optimization of growth in abalone farming can be achieved by cleaning tanks twice instead of once weekly. However, when abalone are cocultured with sea cucumber, tanks need only be cleaned once a week without compromising abalone growth. The coculture of abalone and sea cucumber results in an additional aquacultured product, a reduction in the labour and associated cost of cleaning without an additional cost of production.

AUTONOMOUS, CONTINUOUS AND REACTIVE-FREE NUTRIENT AND MICRO-ALGAL MONITORING IN SEAWATER

G.Orazi, D. Dumet, H. Haddad, I. Khelifi, F. Le Gall

EGM, 444 Route des Dolines – 06560 Valbonne, France

Introduction

The aquaculture is a very promising sector for the future of food production, but it also brings a lot of challenges to be sustainable and profitable. The early detection of harmful algae blooms (HAB) is one of them. Meeting it leads to the need for an autonomous and continuous monitoring of nutrients and micro-algal composition of the seawater.

Solutions for such a challenge has already been explored by, for example, using reagents and colorimetry analysis in an autonomous microfluidic lab. In this paper, we explain the concept and show some preliminary results of an affordable, reagent-free, multi-parameters and autonomous sensor specifically oriented toward the nutrient and micro-algae assessment. It is based on a MEMS spectrometer and an original illumination device coupled to AI models.

Concept of an autonomous muti-parameters water analyser

It is well established that a broad spectrum of physicochemical parameters (e.g., ammonium, nitrate, and dissolved oxygen) can be measured based on their reaction to UV-visible light absorption in the range of 200-800 nm. Moreover, the micro-algae present in the seawater are known to be fluorescent under specific illumination conditions. Consequently, for an early detection of HAB, it is interesting to perform continuous measurements of absorbance and fluorescence of the seawater near the fish containers to get very frequent measurements of nutrients and micro-algal composition. These frequent in-situ measurements can be sent to a cloud storage over a long-range network and provide a live monitoring of the water of the fish tank.

This brings high-level requirements for such a device like autonomy, low power consumption, affordability, and compact design. To meet them, the idea developed in the water analyser presented here is that all the light measurements can be done using a single illumination device designed to be able to do absorbance and fluorescence coupled to a small spectrometer.

MEMS spectrometer

Microelectromechanical systems (MEMS) processes allow to produce tiny mechanical and optical devices using techniques like the ones used in the production of micro-electronic chips. Recently, some manufacturers released spectrometers on the market made by this technology. They are very small (about 20x10x10 mm) lightweight (5 g) and consume less than 0.1 Watts for a decent spectral resolution (less than 10nm) but with a wavelength range limited to the visible spectrum (340 to 850nm). This makes them good candidates to be the basis of an autonomous water analyser.

First prototype

To evaluate the feasibility of an autonomous multi-parameter sensor based on this spectrometer, we coupled it with an original water illumination device to automatically perform absorbance and fluorescence measurements in a single instrument. This device holds the spectrometer on one side of a sample holder and presents holes on the other sides where various LED and lamps are inserted. The hole opposed to the spectrometer is used for absorbance illumination and the two others for fluorescence. On this prototype, one xenon lamp and 6 LED are distributed in these holes.

This first prototype was driven by a microcontroller and an interfacing electronic board that allow to pilot independently each lamp, and which also drive the spectrometer to get the data, pre-process them for background subtraction and store the results on a SD card. This process is run each time a button is pressed. The acquired spectra are then extracted using a companion software running on a computer to be processed further.

Calibration

The way to infer parameters measurements from the acquired spectra can be challenging, especially because of the relatively small spectrum band of the MEMS spectrometer but also because of the complex response of the seawater to illumination. However, it has been demonstrated that a deep learning approach can be very effective to extract information from a spectrum even when a chemometrics approach fails or gives poor results[1]. To do so, it is needed to gather a lot of data samples to train a model and evaluate its performances.

The prototype is running, and a data acquisition campaign is started and will continue during the coming months. The preliminary results will be shown at the conference.

Introduction

Bivalve filter water as part of feeding process and such accumulate large number of various particles and microorganisms. Most common bacteria genera found in marine environment is genus *Vibrio*. In this genus belong bivalve commensal, pathogens and opportunistic pathogens. Besides bivalve pathogens, in this genus we can find human pathogens popularly known as "big four" - *V. alginolyticus*, *V. parahaemolyticus*, *V. cholerae* and *V. vulnificus*, and they cause diseases – vibriosis (Baker-Austin et al, 2018). Thus, it is necessary to determine the structure of natural *Vibrio* community, including the occurrence of potential pathogens, in the eastern Adriatic bivalve aquaculture. Additionally, one of the growing problems in marine environments is the emergence of antibiotic resistance due to the excessive use of antibiotics and anthropogenic discharges into the marine environment. However, antibiotic resistance in eastern Adriatic bivalve aquaculture has been poorly studied (Baralla et al, 2021).

Materials and methods

Focus of our research are two most important species in aquaculture in Croatia - European flat oyster, *Ostrea edulis* Linnaeus, 1758 and Mediterranean mussel, *Mytilus galloprovincialis* Lamarck, 1819. These species were sampled in two protected marine reserves – Lim Bay and Mali Ston Bay, locations which are known for bivalve aquaculture. We determined physico-chemical parameters of seawater and also took samples of seawater, sediment and bivalve tissue (hepatopancreas and gills). Furthermore, culturable heterotrophic and total *Vibrio* bacteria in seawater, sediment and tissues were isolated on Marine agar and *Vibrio* selective TCBS medium on 22°C and 35°C. Additionally, we identified *Vibrio* clades with MALDI-TOF mass spectrometry (Culot et al, 2021) and species with MLSA (multilocus sequence alignment) method (Pascual et al, 2010; Pérez-Cataluña et al, 2016). All *Vibrio* isolates were tested for antibiotic resistance *via* disk diffusion on Mueller Hinton agar for 13 selected antibiotics which are frequently used in aquaculture and medicine. Our next step is to determinate differences between species, locations and seasons for species belonging to *Harveyi* clade with BOX- and ERIC-PCR (Canellas et al, 2021; Culot et al, 2021) and to investigate possibility for infection with species know as human pathogens we will determinate virulence factors for *tdh*, *trh* and possibly other genes.

Results

Our results showed that all observed parameters (culturable heterotrophic and total *Vibrio* bacteria in seawater, sediment, and bivalve tissues) were slightly higher in Lim Bay. Almost 75% of all culturable *Vibrio* bacteria belonged to *Splendidus* clade. Additionally, next most abundant clade was *Harveyi* clade (15%) and *Anguillarum* clade (1%). Species found belonging to *Harveyi* clade were *V. harveyi*, *V. campbellii*, *V. jasicida*, *V. parahaemolyticus*, *V. rotiferianus, V. diabolicus* and *V. alginolyticus*. Of all environmental parameters, we concluded that for abundance and diversity of *Vibrio* species most dominant parameter was temperature. We observed that trend is most visible in tissue samples, while for water and sediment was only observed for *Harveyi* clade. While during colder seasons *Splendidus* clade was more abundant, in warmer seasons *Harveyi* clade dominated. We determinate genomic fingerprinting for isolates belonging to *Harveyi* clade and found differences between species, locations and seasons and also reported presence of *trh* gene for virulence in *V. parahaemolyticus*. Results of antibiotic resistance show that more than 95% of all isolated bacteria are resistant to antibiotics and almost half of them (46.5%) are multi-resistant. Furthermore, most bacteria from all clades were resistant to vancomycin (95%). Next most abundant resistance was to ampicillin (45%). This study shows first report of presence of antibiotic resistance in bivalve aquaculture in Croatia and shows rising concern that with climate change and anthropogenic pressures which can and most likely will change environmental conditions, can negatively affect bivalve aquaculture both with bigger susceptibility of farmed bivalves to colonization by *Vibrio* pathogens and with more resistant *Vibrio* bacteria.

Introduction

As the aquaculture industry grows, so does the emergence of pathogens and, with it, the need to seek new prophylactic measures. Up to now, the number of approved commercial vaccines is still small. Currently, these are vaccines based on attenuated viruses or based on recombinant proteins of viral antigens. Although they are safe, ensuring the stability and functionality of the protein and the type of administration hinder their effectiveness. Therefore, finding new formulations to maintain immunostimulatory or antigenic properties, as well as using oral administration as the most suitable method, remains a challenge. In this context, we have proposed an alternative based on the use of a new prophylactic design called "modular nanopellets (NPs)". It is the nanostructured recombinant protein of a viral antigen fragment coupled to an interferon gamma (IFNγ)-based cytokine effector domain to provide antiviral and adjuvant effects. Our working model consists of rainbow trout (Oncorhynchus mykiss) and two viruses relevant to salmonid aquaculture: VHSV and IPNV.

Materials and methods

At the *in vitro* level, the uptake of labelled NPs in RBCs, RTS11 and RTgutGC cells was quantified by flow cytometry and confocal microscopy. In addition, modulation of the expression of immune response genes in NPs-treated cells was assessed by RT-qPCR. *In vivo*, NPs were administered by intraperitoneal (i.p) injection into individual rainbow trout and the expression of immune response genes was assessed 48 hours post-vaccination. Also, blood sera were collected 30 days post-vaccination for titration of viral antigen specific antibodies and neutralizing antibodies.

Results

The results obtained showed a stimulation of the innate immune response, specifically the interferon pathway, by the modular nanopellets in RTS11, RTgutGC and rainbow trout RBCs. In addition, i.p injection of modular nanopellets demonstrated that fluorescent NPs could be detected in immune relevant tissues and stimulate the gene expression of immune genes in spleen, head kidney and rainbow trout RBCs. Also, VHSV and IPNV –specific antibodies were detected in the serum of individuals immunized by i.p injection. All these considerations provide a new perspective on the role and potential use of the modular nanopellets as a new antiviral prophylactic method alternative to the existing ones.

ANTIVIRAL ACTIVITY OF HIBISCUS (*Hibiscus sabdariffa*), GREEN TEA (*Camellia sinensis*), ECHINACEA (*Echinacea purpurea*) AND GRAPE SKIN (*Vitis vinifera*) EXTRACTS AGAINST THE VIRAL HEMORRHAGIC SEPTICEMIA VIRUS

Introduction

In the last decades aquaculture seems to be the only real alternative for global fish food supply. However, diseases affecting aquaculture produce high economic losses, so chemical agents are usually used, but they can affect the ecosystem. Plant extracts are an alternative because of their pharmacological properties. Previously, the extracts from *Hibiscus sabdariffa, Camellia sinensis, Vitis vinifera* and *Echinacea purpurea* have shown their activity as immunostimulants or antivirals. In this study we evaluated the antiviral activity of these plant extracts against the viral hemorrhagic septicemia virus (VHSV).

Materials and Methods

The antiviral activity of the extracts was evaluated in EPC cell line. The viricidal capacity of the extracts as well as the antiviral activity before or during the course of infection were assessed. Viral loads were evaluated by means of FFC/mL. Cell fusion inhibition capacity assays were also performed to evaluate the viricidal capacity of the extracts. As well, we performed an in silico molecular docking study of the major compounds of the extracts in order to elucidate the most antiviral compounds.

Results

The results indicated that all extracts had antiviral activity, being one of them especially active and reducing the viral load up to a 50%. In addition, it was also observed that the most antiviral extract was able to reduce the fusion capacity of the virus and the major compound of this extract had the highest binding affinity to the viral proteins. In conclusion, the use of plant extracts as antivirals is presented as an alternative to mitigate viral diseases in aquaculture.

DESIGNING PRODUCTION LICENSES FOR SUSTAINABLE AQUACULTURE

Introduction

Public regulation of a successful industry such as aquaculture needs to consider different concerns such as industry growth and development, but also environmental and societal sustainability. Governance systems are continuously challenged to respond in adequate manners to how aquaculture industry develops, especially in terms of how to best handle environmental challenges. We here investigate three different environmental regulations, all which aim to promote the development of more environmentally friendly production technologies to curb the negative environmental impacts of salmon aquaculture.

We ask two research questions:

1. How are production licenses designed to promote the development and ultimate use of environmental technology?

2. What are the main contributions and side-effects of these regulatory designs?

Methods

Based on earlier research, and an investigation of publicly available documents, including responses to public hearing processes, we study the design of three types of production licenses aiming to promote sustainable production of salmon aquaculture in Norway. The so-called "green" licenses, the "development" licenses, and the newly introduced "eco-technology" licenses.

Results

The table below provides an overview of some of the main characteristics and differences between the three types of licenses. The licenses differ in type of license, focus on risk, the requirements for technology development and implementation, area use, and permit requirements. Also, the possible impacts from these licenses will vary, partly due to their difference in volume. A total of 45 green licenses was awarded, while the number of development licenses is not yet finalized, it now shows 118 licenses (November 2021). The proposed availability of eco-technology licenses for the first year is limited to a maximum of 15 000 tons biomass (representing approximately 19 licenses a 780 mt). However, the eco-technology licenses are proposed to become a yearly allocation scheme so the magnitude of this scheme will much likely increase over time.

We find that the design of the licenses has changed considerable across the three schemes, but that the main contributions to regulation is to set the focus on environmental risks, and to give stimulus to technological innovation in fish farming. However, the side-effects are a large administrative burden and long-lasting award processes which at times has been characterized by lack of transparency and predictability.

(Continued on next page)

	Green licenses	Development licenses	Eco-technology licenses
Type of license	Ordinary (no time limit)	Special (time limited up to 15 years), can be converted to a ordinary license, at a fee	Special (proposed as time limited up to 20 years)
Environmental risks	Lice and escapes	Lice, escapes, area use	Lice, discharge, escapes, area use (inshore)
Environmental technology	Implementing new technology, and/or operational solutions aiming to reduce risk of escapes and sea lice. Technology should be tested, yet not commercialized	Developing + testing new technology (production unit) and new siting aiming to reduce challenges with environmental impact and area access. Technology must include significant innovations (compared to traditional technology).	Developing and commercializing technology that contributes to solving environmental and areal challenges. Aimed at various solutions for closed technology.
Area use	Ordinary sites	Ordinary sites + exposed/offshore and sheltered (closed technology)	Ordinary sites + sheltered
Investments	No investments requirements	Significant investments required	No investments requirements
Permit requirements	Requirement of use of technology and/or operational solutions (in line with the application), sea lice limit 0.25/0.1, for group A and B: one ordinary license must be "converted" to green license (following the same requirements) for each awarded green license.	Requirements for developing technology and the use of this during the testing period (in line with the application), no requirements for use of developed technology after conversion	Several indicators (zero dispersion of sea lice/egg, minimum 60 percent accumulation of discharge, and increased escape security), requirements to implement technology within 3 years
Sharing knowledge	Annual reports – available online (DoF)	Fact sheets, reports from developing phase, status reports from operational phase, and a final report at the end of project period – available online (DoF)	Plans for knowledge sharing are mentioned

ASTRAL'S OCEAN LITERACY FOR AQUACULTURE: INCREASING PUBLIC ACCEPTANCE AND AWARENESS OF AQUACULTURE IN THE ATLANTIC

E-mail: natalia.ospina@aircentre.org

\ASTRAL (*All Atlantic Ocean Sustainable, Profitable and Resilient Aquaculture*) is a Horizon 2020 project focused on integrated multi-trophic aquaculture (IMTA) farming, aiming to define, support, and promote this type of sustainable aquaculture production across the Atlantic area. IMTA is the farming of species from different trophic levels in a way that allows one species' uneaten feed and wastes to be used as inputs (fertilisers and feed) for another species. Sharing knowledge and capacity development are among ASTRAL priorities, as well as to build a collaborative ecosystem along the Atlantic Ocean with industrial partners, SMEs, scientists, policymakers, social representatives, and other relevant stakeholders.

ASTRAL is committed to increasing the public acceptance and awareness of aquaculture by fostering public understanding of the value of aquaculture and especially IMTA, as a sustainable way to produce aquatic products. The project is also committed to reinforcing existing international efforts to advance acceptance and awareness about the sustainable exploitation of marine resources. ASTRAL works with a multilayer stakeholder's approach, therefore different Ocean Literacy activities have been designed around the project to ensure that the message reaches all the sectors of interest.

For example, targeting a wide public, specific campaigns in ocean literacy have been developed around the importance of safe and nutritious aquaculture seafood and addressing climate change resilience and ocean influence. During the World Ocean Day 2021, ASTRAL organised, in a coastal fishing community in Lagos (Nigeria), a variety of activities which included: 1) a clean-up campaign with the Makoko fishing community, 2) a thematic session about 'The Ocean and Livelihoods' and 3) training on 'Waste upcycling and women empowerment (Fig.1).

To engage a younger generation, during the Ideation Days 2022 at Terceira Island (Azores, Portugal), different activities were carried out specifically designed for secondary school students (Fig. 2). The activities were focused on science and innovation, including short thematic talks and a Bootcamp to promote in the audience the spirit of innovation and the creation of ideas. ASTRAL introduced the importance of Sustainable Food Production, explaining to the young audience concepts such as trophic level, carbon footprint, sustainability, and food security, and how IMTA contributes to sustainable food production.

Other examples of targeted Ocean Literacy campaigns are those addressing specific issues and engaging selected stakeholders, as in the case of women working in aquaculture. 70% of the global aquaculture workforce is female, nevertheless, the great majority of management of the production is undertaken by men. The lack of data on women in aquaculture and gender-oriented training is one reason why women are invisible in aquaculture policy. ASTRAL is working to reduce this unbalance by empowering women in the aquaculture sector by means of awareness and specific training activities designed to promote the role of women in aquaculture and increase its visibility in the sector. Examples of these activities are included in the All-Atlantic pledge campaign on Women's Empowerment in Aquaculture led by ASTRAL.

ASTRAL is a HORIZON 2020 project (GA 863034) financed under the Blue Growth programme. Further information: www.astral-project.eu/

ECOSYSTEM SERVICES BY INTEGRATED COASTAL AREA MULTI-TROPHIC AQUACULTURE: A STUDY WITH COMMERCIAL FISH FARMING AND BLUE MUSSELS

Sandra L. Østerø*[a], Hardus Diedericks[b], Birgitta Andreasen[a], Tróndur T. Johannesen[a], Gunnvør á Norði[a]

E-mail: sandra@fiskaaling.fo

Integrated Multi-Tropic Aquaculture (IMTA) has been promoted as a sustainable and practical alternative to monoculture that could help solve some ecological issues with intensified aquaculture in cage systems (Chopin et al. 2012, Custódio et al. 2020). IMTA involves the co-cultivation of tropically linked species where the lower trophic levels feed on the waste from the upper trophic levels, treating waste as a valuable resource utilised through natural synergistic interactions between the cultured species (Chopin et al. 2012, Kerrigan & Suckling 2018). Thus, the environmental impact is mitigated whilst economic value is added in secondary marketable products and reduced risk through product diversification (Barrington et al. 2009).

Blue mussels (*Mytilus edulis*) grown in surface waters have often been recommended in IMTA systems to extract particulate waste from finfish production (Cranford et al. 2013). However, it is debated if significant mitigation can be obtained by direct assimilation of fish farm waste (Sanz-Lazaro & Sanchez-Jerez 2017).

In all mitigation applications the local environment and the farming practice of the emitting species must be considered. Thus, a detailed analysis of the system and models of various possibilities must be conducted in order to ensure the best possible ecosystem benefits by the multi-trophic approach.

Salmon farming is the main aquaculture production in the Faroe Islands with most farms located in fjords. Recently the legislation has opened up for farming multiple species in a fjord and thus there is a potential for regional multi-trophic aquaculture.

In this study, the potential for multi-trophic aquaculture with salmon and blue mussels was modelled in a fjord with commercial fish farming. The best mitigation potential by blue mussels was investigated by modelling three spatial arrangements of blue mussels in the fjord with fish farming activity. Two fish farm/blue mussel IMTA conjunctions were investigated and a scenario where the blue mussels and fish farm were not directly connected by the particulate fish farm waste but still located in the same ecosystem.

The production at the commercial fish farm was analyzed to predict the emission of dissolved and particulate nutrients, and the dispersion of particulate waste around the fish farm was modelled. For the two IMTA scenarios the blue mussels were modelled next to the fish farm and below the fish farm and the direct uptake of particulate waste was traced (Fig. 1). In addition to the waste assimilation the nutrient uptake by the blue mussels through assimilation of microalgae was investigated in the three blue mussel farm setups. The hydrographic conditions in the fjord were measured and modelled and a two-year time series of the phytoplankton biomass and nutrient availability, as well as the growth potential of the endemic blue mussels, was investigated.

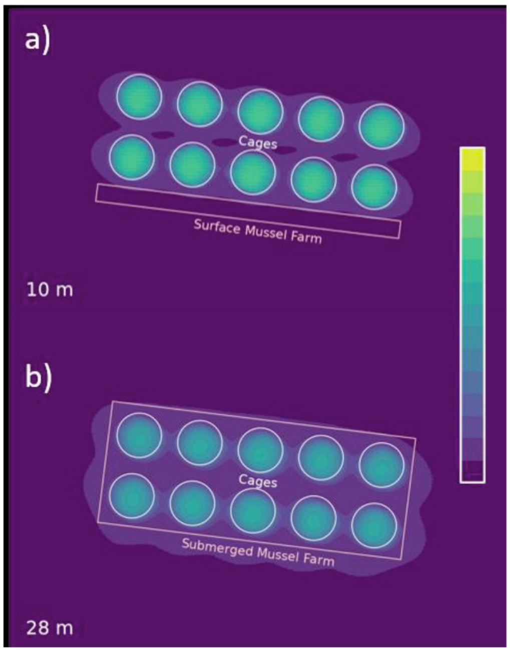

Figure 1. Concentration of waste particles at the base of the blue mussel farm at the surface at 10 m depth (a) and at the base of the submerged mussel farm at 28 m depth (b).From á Norði et al. (2022)

These data were used to investigate the potential removal of nitrogen by blue mussels and the mitigation potential by blue mussels was investigated in a coastal area management context, in order to predict the best mitigation potential considering the local production and spatial constraints in the fjord.

Overturf

Utilizing RNA-seq, this study compared the transcriptomic responses of three improved strains (VSel, PSel, and CSel) of rainbow trout fry during acute stages of challenge with infectious hematopoietic necrosis virus (IHNV). The VSel strain has been selected for resistance against the specific strain of IHNV used in our challenge, PSel has undergone selection for utilization of plant-protein based feeds and previously has shown elevated non-specific disease resistance despite no disease related selection pressures, and the final strain, CSel, is a commercial strain that has been domesticated for several years but has not been selected for specific viral disease resistance. Following a 21-day IHNV challenge, Kaplan-Meier survival estimator curves and cumulative percent mortality (CPM) showed significant differences in IHNV resistance across strains: VSel - 19.3 ± 5.0%, PSel - 67. ± 3.03%, CSel - 94.6 ± 4.1% CPM. To evaluate acute responses to IHNV infection, whole blood, as well as samples from the kidney, liver, and intestine, were collected at 0, 4, 12, 24, and 48 hours post infection (hpi). Serum lysozyme activity, a marker of non-specific innate immunity, showed strain and temporal effects during the acute infection phase with PSel showing the highest activity at 0 and 48 hpi. Differential gene expression responses were detected, with varying degrees, in all tissues, both between strains, as well as across acute timepoints within strains. The VSel strain showed upregulation for a particular subset of viral recognition genes during early infection timepoints and rather limited upregulation of immune genes later, while maintaining and reactivating metabolic pathways. The CSel strain showed a downregulation of metabolic related genes and a limited upregulation of immune genes, while the PSel strain showed similar downregulation of metabolic genes during acute infection, yet when compared to the CSel strain, showed a more robust innate immune response. Evaluation of upregulated immune response genes, as well as interferon-related genes showed the PSel strain to have the greatest number of uniquely upregulated immune genes in both the kidney and intestine, with CSel and PSel showing a similar number of such genes upregulated in liver. A moderate number of immune response genes were shared between PSel and CSel in all tissues, though both PSel and VSel showed a high number of uniquely overexpressed immune response genes in the kidney, and PSel showed the highest number of uniquely upregulated interferon related genes in the intestine. Overall, the VSel response was unique from the CSel with very little overlap in activated immune responses. Findings from this study highlight the disparity in IHNV resistance among genetic strains of rainbow trout, while identifying molecular mechanisms underlying differences in disease phenotypes. Furthermore, our results on trout strains with distinct selection backgrounds yields comparative insights into the adaptive gains brought about by selection programs for pathogen-specific disease resistance, as well as the non-specific immune enhancement associated with selection for utilization of plant-based diets.

INSIGHTS INTO THE OVARIAN DEVELOPMENT OF THE MONANDRIC PROTOGYNOUS BALLAN WRASSE (*Labrus bergylta*)

P. A. Palma[1]*, S. Lwyn[1], E. Jimenez-Fernandez [2], J. Baily[1], and A. P. Gutierrez[1]

[1]Institute of Aquaculture, University of Stirling, Stirling FK9 4LA, Scotland, UK

Email: alejandro.gutierrez@stir.ac.uk

Introduction

The Ballan wrasse (*L. bergylta*) has become a popular choice of biological control against sea lice infection in salmon cages. Captive breeding and seed production technologies for Ballan wrasse are under continuous development and improvement to provide a sustainable source of cleaner fish and fulfill the increasing demand from salmon industry. Broodstock management has proved to be challenging due to the nature of their reproductive development, being a sequential hermaphrodite (Brooker et al, 2018). Current understanding of their reproductive biology is rather limited. For instance, it is still unclear if they are monandric or diandric protogynous hermaphrodite. The correlative endocrine changes during reproductive development in this species is also poorly studied. Thus, we aimed to investigate the onset of gonadal development in Ballan wrasse, specifically the timing and the progression of histological and endocrine features.

Materials and Methods

Ballan wrasse (n=103) were collected from a commercial hatchery in Scotland, UK. Samples ranged from 3-185 g in body weight, 5-19 cm in total length, and from 6 to 36 months of age. Gonads were subjected to standard histological processing and stained with H&E. Blood samples were also collected, plasma was separated and used for etheric extraction of steroids. Circulating levels of sex steroid hormones (17β-Estradiol (E_2), Testosterone (T) and 11Ketotestoterone (11KT)) were then quantified using commercial ELISA kits.

Results and Discussions

Histological examination of the gonads showed that 93% (96 out of 103) of the examined fish exhibited primary growth stage oocytes indicating that they are undergoing female maturation while 7% (7 out of 103) exclusively had oogonia (Table 1). Within a population of diandric protogynous species, some individuals directly undergo testicular development (i.e., primary males) while some mature first as female and then undergo sex reversal to attain male maturity (i.e., secondary males). In some species of reef fish where diandry was previously reported, the observed frequency of primary males in the population ranged from 13% to 30% (Lowe et al, 2021; Palma et al, 2019). In the present study, none of the 103 fish examined showed any signs of spermatogenesis indicating the absence of primary males. On the other hand, the presence of secondary males in this species has been well documented in the wild (Dipper & Pullin, 1979; Muncaster et al., 2013). Taken together, these observations strongly suggest that Ballan wrasse is a monandric protogynous hermaphrodite.

Entry of Ballan wrasse into primary oocyte growth was observed at around 23.9 ± 1.8 g and 10.7 ± 0.3 cm as evidenced by the presence of chromatin-nucleolar stage oocytes. Oocyte development progressed into perinucleolar stage and subsequently into cortical alveolar stage, which was correlated with increasing levels of circulating sex steroid hormones, E_2 and T. A significant increase in E_2 was particularly observed as fish developed cortical alveolar stage oocytes indicating the ensuing vitellogenesis, marked by estrogenic stimulation of hepatic vitellogenin biosynthesis (Lubzens et al, 2020). Gonadosomatic index also increased along with the observed ovarian development. Analysis of plasma 11KT showed basal values consistent through various stages, which further support the idea that all fish examined were developing towards female maturity.

In summary, our findings suggest that Ballan wrasse is a monandric protogynous hermaphrodite. Moreover, this is the first study to describe the histological features and correlative steroid hormone profiles during the onset of gonadal development in Ballan wrasse. Ongoing analysis is being conducted to determine the expression levels of reproductive genes in the gonad as well as the circulating levels of gonadotropins. Information generated from this study provides a basis for the development of effective broodstock management and reproductive technologies for Ballan wrasse.

Introduction

Yellowtail kingfish is a fast-growing athlete that requires sufficient water flow over the gills to meet the oxygen demands. It is successfully being farmed in marine RAS but energy economy under these conditions poses challenging metabolic issues. Moreover, swim-training at optimal speed enhances body growth, lowers feed conversion ratio, increases cardiac output capacity (Palstra et al., 2015) and represents a promising approach for application at the farm.

In this study, we attempted to gain more insight into the energy economy by investigating heart rate and acceleration, as determined by application of Starr-Oddi loggers, at increasing swimming speeds during a swim-fitness test, and during an induced stress challenge test by repeatedly lowering of water levels (Svendsen, 2021). Oxygen consumption was measured and locomotory behavior (including tailbeats and respiration frequencies) monitored by high speed camera recordings during the swim-fitness test and parameters were related to heart rate and acceleration. Ultrasound was used as additional determinator of heart rate, although under anesthesia.

Materials and methods

Fish – Yellowtail kingfish from the Kingfish Zeeland farm were transported to the animal experimental facilities of CARUS in Wageningen. N= 16 fish were used for surgical implantation of the loggers and N= 14 fish were controls without a logger. Implanted fish was allowed to recover for 10 days before experiments were started.

Loggers – DST milli-HRT ACT (Starr-Oddi, Gardabaer, Iceland) loggers were implanted (Fig 1AB). Heart rate was derived from the Electrocardiogram (ECG) signal at 200 Hz recorded every 10 min as beats per minute (bpm) and acceleration as average external acceleration value (AvEA in milli-g-force, which is an average of 600 measurements over 1 minute) recorded at 10Hz.

Swim-fitness test – Fish were swum in series of three in three Blazka type swim tunnels (van den Thillart et al., 2004; Fig. 1C). Fish were kept at rest and then swimming at incremental swimming speeds of 0.2, 0.4, 0.6, 0.8 and 1.0 m s^{-1} for one hour each. The first N= 8 implanted fish were immediately dissected for the loggers after the swim test, the next N= 8 implanted fish were used for the stress challenge test.

Stress challenge test and cortisol – During the stress challenge, N= 8 implanted fish were kept with the controls in a tank and then exposed to four conditions: reducing water level and (1) filling up immediately, (2) after 1 min, (3) after 5 min, and (4) after 5 min with chasing the fish (Fig. 1DE).

Ultrasound – An Esaote MyLabFive Vet ultrasonography unit (Esaote Europe BV, Maastricht, the Netherlands) with a 18MHz LA435 ultrasound transducer and Pulsed Wave and color (CFM) Doppler was used as second methodology for determining heart rate, under anesthesia after swim fitness and stress challenge tests.

Results and discussion

(Continued on next page)

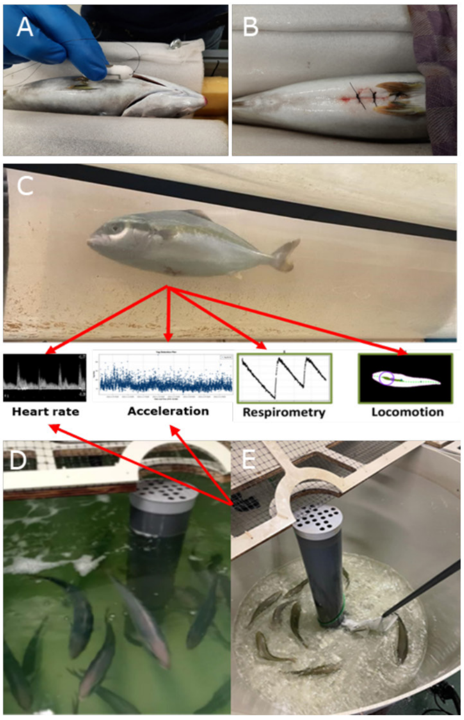

Figure 1. Overview of the experimental approach, showing (A) the positioning where the logger was implanted, (B) the stitch to anchor the logger and two additional stitches to close the wound, (C) a swimming yellowtail kingfish with implanted logger in the swim-tunnel where, additional to heart rate and acceleration, also oxygen consumption and locomotory behaviour were monitored, (D) the fish still at high water level and (E) at low water level inducing stress.

When fish were subjected to the swim-fitness test, implanted fish measured 33.2 ± 2.2 cm total length (TL) and weighed 652 ± 152 g body weight (BW), control fish measured 34.7 ± 2.2 cm TL and weighed 729 ± 122 g BW. Optimal swimming speed (Uopt) for implanted fish was 0.84 ± 0.06 m s^{-1} at a Cost of Transport (CoT) of 169 ± 32 mg kg^{-1} km^{-1}, for control fish Uopt was 0.82 ± 0.11 m $s^{-1}$and CoT was 178 ± 40 mg kg^{-1} km^{-1}. There was no impact of the logger on the oxygen consumption during swimming.

Base line heart rate of fish in the tank was 110 ± 19 bpm and accelerations were AvEA= 12 ± 4 milli-g. Heart rates of fish in the swim tunnel were higher but stable between 126 to 139 bpm up to swimming at 0.6 m s^{-1} and then increased up to 155 ± 2 bpm at 0.8 m s^{-1} and 162 ± 7 bpm at 1.0 m s^{-1}. Accelerations increased linearly with swimming speed from AvEA= 11 ± 1 to 26 ± 4 milli-g. The first, second and third lowering of the water level increased heart rate up to 138-144 bpm and accelerations were up to AvEA= 26 milli-g during the first but decreased to AvEA= 19 and 15 milli-g during the second and third stress induction. The fourth lowering of the water level that included the chasing caused the highest heart rates at 186 bpm with accelerations of AvEA= 44 milli-g. When anaesthetized, the eight implanted fish that were subjected to the stress test had a heart rate of 47 ± 11 bpm as determined by ultrasound.

An integrative data analyses will be presented also including the locomotory behavior results which are currently being analyzed.

OUT-OF-SEASON REPRODUCTION OF TWO DIFFERENT PIKEPERCH (*Sander lucioperca*) STRAINS: EVALUATION OF BROODSTOCK REPRODUCTIVE PERFORMACE AND EARLY LIFE STAGE DEVELOPMENT OF THEIR OFFSPRING

E. Panana* and S. Teerlinck

Inagro, Practical Research Aquaculture Center, Ieperseweg 87 8800 Rumbeke- Beitem (Belgium)
E-mail: edson.pananavillalobos@inagro.be

Introduction

The commercial farming of pikeperch (*Sander lucioperca*) has improved over the last years. Due to the development of different applied protocol, several production bottlenecks, such as controlled reproduction and constant supply of juveniles, have been tackled. As a result, the production of pikeperch in controlled conditions is slowly but constantly increasing in Europe. Despite the substantial progress observed over the last decade, pikeperch is still considered an emerging aquaculture fish species, facing different challenges throughout the production cycle. One of these challenges is the lack of information on broodstock management. While some research has focused on the nutritional requirement of the broodstock, and effect of rearing environment, there is a lack of information about the performance of different strains under similar controlled conditions. Therefore, the aim of this study was to evaluate the reproductive performance of two different pikeperch broodstock strains and the development of their offspring during the early life stage, under similar controlled conditions, in recirculating aquaculture systems (RAS).

Material and methods

In 2018, RAS-grown pikeperch (MBW= 0.5 ± 0.1 kg) coming from two different origins, “Inagro19”, origin A, and “Germany19”, origin B, were tagged and placed in a RAS-broodstock climate room (mixed tank). For two years, the fish were exposed to Inagro’s photo-thermal protocol for gonadal cycle induction, but they were not propagated. In 2021, during the third photo-thermal regime, oocytes from all the females were periodically sampled to determine oocyte growth and for the selection of females for the artificial reproduction. Sixty fish in total (15 females and 15 males from each strain; MBW = 2.1 ± 0.3 kg), were artificially propagated according to the protocol described by Żarski et al. (2019). The reproduction performance of both strains was evaluated by assessing different parameters during the propagation such as oocyte maturation kinetics, egg quality, fertilization, survival and hatching rate among others.

After hatching, larvae from each strain were randomly distributed in eight 220-L tanks connected to a RAS (4 tanks per strain) with an initial density of 110 larvae per liter. For twenty-nine days (29 DPH) larvae were reared according to Inagros’ hatchery protocol. Briefly, water temperature was kept at 16 ºC, initial live feed (AF + EG enriched artemia) followed by weaning to dry feed and a photoperiod of 16L:8D. During this period, growth performance, swim bladder inflation (SBI), survival rate and malformations were evaluated. Data was statistically analyzed for significant differences (α = 0.05) between strains.

Table 1. Reproductive performance of pikeperch females from two different strains (Inagro19 and Germany19) during artificial propagation

Parameters	Inagro19	Germany19	*P*
Ovulated females (%)	100	93	0.99
Fertilized females (%)	67	50	0.46
PGSI (%)	10.5 ± 2.6	12.2 ± 3.1	0.19
fertilization rate (1-cell stage)	84.2 ± 5.1	82.4 ± 6.04	0.69
Hatching rate %	69 ± 29	81 ± 15	0.21

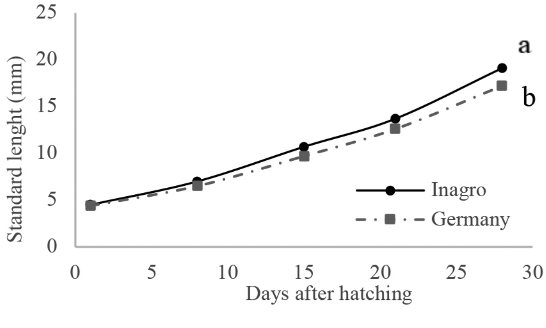

Figure 1. Standard length of pikeperch larvae from two different strains (Inagro19 and Germany19) reared from 29 day under similar condition

(Continued on next page)

Results

In general, the reproductive performance of both strains was similar. The oocyte growth during the photo-thermal protocol was slightly higher in Inagro19 compared to Germany19, however, no significant differences were found ($P>0.05$) between strains. Similar results were found in the parameters evaluated during propagation (Table 1). On the other hand, differences in oocyte maturation kinetics were found between strains. Inagro19 females reacted faster to the hormonal treatment, reaching oocyte stage 3-4 after 72-hour hormonal injection, while oocytes of Germany19 females were at stage 1-2, with some exceptions, after 72-hour hormonal injection.

Regarding growth performance of the offspring, at 29 DPH larvae from Inagro19 strain were significantly larger than larvae from Germany19 strain (Fig 1). Similar results were observed in mean body weight, with larvae from Inagro19 being 28% heavier compared to those from Germany19.

Discussion

More information regarding the origin of the fish is being collected in order to better understand the results obtained. This information will be added and discussed during the presentation.

Introduction

The European seabass is among the most farmed species in the Mediterranean Sea for its environmental characteristics that make it suitable to thrive between 5° to 28°C and from brackish to seawater conditions. The aquaculture of European seabass in southern latitudes can greatly benefit from all-year round productions due to the lack of cold seasons and the possibility to obtain optimal feed conversion ratio (FCR) and specific grow rate (SGR) at temperatures of 26°C-30°C.

With its long coastline, different climatic conditions and good quality water the Kingdom of Saudi Arabia is particularly advantaged in developing marine aquaculture. The northern part of the Red Sea looks the most promising for the farming of Mediterranean species due to its average temperatures between 27°C to 29°C despite higher salinity of 42 g L^{-1}. The scope of the current research was to determine the growth performance and nutrient retention of juvenile and pre-adult European seabass fed with commercially available marine feeds and to compare the performances against the results obtainable in the Mediterranean Sea.

Materials and Methods

For the first trial (Run 1) juvenile fish of 126.6 g fish were stocked in 1 m^3 tanks at a density of 4.2 kg m^{-3}. For the second trial (Run 2) pre-adult fish of 314.0 g fish were stocked in same capacity tanks at a density of 5.9 kg m^{-3}. Fish were reared at a salinity of 42 g L^{-1} and average temperature of respectively 27.0°C (Run 1) and 25.9°C (pre-adult) under a photoperiod of 12:12 hours. The duration of the trials were respectively 84 days (trial 1) and 80 days (trial 2).
Fish were fed at libitum daily twice a day four types of locally available commercial feed with the following levels of crude proteins and crude fat (CP/CF): 47/14 (Diet 1), 48/14 (Diet 2), 47/12 (Diet 3), 42/20 (Diet 4).

All data was analyzed using one-way ANOVA followed by Fisher Least Significant Difference (LSD) test.

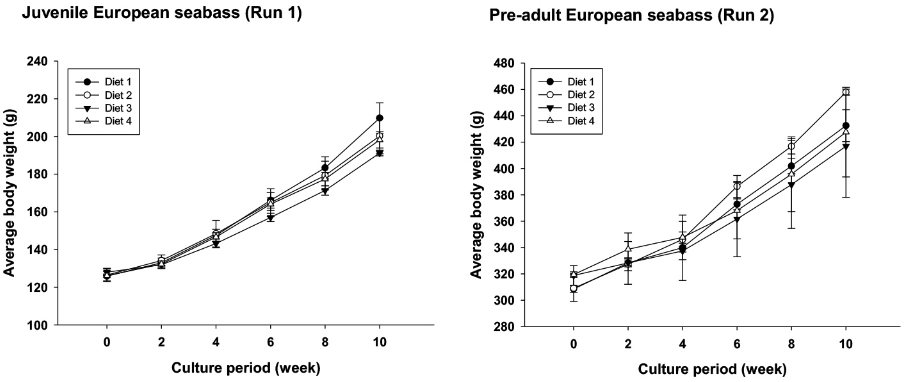

Fig. 1. Initial and final average body weight of juvenile and pre-adult European seabass fed the different commercial diets. Values represent means ± S.E.M. (n=3).

(Continued on next page)

Results

For the first trial the final body weight ranged between 191 g and 210 g, but no significant differences were noted among the diets, however the SGR was highest ($P < 0.05$) in Diet 1 (0.65) and lowest in Diet 3 (0.51). No statistical differences were noted among Diets for FCR (1.73 - 1.76) with the exception of Diet 3 (1.97) ($P < 0.05$).

For the second trial fish reached the final body mass of 417-458 g, but no statistical differences were observed. No differences were also seen for SGR, with values ranging between 0.35 and 0.52. Similarly the FCR showed no statistical differences, with values being respectively 1.7, 1.5, 2.5 and 1.9 among the Diets 1-4.

Discussion

The current study showed that the growth performances of the E. seabass are comparable to other researches carried out at lower temperatures or salinities, where juvenile fish could attain SGRs and FCRs of respectively 0.5-0.7 and 1.30-1.8 (Tibaldi et al., 2015; Güroy et al., 2006; Eroldoğan et al., 2000).

The pre-adult fish had similar or better results than other studies, where fish could achieve SGRs of 0.3-0.6 and FCRs of 1.8-2.2 (Mladineo et al., 2010).
The proximate analysis of the whole body of the fish did not show any differences among treatments for both crude protein, lipid, ash, with the only exception of higher ($P < 0.05$) gross energy in Diet 2 (12.32 MJ kg^{-1})

The protein retention efficiency showed values of 11.8 - 16.4, much lower than those measured by Lanari and D'Agaro (2005) (24.5% - 25.0%), which may have been caused by lower levels of digestibility of the feed ingredients or lower levels of essential amino acids (EAA).

Conclusions

The growth of European seabass in Red Sea condition is comparable to other researches. Further improvements in growth and FCR can be easily achieved through feeds that make use of more digestible ingredients and increased levels of EAAs.

Introduction

The first steps in greater amberjack domestication have been completed and the species can be currently produced under captivity. However, hatchery-reared fish have difficulties in achieving reproductive maturation under captivity and exhibit smaller gonads, lower levels of sex steroids and extensive oocyte atresia compared to wild individuals (Zupa et al., 2017). The aim of the present study was to explore the role of epigenetics, and more specifically of small RNAs, in ovarian development of hatchery-reared greater amberjack. With this aim, immature, maturing (late vitellogenesis) and spent ovaries of hatchery-reared greater amberjack were collected, and the differential expression of small RNAs in the three different ovarian maturation stages was studied.

Materials and Methods

Gonads used in the present study were collected from hatchery-reared greater amberjack at the end of the first year of life (immature, Papadaki et al., 2021) and at two different samplings at Argosaronikos fish farm, Salamina, Greece in June (maturing) and July 2015 (spent, Zupa et al., 2017). Four female fish from each group were killed on ice, the gonads were excised, one piece was preserved in a formaldehyde solution for histology and another piece in RNAlater for RNA extraction. After RNA extraction and quality check, micro RNA (miRNA) libraries were generated, sequenced and differential expression analysis was conducted.

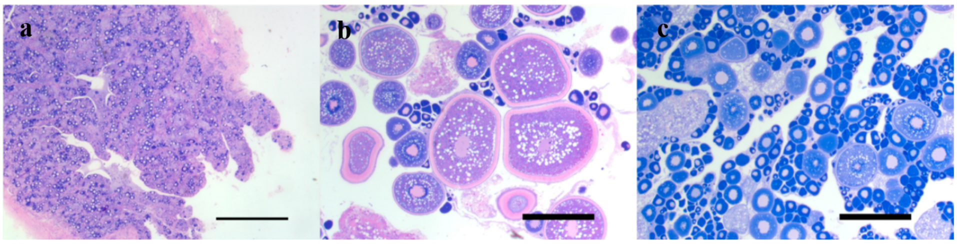

Figure 1. (a) Immature ovaries, mostly containing oogonia and primary oocytes, b) maturing ovaries, exhibiting late vitellogenic oocytes and c) spent ovaries with primary and atretic oocytes of hatchery-reared greater amberjack.

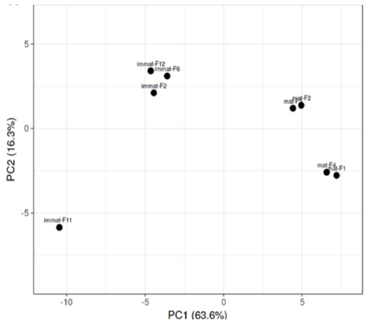

Figure 2. Principal component analysis of immature (IF2, IF6, IF11 and IF12) and spent (MF1, MF2, MF3 and MF4) greater amberjack ovaries. X and Y axis show principal component 1 and 2 that explain 63.6%, and 16.3% of the proportion of variance, respectively.

(Continued on next page)

Results

Immature individuals exhibited gonads, containing mostly oogonia and primary oocytes (Fig.1a), maturing individuals exhibited vitellogenic oocytes (Fig.1b) and spent individuals showed mostly primary and atretic oocytes in their gonads (Fig.1c).

Regarding sequencing results, the average number of reads for each sample after quality and adaptor trimming was 12 million reads. Between immature and spent females, two distinct groups were revealed by Principal Component Analysis (PCA, Fig. 2), with principal component 1 and 2 explaining 63.6% and 16.3 % of the total variance, respectively.

Discussion

Hatchery-reared greater amberjack can reach vitellogenesis under captivity but exhibit elevated atresia and low sex steroid levels. In the present study, the differential expression of small RNAs and the relevance with the ovarian maturation stages in hatchery-reared greater amberjack are discussed.

EFFECT OF FEEDING FREQUENCY ON PRODUCTIVE INDICES IN OPTIMUM OXYGEN SATURATION LEVELS FOR SEA BREAM (*Sparus aurata*) AND SEA BASS (*Dicentrarchus labrax*)

Introduction

Along with the quality and type of feed in a fish farm, the formation of an optimal and most effective nutritional protocol is influenced by many factors. It is a fact that the feeding frequency can affect the amount of feed consumed, the behavior of the fish and their growth performance. Optimal feeding frequency reduces fish farm production costs and prevents water quality degradation caused by overfeeding (Daudpota *et al*., 2016). This study aimed to investigate the effect of feeding frequency on productive indices in sea bass and bream in optimum oxygen saturation levels.

Materials and Methods

Two feeding frequency trials were conducted at the Aqualabs facilities of the Institute of Marine Biology, Biotechnology and Aquaculture (IMBBC) of the Hellenic Centre for Marine Research (HCMR) for sea bream and sea bass. Thirty-five individuals were used for both experiments. The trials were carried out in closed recirculation systems (RAS), each consisting of 500L capacity tanks under fully controlled oxygen, light and water flow conditions. In each closed circuit, the optimal level of oxygen saturation in the rearing water for each species was applied, as determined by previous experiments. Specifically, for sea bream, the oxygen range was 60-80%, while for sea bass was 80-100%. Different feeding regimes were applied in each RAS. Three treatment groups were fed to satiation at one of three frequencies (one, two and four meals per day) for 90 days. Three replicates were performed for each feeding regime. The feedings frequencies were determined by the rate and degree of gastric evacuation (stomach and intestine), from previous experiments (Table 1). Three gastric evacuation points were chosen at 25% (four feedings per day), 50% (two feedings per day), and 75% (one feeding per day).

Table 1. Feeding frequency and feeding times for sea bream and sea bass

Feedings	1st – four feedings	2nd – two feedings	3rd – one feeding
	Daily feeding hours		
1^{o}	8:00	8:00	8:00
2^{o}	12:00	16:00	
3^{o}	16:00		
4^{o}	20:00

(Continued on next page)

Results and Discussion

Growth indices for sea bream are shown in Table 2, whereas for sea bass are in Table 3. The results for sea bass showed that the recommended number of feedings is two per day (at 8:00 and 16:00), with 8-hour feeding interval. In both sea bass and sea bream, a reduction in the amount of feed consumed in the first meal was observed for the groups that had repeated meals within the day (Kikuchi et al., 2006). However, no improvement in growth was observed when the frequency of feeding was increased from two to four per day for both species. The FCR remained constant in both species. Despite the higher feed consumption for the group of four feedings compared to the others for sea bass, this is not reflected in the growth performance of the species. In the case of sea bream, no statistically significant difference was seen even in the amount of feed consumed between the groups for the duration of the experiment. Fish fed fewer times per day showed greater motility during feeding, as the opportunities to receive feed were limited per individual, thus developing an anticipatory food activity (AFA). According to Chen and Purser (2001) this developed ability of fish helps to increase feed intake and feeding efficiency.

[2]Istituto Zooprofilattico Sperimentale della Sicilia "A. Mirri" Area Sorveglianza Epidemiologica
Via Gino Marinuzzi, 3 – 90129 Paalermo - Italy

Mediterranean trout (*Salmo cetti*), is endemic species belonging to *Salmo trutta* group which is widespread exclusively in Sardinia, Sicily on a few areas of the Italian Tyrrhenian side. Following repopulation carried out with Atlantic trout, its presence on the Italian territory has undergone a strong contraction due to hybridization and introgression effects. At the moment, *Salmo cettii* is on the IUCN Red List, rated as Critically Endangered (CR). The selection of pure breeders with high genetic variability and the storage of their sperm in a cryobank become important tools to make the management of the conservation of endangered species more efficient. Recent pieces of evidence indicated the presence of a specific haplotype in the Iblei Mountains of Sicily suggesting the presence of some conserved areas with the endemic populations (Segherloo et al., 2021). The objective of the work was to genetically characterize a population of Mediterranean trout (*Salmo cettii*) caught in different waterways of the Iblei Mountains of Sicily in order to verify its level of introgression with the allochthonous Northern Atlantic haplotypes and evaluate the possibility to use this population as a precious resource for future restocking plans.

Materials and methods

57 wild Mediterranean fish were caught from different waterways of Sicily Iblei Mountains, in order to sample their genetic material. For the comparative genetic analysis, the samples from 41 *S. trutta* of Northern Atlantic lineage were collected (29 from Morgex Val d'Aosta and 12 trout from Fiumelatte –(Como) hatcheries). Genetic analyses were performed using: i) 16 autosomic STR microsatellite; ii) SDY E2S, a sex marker; iii) the Locus LDH-C1; iv) the mtDNA D-loop. Allele frequency-based analyses was detected by GenAlEx program (Peakall and Smouse 2012). Genetic structure and gene flow were analyzed by STRUCTURE 2.3.4 (Pritchard et al.2000). The combination of the results deriving from the analysis of the LDH-C1 and the mitochondrial D-loop were performed by the hybridization index (Penserini et al. 2006).

Results

The analysis of the SDY-ES2 locus revealed that, out of the total Sicily Mediterranean trout, 42 were males and 15 females. The expected and observed heterozygosity (He: 0,630 and Ho: 0,627, respectively) was quite low, as was the actual number of alleles (Ne: 2,70). A deviation from a Hardy-Weinberg equilibrium was found for 9 out of 16 loci ($p < 0.05$). STRUCTURE analysis clearly revealed the presence of 2 distinct populations, with few misassignments in the Northern Atlantic populations.

The Locus D-loop mtDNA analysis showed that the Sicily Mediterranean population 100% matched with the haplotype sequence present in the database for *Salmo cetti* (GenBank MW251439.1, Segherloo et al., 2021), except for 3 individuals. The screening of the LDH-C1 Locus revealed the presence of 3 individuals with allele LDH-C1 * 90. The hybridization index indicated the 87% of individuals belonging to Class VI (zero potential of hybridization), 6% to Class V and only 8% to Class II (high potential of hybridization) (Pensierini et al., 2006).

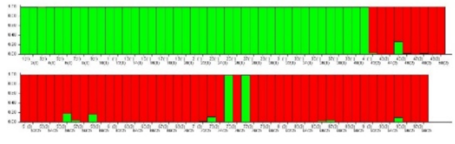

Figure 1. Barplots of individual, STR-based admixture as obtained through the Bayesian clustering analysis in STRUCTURE

(Continued on next page)

Discussion and Conclusion

The results obtained in this study indicated that the Mediterranean trout population sampled in some waterways of Sicily Iblei Mountains showed a very low level of introgression with the Norther Atlantic lineage, despite the numerous releases of the allochthonous individuals occurred in the past. Probably, the extreme conditions of the waterways and the permanence to which they are forced make difficult the survival of the North Atlantic haplotype and the relative hybrids. At the same time, the geographic isolation of individuals, due to the characteristics of the waterways, represent a limit to the genetic variability of the population, which was found quite low. The genetic results obtained in this preliminary study suggests a potential use of the Sicily Iblei Mountains trout population as a precious resource for planning native fish restocking activities.

Introduction

The new Strategic Guidelines for the sustainable development of EU aquaculture adopted by the Commission in spring 2021 intend to further promote organic aquaculture as strategy to meet consumer demand for diversified high quality food produced in a way that respects the environment and ensures animal welfare. EU organic regulation (889/2008 and 848/2018) established that only fish meal derived from fish trimmings and from whole fish caught in fisheries certified as sustainable together with vegetable raw materials derived from organic plants can be used as the main protein sources for organic aquafeed. The difficult to reach certified ingredients, together with the high production costs, are the main problems of low production of organic EU fish. The needs for additional types of raw materials and reconsidered the sourcing of plant feed ingredients has been recognised as necessary to promote EU organic aquaculture. The aim of this study was to test the effects of certified organic novel raw materials (organic pea protein, organic yeast, organic seaweed) on growth, fish welfare and products quality of rainbow trout, gilthead sea bream and meagre.

Materials and Method

Three feeding trials (one for each species) were performed in order to replace 60, 50 and 45% fishmeal trimming (FM) in rainbow trout (RT), sea bream (SB) and meagre (M) respectively, using increasing level of organic pea protein (PP), organic seaweeds and organic yeast. Three experimental diets for rainbow trout (control, RT-C; PP 10%, RT-PP10; PP 21%, RT-PP21) and sea bream (control, SB-C; PP 8%, SB-PP8; PP 19%, SB-PP19) and four diets for meagre (control, M-C; PP 7%, M-PP7; PP 18%, M-PP18 and M-PP27) were formulated using organic raw materials according to EU organic regulation. Diets were tested in triplicated fish groups (initial weight, RT: 63g; SB:146g; M: 33g) to satiation over 60 days for RT and SB and during 85 days for M.

At the end of the trials specific growth rate (SGR), feed intake (FI), feed conversion rate (FCR), somatometric indexes (hepatosomatic index, HSI; viscerosomatic index, VSI) and nutritional indices (protein efficiency ratio, PER; gross protein efficiency, GPE) were performed for all species. In addition, fish quality parameters (fillet and liver proximate and fatty acids composition and sensory quality by trained panellists) were performed in SB and RT. In M fish health was assessed by plasma biochemistry and gut microbiome by next-generation sequencing. Differences among treatments were considered significant at $P < 0.05$.

Results

At the end of trials, no significant differences in growth (SGR, FI, FCR) were observed in M, while SB-PP8, SB-PP19 and RT-PP21 showed lower SGR in comparison to the respective control diets. FCR was lower in RT-PP10 than RT-C and RT-PP21. Concerning welfare parameters glucose was higher in animals fed M-C and lower in M-PP27. Total protein and albumin showed higher values in animal fed M-PP18 and lower values in M-C. Albumin/globulin was higher in animals fed M-PP27. In RT and SB no significant differences were observed in HSI and fillet yield while VSI was higher in RT-PP21 than the other treatments. Fillet in both SB and RT showed a higher protein but lower lipid content in PP21. In RT, fillet showed a higher content of DHA and N3-PUFA in the fish fed RT-PP21 in comparison to the other diets. Similarly, DHA and N3-PUFA were higher in SB-PP21 than SB-C. Some similarities in sensory characteristics were observed when comparing SB and RT samples fed with organic feeds containing different proportions of PP. Effects were observed in odour, appearance, and textural sensory attributes. In particular, flesh of both species had a less intense ammonia odour, a lower quantity of exudate and was firmer but also less crumbly and juicy. In addition, the inclusion of PP significantly increased the bitter flavour perception in SB and RT, even though the effect was not significant for RT samples.

(Continued on next page)

Discussion

This study highlighted the possibility to partially replace FM using novel organic vegetable raw materials (pea protein, seaweed and yeast) in rainbow trout, sea bream and meagre. The inclusion of organic pea protein at low levels in combination with organic seaweed and/or organic yeast did not produce any effect on growth and/or composition of the fish, however a high inclusion of pea protein produced a lower growth in trout, but not in sea bream and meagre. The inclusion of the organic raw materials tested induced a higher accumulation of N-3 PUFA in the fillet of trout and sea bream. Similarly, the results of the sensory characterisation of the fillet also showed a positive effect of pea protein inclusion on odour, appearance and textual sensory attribute leading to a higher product quality.

Email: fpascoli@izsvenezie.it

Introduction

The study of animal behavior is a sector that is attracting increasing interest from the scientific community, also thanks to the new technologies available to researchers. In recent years, fish have also entered this type of study, despite the difficulties of observation due to the aquatic medium.

Materials and methods

In this pilot study, the critical points in setting up studies of this kind in an experimental aquarium were evaluated and the applicability of the system to observe the behavior of sea bass (*Dicentrarchus labrax*) infected and not with *Betanodavirus* was evaluated by daily video recording of 2 tanks and subsequent analysis using dedicated software (EthoVision XT, Noldus Information Technology, Wageningen, The Netherlands).

Results

The results highlighted several critical issues in the experimental set-up, both at the hardware level (lighting, aerosol, humidity) and at the software level (reflections, shadows, individual tracking). Concerning behavioral analysis, the infected fish had a lower movement speed and distance covered and a higher state of inactivity than the control group. In addition, the infected fish showed greater dispersion within the tank than the control group.

Conclusions

These results highlight how the progression of the disease under examination influences the behavior of fish, beyond the clinical signs, providing interesting and useful predictive tools for the improvement of animal welfare and the management of diseases.

The research leading to these results has received funding from the European Union's Horizon 2020 research and innovation programme under grant agreement No 731014 (VetBioNet project).

DIETARY CHITIN LEVEL AFFECTS NUTRIENT DIGESTIBILITY AND PLASMA ENZYMES AND METABOLITES IN RAINBOW TROUT (*Oncorhynchus mykiss*)

G. Pascon*, M. Messina, G. Cardinaletti, F. Tulli

Dept. of Agriculture, Food, Environment and Animal Science, University of Udine – Italy
E-mail: pascon.giulia@spes.uniud.it

Introduction

Chitin-containing invertebrates, in particular insects, are a promising protein- and mineral-rich resource, characterized by a low environmental footprint and increasing availability. For the above-mentioned reasons, they have recently become attractive as a potential aquafeed ingredient[1–3]. The use of this innovative ingredient, as a partial substitute for conventional protein sources, has been tested for different aquacultured species[4–7]. The observed results are promising both for growth performance and diet digestibility, even if impairment in growth performance and nutrient availability due to the presence of chitin has been reported with contrasting results according to finfish species[8,9]. Therefore, the effect of the inclusion of 0%, 1,5%, 3%, and 4,5% chitin from prawn shells in semi-purified diets for rainbow trout (*Oncorhynchus mykiss*) on growth, feed utilization, nutrient digestibility, and plasma parameters has been investigated.

Materials and methods

Four dietary treatments have been formulated to contain 48% crude protein and 16% crude lipid. All diets were added Celite® as an inert marker before being cold extruded and dried into 3 mm pellets at the facilities of the University of Udine. The diets tested were the control diet (0% chitin), and three diets where graded levels of chitin (Merck, cod. C9213) 1,5, 3,0 and 4,5% replaced cellulose. These levels simulate the dietary inclusion levels of 15, 30 and 50% of a commercial partially defatted insect meal from black soldier fly (Protix**®)**. The fish used in the study were purchased from a commercial fish farm and were adapted to the experimental conditions 2 weeks prior to the onset of the experiment. Almost constant temperature (13±0,7**°C) and water conditions were assured during the trial. One hundred and eighty rainbow trout (**27,4±2,38g) were randomly allotted among five tank units each including three vessels singularly stocked with 15 fish and fitted with a settling column for faeces recovery[10]. Fish were hand-fed one daily meal (9:00) to a fixed ration (1% live weight). After the meal, feed eventually refused were promptly removed. Per each diet, faeces were collected over two independent 15-day periods. At the end of the trial, fish were group-weighed after 6 hrs fasting and 6 fish per treatment were euthanized with an overdose of anaesthetic (150 mg/L MS 222) and blood samples were immediately collected from the caudal vein for plasma enzymes and metabolites analysis. Freeze-dried faecal samples were analysed for dry matter, ash, nitrogen, lipid, and acid insoluble ash as outlined by National Research Council (2011)[11]. Apparent digestibility coefficients (ADCs) of dry matter, crude protein (CP), organic matter and lipid were calculated[12].

Results

Fish promptly accepted all the diets. Feed intake, growth performance, feed conversion and specific growth ratios of rainbow trout were calculated over 10 weeks. Dietary chitin did not affect weight (56,87±2,05g), feed utilization (1,01±0,07) or specific growth rate (1,08±0,11%) till 3% inclusion level. The higher inclusion level of chitin (4,5%) significantly reduced both final weight (42,48±1,05g) and growth rate (0,73±0,06%) and feed utilization (1,66±0,25) ($P<0,05$) and this was first a consequence of the lower absolute feed intake.

The *in vivo* digestibility coefficient for lipid and protein showed a significant decrease when the chitin was included at the highest percentage ($P<0,05$). The apparent digestibility coefficient (ADC) for the control diet resulted in 87,68 % for protein, 91,99 % for lipid and 69,97% for organic matter. The ADC of test diets resulted 86,76%, 83,91% and 68,30% for protein; 93,60%, 93,39%, and 81,54 for lipid; 69,89%, 65,47% and 57,74% for organic matter, respectively for diet CHI1,5, CHI3, and CHI4,5.

Most of the plasma enzymes and metabolites related to nutritional (cholesterol, glucose, triglycerides, protein and albumin) and physiological conditions (lactate dehydrogenase (LDH), aspartate aminotransferase (AST/GOT), alanine aminotransferase (ALT/GPT)) were not affected by feeding chitin up to 3% included diets. In particular, fish fed CHI0, CHI1,5 and CHI3 diet, showed the highest values for cholesterol (197±43,6, 216,9±40,7 and 226,5±36,5 mg/dl), triglycerides (168,31±55, 179,1±42,1, 170,54±41,3 mg/dl), protein (2,23±0,2, 2,32±0,2, 2,09±0,2 g/dl) and albumin (1,75±0,2, 1,63±0,2 1,62±0,2 g/dl respectively). On the other hand, fish fed the highest dietary chitin inclusion level showed the lowest value for cholesterol (122,05±36,3 mg/dl), triglycerides (84,9±28,5 mg/dl), protein (1,7±0,2 g/dl) and albumin (1,29±0,2 g/dl) also ($P<0,05$ for cholesterol and triglycerides; $P<0,001$ for protein and albumin).

(Continued on next page)

Discussion

Recent years have seen an increasing interest in insect meals as a sustainable and nutritious innovative ingredients to be included in aquafeed [13]. More recently, their health-promoting potential is also going to be explored. This experimental trial showed that a dietary chitin level of up to 3%, does not affect the zootechnical performance, the nutrient digestibility and the plasma enzymes and metabolites in rainbow trout. On the contrary, 4,5% chitin (roughly simulating a diet including 500g/kg of defatted *Hermetia illucens* meal) negatively affected growth performance, feed utilization, nutrients digestibility and plasma parameters.

Conclusion

Dietary chitin inclusion up to 3% is well tolerated in rainbow trout while higher inclusion (4,5%) level significantly affected growth, feed utilization, nutrient digestibility and plasma enzymes and metabolites levels. This suggests that insect meal can only partially replace conventional protein sources in diets for rainbow trout and insect protein derivatives could be considered.

THE ROLE OF ALGAL BIOFILMS AS CUE FOR SETTLEMENT AND EARLY GROWTH IN THE SEA CUCUMBER *Holothuria tubulosa*

V. Pasquini*, A. A. Giglioli and P. Addis

Department of Life and Environmental Sciences, University of Cagliari
Via T. Fiorelli 1, 09126 Cagliari (Italy)
Email: vivi.pasquini@yahoo.it

Introduction

The larval settlement is one of the trickiest stages during the development of many benthic marine invertebrates due to the complex processes of interaction between biotic and abiotic factors operating at different spatial and temporal scales. Such a process interests the larval cycle of *Holothuroidea* species that is characterized by three main stages, a feeding planktonic auricularia, a non-feeding planktonic doliolaria, followed by the settlement into pentactula, which feeds on the substrate (Rakaj et al., 2018). Such a critical step is also reflected in the rearing of sea cucumbers, where the low settlement success and the low survival rate of post-settlers represent the bottleneck to the feasibility of commercial-scale production. Several cues have been used to stimulate the metamorphosis of sea cucumbers, including natural biofilms, the addition of seagrasses extract, and the conditioning of settlement plates with diatoms biofilms (Agudo 2006; Rakaj et al., 2018).

In order to improve the information on the role of algal biofilm in the induction of larval metamorphosis, we investigate the effect of different biofilms on the settlement success of the doliolaria of *Holothuria tubulosa* and we also provide information on the growth of juveniles reared for two years in a pilot-scale hatchery.

Materials and methods

The metamorphosis of doliolaria larvae of *H. tubulosa* was tested with three treatments: the diatom *Amphora spp.*; the green algae *Ulvella lens* and the Control (no biofilm). The experimental design considered multiple chamber plates (6 chambers each plate; 4 replicates each treatment) with a volume of 3 ml for each chamber. Before the trials, the plates were conditioned with the respective biofilms.

The larvae used in this study were bred in three 150-L tanks (1 larva ml^{-1}) and were fed with the pabulum made of a mix of the microalgae *Chaetoceros calcitrans*, *Isochrysis galbana*, and *Tetraselmis suecica*. The larvae reached the doliolaria stage after 25 days post-fertilization. From this batch of larvae, 72 doliolaria were transferred individually in the trial chambers that were kept at 24°C with a photoperiod of 12h light and dark. The progress of the settlement was followed under a stereomicroscope, every five days, by observing the morphological changes from doliolaria to pentactula. When the second posterior podium appeared, the specimens were considered juveniles. The settlement success was calculated as the ratio of the number of settlers (pentactula and juveniles) to the number of initial larvae, expressed in percentage. The settlement performance was tested at the end of the experiment after 35 days. Prior to the one-way ANOVA ($P < 0.05$), Cochran's C-test ($P>0.05$) was used to check the assumption of the homogeneity of variances. *Post-hoc* multiple comparisons were performed using the Tukey HSD test. The remaining doliolaria larvae of the batch described above (ca. 60000), were transferred in three 500-L tanks provided with *Amphora spp.* biofilms. For the following two months, larvae were fed with diatoms *ad libitum*. After this period, larvae were fed three times a week with spirulina (*Arthrospira platensis*) mixed with fine sand and a commercial feeding powder (at a feeding rate of 3% of juveniles' weight). Every three months sea cucumbers were visually counted for survival rate determination and a subsample of 10 juveniles was randomly collected from each tank, measured (total length in mm), and weighed (total wet weight in g) for growth parameters determination.

Results

The settlement success at the end of the experiment was about 21%±12.5se with *Amphora spp.*, and 54%±12.5se with *U. lens*, which was the only treatment significantly different from the Control. Moreover, the treatment *U. lens* showed the highest post-settler survival, with 25% of juveniles, while in the treatment *Amphora spp.* only 4% of the larvae reached the same stage. The percentage of swimming doliolaria decreased with the progression of the settlement, except in the Control plates, where at the end of the experiment, 62% of the doliolaria were still present.

The larvae transferred in the pilot-scale hatchery showed survival of about 1% after seven months post-fertilization, with the production of ca. 600 juveniles, of which, 50% survived after 15 months post-fertilization and showed a mean weight of 6.8g ±3.0sd, a mean length of 41mm± 10.4sd.

(Continued on next page)

Discussion and conclusion

Sea cucumbers larvae bred in captivity are generally induced to settle on natural biofilms obtained by immersing the plates in diatoms cultures for a few days or adding an extract of *Sargassum sp*. or seagrass leaves (Agudo 2006, Rakaj et al., 2018). Our results showed that all the plates conditioned with algal biofilm allowed the settlement of the doliolaria and its metamorphosis into pentactula. The best settlement performance was achieved with *U. lens*, which allowed the metamorphosis of the 54% of the larvae into pentactula, confirming the high performance of this alga in fostering the settlement of echinoderms larvae (Hannon et al., 2017). It is particularly interesting to observe that larvae that survived in the Control plates were still in the doliolaria stage for the whole duration of the experiment. This fact indicates that the presence of some sort of cue is a necessary condition to proceed with the metamorphosis of *H. tubulosa* and that larvae are able to delay metamorphosis when no substrate is available. These results could be explained by the *Desperate Larva Hypothesis*, revised to be applicable to the non-feeding stage of the larval cycle (Botello and Krug, 2006). According to this hypothesis as the non-feeding stage continues, larvae became "desperate" to settle and the level of selectivity towards the substrata decreases. Indeed, the lower number of juveniles in the treatment with *Amphora spp*. (4%) can indicate that while the cue seems to be enough to induce the settlement, *Amphora spp*. alone, might not be able to ensure high survival of the post-settlers and their growth.

The results provide practical applications increasing the efficiency of the current rearing protocols for sea cucumbers. In fact, we reported the first record of growth-out of juveniles at a pilot-scale hatchery for *H. tubulosa*.

Introduction

The increase of uncontrolled harvesting led to the overexploitation of many holothurians species, including the Mediterranean sea cucumber *Holothuria tubulosa* (Gmelin 1791). Commercial-scale aquaculture can represent the alternative to the exploitation of wild populations and such technologies have been provided for the most valuable species (i.e. *Holothuria scabra*) (Agudo, 2006). Experimental attempts to breed Mediterranean sea cucumbers were recently reported by different authors (Domínguez-Godino and González-Wangüemert, 2018; Rakaj *et al.*, 2018). However, the adaptation of the technologies and the breeding protocols used with tropical species to the Mediterranean ones presents some criticisms, including the low effectiveness of the stimuli used to collect the gametes. To optimize the current breeding protocols, we explored new different triggers to stimulate the spawning in *H. tubulosa* broodstock.

Materials and methods

A total of 200 adults in a reproductive stage were collected by SCUBA diving in the Gulf of Teulada (Italy, Sardinian Sea) in August 2020. After collection, each broodstock was placed in a 3-L plastic bag and transported to the experimental hatchery in cooling boxes to avoid thermal stress. Once in the hatchery, specimens were divided into four acclimation tanks (350L), at a reference temperature of 25°C, with the natural light regime, for 48h prior to the experiment.

To trigger the gametes emission from broodstock, the following set of stimuli was considered: thermal stressors (alone or combined with air exposure), the addition of conspecific sperms or feeding excess and bubbling (Agudo 2006; Ferranti et al., 2018; Rakaj et al., 2018). Each treatment was replicated in 6 independent tanks (15-L), containing 3 sea cucumbers each, and all treatments lasted 180 minutes. Except for the thermal stressors, the water temperature in the treatment tanks was set at a reference value of 25° C, i.e. the same temperature as the acclimation tanks. At the end of the exposure, specimens were moved into the spawning tanks (one for each replica), filled with seawater (25°C). During the treatments and the next 9h, the behavior of sea cucumbers was observed to detect whether they assumed the pre-spawning position (Ocaña and Tocino 2005) and/or they have spawned. When spawning occurred, specimens were isolated in separate tanks.

The gametes obtained with the most effective trigger were used to perform the hatching rate trials in 2-L tanks (three replicates), using the following densities of the fertilized eggs: 4, 8, 25, 50, 100, 200 eggs ml^{-1}. The embryos were kept in the dark, with static water at 24°C. After 24h, the hatching rate was volumetrically estimated by collecting 1 ml subsample (n=3) from each replicate and the number of swimming larvae in the gastrula stage was counted.

One-way analysis of variance was performed to test differences in the spawning trials and the hatching rate trials. Data expressed in percentage were arcsin transformed ($x' = \arcsin\sqrt{x}$). Prior to performing the ANOVA, we tested for homogeneity of variance with Cochran's test. The *post-hoc* Tukey HSD test was applied to test significant effects between each treatment and the Control and/or among treatments ($P < 0.05$).

Results

All the specimens used in the experiment showed no signs of stress (e.g. evisceration) and no mortality occurred. The triggered specimens showed the pre-spawning behavior, followed by the emission of the gametes. The best trigger was the bubbling, with the emission of 61%±25.1 of specimens, followed by the feeding excess (22%±17.2) using diatoms. Both these treatments were different from the control, where no specimens spawned. Few specimens also spawned in with the two types of thermal stressors (6 %±13.6). The eggs released in the treatment bubbling were estimated in 5.4±1.5sd million oocytes, and this batch was used to assess the hatching rate of the fertilized eggs. The hatching rate was negatively affected by the increase of the densities and drastically dropped at the highest density, with only the 3%±0.6 of hatched eggs.

(Continued on next page)

Discussion and conclusion

Among the investigated treatments, bubbling was the most effective stimulus, leading to the emission of more than 60% of specimens. This stimulus, despite having never been investigated with echinoderms, is the most common method used for the reproduction of other broadcast spawners marine invertebrates (Ferranti et al., 2018). This treatment acted by increasing the water turbulence in the tanks using vigorous air insufflations, possibly recreating the turbulence of the wave motion, whereas in all the other treatments the water in the tanks was static. Indeed, the water movement can also be the cause of the spawning of sea cucumbers during the transportation from the wild to the laboratory, which can be enough to trigger the specimens (Agudo, 2006; Rakaj et al., 2018). The sensitivity of sea cucumbers to the increase of water turbulence as a stimulus to trigger the gametes' release might be an adaptive strategy for these broadcast spawners. In fact, moderate water turbulence can enhance the dispersion of the gametes, increasing the probability of their encounter and the subsequent fertilization (Gaylord 2008), thus fostering the reproductive success.

In conclusion, the trigger "bubbling" can provide a considerable amount of vital gametes, both oocytes and sperms. These can be fertilized and hatched into the gastrula stage, which, in the vision of a commercial-scale hatchery, can improve sea cucumber production.

[c]Naturedulis, Goro (FE), Italy

Introduction

Shellfish culture is traditionally supported by the collection of wild juveniles. For Ostrea edulis, however, this practice is inefficient given the scarcity of biological material available in the lagoon. The productive recovery of native species requires strengthening the production capacity of existing hatcheries. However, the production increases should not adversely affect the environment and ecosystem in which these are grown, especially when they are located in fragile areas but of high cultural, landscape and natural value. The objective of the present study is to evaluate new technologies and solutions to improve the productivity and environmental sustainability of hatcheries for pre-growing of Ostrea e. for their productive recovery.

Experimental

The study can be divided into three main steps:
Optimization of reproduction condition through digitalization.
Synthesis of feed for oysters from macroalgae
Biofilters from waste (shells)

Results

Optimization of reproduction condition through digitalization.
Long-term tests were performed to verify the stability of the response of the sensors placed in the closed-circuit tanks of the hatchery. The purpose of the tests was to verify the accuracy of the data provided by the sensors (pH, salinity, dissolved oxygen, temperature, chlorophyll, ammonium, and nitrate) and to establish the timing required for their maintenance (cleaning and calibration) in order to ensure their optimal operation and the reliability of the results obtained. The survival rate of specimens divided by size class of Ostrea edulis in tanks controlled with sensor and non-sensor systems were monitored.

Synthesis of feed for oysters from macroalgae
Average composition of the main nutritional constituents of algae (Ulva lactuca and Gracilaria) undergoes some significant variation in relation to seasonality. The two seaweed species studied differ significantly in ash and lipid content. Ulva lactuca shows a higher content of both. Since the uses and health benefits of unsaturated lipids contained in many marine animal and plant species are known, the lipid profile of seaweeds was studied. In addition, the suitability of microalgae extracts for use as feed ingredient for oysters. In particular, the organic and inorganic micropollutants were determined. The algae-based material was encapsulated using a mixture of lipids and alginate to produce small droplets. The encapsulated feed was tested on bivalve mollusc larvae. The results obtained showed that the optimal growth rate of the larvae was achieved by using a mixture of encapsulated feed and 50% phytoplankton.

Biofilters from waste (shells)
A wastewater filter system was installed at Naturedulis (Figure 1), consisting of a cylinder filled with a mixture of adsorbent materials obtained from shells.The efficiency of the proposed system in the relevant environment was tested. Water samples were taken before and after the filter treatment, which are subjected to chemical analysis. The data obtained shows that the filter system removes more than 50% of the heavy metal in water.

APPLYING THE CONCEPT OF TOLERANCE LANDSCAPES TO BUILD SCENARIOS OF CLIMATE IMPACT FOR CULTURED BIVALVES

Bertolini, C.[1] ; Glaser, D.[1]; Canu, D.M.[2] Pastres, R.[1]*

1 DAIS, Ca' Foscari University of Venice, 30170, Venezia
2 National Institute of Oceanography and Applied Geophysics - OGS, Trieste, Italy
*pastres@unive.it

Introduction

With ongoing climate change, extreme climatic events, such as heatwaves, are predicted to increase in frequency, intensity, and duration. The thermal tolerance of organisms is also dictated by a combination of exposure intensity and duration.: long exposures at temperatures lower than the critical temperature (CT_{max}) can still be deleterious. Since bivalve farming has been recently advocated as a 'restorative aquaculture' practice with some climate mitigation potential, it would be of key to understand how these species are faring under current climate change scenarios.

Methods

Tolerance landscape theory (Rezende et al., 2014) where was used in this study to predict the effects of heatwaves. Two species were chosen: the Mediterranean blue mussel *Mytilus galloprovincialis* and the manilla clam *Ruditapes philippinarum:* the former is farmed in the water column while the latter on the seabed, and together they account for more than 95% of all farmed shellfish in Italy. A tolerance model for *R. philippinarum* was already developed by Bertolini & Pastres (2021) and the same procedure was followed to build a model for *M. galloprovincialis,* based on literature data. The main goal of this study was to investigate how heat waves could affect the mortality of these species, considering the different dynamics of water and sediment temperature in a shallow water body. To this aim, scenarios of both water and sediment temperature in the Lagoon of Venice, where both species are farmed, were constructed for the decades 2020-2100. The water temperature scenarios were defined by assuming an additive structure of the time series. Average hourly values were obtained by interpolating monthly values provided by OGS in the framework of the "Venezia 2021" research project. Scenarios of water temperature until 2100 were based on estimates provided by the SHYFEM model, a deterministic model using a 2D grid over the ~~whole~~ water body, which assumes the RCP 8.5 climate scenario. These monthly values were interpolated to hourly values to form a general trend. Daily oscillations were estimated based on the spectral analysis of a comprehensive set of bi-hourly water temperature time series collected in the Lagoon of Venice from 2008 to 2018 (SAMANET network).

Sediment temperature scenarios were estimated based on a cross-correlation model between time series of water and sediment temperature data collected in 2020/21, The temperatures below ground were lower in summer and higher in winter, thus two separate linear models were applied to predict the sediment temperature based on the daily mean water temperature. For each year , 2019-2100, the highest value of consecutive hours spent above each temperature threshold starting from 25°C at 0.1°C until the maximum temperature recorded (30°C) was used to compare against the thresholds identified by the tolerance landscapes (water temperatures for *M. galloprovincialis* and sediment temperature for *R. philippinarum*).

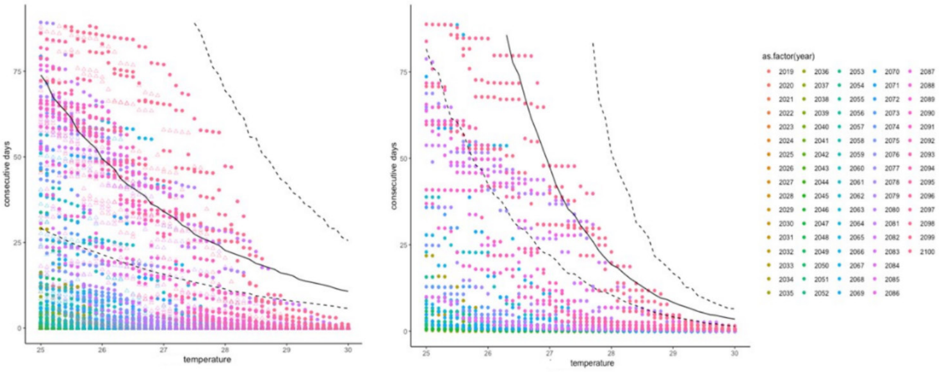

Fig.1 Maximum value of consecutive days above each temperature (left: sediment, right: water) compared to tolerance landscape (full line, dotted lines represent 95% CI) for *R.philippinarum* (left) and *M. galloprovincialis* (right).

(Continued on next page)

Results & Discussion

The values of CT_{max} and z for *M. galloprovincialis* were 39.7 °C (± 1.7) and -2.64 (±0.4) °C, while the values for *R. philippinarum* in Bertolini & Pastres (2021) were 54.5 °C (± 2.3) and - 5.72 °C (± 0.66), both consistent with bivalve values from Rezende et al. (2014). The values suggest that blue mussels have a lower CT_{max} but can sustain high temperatures for longer compared to clams, due to a lower value of z.

When scenarios of water temperature and sediment temperatures are compared to the thresholds (Fig.1) it is observable that temperatures for both species are reaching and surpassing the threshold within the end of the century, for *R. philippinarum* entering the lower confidence boundary by the 2070s (with some outlier years in previous decades) while for *M. galloprovincialis* towards the end of the 2070s. It is also noticeable that the surpassing of the threshold is happening in greater proportion at the lower temperatures, in particular for the earlier years.

Conclusions

This study shows that, towards the end of the century, both of these commercially important species will face detrimental conditions, in which temperatures regularly exceed their thresholds. Findings also demonstrate that the duration of moderate heat waves can be a more severe threat to clam survival than short, extreme heat waves. However, since temperature forecasts were developed using the RCP 8.5 climate scenario, these results resemble the worst-case scenario.

VISIBLE EFFECTS OF STRESS ON FISH

P. Pawlak*, J. Konrad, C. Pietsch

School of Agricultural, Forest and Food Sciences (HAFL), Applied University Bern (BFH), 3052 Zollikofen, Switzerland
E-Mail: paulina.pawlak@bfh.ch

Introduction

An increasing number of tools is being developed for assessing the effects of stress on fish. But most of these methods are invasive and often require the sampling of blood or other tissues for the analyses. Consequently, using visual procedures for assessing the effects of stress on fish may be advantageous since they don`t require the handling of the animals. In our study, the chronic effects of stress on common carp (*Cyprinus carpio* L.) were investigated.

Material and methods

The fish were kept in groups of six in separate 90l aquaria. Animals were treated with one of 6 different stressors every day for 7 and 28 days in order to avoid habituation to the stressors, and were challenged on the sampling days with air exposure as an additional stressor. Control groups were reared in parallel and either left untreated during the entire experiment or challenged with air exposure only on the sampling days. In week 1 and 4 of the experiment, the fish behaviour was monitored for 20 min each day using GoPro Hero9 cameras, and after 28 days of treatment also images of the body have been taken in order to analyze the body coloration.

Results and discussion

Our results show that the analysis of fish behaviour and body coloration may be useful as indicators of stress. The behaviour of fish clearly is influenced by exposure to different stressors. However, assessment of behavioural differences is time-consuming and automatization strongly depends on the quality of the video material. Thus, taking pictures of the fish may be an easier way to assess effects of stress since automatic analyses of images is more efficient.

Introduction

The intensive freshwater aquaculture using the recirculating aquaculture systems (RAS) is new approach for getting more efficient, stable, profitable and high-quality marketable fish production which is currently mainly supported by the traditional pond and water through culture methods (Martins et al. 2010)i.e., to produce food while sustaining natural resources is achieved only when production systems with a minimum ecological impact are used. Recirculating aquaculture systems (RASs. The using of polyculture in the RAS with similar requirements on environment and with different behavior, swimming and feeding activity, offers great potential to more effectively use capacity of this kind of aquaculture (Thomas et al. 2020). The aim of this study was to optimize the intensive largemouth bass culture in the RAS and to monitor the impact of the initial density on the efficiency of its production, as well as to compare the impact of the biculture of largemouth bass and pikeperch on their production efficiency with the monoculture of both species.

Material and methods

The first 140days experiment assessed the effect of initial fish density in three levels: low: 23kg.m^{-3}; medium: 35 kg.m^{-3}; high: 46 kg.m^{-3}. In total, 3303 pcs. of experimental fish [with total length (TL) = 217.8–225.2 ± 18.2–19.7 mm and body weight (BW) = 139.9–157.1 ± 37.2–43.6 g] were stocked in nine tanks connected to large scale experimental RAS. After 8 hours of light, the fish were kept for another 4 hours at a reduced light intensity (until 7:00 pm) of 70–80 lux in order to offer the largemouth bass an optimal light period and support fish sufficiently by feed and maintain all routines in RAS. Experimental fish of all groups in all tanks were fed 50% by hand and 50% by belt feeder from 8:00 am to 7:00 pm with actual calculated daily feeding rate (DFR) at 28day interval. At the beginning of the experiment, DFR was set at 1.5% of fish biomass and DFR was reduced to 0.75% of fish biomass from the middle of the experiment (from 72nd day of this experiment). Fish were fed commercial floating feed R-2 Europa F 15 (Skretting, Norway) with a size of 2.0 mm (at the beginning of the experiment) to 3 mm (at the end of the experiment). Such pelleted feed was collected, and all non-consumed pellets were counted.

The second experiment tested the effect of mixed culture of largemouth bass and pikeperch compared to monoculture of both species during 60days intensive aquaculture. Same aged fingerlings of largemouth bass (TL = 103.8 ± 3.5 mm; W = 12.5 ± 2.5 g) and pikeperch (TL = 121.7 ± 5.5 mm; W = 12.2 ± 1.9 g), which were produced by a combination pond and RAS culture according Policar et al. (2013). In total, 700 fish were stocked in each tank (in monoculture only one species a in biculture both species with ratio 50:50) with initial density 1.17 fish and 14.5–14.8 g per liter. Before the experiment, all experimental fish of both species were size sorted and only fish with minimum size differences (9.0–16.0 g) in individual body weight were selected for this study. At the end of the experiment, all the fish were weighted again, and the frequency of the fish at same 1 g interval with final size difference (11.1–75.0 g) was again calculated.

Results

In the first 140days experiment, all three densities provided same high specific growth rate (SGR = 0.22–0.24 %.d^{-1}). Feed conversion ratio (FCR) was the lowest for low (1.39 ± 0.21 g.g^{-1}), the highest (1.61 ± 0.08 g.g^{-1}) for medium density. High density did not have any different FCR (1.50 ± 0.17 g.g^{-1}) compared to other tested densities. Analogous results as for SGR were also obtained for survival rate (97–100%). The second 60days experiment tested the effect and comparison groups of largemouth bass and pikeperch (*Sander lucioperca*) within monoculture and biculture on production efficiency. The higher FC was evaluated higher in both groups (monoculture and biculture) of largemouth bass (1.09) compared to groups of pikeperch (0.74–0.78). SGR were the lowest for both groups (monoculture and biculture) of largemouth bass (1.20–1.28%.d^{-1}). In contrast, the highest SGR was in the group of biculture pikeperch (1.88 %.d^{-1}). The similar results such as SGR were also assessed for FCR, where the higher FCR were in both groups of largemouth bass (1.44–1.48 g.g^{-1}) than in the biculture of pikeperch (0.73 g.g^{-1}). All four tested groups had a high survival rate (98.61–99.99 %) (Fig. 1).

(Continued on next page)

Discussion

The optimal fish density as high as possible is very important fact of successful intensive aquaculture in many species (Ronald et al. 2014). Higher density of intensively cultured juvenile Eurasian perch (0.5–15 g) from 400 to 10 000 fish.m^{-3} can increase growth rate and decrease growth heterogeneity. This positive correlation between fish density and growth rate was valid until 10–16 g perch juveniles. In bigger perch juveniles up to 16 grams, increasing density from 20 to 60 kg.m-3 decreased growth rate (Mélard et al., 1996). This positive relationship can have effect on higher survival rate of cultured fish. The results show that fish survival rate during the experiment was significantly lower for the pikeperch than for the largemouth bass. There may be several reasons for these differences in survival of both tested species, which have the slightly different physiological processes, their tolerance and adaptation to conditions of intensive farming (Bell 2013)but its operation is restricted by ecological and genetic constraints. The cost of natural selection expresses the limited capacity of a population to sustain the load of mortality or sterility required for effective selection. Genostasis expresses the lack of variation that prevents many populations from adapting to stress. While the role of relative fitness in adaptation is well understood, evolutionary rescue emphasizes the need to recognize explicitly the importance of absolute fitness. Permanent adaptation requires a range of genetic variation in absolute fitness that is broad enough to provide a few extreme types capable of sustained growth under a stress that would cause extinction if they were not present. This principle implies that population size is an important determinant of rescue. The overall number of individuals exposed to selection will be greater when the population declines gradually under a constant stress, or is progressively challenged by gradually increasing stress. In gradually deteriorating environments, survival at lethal stress may be procured by prior adaptation to sublethal stress through genetic correlation. Neither the standing genetic variation of small populations nor the mutation supply of large populations, however, may be sufficient to provide evolutionary rescue for most populations. © 2012 The Author(s.

INTEGRATING SEA CUCUMBERS IN FISH AQUACULTURE WASTE RECYCLING: A MODEL OF SUSTAINABLE BLUE GROWTH

D. Pensa*, L. Grosso, A. Fianchini, M. Scardi, A. Rakaj

Experimental Ecology and Aquaculture Laboratory, Department of Biology, University of Rome Tor Vergata
Via Cracovia 1, 00133 Rome, Italy
E-mail: davidee.pensa@gmail.com

Introduction

Fin-fish aquaculture negatively affects the benthic community's health through the depositions of large amounts of fecal matter, leftover food and catabolites on the sea bed. In this context, the polyculture of species with different ecological role and feeding behaviors in the same integrated multi-trophic aquaculture (IMTA) system is an innovative culture approach to minimize the environmental impact caused by the strong growth of the fin-fish industry. Among extractive species, deposit-feeding sea cucumbers are the most promising to diversify and maximize production, reducing at the same time the organic load of impacted areas. Sea cucumbers, indeed, are able to ingest sediment and organic material, playing an important role in cycling and energy flow in benthic ecosystems. Moreover, these marine invertebrates are economically attractive species being considered luxury seafood, especially in Asian countries. Laboratory and pilot-scale studies have already suggested Mediterrenan sea cucumber species as promising candidates for IMTA applications (Neofitou et al., 2019). However, a scarcity of information is available about their culture under open-water farms (Tolon et al., 2017; Bastien Sadoul et al., 2022; Cutajar et al., 2022). This study, therefore, aimed to provide baseline information on the survival and growth performances of Mediterrenean sea cucumber species, *Holothuria tubulosa* and *Holothuria polii*, when cultured at three different rearing densities under a productive sea bream farm.

Materials and Methods

During the Summer of 2020, a IMTA experiment was carried out at "Piscicoltura del Golfo di Gaeta Soc. Agricola a.r.l.", which is a commercial fin-fish farm located in the central Tirrenean Sea (Italy). Sub-adults of *H. tubulosa* and *H. polii* were collected at Torre Astura (Italy) and starved for 48 h in lantern nets. After starvation, for each species, individuals were weighted and placed in seabed cages beneath the fin-fish cages at three rearing densities: Low, Medium and High, respectively of 500-1000 g m^{-2}, 1000-2000 g m^{-2}, 2000-3000 g m^{-2}. The suitability of *H. tubulosa* and *H. polii* to use fin-fish waste as the sole food source was evaluated in terms of Survival and Relative Weight Gain (RWG %) over a four-month experiment.

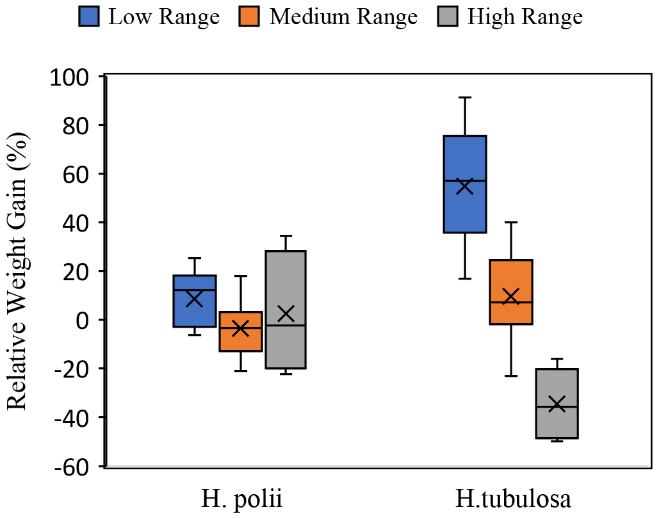

Figura 1. Relative Weight Gain (%) of H. tubulosa and H. polii cultured at three stocking density range (Low, 500-1000 g m^{-2}; Medium, 1000-2000 g m^{-2}; High, 2000-3000 g m^{-2}) under commercial fin-fish farm for three months.

(Continued on next page)

Results

At the end of the experiment, the mean survival and mean RWG % in *H. tubulosa* (respectively 88.7 % and 13.5 %) resulted significantly higher than in *H. polii* (respectively 66.7 % and 0.62 %). When comparing growth performances among rearing densities, a clear trend was observed in *H. tubulosa* with significant differences among rearing conditions. In fact, the RWG % resulted lowest at High density, progressively rising with the decrease of rearing density (Fig.1). Instead, in *H. polii,* although the highest RWG % was also obtained at Low density, no significant differences emerge among rearing experimental conditions (Fig 1).

Discussion

The present study highlighted for the first time the different compatibility of *H. tubulosa* and *H. polii* in polyculture with fin-fish, evidencing that these two sea cucumber species have different feeding behaviors and culture requirements. *H. tubulosa* and *H. polii* adopt different trophic strategies in the wild feeding conditions. *H. tubulosa* actively select the organic matter from the surface sediment layer. Conversely, *H. polii* is able to dig into the sediment in order to feed on meiofauna, microorganisms, and organic detritus in the deeper sediment layer. However, this burrowing behavior may not be compatible with the physicochemical factors below the fin-fish farms (e.g. reduced oxygen availability, excessive organic sedimentation, excessive shell drop, nitrate release), which potentially affected the growth and survival of *H. polii* during this study. In conclusion, *H. tubulosa* resulted a better candidate than *H. polii* as extractive species in IMTA with fin-fish. In fact, at the end of the four-month experiment *H. tubulosa* was able to increase energy-use efficiency inside commercial farms, promoting productivity increase and rearing diversification. Furthermore, our results highlighted that the stocking rearing density significantly affected the growth performances of this sea cucumber species in IMTA system. Hence future investigations must consider the rearing density of sea cucumber species as a key aspect in aquaculture trials.

Introduction

Probiotics are live microorganisms that confer a health benefit to the host when administered in adequate amounts. *Shewanella putrefaciens* Pdp11 has been described as a probiotic for farmed fish species such as *Solea senegalensis* and *Sparus aurata* Tapia-Paniagua et al., 2012). In contrast, other strains of *S. putrefaciens* have been described as pathogenic for other cultured fish (Esteve et al 2017)damage of the mouth, extensive skin discoloration, exophthalmia, ascites and bad odour. The S. putrefaciens group was recovered from freshwater samples taken at the L′Albufera system, along autumn–winter 2015. Its counts significantly increased in freshwater parallel to hypoxia and temperature rising. Shewanellae strains were identified as S. putrefaciens and S. xiamenensis by 16S rRNA gene sequencing. These isolates recovered from sick eels or freshwater were virulent for European eel by IP challenge (LD50 106 CFU g−1 body weight. The plasmids plays an important role in the genes transfer and insertion then there can been implicated in antibiotics resistance, degradative pathway and pathogenicity characteristics (Kornelia et al 2015). The genetic variation conducted by plasmid could induce an impact in probiotic proprieties. In this research, we searched the present or absent of plasmids in pathogenic and probiotic strains of *S. putrefaciens*. As well as, this plasmids implication in development of virulence factors.

Material and methods

Shewanella putrefaciens strain Pdp11 was isolated from skin mucosa of healthy gilthead seabream (*Sparus aurata* L.) (Chabrillón *et al.*, 2005) and *Shewanella putrefaciens* SH12, SH4, SH6, SH9, SH16 have been associated with diseases in eel (*Anguilla anguilla* L.)(Esteve, , 2017)damage of the mouth, extensive skin discoloration, exophthalmia, ascites and bad odour. The S. putrefaciens group was recovered from freshwater samples taken at the L′Albufera system, along autumn–winter 2015. Its counts significantly increased in freshwater parallel to hypoxia and temperature rising. Shewanellae strains were identified as S. putrefaciens and S. xiamenensis by 16S rRNA gene sequencing. These isolates recovered from sick eels or freshwater were virulent for European eel by IP challenge (LD50 106 CFU g−1 body weight.All *S. putrefaciens* strains were grown on 10ml of Tryptone soja broth supplemented with NaCl 1.5% (TSBs) for 24h at 23ºC. Given the possibility that, the hypothetical plasmids could be integrated into the bacterial genome, strains were cultured under different and strict growth conditions (temperature, incubation time, growth medium and freeze-thaw) to favor their excision. For this, all strains of the study were cultured in 10 mL tubes of TSBs and minimal media (M9), and incubated at 23ºC or 4ºC for 24h and 48 h on shaking at 80 rpm. Cultures inoculated in parallel with TSBs medium containing glycerol (20 %) were subjected to a freeze-thaw cycle for 24 h at -80 ºC before incubation. The positive control was *Escherichia coli* V157, a strain harbouring seven plasmids, grown on Luria Bertani broth (LB) for 24h at 37ºC under agitation at 80 rpm. The cultures were centrifuged and the pellet was used for plasmid DNA (pDNA) isolation. pDNA integrity was checked by agarose gel. Rolling circle amplification (RCA) was performed using the TempliPhi 100 amplification kit for each isolated plasmid following the manufacturer’s instructions.

The Illumina sequences were obtained by Seoane et al. 2019, and Plasmid-specific Sanger sequences from pDNA isolation and RCA amplification as above. Vector removing and quality trimming steps of Sanger reads were performed with BBDuk. Two sets of vector-free Sanger reads were obtained in the quality trimming. The low stringency threshold generates longer reads used to capture plasmid-specific Illumina reads and the high stringency threshold for the final assembly. Then, plasmids were assembled *de novo* using a workflow integrating Sanger and Illumina reads. Plasmid sequences were recircularized by the MARS method, and plasmids were aligned by the Clustal method of the Seaview program to finally obtain the plasmid consensus sequences. The plasmids annotation and functional characterization were performed. The sequence analysis showed that the plasmids encoded a putative replication initiator protein of the repB family, and proteins related to plasmid stability and a toxin-antitoxin system.

(Continued on next page)

Results and Discussion

Using a workflow integrating Sanger and Illumina reads, the complete consensus sequences of the plasmids were obtained. We found that the main ORFs conserved in both plasmids pSH4 and pSH12 belong to the replication protein initiator repB superfamily, and PemK/PemI family protein. The Rep proteins are especially important as they are primarily responsible for the initial DNA binding and nicking activities (Stolz, 2014). Another major ORF identified is the PemK protein as part of toxin-antitoxin (TA). This system is found both in bacterial chromosomes and in MEGs such as plasmids and prophages (Bukowski et al., 2019).

The presence of plasmids is expected to be associated with bacterial survival and, commonly, with virulence factors. The probiotic strain *S. putrefaciens* Pdp11 did not present plasmid, which was only found in two of the five pathogenic strains. The results allowed us to discard the probiotic Pdp11 could present a pathogenic characteristic as the TA type II system as a virulence factor and its self-regulating characteristics, which may be behind its probiotic nature, making the Pdp11 strain unique in comparison to other *S. putrefaciens* strains.

Introduction

Shewanella putrefaciens Pdp11 and *V.proteolyticus* DCF 12.2 are strains isolated by our research group. *S. putrefaciens* Pdp11 has been described as a probiotic for farmed fish species such as *Solea senegalensis* and *Sparus aurata* [1].Although the probiotic potential is well described some studies reference to application of postbiotic as functional bioactive compounds produces by probiotics. Recent works have been focused in the identification of substances as alternative of anti-biofilm methods and their implication in surface attachment inhibition [2]. In this research, *S. putrefaciens* Pdp11 and *V.proteolyticus* DCF 12.2 have been cultured under different growth conditions (temperature, culture media and during 24 and 48 hours of incubation) and their extracellular products (ECPs) have been extracted and tested as potential postbiotics that affect the biofilm formation of several fish pathogenic strains.

Materials and Methods

The probiotic strains were grown on tryptic soja agar plates supplemented with NaCl (1,5%) for 24h at 23ºC. Then, one to two colonies were picked up in 10ml of tryptic soy broth supplemented with NaCl (1.5%) (TSBs) and incubated at 23ºC and 15 ºC for 36h (stationary phase). Then, extracellular products (ECPs) from solid medium3, 1 ml of the cultures were spread on TSAs plates as control condition. Another 1 mL was spread on plates containing: Pdp11 was culture in a medium with 25% of algae mix (diet 1) and supplement with a commercial diet (diet 2) were incubated to 23ºC for 24h. While *V. proteolyticus* DCF 12.2 was incubated in a commercial and algae mix diet (diet 3) and with 25% of algae mix (diet 4) to 15 and 23 º C during 48 and 24h respectively. After incubation, the ECPs were recovered with 5 ml of sterile phosphate buffer saline (PBS), and centrifuged (10000xg, 4ºC, 10 min) and the supernatant was filtered (0.22µm, pore diameter). ECPs were conserved at -80ºC until use. The biofilm inhibition was determined for the pathogenic strains: *S. putrefaciens* SH4, SH12, SH6 and SH9 4damage of the mouth, extensive skin discoloration, exophthalmia, ascites and bad odour. The S. putrefaciens group was recovered from freshwater samples taken at the L′Albufera system, along autumn–winter 2015. Its counts significantly increased in freshwater parallel to hypoxia and temperature rising. Shewanellae strains were identified as S. putrefaciens and S. xiamenensis by 16S rRNA gene sequencing. These isolates recovered from sick eels or freshwater were virulent for European eel by IP challenge (LD50 106 CFU g−1 body weight using 96 well plates by adding 90µl ECPs + 90 µl TSBs + 20 µl of pathogenic bacterial suspension adjusted to OD600nm ~ 0.5, per well. The plates were incubated at 23ºC during 24h. The biofilm formation assay was performed by crystal violet (CV) staining5"ISSN":"0044 8486","abstract":"The use of effective biocides as disinfectants is essential in aquaculture facilities. However, while most biocides act effectively on free-living planktonic pathogens, they are seldom useful against biofilms. In this study, we evaluate the biocidal efficacy and antimicrobial specific contact time of three disinfectants, Virkon™Aquatic (VirA and quantify at OD595nm in a plates reader. The results were analysis by two-way Anova method.

Results and Discussion

Two different ECPs concentration were assayed to check the potential inhibition of the biofilm formation, 0.45 and 0.25 µg protein/ml (Figure 1). The SH4 and SH12 pathogenic strains did not present biofilm formation in contrast to SH6 and SH9 strains. The biofilm of SH6 presented the highest inhibition at a concentration of 0,25 µg/ml of respect to control in each condition. On the contrary, the biofilm of SH9 presented inhibition by at 0,014 µg/ml of ECPs. Some authors describe that the biofilm inhibition can be mediated by soluble antimicrobial peptides (AMPs) secreted on ECP of probiotics strains [6]. This assay results evidence that Pdp11_Pmix_2324 ECPs have showed the most impact in the biofilm formation of pathogenic strains. Therefore, ECPs secreted by Pdp11 and *V.proteolyticus* DCF 12.2 are implicated in the inhibition to adhesion of pathogens on surfaces.

Introduction

Bivalve molluscs such as mussels, oysters, scallops, cockles, and clams are organisms of great ecological and commercial importance in Europe. The pullet carpet shell is a clam species very appreciated by consumers. Unfortunately, natural stocks decrease and the production of seed in hatcheries is hampered by different factors among which are broodstock conditioning, settlement and metamorphosis and diseases.

Clam larvae develop competence before recognizing appropriate exogenous cues to settle and metamorphose. Previous studies have shown the induction to metamorphosis using analogues of natural inducers in bivalve larvae from different species (Coon et al. 1985; Estupinan and Waite 1988; Dobretsov and Qian, 2003, García-Lavandeira et al. 2005; Alfaro et al. 2011; Mesías-Gansbiller et al. 2008, 2013). The aim of this study is to identify the chemical inducer capable of raising metamorphosis rates in pullet carpet shell clam larvae and in consequence to enhance their production and survival.

Materials and methods

The larvae were cultured in the facilities of the CIMA and the IGAFA. A semi-continuous larval culture system was used, with water renewal every 48 hours and feeding from axenic microalgae cultures. The water was treated with ultraviolet light. Three experiments of induction of the metamorphosis were carried out, with competent larvae of *V. corrugata* (between day 17 and day 20 of culture) using the protocols previously described in García-Lavandeira et al. (2005) and Mesías-Gansbiller et al. (2013). Competent larvae of *V. corrugata* were treated with several neuroactive compounds: GABA, L-DOPA, IBMX, serotonin, acetylcholine and the catecholamines epinephrine and norepinephrine. Three different concentrations of the potential inducers were used: 10^{-4}M, 10^{-5}M and 10^{-6}M with the aim of determining the optimal concentration. Experiments were carried out on a laboratory scale in Petri dishes of 90mm, at a density of 4 larvae/ml. Each experiment was performed in triplicate for each of the three concentrations mentioned above and also included a control with FSW (filtered sea water) and no potential inductor. After an exposure time to inducers or FSW of 72h larvae were observed with a Leica DM750 microscope. Larvae were considered to go through metamorphosis when they had a food to crawl and lost their velum. The percentage of metamorphosis was calculated by dividing the total number of larvae metamorphosed by the total number larvae and multiplying by 100. Percentages of both metamorphosis and mortality were analysed by ANOVA using the statistical package SPSS 20.0. The results were significantly different when $p<0.05$.

Results and discussion

Maximum percentages of settlement were observed with 10^{-4}M epinephrine, norepinephrine, and serotonin after 72 h of exposure to the inducer. These percentages were significantly different from the control with FSW. The percentage of larvae that passed metamorphosis in the control amounted approximately to 61%. Furthermore, exposure to 10^{-5}M epinephrine and serotonin also increase significantly metamorphosis. The percentage of metamorphosed larvae on *V. corrugata* obtained with 10^{-4}M acetylcholine was slightly significant comparing to the control larvae. In the cases of GABA and IBMX, they did not produce any positive or negative influence on the percentage of metamorphosis. By contrast, L-DOPA had negative effects on the metamorphosis rates, this compound resulted toxic for the larvae and reduce the percentage of metamorphosis comparing to the control larvae. Mortality of larvae was not affected by serotonin, epinephrine, norepinephrine and acetylcholine.

(Continued on next page)

As a consequence of these results, we can conclude that serotonin, epinephrine and norepinephrine are the best inducers of metamorphosis in *V. corrugata* larvae, although acetylcholine at high concentrations was also a good inducer. Acetylcholine and serotonin were also effective inducers of larval metamorphosis in the clam *Ruditapes philippinarum* larvae (Urrutia et al. 2004, own results). Furthermore, García-Lavandeira et al. (2005) found that epinephrine was an active inducer of metamorphosis in two clam species *Venerupis pullastra* (now named *V. corrugata*) and *R. philippinarum*, although the percentages of metamorphosis obtained by these authors were very low compared to those obtained in the study presented here. The different effect of chemical compounds in the induction of metamorphosis is clearly determined but not only by the species under study, as observed in the data obtained by different authors in different species of clams.

Introduction

Bivalve aquaculture production in the eastern Adriatic is based on two species, namely, Mediterranean mussel *Mytilus galloprovincialis* Lamarck, 1819 and European flat oyster *Ostrea edulis* Linneaus, 1758. Sheltered bays and estuaries are preferred bivalve farming areas of optimal productivity in terms of nutrients and organic matter load. These sites display spatio-temporal heterogeneity of hydrological conditions and nutrients availability and are typically under risk from anthropogenic pollutants that may be delivered from land-based sources (Gavrilović et al, 2007; Milun et al, 2016; Šilović et al, 2012). As the overall performance of bivalves is tightly linked to marine ecosystem quality, it is necessary to evaluate whether these external stressors, alone or in combination, may affect the farmed organisms and consequently the seafood production success.

Materials and methods

This work was carried out in two distinct and geographically distant ecosystems of the Eastern Adriatic: Lim Bay and Mali Ston Bay, long been known for bivalve and fish farming. Both Lim Bay and Mali Ston Bay are legally protected marine reserve in the eastern Adriatic Sea. Samples of seawater, sediment and adult bivalves were collected bimonthly from June 2020 to May 2021 and processed in accordance to standardised protocols. Briefly, seawater parameters – temperature, salinity and oxygen saturation - were assessed immediately upon sampling of seawater. Total coliforms, *E. coli* and enterococcus as faecal indicators of microbiological quality were determined for seawater and sediment by substrate technology (IDEXX). Culturable heterotrophic bacteria in seawater, sediment and bivalve tissues were isolated on Marine agar and enumerated following 24-48 h incubation at 22°C. Chemical analysis of metals, PAHs, PCBs and pesticides in sediment and whole tissue was also carried out. Aliquots of seawater samples were stored and later used for total heterotrophic bacteria, chlorophyll a and particulate organic matter analyses. Condition index of mussels and oysters was determined according to Davenport and Chen (1987).

Results

Seawater physico-chemical parameters displayed typical seasonal variations, while microbiological quality and the content of chemicals displayed both seasonal and site-specific patterns. Faecal indicators in seawater and sediment, namely, total coliforms, *E.coli* and enterococci, occasionally displayed slightly higher values at Lim Bay site. A markedly higher levels of heterotrophic bacteria were recorded over almost the whole investigation period in samples of bivalves, seawater and sediment from Lim Bay. Concentration of metals and PAHs displayed species and site specific patterns, while the levels of PCBs and pesticides in both the sediment and tissues were below detection limits. Condition index of mussels and oysters also differed between two sites.

Discussion and conclusion

The overall results reflect specificities of each farming site arising from differences in nutrients enrichment and hydrological conditions at Lim Bay and Mali Ston Bay. Since further aggravation of environmental conditions driven by climate changes has been anticipated, the awareness of the policy makers and overall public on the necessity for preservation of coastal natural resources and vulnerable farming habitats will be crucial for sustainability and growth of eastern Adriatic bivalve aquaculture in the future.

Introduction

Co-culture systems are lately being explored as a potential replacement for monoculturing of various microorganisms in order to enhance the biomass yield, and increase synthesis of described and yet unidentified bioactive compounds. Utilization of microalgae-bacteria co-cultivation has been well documented in wastewater treatment and downstream processing such as biomass harvesting (Padri et al. 2022). In contrast, very little data is known considering the identification of novel metabolites produced only during co-cultivation. This area of research is of particular interest since most of these compounds have a great potential for medical and biotechnological applications. *Chlorella vulgaris* is a model microalgae intensively investigated due to its ability to produce various bioactive compounds beneficial for human health. Streptomycetes are well-known bacterial producers of antibiotics, anticancer and immunosuppressors. Abundantly present in the soil, they are adapted to various ecological niches. The capacity to produce diverse metabolites is a result of their interaction with various organisms. *Streptomyces rimosus* G7 is specifically known for its ability of oxytetracycline production.

Materials and methods

In this study, S.*rimosus* and C.*vulgaris* consortium was cultivated in Tryptic Soy Broth medium, under mixotrophic conditions. Regular monitoring of growth curves served to determine the most relevant bioprocess parameters under which these organisms co-existed. Extracted biomass, as well as metabolites excreted into the medium, were investigated in order to determine the significant effects on their metabolomic flux. Determination of biomass composition of both microorganisms has been performed using Nile Red (NR) method with fluorescence microscopy for lipid accumulation; spectrophotometry for pigments and the Lowry method for protein yield (Galić et al. 2021). Antimicrobial activity was tested using agar well diffusion method for detection of antibiotics (Petkovic et al. 2006).

Results

Co-culture systems resulted in an increased yield of neutral lipids which identification and quantification was furtherly studied using gas chromatography (GC). Interestingly, antimicrobial activity of S. *rimosus* as tested using the agar well diffusion method, and showed decreased antibiotic production in co-culture systems. Pigment content also decreased which can be linked to allelochemicals production, while protein composition remained the same.

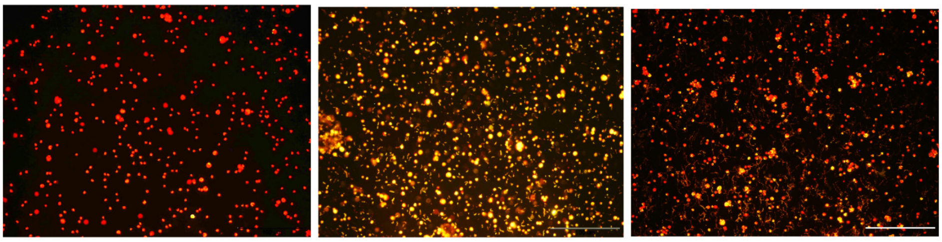

Figure 3. Fluorescence microscopy pictures of Nile Red stained lipids in *C. vulgaris* cells monoculture (a), *C. vulgaris* + *S. rimosus* (1:100 dilution) co-cultivation system (b) and *C. vulgaris* + *S. rimosus* (1:1000 dilution) co- cultivation system (c) on the last day of cultivation. Red stains represent polar lipids while yellow represent neutral lipid content.

Discussion

Optimization of bioprocess parameters of the co-culture system was successfully carried out in both Tryptic Soy Agar and Tryptic Soy Broth culture media. The total pigment content of chlorophyll a, b and pheophytin a, b was analysed regularly during co-cultivation. Moreover, the content of neutral lipids in the co-culture of *C. vulgaris* and *S. rimosus* (1:100 dilution) showed a significant increase in triolein production, which was 4,353 mg/mL on the last day of cultivation. These results indicate the potential of co-culture systems for biodiesel production and still need to be confirmed by gas chromatography (GC). Interestingly, the antimicrobial activity assay showed that oxytetracycline was not produced in both *C. vulgaris* + *S. rimosus* 1:100 and 1:1000 dilution systems. This specific metabolic shift in co-culture systems will also be further validated by high-performance liquid chromatography (HPLC). Metabolites synthesized and released in the culture medium, as well as those embedded in the biomass, will also be analysed by quadrupole time-of-flight (q-TOF) mass spectrometry to reveal the production of new compounds.

THE EFFECT OF LIGHT INTESIVITY ON THE GROWTH AND SURVIVAL OF COMMON DENTEX *Dentex dentex* (L., 1758)

B. Petani*[1], S. Čolak[2], R. Barić[2], A. Uhoda[1], M. Kolega[2], D. Mejdandžić[2], B. Mustać[1], I. Župan[1], L. Bavčević[1], T. Šarić[1]

Introduction

Common dentex (*D. dentex*) belongs to the family of the Sparidae. It is characterized by rapid growth, high meat quality and it is a very desirable candidate for aquaculture farming (Abellán, 2000). Common dentex rearing in the Republic of Croatia began in the 1990s but was not successfully implemented commercially. The assumption is that low survival rates were present due to inadequate food, breeding conditions and diseases (Efthimiou et al., 1994). One of the most frequent cause of common dentex's disease and mortality is stress sensitivity (Efthimiou et al., 1994). Due to lack of the data and insufficiently known facts about commercial common dentex breeding, but also the great breeding potential of this species and the economic viability of the product, we focused on studying the impact of abiotic factors that could be useful in the cultivation of this species (Abellán, 2000). The obtained results can expand the knowledge about the effects of abiotic environmental factors on the growth and survival of this species. Furthermore, this „*in situ*" experiment investigated how light intensity influence growth and survival of common dentex.

Materials and methods

The research was conducted in the middle Adriatic at Mala Lamjana fish farm, Bisage breeding site on the south side of the island of Ugljan, Croatia (Figure 1). D.dentex with initial average weight were distributed in four floating cages (9 x 5 x 5 m), 4 000 fish were placed in each cage.

Figure 1. Study area in the middle Adriatic at Mala Lamjana fish farm, Bisage breeding site on the south side of the island of Ugljan, Croatia.

(Continued on next page)

Experimental design included two groups of common dentex where the first group was shaded (K1 and K2) and the second group was exposed to natural light (K3 nad K4). Light intensity was measured with digital lux meter once per week, while temperature and oxygen were measured on a daily basis. Biometry samples were taken on a monthly basis and included total length, weight and condition index of the fish. In addition, mortality was controlled three times per week.

Results and Discussion

The experiment was conducted from January to June 2020. In the period of our research, sea temperatures oscillated from 13 ° C in February to 19 ° C in June when the sea temperature was the highest. Fish reared in cages K1, K2 were under the shade and cages K3, K4 were exposed to sunlight. The month of June showed the greatest improvement in the obtained average weight of all cages, K1 was the smallest, K2 and K3 were in a small difference from each other while K4 got the most on weight. The results we obtained do not confirm that light affects the growth of individuals because there is no statistically significant difference in the total growth of fish farmed under light and shade. Moreover, there is no negative impact of light founded on the fish growth and survival of common dentex exposed to light compared to the group of common dentex that were in the shade. However, this experimental results can be useful for better future selection of aquaculture technology for this new species.

ASSESSMENT OF WELL-BEING OF FARMED EUROPEAN SEA BASS AND GILTHEAD SEA BREAM THROUGH A SMART OPERATIONAL TOOL

T. Petochi[1*], A. Feraldi[1], F. Cardia[1], F. Padrós[2], G. Marino[1]

[1] ISPRA Italian Institute for Environmental Protection and Research, Rome, Italy
[2] Fish Diseases Diagnostic Service, Universitat Autònoma de Barcelona, Spain
E-mail: tommaso.petochi@isprambiente.it

Introduction

Animal welfare is a key issue for the sustainable and competitive development of food production systems, including aquaculture (Franks et al., 2021). Methodologies to score the welfare of farmed fish are under investigation to meet the raising interest for animal-friendly husbandry practices (Saraiva et al., 2019; Tschirren et al., 2021).

This work reports an application of the welfare scoring system developed in the H2020 PerformFISH project (Petochi et al., 2021), to assess the well-being of sea bass and sea bream farmed in EU using a dataset provided anonymously by aquaculture companies.

Materials and Methods

Welfare Assessment: on 191 batches accounting for 66 million of stocked fish (31 M sea bass and 35 M sea bream) farmed in 18 net pens farms; at the end of on-growing cycle (fish size 800g).

Operational Welfare Indicators (OWIs): animal-based and indirect OWIs, including mortalities (total, by diseases, at 3 and 10 days after first stocking), fish vaccination by diseases, antiparasitic and antibiotic treatments, feed intake, stocking density at harvest and discharged fish at slaughter.

Welfare Index: composite indicators approach (Adjusted Mazziotta–Pareto Index, AMPI), which consists in the aggregation of a certain number of elementary indicators representing different issues of the same multi-dimensional phenomenon (Mazziotta and Pareto, 2018).

Welfare Tool: PerformFISH Bass&Bream Welfare Scoring Tool (BBW-Tool)

Results

Welfare Index, as well as normalized OWIs values, fell correctly within the expected AMPI range of 70–130. Overall results showed a better welfare score in sea bass batches compare to sea bream (Fig. 1), with average W-Index of 101.3 (95% Confidence Interval: 100.1–102.5) and 92.7 (95% Confidence Interval: 91.6–93.8) respectively.

The multiple linear regression model highlights the significant effect of all the selected sea bass and sea bream OWIs on the W-Index (Figure 2) and their usefulness for assessing welfare during on-growing cycle. The percentage of vaccinated fish against *Photobacterium damselae* and *Vibrio anguillarum*, feed intake and mortality rate within the first 3 days after transport-stocking showed the higher effect on the W-Index. Vaccination is confirmed as the most influent OWI on the W-Index also when the analysis is performed separately for sea bass and sea bream.

Discussion and conclusion

The well-being of sea bass and sea bream can be measured at batch and farm level using the BBW-Tool, which represents a promising noninvasive methodology for benchmarking and improving standards of production (COM(2021) 236 final). Among composite multidimensional indicators, the AMPI resulted a good statistical tool for the holistic assessment of the well-being of farmed fish. The BBW-Tool is being implemented through smart solutions for data collection, analysis and visualization.

She has participated in European innovation projects in the Blue Economy field and to US projects funded by the US Department of Energy.

MONITORING OF BENTHIC INDICATORS OF ORGANIC ENRICHMENT UNDER AQUACULTURE SITES OVER MIXED BOTTOM SUBSTRATES DURING A FISH PRODUCTION CYCLE

C. Pezzola[1,3,*], S. Svensson[1], K.M. Dunlop[2]

[1] Institute of Marine Research, 5817 Bergen, Norway
[2] Institute of Marine Research, 9007 Tromsø, Norway
[3] *Present address*: University of Groningen, 9701 Groningen, The Netherlands
E-mail: caterinapezzola@hotmail.com

Norway's sheltered coastal and fjord systems provide an ideal environment for marine fin-fish farming, a growing industry worldwide. However, fin-fish aquaculture is associated with several environmental issues, including the deposition of organic waste (uneaten feed and faeces) to the seafloor and the consequent impact on benthic communities. In Norway, a system of monitoring investigations is already in use for the assessment of benthic organic loading and community responses for soft-sediment environments. However, not uncommonly on the Norwegian coast, grab sampling is made difficult by the presence of mixed- and hard- bottom substrates. The aim of this study was to detect the presence of benthic visual indicators of organic enrichment (organic pellets, sulphur oxidizing bacteria-mats, opportunistic polychaete complexes (OPC), the lugworm *Arenicola marina*, polychaete tube aggregations, epifauna) through image analysis, and to determine the environmental factors affecting their distribution. Changes in the epifaunal community structure through time, and over different locations and habitats (soft-, mixed-, hard- bottom substrate), were also investigated. Images were collected beneath 3 fish cages (and a reference site) at a fin-fish farm site on the Western coast of Norway. A method was developed to characterize images and provide quantitative information on the ecological state under the farm throughout a fish production cycle. Using the software Biigle 2.0, pictures were examined for surface area coverage of organic pellets and abundance of bacterial mats, OPC, *A. marina*, polychaete tube aggregations and epifauna. Results showed that the presence of organic material and bacterial mats was not indicative of a particular level of organic enrichment, as they were present throughout the whole fish production cycle. Benthic organisms such as the lugworm *A. marina* and aggregations of polychaete tubes were indicators of relatively low levels of organic enrichment and early stages of the production cycle. On the other hand, opportunistic polychaete complexes were indicators of relatively high levels of organic enrichment from the farm. Epifaunal community structure was considerably affected by the deposition of organic waste, as well by the sediment type, and taxa richness was considerably higher at reference sites (100 meters from farm cages). These results provide knowledge on the temporal impact of organic enrichment on benthic communities beneath fish farms over mixed- bottom substrates and highlight how the use of image characterization can improve the monitoring of benthic communities. The outcome of this study can contribute to the development of an environmental index to assess the ecological state around aquaculture farms placed over mixed- and hard- bottom areas.

ASTRAL POOL OF TECHNOLOGIES: DIGITAL TWINS TO SUPPORT MULTI TROPHIC AQUACULTURE WITHIN THE ATLANTIC AREA

M. Pias*, G. Orazi, M. Paris, P. Drews, C. Dupont, M. Smith, K. Michalek, L. Lain , J. Martinez, I. Khelifi, S. Bamber, B. Henriksen, A. Abid, A. Tré-Hardy, A. Garcia, X. Rodriguez, B. Guterres and E. Ravagnan

E-mail: mpias@furg.br

Introduction

Aquaculture is a fast-growing economic activity to boost sources of animal proteins worldwide, leading to significant industry investment[1]. The project All Atlantic Ocean Sustainable, Profitable and Resilient Aquaculture (ASTRAL) focuses on integrated multi-trophic aquaculture (IMTA) farming to support and promote sustainable aquaculture production across the Atlantic area. IMTA applications are exposed to many threats from external factors, such as climate change, increased risk of diseases[2], parasites and Harmful Algae Blooms (HABs)[3]. These activities also experience production and infrastructure risks from extreme weather events, changes in critical water physicochemical parameters (e.g. nutrients, temperature and dissolved oxygen). Besides, microplastics – an emerging pollutant – need to be carefully monitored because of impacts such as ingestion or filtration by aquatic fauna[4].

Supporting sustainable IMTA activities within the Atlantic area calls for a complete technological suite to best address end-user needs. The ASTRAL pool of technologies aims at supporting these activities through a set of innovative components, including an Artificial Intelligence (AI) data analytics platform, emerging sensors, cost-effective Internet of Things (IoT) kits, off-the-shelf cameras and hardware solutions. All technologies embed some form of intelligence with advanced deep neural networks trained and validated in relevant environment spanning across Brazil, South Africa, Scotland, Ireland and Argentina. The present abstract showcases such a pool of technologies and its associated benefits to IMTA applications.

Aquaculture Digital Twins

The ASTRAL project proposes developing a set of technologies to support IMTA applications. It aims to pilot emerging sensor technologies coupled with IoT/AI solutions to help and improve aquaculture activities while monitoring the surrounding environment. The proposed set of **Aquaculture Digital Twins** enables virtual replicas of the farming environment, species and facilities.

Cost-effective IoT Kits facilitate real-time aquaculture monitoring through multi-sensor twins for crucial water parameters (e.g., dissolved oxygen, temperature, chlorophyll-A, turbidity). The deployment at the aquaculture facilities extensively uses functional capabilities of long-range communication, optimised self-powering, improved software and sensor calibration models. Another type of monitoring twin leverages MEMS-based UV-VIS fluorometer-spectrometer to deliver complementary monitoring information ranging from nutrients to and physico-chemical parameters (e.g., ammonium, nitrate and dissolved oxygen).

AI Vision digital twins can benefit aquaculture farmers with automation to increase sampling capabilities and improve accuracy in visual-based inspection tasks. Work is underway to design and validate vision twins using cost-effective off-the-shelf cameras integrated into recent embedded AI GPUs for edge perception and processing in the aquaculture environment. The AI vision systems support macro-level animal biomass estimation on which AI models are trained specifically for multi-species fine-grained assessment of shrimps and urchins temporal profile growth. At a micro-level, the proposed AI vision twins provide a bench-top solution for HABs and microplastic monitoring, further customised with AI models trained for a diverse set of IMTA conditions (e.g. low to high water turbidity).

(Continued on next page)

Considering that the IMTA is exposed to several risks, a holistic water monitoring solution is key technology to ensure optimised farm operation. Biosensor technologies based on bivalve behaviour are sensitive solutions for many of the events of concern (e.g HABs, toxic compounds) and physicochemical monitoring parameters. ASTRAL technology employs bivalve behaviour data coupled with AI models as “proxies” for water quality assessment. The biosensing twin uses either vision or MEMS-based inertial sensors as the underlying technology for AI model training and real-time inference.

The AI data analytics platform (AIDAP) aims at integrating all aquaculture digital twins to operate in real-time supporting end-user decision making. The AIDAP is an analytics off-premise (e.g., cloud-based) architecture that hosts multi-modal time-series sensor data, AI models and visualisation dashboards for the end-users. The platform enables anticipation of scenarios and events using predictive modelling of physicochemical parameters and biological water quality indicators built upon the latest developments in data science. The platform connects all the aquaculture digital twins via web-based API interfaces. Sensor data is fed into this platform to develop and improve data modelling algorithms.

Conclusions

The ASTRAL pool of technologies provides a complete digital twin solution for IMTA applications. Technology validation is currently underway to improve the technology maturity level in the relevant environment (IMTA activities in Brazil, Scotland, Ireland, South Africa and Argentina).

CLIMATE CHANGE AND AQUACULTURE

Nadia Pinardi

Department of Physics and Astronomy, University of Bologna

An overview of the **short term scenarios** of how climate changes will affect temperature, sea level, severe weather, flooding, erosion, acidification for the Med and Adriatic. Followed by specific aquaculture climate impacts and challenges - with case studies of iconic fish and shellfish species.

Nadia PINARDI holds a Ph.D. in Applied Physics from Harvard University, and she is full professor of Oceanography at Bologna University. Her interests range from ocean numerical modelling and predictions to data assimilation, numerical modelling of the marine physical-biological interactions and pollutants at sea.

Her major achievement is the conceptual design and practical implementation of ocean forecasting systems across the world ocean: she started with the contribution to the very first real time ocean forecast in the California Current system to the complete development of monitoring, modelling and data assimilation components for the Mediterranean, Marmara and Black Sea.

From 2012 to 2019 she was co-president of the Joint Committee for Oceanography and Marine Meteorology (JCOMM) of UNESCO-IOC and WMO and she is, since 2019, elected vice-president of the Commission for Observation, Infrastructure and Information Systems (Infrastructure Commission) of WMO. She is chair of the UN Decade for Ocean Science Program “CoastPredict”. Nadia Pinardi was awarded in 2007 the European Geophysical Union (EGU) Fridtjof Nansen Medal for Oceanography, in June 2008 the Roger Revelle Unesco Medal, in 2015 she received the Italian Republic Honors “Commendatore Ordine al merito della Repubblica italiana” and in 2017 the Laurea Honoris Causa for Operational Oceanography at the University of Liege, Belgium.

Mariana Mata Lara - Geonardo Environmental Technologies
Mariana is a Senior Project Manager for Geonardo Environmental Technologies focusing on EU funded projects in the areas of Blue Economy and Science Education. She was the coordinator of AQUA-LIT project, focusing on developing with the aquaculture sector a toolbox to bring together existing, upcoming and implemented tools, case studies, best practices, policy recommendations and action plans for addressing the 3 main components of marine littering: prevention & reduction, monitoring & quantification, and removal & recycling. Currently, she is helping develop the Knowledge Exchange Platform for the COASTAL project, focused on bringing evidence-based solutions and policy recommendations for creating synergies and business opportunities between the coastal and rural areas in Europe.

PULSED ELECTRIC FIELDS (PEF) AND ACCELERATED SOLVENT EXTRACTION (ASE) FOR THE VALORIZATION OF SHRIMP BY-PRODUCTS: RECOVERY OF ASTAXANTHIN AND ANTIOXIDANT EXTRACTS

Introduction

An important category of by-products from seafood processing includes crustacean ones. Approximately 6-8 million tons of crustacean waste is produced worldwide every year (FAO, 2014) Shrimp and prawns are one of the most important internationally traded seafood products, and one of the few that can be considered a "commodity", with a value of US$10 billion (or 16% of world fishery exports) (Gillett, 2008). Shrimp by-products represent important natural sources of carotenoid, among which astaxanthin (ASX) is the major one. Recently, pulsed electric field (PEF) treatment showed to be a promising method for the isolation and extraction of several components from seafood by-products such as calcium, chondroitin sulphate, collagen, chitosan, and protein (Bruno et al., 2019). Accelerated solvent extraction (ASE) is considered a green technique to recover bioactive and nutritional compounds in plants and food matrices (Sun et al., 2012). The main objective of the present study was to apply PEF and ASE using two different organic solvents (dimethyl sulfoxide, DMSO and ethanol, EtOH) to recovery ASX from shrimp by-products, and evaluate the effects of these technologies used independently or in combination on the ASX content and antioxidant activities of the extracts.

Materials and methods

In this study, fresh samples of red shrimp (*Aristeus antennatus*) and camarote shrimp (*Melicertus kerathurus*) were obtained from a local market in Valencia, Spain. Dimethyl sulfoxide (100% DMSO) or ethanol absolute (EtOH) were used as organic solvents. The combined and independent effects of the emerging technologies PEF and ASE using different solvents (EtOH and DMSO) on the extraction of astaxanthin were evaluated for each shrimp species. ASE (50 °C, 15 min, 103.4 bar) and PEF (3 kV/cm, 100 kJ/kg, 74 pulses) were used as extraction technologies. The antioxidant capacity of the extracts was evaluated by and Trolox equivalent antioxidant capacity (TEAC) and oxygen radical absorbance capacity (ORAC) assays. Experimental data were subjected to one-way analysis of variance (ANOVA) to determine the significant differences among samples. Tukey HSD (Honestly Significant Difference) multiple range test, at a significance level of $p < 0.05$, was applied.

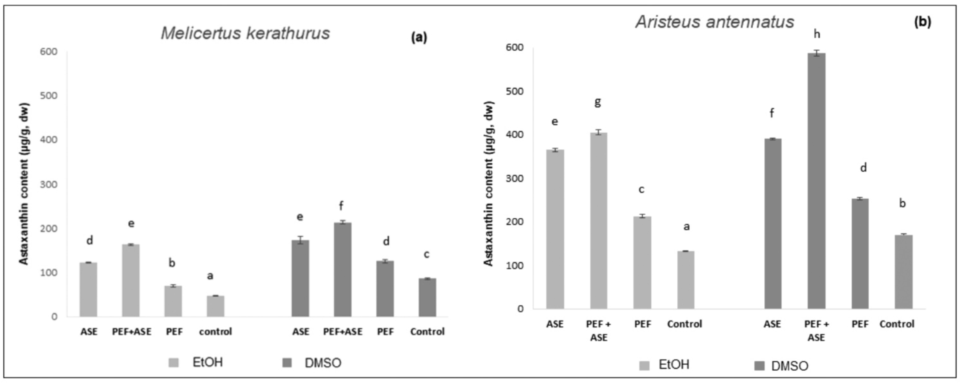

Figure 1: Astaxanthin content in *M. kerathurus* (a) and *A. antennatus* (b) by-products. Different letters above the bars indicate statistically significant differences between treatment averages ($P < 0.05$).

(Continued on next page)

Results

Preliminary results showed that ASE and PEF increased the astaxanthin content in the extracts for both shrimp species and solvent used, and the higher recovery was obtained using their combination (Fig 1).

Both technologies seem to be an effective tool to recover astaxanthin and antioxidant extracts from shrimp by-products. However these promising results should be confirmed by extending the study to other valuable compounds from crustacean by-products.

Introduction

The demand for seafood has increased greatly due to their attractive nutritional properties but its rapid perishability remains the greatest challenge to its preservation. Therefore, an increasing number of emerging strategies are being considered to complement or even replace traditional preservation methods to ensure food safety and extend shelf-life (Tsironi, et al. 2020). Smoked salmon is an important added value 'ready-to-eat' food. It is estimated that about 40-50% of farmed Atlantic salmon reaches the final consumer as a cold-smoked product (Lakshmanan et al. 2003). The smoke contains several phenolic compounds that impart flavor to the product, the absorption of which depends on the temperature and smoking time (Arvanitoyannis and Kotsanopoulos 2012). The purpose of the present study was to evaluate an innovative cryogenic smoking technology to obtain ready-to-eat smoked salmon.

Materials and methods

Salmon (*Salmo salar*) used in the present study came from the Salmar farm (Kverva, Norway) where they were reared for approximately 12 months in floating cages in the open sea. After catching, fish were placed inside containers with polystyrene, stored in super-chilling and sent by plane to Italy. After 48 hours, they were filleted, vacuum-packed and frozen at -40°C and maintained at this temperature until salting and smoking procedures were performed. Thawed fillets were salted with a mixture consisting of 70% NaCl and 30% sucrose in a proportion equal to the weight of the fillet, vacuum-packed, and stored in cold storage at 4 ± 2°C for 24 hours. Dry-salted Atlantic salmon fillets were smoked using an innovative nitrogen-based prototype working at different temperatures (5, 20 and 45 °C) for 2 hours. Textural and colorimetric properties, NaCl content, water activity, water content, pH and polycyclic aromatic hydrocarbon (PAH) levels were determined. In addition, ^{1}H-NMR was used to monitor freshness-related parameters (e.g., K-index, trimethylamine content, biogenic amine content).

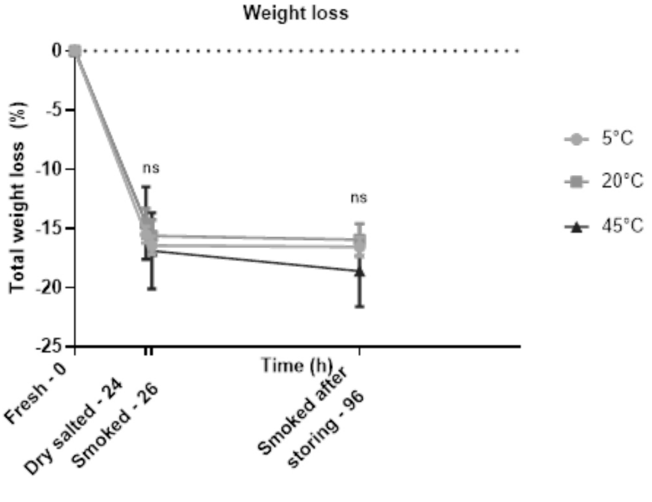

Fig. 1 - Kinetics of percentage weight loss of salmon fillets, fresh (0h), dry salted (after 24h), smoked at 5, 20 and 45°C for 2h and after 96h of vacuum-packed refrigerated storage.

(Continued on next page)

Results

For most of the parameters evaluated, the group of samples smoked at 45°C differed significantly from those obtained at 5 and 20°C. In particular, they were characterized by a greater weight and water loss, higher salt content, higher pH, lower shear force, increased lipid oxidation index, and a greater color change during the process with an increase in the red component. Between the samples smoked at 5 (cryo-smoking) and 20°C (cold-smoking), the only slight difference found was less weight loss of the samples during the process at the lower temperature (Figure 1).

An increase in TBARS values with the temperature rising has been evidenced, although the differences between the groups treated at 5 and 20°C were not significant.

The results allowed samples to be discriminated based on smoking temperature, and the innovative smoking process showed great potential for the preparation of high-quality smoked salmon product with high nutritional characteristics. The metabolomic approach provided a better understanding of the effect of smoking temperature on the quality of the final product. From a technological point of view, cryo-smoking is therefore promising for industrial application considering the lower weight loss of the product during the process. Further studies are needed concerning the shelf-life and microbiological quality of the final product. Moreover, it is advisable to investigate the organoleptic properties by sensory analysis in order to have a complete view of how the innovative treatment affects the quality of the finished product.

Introduction:

Zebrafish is a model animal widely used in many areas of scientific research. However, lack of standard feeding protocols has led to results difficult to reproduce when used in different facilities. Usually, in the laboratory, zebrafish are fed with a mixture of inert and live feed, such as brine shrimp or rotifers. As rotifers have a poor nutritional profile, their enrichment can be carried out with protein- and lipid-rich microalgae containing polyunsaturated fatty acids such as DHA or EPA. The values of these essential fatty acids can be further enhanced when microalgae are subjected to abiotic stress, such as temperature, salinity, and depletion of nitrogen and/or phosphorus.

This work aims to produce microalgae with an enhanced biochemical profile to enrich rotifers and meet the nutritional needs of zebrafish.

Methodology

In this study, *Tetraselmis verrucosa f. rubens* was cultured with Nutribloom Plus® in 1-L photobioreactors using two concentrations of nitrates, 2 and 10 mM. Rotifers were enriched daily with either *T. verrucosa* or Green Formula (GF, *Nannochloropsis,* Necton), the latter used as control. Zebrafish larvae were fed exclusively with rotifers enriched with microalgae or with control diet, Zebrafeed (Sparos). At 15 dpf, length, weight and condition factor were evaluated. At 30 dpf, survival, length, weight and condition factor, histology, skeletal deformations and biochemical profile of microalgae, rotifers and larvae were analyzed.

Results:

When analyzing the biochemical profile, there were significant differences in the lipid and protein content of the cells grown in the 2- or 10-mM nitrate growth media, with the latter being the best treatment for both parameters. Larvae fed exclusively with rotifers displayed a survival rate of over 90%, while larvae fed with inert food had a survival rate of only 56% (Figure 1). The incidence of skeletal deformities in the treatments of rotifers enriched with both GF and *T. verrucosa* grown in the 10 mM nitrate growth medium was 46%. Conversely, larvae fed with either *T. verrucosa* at 2 mM nitrate or ZF presented a higher incidence of skeletal deformities, 66% and 75%, respectively.

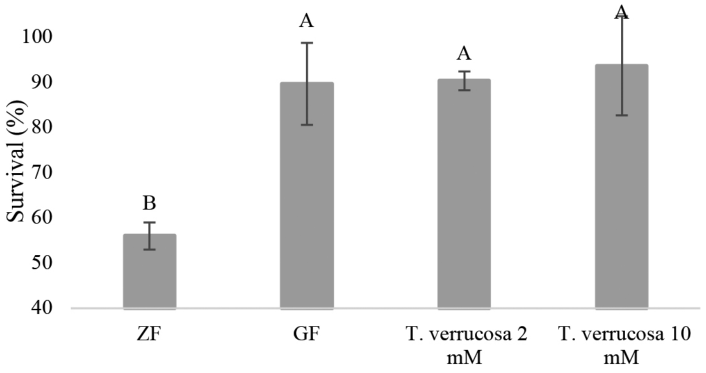

Figure 1 - Survival of zebrafish 30 dpf fed with inert food (**ZF**) and rotifers enriched with: Green Formula (**GF**), *T. verrucosa* cultivated with 2 mM nitrates (***T. verrucosa* 2 mM**), and *T. verrucosa* cultivated with 10 mM nitrates (***T. verrucosa* 10 mM**). Statistics: One-way ANOVA ($p \leq 0.05$). Different letters mean significant differences between samples.

(Continued on next page)

Discussion

The microalga *T. verrucosa* is a microalga rich in lipids (Cardoso et al, 2020), essential amino acids (Brown, 1991) and vitamins A, B and C (Fabregas and Herrero, 1990), all important for the development of zebrafish. In comparison, *Nannochloropsis* (GF) is a species rich in essential amino acids and polyunsaturated fatty acids, EPA in particular, which are essential for normal larval development (Liu et al, 2017; Chua and Schenk, 2017). This appropriate nutritional profile might have led to the observed decrease in skeletal deformation upon enrichment of rotifers fed with either GF or *T. verrucosa* at 10 mM, suggesting that high quality live feed is indeed beneficial for proper zebrafish growth and development (Kobayashi et al, 2008; Castaldi, 2019). Zebrafish have shown some growth delay when fed exclusively with microdiets, when compared to live feed. Moreover, inert feed has led to lower water quality by accumulation of debris, resulting in a significant decrease in survival (Harper and Lawrence, 2011).

In conclusion, GF-enriched rotifers are suitable for enhancing larval growth. Moreover, rotifers enriched with GF or *T. verrucosa* grown at 10 mM nitrates were able to decrease skeletal deformation in zebrafish larvae, while increasing dramatically larval survival.

Introduction

FLOCponics is an offshoot of conventional aquaponics in which the filter-based recirculating aquaculture system (RAS) is replaced by a system based on biofloc technology (BFT) (Pinho et al. 2022). Such replacement is usually justified by the potential benefits of BFT for tilapia juveniles culture and nutrition. Enabling the use of less protein in the fish diets is one of the great benefits of BFT (Emerenciano et al. 2021) as it favours the aquaculture sector in both economic and environmental terms (Bossier and Ekasari 2017, Emerenciano et al. 2021). The use of low dietary protein may result in (i) lower feed costs since protein is the most expensive nutrient in fish diets; (ii) lower use of fish meal and, on a large scale, minimizing the overexploitation of natural fish stocks; and (iii) decreased input of N and, depending on the production system, less discharge of N into the surrounding environment. This last consequence of reducing the amount of protein may also influence plant production in an integrated FLOCponics system. The effect of using less protein in the fish diet on plant growth must still be understood. Also, whether the nutritional benefit of BFT for tilapia juveniles production also occurs in FLOCponics has not yet been reported. Thus, this study was designed to investigate and evaluate the production of lettuce and tilapia juveniles in an on-demand coupled FLOCponics system using different levels of crude protein (CP) in the fish diets.

Material & methods

The zootechnical performance of tilapia juveniles and lettuce growth in on-demand coupled FLOCponics (FP) systems were evaluated, using different diets containing 24, 28, and 32% CP. Fish production in FP systems was compared to those reared in conventional on-demand coupled aquaponics systems and in stand-alone biofloc-based systems, both fed with 32% CP diet. The experimental period of tilapia juvenile production lasted 56 days. Lettuce production in two cycles was also performed in FP systems with different CP levels and their growth was compared to those in conventional aquaponics and hydroponics systems, as control treatments. In Cycle 1, the seedling phase was evaluated in a 14-day trial. In Cycle 2, the final production phase was performed for 21 days until harvest.

Results & Discussion

As expected, the results for tilapia growth demonstrated that the well-known benefits of BFT for juvenile nutrition are also found in the FLOCponics systems. The results showed that fish in FP-32 and BFT-32 grew similarly and 22.7% more than those in conventional aquaponics also fed with 32% CP. Additionally, tilapia reared in on-demand coupled FP and fed with 24 and 28% CP grew similarly to those in conventional aquaponics fed with 32% CP diet. These results suggest that even in an integrated system the *in situ* food present in biofloc-based systems is used by tilapia juveniles to complement their dietary protein needs. (Table 1). With respect to the question of whether DFP might enable lettuce production in comparable yields to conventional aquaponics and hydroponics, this study found no differences amongst the treatments for the growth parameters in the seedling (Cycle 1) and final production phase (Cycle 2). Interestingly, to achieve these similar yields, less commercial fertilizer was required in the DFP-32 compared to the other treatments.

Conclusion

The results obtained in this study indicate that using less crude protein in fish diets to produce lettuce and tilapia juveniles is technically possible and feasible in an on-demand coupled FLOCponics system.

Introduction

Sulphated polysaccharides (SP) are among the most abundant natural compounds produced by living organisms and are known for their antioxidant activity, immunomodulatory and anti-inflammatory properties[1]. They are highly soluble in water and can be found among Extracellular Polymeric Substances (EPS) present in high amounts in intertidal areas, where the marine organisms that excrete them can be found[2]. SP represent most of the organic components present in sea salt polymeric material[3] and Nunes *et al.*[4] have shown that salt pan brine water may be a suitable source of SP with immunostimulant properties that could have applications for fish health in aquaculture or research settings[4]. Zebrafish (*Danio rerio*) is an experimental animal model widely used in ecotoxicology but also to study processes related to fish farming[5,6]. In this context we studied the bioactivity of SP purified from brine water in zebrafish larvae, focusing on the effects over mineralization of the opercular bone. The immunogenic effect of SP was assessed using the Atlantic salmon (*Salmo salar*) head-kidney derived cell line SHK-1 through gene expression analysis.

Materials and Methods

Polymeric material was purified from salt pan brine water through four different methods, lyophilized and kindly provided by Nunes *et al.*[4] (University of Aveiro; Portugal). The amount of SP in each extracts – named SP1, SP2, SP3 and SP4 – were as follows: SP1, 311 mg/g; SP2, 293 mg/g; SP3, 313 mg/g; SP4, 324 mg/g.

Zebrafish were kept from egg fertilization to 3 days post-fertilization (dpf) larvae in 1-L breeding tanks (Tecniplast, Italy) with system water supplemented with 0.05% of methylene blue. Larvae were exposed in 6-well plates from 3 to 6 dpf to the different SP extracts at 0.0001, 0.0033 and 0.01% (w/v) and to negative controls made with artificial salt water (AS) and system water (NE – no exposure). At 6 dpf, larvae were stained with alizarin red S (0.025%) and imaged under a stereomicroscope Zeiss Axio Zoom V.16 equipped with a green fluorescence filter. Operculum area was determined through morphometric analysis using ImageJ macros[7,8].

SHK-1 cells[9] were cultured at 20ºC using Leibovitz's L-15 medium supplemented with 15% fetal bovine serum, 1% penicillin-streptomycin, 1% L-glutamine and 0.2% fungizone. Cells were seeded into a 6-well plate at a density of 5×10^5cells/well. After 48 h of incubation, cells were exposed for 4 h to 0.005% of SP extracts, 1 μg/mL of LPS from *E. coli* (positive control) or water (negative control), then RNA was prepared using NZYol. Expression of genes involved in the immune response (*tnfα, il6, il8*) and oxidative stress response (*cox2, sod*) were determined by qPCR from cell RNA using the ΔΔCt method.

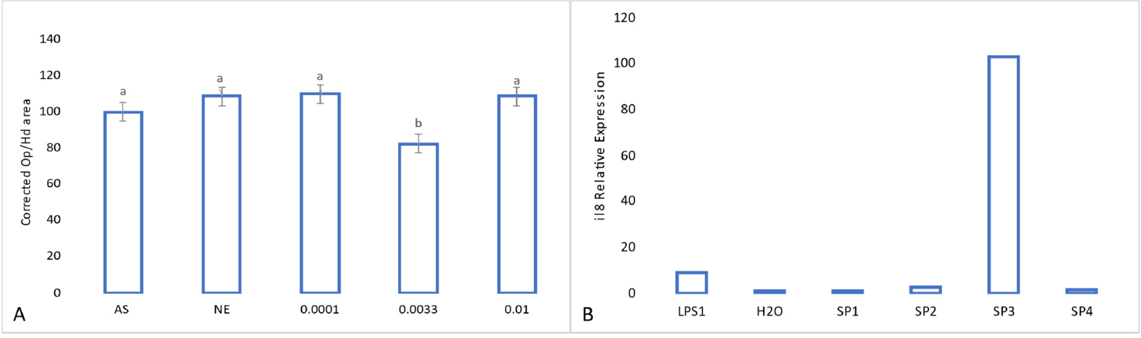

Figure 1. *A, Effects of SP3 treatment on corrected operculum area (Operculum/Head) in zebrafish larvae for different conditions: AS (n=45), NE (n=45), 0.0001 (n=43), 0.0033 (n=30), 0.01 (n=45). Different letters indicate statistical differences (one-way ANOVA, Tukey´s HSD, p < 0.05). B, Relative expression of il8 in SHK-1 cells exposed to SP3 (n=1).*

(Continued on next page)

Results

A preliminary toxicity test was performed with a broader range of concentrations on zebrafish larvae to establish the non-lethal concentrations. Operculum mineralization was not significantly altered in larvae exposed to SP extracts when compared to the negative control (AS). The highest values were observed for the SP3 treatment at 0.0001% and 0.01% (Figure 1A), while extract at 0.0033% resulted in a significant decrease in mineralization (possibly due to a smaller n). This suggests the existence of mineralogenic compounds in SP3. The exposure of SHK-1 cells to SP also identified SP3 as the most bioactive extract. It induced an overexpression of *tnfα, il6, il8 and cox2*, while expression of *sod* was not affected. This suggests a pro-inflammatory activity of SP3 extract, not observed in other extracts. The effects of SP3 on gene expression are particularly noticeable for the *il8* gene with a 100 times overexpression when compared to the negative control (H_2O; Figure 1B).

Discussion

SP3 extract slightly increased operculum mineralization, although not significantly, possibly indicating a pro-mineralogenic effect, as already reported for brown algae fucoidan (SP type) extract, which could accelerate the formation of calcium accumulation in murine mesenchymal cells[10], and triggers osteogenic differentiation in 7F2 murine pre-osteoblast cells and bone mineralization *in vivo* in mice[11]. Further studies should aim at testing higher concentrations and/or a longer exposure time in zebrafish. Our *in vitro* data indicate that SP3 may trigger a strong immunogenic effect, comparable to LPS effect. In that regard, we suggest that SP3 may have a similar effect to LPS that has been shown to stimulate salmonid lymphocytes proliferation, respiratory burst and phagocytic activity of macrophages in *in vivo* studies[12,13]. In addition, studies performed with SHK-1 cells showed an activation of innate immune markers upon LPS stimulation[14]. From the four fractions tested, SP3 exhibited the greater effect on gene expression levels showing pro-inflammatory effect. Further trials are being conducted with higher SP concentrations to understand if there is a dose related response. In addition, a concomitant exposure of LPS and SP molecules will be done to determine if SP could modulate LPS inflammatory effect.

Introduction

In recent years, functional nutrition and nutritional biotechnologies have become fundamental to modern aquaculture practices. The inclusion of probiotics in fish diets has been shown to positively modulate the fish intestinal microbiota and immune status, reducing the incidence of pathologies and related medicinal treatments, and increasing somatic growth. Also, probiotics interventions can modulate the communication between the digestive and the nervous systems; i.e. microbiota-gut-brain axis (Cryan, 2011).

The aim of this study was to determine the effects of an in-feed probiotic mix of *Lactobacillus helveticus* and *Bifidobacterium longum*, with reported psychotropic-like properties, on behavioural and molecular stress biomarkers in a model fish species (zebrafish *Danio rerio*). In addition, given the existence of efficiency rhythms for drugs and medicines (Paschos et al., 2010), the influence of the time of administration was also studied.

Methodology

Wild-type adult zebrafish were divided into three experimental dietary treatments: Control (CTRL=standard diet provided both in the morning and in the evening); Probiotics-Morning (PB-M= standard diet supplemented with the probiotic mix in the morning and standard diet in the evening); Probiotics-Evening (PB-E=standard diet in the morning and the probiotics-supplemented diet in the evening) (n=30/dietary group). After 4 weeks, half of the fish from each dietary group were submitted to a stress challenge (air exposure for 1 min). Then, fish were allowed to recover for 30 min and both Stressed (S) and Non-Stressed (NS) groups were euthanized and brain samples collected to measure the expression of key genes involved in fish stress response and the GABAergic system. In addition, to evaluate the effect of the probiotic mix on zebrafish behavioural response, zebrafish from the same stock and subjected to the same dietary treatments (CTRL; PB-M; PB-E) were used to assess fish anxiety-like behaviours and locomotor activity with a novel tank-behavioural test, at two different times of the day (morning and evening; n=9/dietary group/time point), using Anymaze ® software. In both experiments, statistical differences were analyzed by two-way ANOVA (ANOVA II).

Results

In brain, a significant effect of the dietary treatment was found in the expression of genes coding for the glucocorticoid receptor (*gr*) and corticotropin releasing hormone binding protein (*crhbp*). For both genes, the expression levels were significantly lower in the PB-E group than in the CTRL, with the fish fed the probiotic mix in the morning (PB-M) showing intermediate levels (Fig. 1A and 1B). Regarding genes involved in the GABAergic system, a significant effect of diet was also observed for *gad2* (coding for the enzyme responsible for GABA synthesis) and *slc6a1a* (GABA transporter), which showed lower expression levels in the PB-M group in comparison to the CTRL. Besides, exposure to the stress challenge significantly increased the expression of *bdnf* (a neurotrophin which mediates behavioural responses in fish) compared to the Non-stressed group. As for the novel tank test results, significant effects of the dietary treatment were found on two anxiety-like behaviours analyzed: *Latency to top* and *Time in bottom.* Fish from both probiotic groups (PB-M and PB-E) took less time to enter for the first time at the top zone of the tank than the CTRL fish (Fig. 1C), whereas PB-M fish group spent less time at the bottom of the tank in comparison to the CTRL (Fig. 1D). In addition, some behavioural parameters were significantly affected by the time of the day in which the test was performed. Thus, *Mean speed* and *Travelled distance* were higher when the fish were exposed to the novel tank in the evening, whereas *Path efficiency* and *Latency to freezing* were lower in the evening than during the morning test.

(Continued on next page)

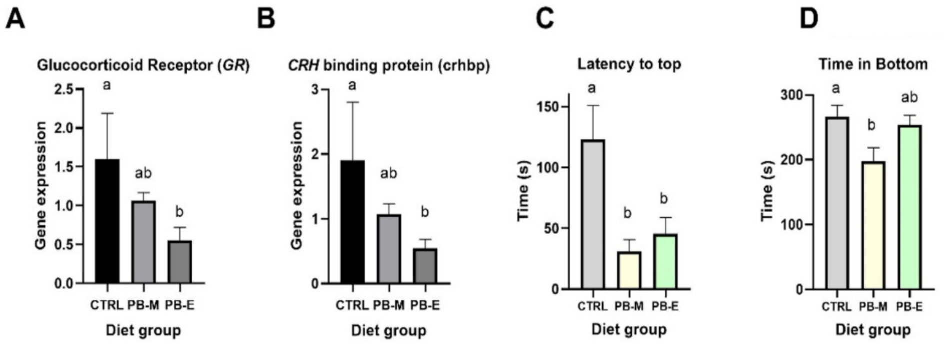

Figure 1. Effects of dietary treatments on zebrafish gene expression (A, B) and behaviour (C-D).

Discussion and conclusion

Feeding zebrafish with the probiotic-supplemented diet elicited significant effects at both behavioural and brain (gene expression) levels. Lower brain *gr* and *crhbp* expression observed in the PB-E group could indicate a lower activation of the HPI axis on these fish, suggesting that fish fed the diet supplemented with probiotics in the evening might present lower stress levels than those being fed only the standard diet. In addition, lower expression of both *gad2* and *slc6a1a* in the PB-M group might be related to lower levels of brain GABA, which would also reflect a lower activation of the HPI axis and lower stress levels in this probiotic-fed group. At behavioural level, the stress response triggered by transfer into the novel tank system was lower in the zebrafish fed the diet supplemented with probiotics in comparison to the CTRL fish irrespective of the time of administration (PB-M and PB-E groups), also pointing to an anxiolytic effect of the probiotic mix. In addition, exposure of fish to a novel environment was more stressful in the evening than in the morning, regardless of the dietary treatment. To conclude, these findings showed a positive effect of the probiotic mix on zebrafish stress response at both brain and behavioural levels opening the way to the potential application of psychobiotic to support animal health and welfare in the aquaculture industry.

The mankind stands on the edge of a technological revolution that will fundamentally alter the way we live, interact, and consume. It is not clear yet how it will unfold, however, one thing is clear: it must tackle the challenge of a rapidly increasing global population and its subsequent increased nutritional needs. The nutritional resources of the planet are reaching to a limit and already the 9.9% of the population is facing food insecurity and all forms of malnutrition, based on the 2021 report by the Food and Agriculture Organization of the UN. It is not only the low "quantity" of the available food, but it is also the low "quality", the deficiency of macro- and micronutrients, known as Protein-Energy Undernutrition (PEU).

Fish provides about 16% of the total animal protein consumed by humans globally and, in addition, it is an important source of essential minerals and fatty acids. Therefore fisheries and aquaculture industries are playing a central role in meeting food and nutrition security goals (Béné et al., 2015). However, the production cost, to make fish affordable for low-income people, and the maintaining, or even restoring, of the environmental sustainability are the main challenges of the sea-food-related industries that have to be meet (Béné, Barange, Subasinghe, Pinstrup-Andersen, Merino, Hemre and Williams, 2015).

The production of microalgal biomass, including eukaryotic organisms and photosynthetic cyanobacteria, could tackle the global PEU as it provides high-value biomass, while the existing diversity of microalgae species allows the production of different types of products. The advantages of using marine and freshwater microalgae species as nutritional supplements in human diet include: (1) the much higher concentration of proteins, compared to animal and plant biomass, (2) the presents of all valuable amino acids, (3) high concentration of lipids and fatty acids, (4) increased collection of vitamins and (5) antioxidants (Chen et al., 2019, Fields et al., 2020, Torres-Tiji et al., 2020). Clearly, several algal species are nutritionally complete foods, and in addition, their yields outperform most plant crops, and also are less vulnerable to climate change effects compared to animal and plant production. Moreover, cultivating microalge could allow the remediation of wastewaters from various urban and industrial sites, in addition to biomass production (Abinandan et al., 2018).

Currently, the available systems for the production of algal biomass are almost exclusively land-based, consuming valuable land, water and other resources. In addition, the cost of biomass production is still high compared to the market value of most production compounds (Araújo et al., 2021, Vázquez-Romero et al., 2022). Therefore, a cheaper with low environmental footprint algal cultivation method is needed.

In the frame of the EU & Greek-funded research project "Innovative Development of Multitrophic Aquaculture", funded by the "Innovation in Fisheries" EU-Greece Operational Program of Fisheries and Maritime, EPAL 2014–2020 (grant number 5029294), we designed and constructed a novel in-situ floating bioreactor (isFlBR) for the cultivation of marine microalgae.

The main construction material of the isFlBR is plexiglass® due to its increased transparency and mechanical strength for in-situ applications. The edges of the plexiglass® tubes are covered by thin albeit high-strength PVC rings which host the planktonic nets and filters that are needed to keep the micro-algal cells inside the tubes. The arrays of isFlBR tubes are placed in close proximity to the aquaculture cages in order to exploit the maximum of the dissolved nutrients that will are released to the water column.

The ongoing research activities include the cultivation of 3 micro-algal species with increased nutritional and biotechnological value *(Chlorella sp, Isochrysis sp, Nannochloropsis sp*) in both meso- and oligotrophic marine environments next to established aquaculture production units in Central and Southern Greece.

It is clear that the algal cultivation inside the natural marine environment cannot compete the high-yield biomass and constant production of the land-based systems, in terms of total biomass, since no extra nutrients, CO2, radiation is provided. In addition the environmental conditions are very variable over seasons not allowing constant and predictable production rates. Moreover, the in-situ cultivation of microbes makes it more vulnerable to contamination. However, (1) the low installation and running costs of such system, (2) the low environmental impact production due to no usage of land, water or other limiting resources, (3) the remediation of the water column and the production of oxygen during photosynthesis which could decrease the environmental footpring and increase the fish production of the aquaculture, (4) the potential of cultivation of algal species and/or biotechnological interesting metabolites that are not possible in-vitro; makes the use of inFlBR as an excellent supplementary algal production method which could provide additional financial and environmental benefits to the aquaculture industry.

Introduction

The integrated multitrophic system emerges as a more sustainable alternative to traditional biofloc systems. The purpose of integrating shrimp and fish is to ensure that the fish can consume excess of bioflocs and use the microbial protein for their growth. The present study aimed to evaluate the performance of *Litopenaeus vannamei* shrimp and Nile tilapia *Oreochromis niloticus* in an integrated multitrophic culture with a biofloc system approaching the heterotrophic and chemoautotrophic pathways.

Methodology

The experiment was carried out at the Marine Aquaculture Center, Institute of Oceanography, Federal University of Rio Grande – FURG/ Brazil, for 75 days. Each system consisted of a 17 m^3 tank where the shrimp were allocated (400 shrimp/ m^2), a 4 m^3 tank where the tilapia were allocated (45 fish/m^3) and 1 m^3 were introduced 3 kg of *Ulva lactuca*. These tanks were interconnected and the water circulated between them by submerged pump and the water returned by gravity. There are two treatments: Chemoautotrophic and Heterotrophic, with three replications each. Shrimp had an initial weight of approximately 1g and tilapia 25g.

In the chemoautotrophic treatment was fertilized with inorganic compounds, the system water was matured to stimulate the development of nitrifying bacteria (Ferreira et al., 2021). In the heterotrophic treatment, ammonia was controlled by fertilization with organic carbon (sugarcane molasses) after storage of the animals, when the concentration reached 1.0 mg/L or. The animals were fed twice a day (8:00 am and 4:00 pm), the tilapia were underfed with 1% of the tank biomass to stimulate the consumption of bioflocs (Poli et al., 2019).

Results

The mean values of temperature, dissolved oxygen, pH, alkalinity, total suspended solids (TSS) and settling solids (SS) were equal between treatments. The mean values of nitrite (Figure 2) and ammonia were higher in the heterotrophic treatment. The mean values of nitrate and phosphate were higher in the chemoautotrophic treatment, as well as the clarification time (Table 1). The zootechnical performance of shrimp was better in the chemoautotrophic treatment. Only FCR and survival showed no significant difference between treatments. There was no significant difference in any of the zootechnical parameters for the fish.

The results regarding algae are being processed and could not be incorporated until now.

Table 1. Water quality (mean and sd) results in the tratments chemoautotrophic and heterotrophic.

	CHEMOAUTOTROPHIC	HETEROTROPHIC
Ammonia (mg/L)	0.74±1.27^{b}	1.44±2.38^{a}
Nitrite (mg /L)	3.07±3.72^{b}	8.01±8.36^{a}
Nitrate (mg/L)	78.88±4.83^{a}	47.18±3.89^{b}
Phosphate (mg/L)	3.44±0.31^{a}	2.50±0.18^{b}
Alkalinity (mg/L CaCO3)	178.79±14.9	161.86±2.51
TSS (mg/L)	285.72±93.07	313.10±103.88
SS (ml /L)	10.06±7.56	10.37±6.78
Clarification time (hours)	160^{b}	240^{a}

TSS: Total solid suspended. SS: Settleable Solids. Different letters indicate significant difference between the treatments by t-t.

Table 2. Shrimp and fish performance after 75 days.

	Chemoautotrophic	Heterotrophic	Chemoautotrophic	Heterotrophic
	Shrimp		Fish	
Final mean weight (g)	11.24 ± 1.97^{a}	8.25 ± 1.50^{b}	171.62 ± 17.81	180.28 ± 9.23
FCR	1.15 ± 0.06	1.23 ± 0.15	1.13 ± 0.61^{a}	0.75 ± 0.14^{b}
SGR (g.week $^{-1}$)	0.85 ± 0.03^{a}	0.60 ± 0.03^{b}	12.22 ± 1.48	12.98 ± 6.77
Biomass (kg)	60.51 ± 2.89^{a}	40.41 ± 4.68^{b}	18.22 ± 8.00	22.21 ± 3.88
Yield (kg.m^{-3})	5.06 ± 0.12^{a}	3.65 ± 0.12^{b}	1.11 ± 0.37	1.29 ± 0.19
Survival (%)	95.5±5.8	94.3±2.2	75.05 ± 24.42	83.81 ± 8.93

FCR: Feed conversion rate. SGR: specific growth rate. Different letters indicate significant difference between the treatments by t-test.

Discussion

For maturation of the chemoautotrophic system, inorganic fertilizations with ammonium chloride and sodium nitrite were performed for 52 days, with the objective of maturing the nitrite-oxidizing bacteria in the system, before the animals were stored. The objective of the predominantly chemoautotrophic system is for the ammonia excreted by the animals to be converted into nitrate through nitrification. When compared to the predominantly heterotrophic system, which converts ammonia into microbial biomass, this process generates about 40x less total suspended solids (Ebeling et al., 2006). The previous inorganic fertilization in the chemoautotrophic treatment was efficient to keep the levels of nitrite low and this reflected in the better zootechnical performance of the shrimps. With higher biomass, consequently, the feed supply was higher in the system, reflecting higher TSS concentrations. It was not possible to identify a significant difference in the consumption of TSS by the fish, but the FCR lower than 1 in the heterotrophic treatment, without statistically differing from the chemoautotrophic treatment, indicates that the animals used the bioflocs as a food supplement. The chemoautotrophic system showed better shrimp productivity, but the tilapia performance was better in the heterotrophic treatment.

Introduction

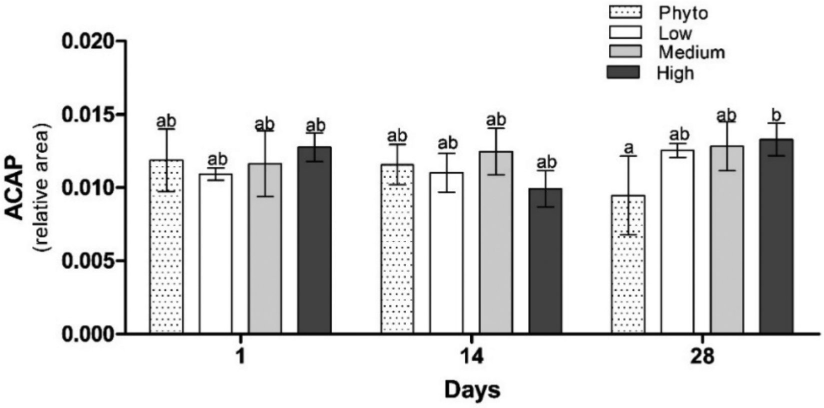
Oysters are known filter feeders and can play a role as consumers of bioflocs in integrated farming with other species (IMTA system). However, the tolerance of these bivalves to the high levels of total suspended solids (TSS) characteristic of cultures in biofloc systems is not known. Thus, the aim of the present study was to evaluate the biological responses of the oyster Crassostrea gasar when exposed to different concentrations of total suspended solids in biofloc culture systems, based on behavioral and biochemical analyses.

Methodology

Oysters with an initial weight of 54.18 ± 13.45g; height of 68.2 ± 4.44 mm; length of 50.4 ± 3.50 mm and width of 24.1 ± 5.02 mm and were cultivated for 28 days in 100L tanks. Four treatments were studied. Phyto: control treatment supplied daily with the microalgae Chaetoceros muelleri at a concentration of 16 x 104 cel/ml; Low BFT treatment – with maintenance of approximately 100 mg/l of TSS; Medium BFT treatment – maintained above 100 to 200 mg/l TSS; High BFT treatment – maintained above 200 mg/l TSS, each with 4 replicates.

The oyster valve activity was monitored using Hall effect sensors according to the methodology of Guterres et al. (2020). The total antioxidant capacity against peroxyl radicals (ACAP) was determined according to the methodology of (Amado et al., 2009).

Figure 6: Antioxidant capacity (relative area) in the gills of C. gasar oysters in the different treatments over a four-week experiment. The bars represent the mean values and vertical lines at the top of the bars represent the standard deviation of the values. Lower case letters in different days and treatments represent significant differences ($p<0.05$).



(Continued on next page)

Results

The use of aperture sensors indicated that there was a significant difference between treatments. The BFT High treatment had a shorter valve opening time, followed by the BFT Medium, BFT Low and control (Fito) treatments (Table 1). Table 1 shows the frequency (%) with which oysters open their valves and were classified as "Closed", "Slightly Open", Open and "Fully Open" (Table 1).

Regarding the total antioxidant capacity against peroxyl radicals (ACAP), there was a significant difference between treatments at the end of the experiment. The BFT High treatment showed a larger average area than the Fito, while the BFT Low and BFT Medium treatments showed no differences between the other treatments (Figure 1).

Discussion

The results demonstrate that oysters remain closed longer when the concentrations of total suspended solids are high. Although the high concentrations are within the ideal range for shrimp culture in a biofloc system (Samocha and Prangnell, 2019), for oyster insertion in an integrated system with shrimp, for example, these values should be kept at up to 200 mg/L. Stressful conditions in culture tanks can cause physiological changes including metabolic changes, decreased antioxidant capacity and oxidative stress, with consequences that can lead to the death of organisms (Romano and Zeng, 2013). After 28 days of culture, a reduction in the total antioxidant capacity (ACAP) of oyster gills in the BFT Alto treatment was also recorded, showing a break in the normality pattern compared to the control. Possibly, the valve closing behavior in the High BFT treatment resulted in the reduction of the total antioxidant capacity, when at week 3 there were limitations in the opening of the oyster valves, and influencing the biochemical responses of the bivalves.

Introduction

Cultivation in bioflocs (Biofloc Technology – BFT) is formed by aggregates of bacteria and other microorganisms that carry out the transformation of nitrogenous compounds in the system, with the accumulation of nitrate, phosphate and total suspended solids during the course of cultivation (Krummenauer et al, 2011). The presence of these nutrients in the system favors the insertion of macroalgae in integrated cultivation, which may lead to an increase in macroalgae biomass, nutrient absorption and an increase in the system's productivity. However, due to the high load of organic matter in the system, little is known about the influence of luminosity in the water column for the cultivation of macroalgae. The main objective of the study is to evaluate the effect of different depths of structures on the growth of the macroalgae *Ulva lactuca* in an integrated system with *Litopenaeus vannamei* and *Oreochromis niloticus* in bioflocs.

Materials and methods

The experiment was carried out in an agricultural greenhouse in 70 days of cultivation, consisting of six systems, each system was formed by a tank of 15 m^3 of useful volume with shrimp, and two tanks with 3 m^3 of useful volume with fish and macroalgae, separately. The density used was 300 shrimp/m^3, 35 fish/m^3 and 0.1g of macroalgae/L. Two treatments were performed with three replicates, namely: IMTA R shallow float (up to 10cm) and IMTA F deep float (up to 25cm), made of PVC pipes and 5mm mesh polyethylene nets. The initial average weight of the algae was 2.40±1.21 kg, weighing every two weeks to perform the Specific Growth Rate (SGR).

Water quality monitoring was performed, with temperature, dissolved oxygen and pH measured daily, and salinity and alkalinity were measured once a week. Nutrients and solids were performed twice a week, namely, total ammoniacal nitrogen, nitrite, nitrate, phosphate, total suspended solids (TSS), turbidity and settling solids (SS).

Data normality and homoscedasticity were verified using the Shapiro-Wilk and Levene tests, respectively. Once the assumptions were met, a t test was performed to verify the difference between treatments. A minimum significance level of 5% ($p<0.05$) was applied in all analyses.

Table 1 – Water quality parameters and macroalgae performance in integrated culture with shrimp and fish, in 70 days of cultivation.

Parameters	Shallow	Bottom
Seaweed		
Initial mean weight (g)	2401,00±0,20	2401,00±0,10
Final mean weight (g)	2629,33±0,227^{a}	1942,00±0,201^{b}
RGR (%/dia)	0,14±0,14^{a}	-0,35±0,17^{b}
Qualidade de água		
TAN (mg/L)	0,18±0,20	0,15±0,19
Nitrite (mg/L)	2,16±2,38	1,29±1,30
Nitrate (mg/L)	64,40±28,39	61,71±24,17
Phosphate (mg/L)	5,99±4,24	5,43±3,78
Turbidity (NTU)	219,49±86,66	196,02±68,72
SS (ml/L)	3,88±2,09	5,01±2,27
TSS (mg/L)	307,92±87,48	303,43±91,60

(Continued on next page)

Results

As a result, the first and second IMTA R weighings showed a TCE of 0.95±0.54 and 0.23±0.78%/day, respectively, with a significant increase in biomass. However, IMTA F treatment showed biomass loss -1.06±0.43 and -0.39±0.48%/day also in the first and second. On the other hand, in the penultimate weighing, TCE was negative for both treatments, with loss of biomass, with no statistical difference between treatments (-0.58±0.19 and -0.63±0.84).

There was no significant difference in water quality between treatments, with temperature, dissolved oxygen, pH, salinity and mean alkalinity of 22.29±0.01, 6.71±0.01, 8.03±0.04, 19 .46±0.65 and 219.02±1.24.

Discussion

Due to the high turbidity and solids in the biofloc system, there is little light penetration into the water, therefore, a shallower depth of structure increases the light absorption capacity of macroalgae due to their proximity to the surface. A decrease in temperature to 15°C was noted in the fourth week, which could be a stress factor for the macroalgae and thus initiate a reproductive event, as an indication of "ghost tissues" were found in the macroalgae tissue, as found by Da Silva et al. there, (2009).

With the exception of temperature, which remained low for shrimp farming (Wyban et al, 1995), the parameters were in optimal conditions for the cultivation of the species. The absorption of nutrients by macroalgae was not significant due to the low density of macroalgae used in the system.

Conclusion

Therefore, we can conclude that to improve the growth of macroalgae in integrated culture with shrimp and fish in a biofloc system, the use of shallow floats up to 10 cm are more efficient.

Introduction

The use of alternative ingredients is a relevant area in the nutrition of aquatic organisms. In this sense, the macroalgae *Ulva lactuca* is an excellent candidate due to its antioxidant concentration, fatty acid and amino acid profile (Shuuluka et al., 2013). Water obtained from different environments can provide changes in the biochemical and nutritional composition of macroalgae (Duke et al., 1989). Therefore, the cultivation of macroalgae in biofloc systems with high concentration of nutrients and solids can change the nutritional composition of macroalgae. The aim of this study was to evaluate different inclusions of *Ulva lactuca* macroalgae produced in Biofloc system in the Nile tilapia diet *Oreochromis niloticus*.

Materials and methods

The experimental design consists in the use of three levels of macroalgae inclusion: 5, 10 and 15% *U. lactuca* in diet and a control treatment, without macroalgae, all with three replicates (Table 1). The experiment lasted 35 days and was performed at Estação Marinha de Aquacultura – FURG, with controlled temperature, at salinity 15. Ten juveniles with initial average weight of 2.12 ± 0.02g were stocked per experimental unit (50 L useful volume). The feed frequency used was 3 times/day, with 6% of the total biomass. Feces and uneaten food were siphoned off every day, and water changes were performed twice a week. Temperature, dissolved oxygen, pH, TAN, and nitrite were measured every day. Weighing measurements were performed weekly to adjust the amount of feed and to determine the feed conversion (FCR) and specific growth rate (SGR). The normality and homoscedasticity of the data were verified by the Shapiro-Wilk and Levene tests, respectively. All the data were performed with a one way ANOVA.

Table 1: Ingredient composition of experimental diet (% dry matter) containing *Ulva* meal in different levels.

Ingredients	**Experimental diets**			
	Control	**5%**	**10%**	**15%**
Fish meal	40.00	40.00	40.00	40.00
Soybean meal	33.00	32.00	31.00	30.00

Mean (n=3 ± S.D.)

(Continued on next page)

Results

In the experiment, there was no significant difference in the growth parameters among treatments. The high values of the deviation are due to the high mortality in one of the replicates.

Discussion

The results obtained by Suryaningrum et al., (2020) suggest that up to 10% of the inclusion of macroalgae in the feed is beneficial to the animal, greater inclusions can interfere with zootechnical performance due to low digestibility. In this study, the treatment with the highest inclusion (15%) was not significantly different from the others. In previous studies, an increase in protein of the macroalgae *Ulva lactuca* was observed when cultivated in an integrated system with bioflocs, with values of 22.4% compared to cultivation in a laboratory solution of 12.4% protein (Chagas, 2021). The use of this biomass can generate better results in the digestibility of the feed and reduce or not use ingredients such as wheat flour. The similarity of the initial weight of the fish may cause an increase in aggressive behaviours during the experiment (Boscolo et al., 2011), which may explain, in some cases, the mortality rate.

Conclusion

Macroalgae meal, that up to 15%, can be used in Nile tilapia diets without interfering with the zootechnical performance and replacing ingredients.

EUROPEAN EEL LARVICULTURE:
FIRST ESTABLISHMENT OF FEEDING LEPTOCEPHALUS CULTURE

Introduction

Anguillid eels are targeted, high-value species for aquaculture in Asia and Europe. Unfortunately, eel farming is still capture-based, exclusively relying on wild-caught glass eels and thus, the sustainability of this industry is challenged by the present critically low stock abundance, which is especially the case for European eel, *A. anguilla* (Pike et al., 2020). Hence, it is urgently needed to further develop and establish captive breeding techniques and technologies for this critically endangered fish species. Advances in Japanese eel culture (Okamura et al., 2013) have formed the baseline for eel research, promoting recent development of hatchery protocols for European eel (Tomkiewicz et al., 2019). While offspring culture techniques for the European eel encompass the endogenous feeding stages (Sørensen et al., 2016), the transition to exogenous feeding is still challenged by lack of insights regarding the feeding stages and dietary requirements for the unique leptocephalus larvae. Research has been conducted to identify natural eel larval feeding sources (Miller, 2009) and physiology (Knutsen et al., 2021), but despite increasing knowledge on larval feeding ecology, the natural first-feeding regimes of *Anguillid* pre-leptocephali remain an enigma. Scientific inquiry has focused on identifying potential first-feeding diets with the first exogenously feeding experiments of hatchery-reared European eel larvae only recently attempted (Butts et al., 2016; Politis et al., 2018), in combination with enhanced rearing techniques aiming at improving larval survival (Tomkiewicz et al. 2019; Politis et al., 2021). In continuation of this work, research in the innovation project ITS-EEL has focused on developing prototype diets, exploring feeding and gut-priming regimes as well as testing larviculture procedures by applying progressively advancing culture techniques and technology. The presentation will overview these progressive advancements regarding the requirements of larval European eel in terms of abiotic (such as temperature, salinity, light, pH) and biotic (such as gut-priming, feeds, feed amounts, feeding regimes, microbial control, water quality) factors, from a morphological and molecular point of view.

Material and methods

European eel gametes were obtained through assisted reproduction using routine procedures as previously described by Kottmann et al. (2020). After fertilization, the floating layer was transferred to 60 L black conical incubators, supplied with conditioned filtered seawater (Politis et al., 2018) at a flow through rate of ~350 mL min^{-1}, while gentle aeration was added. Temperature was set to 18°C, salinity to 36 psu and light to low intensity of ~10 lx for better embryonic development (reviewed in Tomkiewicz et al., 2019). Larvae hatched at ~56 hpf, which were then reared in ~80 L tanks, connected to a recirculating Aquaculture System (RAS), until reaching the feeding stage. Thereafter, larvae were moved into ~8 L Kreisel tanks, connected to a new RAS, where temperature was kept at ~20°C and salinity lowered to ~18 psu (Politis et al., 2021). Here, larvae were fed prototype liquid diets, provided to the bottom of each tank. During feeding, water flow was stopped and lights turned on at high intensity of ~20 µmol m^{-2} s^{-1}. After ~30 min feeding time, the remaining food was flushed away, water circulation was restarted and the light turned off again. Larvae were fed using this procedure five times per day.

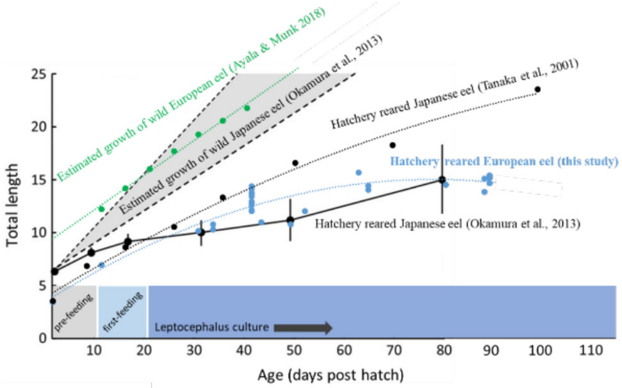

Fig. 1: Length of hatchery reared & wild European and Japanese eel offspring

Results and Discussion

Following constantly updated assisted reproduction protocols, the amount and quality of European eel larvae reaching the first-feeding stage has steadily increased enabling research efforts around larval feeding culture. Knowledge about larval European eel requirements and preferences, regaridng abiotic (temperature, salinity, light, pH) and biotic (gut-priming, feeds, feed amounts, feeding regimes, microbial control, water quality) factors has enhanced survival. Moreover, the European eel larval rearing systems and diets have been progressively upgraded and refined by incrementally integrating gained knowledge, resulting in the first ever European eel leptocephalus culture, surviving up to ~140 dph. Notably, European eel larvae grew from ~3 mm (~1.5 mm^2) at hatch, to 7-8 mm (3-4 mm^2) at the first-feeding stage (10 dph). The majority of larvae started feeding at 10-12 dph, while the larvae that did not feed or start feeding too late, entered the so called "point-of-no-return" and perished at 20-24 dph. In contrast, larvae that initiated exogenous feeding success-fully, survived beyond this point and transformed into the characteristic leaf-like leptocephalus shape. So far, applying advanced rearing and feeding procedures have led to European eel larvae growing to a length of ~15 mm and body area up to ~20 mm^2. These results are comparable to Japanese eel larviculture (Tanaka et al., 2001; Okamura et al., 2013), while growth rates are lower compared to estimate patterns for wild leptocephali (Fig. 1). Overall, our results, enabling the first ever European eel leptocephalus culture, present a new promising step towards closing the life cycle of this critically endangered species in captivity. Now, the challenges ahead involve progression of diets, advancement of rearing techniques and improvement of larval survival throughout the leptocephalus stage, to reach the glass-eel stage.

The growing demand for sea cucumber products constitutes a continuing threat to wild stocks and to the habitats in which they live in. A possible way to mitigate the detrimental effects economic demand has on ecosystems around the world is to increase supply, as such, aquaculture stands as an emerging alternative. A promising species for future European aquaculture production, with high commercial interest, is the sea cucumber *Holothuria arguinensis*. With a natural distribution along the North-Eastern Atlantic, including the coast of Portugal, this species is already showing a decrease in wild populations due to unregulated exploitation. With the implementation of successful larval rearing and settlement, more emphasis needs to be placed on the on-growing phase of juveniles. The optimisation of the diets and feeding of *H. arguinensis* juveniles to reduce their mortality and increase growth performance has not yet been studied. This species feeds on the sediment and studies with other detritivores species point to the inclusion of macroalgae as part of the diet. In this regard, the following study aimed to assess growth and survival rate of hatchery-reared *H. arguinensis* juveniles (n=324; mean weight: 20±7 mg; mean length: ≈ 1 mm). Individuals were distributed in 3 RAS, each with three 50 L tanks with sandy substrate and were fed during 6 months with three diets (Diet 1 = *Rhodomonas baltica* + *Chaetoceros calcitrans*; Diet 2 = *Rhodomonas baltica* + *Saccorhiza poliscides* and Diet 3 = *Rhodomonas baltica* + *Chaetoceros calcitrans* + *Saccorhiza poliscides*) administered 3 times a week. *H. arguinensis* fed with diet 2 showed the highest survival rate (84.26±14.25%) when compared with individuals fed with diet 1 (59.26±12.83%) and diet 3 (40.74±21.03%). Juveniles fed with diet 2 and diet 3 showed a significantly higher final weight (diet 2: 570±150 mg and diet 3: 480±50 mg) and a higher length (diet 2: 19±4 mm and diet 3: 17±9 mm) than individuals fed with diet 1 (270±80 mg and 11±2 mm). Specific growth rate (SGR) was higher in juveniles fed with diet 2 (9.23 % month^{-1}) than in juveniles fed with the diet 1 (4.11 % month^{-1}) or with the diet 3 (7.60% month^{-1}). The addition of the macroalgae *S. poliscides* in the *H. arguinensis* juvenile diet shows potential benefits on growth. At the end of the trial juveniles whose diet was supplied with *S. poliscides* showed an increased growth observed with a higher final weight, length and SGR when compared to individuals without this macroalgae in their diet. Results were most promising particularly with diet 2 where there was a higher survival rate. To optimize sea cucumber *H. arguinensis* rearing more trials should be conducted with hatchery-reared juveniles comparing sediment enrichments, the efficacy between macroalgae diets, the production with fishfarm waste or the growth in integrated multi-trophic aquaculture systems (IMTA).

Mussel farming has faced challenges such as the establishment of non-indigenous species that may become invasive (NIS) in the farming environment. These introductions often occur at an accelerated rate and fouling NIS can have a relevant negative impact in mussel production, such as mechanical interference with the shell function and competition for food and space. The presence of biofouling in marine aquaculture represents one of the main barriers to an efficient and sustainable production and its control is a challenge for which solutions are still being investigated. Some NIS, such as tunicates, cause significant negative effects on mussel productivity, by reducing the mussels' growth rates and causing severe mortality of the reared mussels. The tunicate *Styela plicata* is a widely distributed, temperate to subtropical, biofouling ascidian, which is associated with damages caused in aquaculture. This study focused on the reproductive biology of *S. plicata* present in mussel cultures in the Albufeira coastal lagoon (SW Portugal), aiming at contributing to a better understanding of how environmental variables such as temperature and salinity can influence its establishment and development. The reproductive cycle of *S. plicata* was characterized through the evaluation of the gonadosomatic index (GI). The histological analysis of the gonads was performed monthly (n=30) over an 18-month period to identify the gametogenic stages of the gonads of individuals collected from a mussel farm raft located in the Albufeira coastal lagoon. GI was highest in summer when the highest temperatures and salinities were also recorded. No clear seasonal reproductive pattern was observed since mature gametes were present throughout the year. Spawning can occur continuously, although more pronounced in late summer and early autumn. The present study confirmed the occurrence of an established population of *S. plicata* in the Albufeira coastal lagoon since the individuals analysed were fertile all year-round. A prolonged reproductive period can confer *S. plicata* a competitive advantage, favouring its permanence in areas that have already been invaded and offering the opportunity to expand its area of occurrence. Moreover, the temperature and salinity of the lagoon do not exceed the tolerance limits for the reproduction of the species and the low hydrodynamics favours the survival and the successful establishment of this tunicate. Therefore, it can be concluded that the current environment of the Albufeira lagoon offers advantages for *S. plicata*. These results suggest that additional studies on the dynamics of this population are needed, especially to clearly identify the time of greatest larval settlement and help to put in place actions to mitigate the adverse effects of this biofouling ascidian on mussel farming.

Introduction

Inappropriate water temperature and other physico-chemical water parameters can cause slow growth, induce stress or can even cause mortality, making the aquaculture less efficient. Considering that there is space on the Portuguese coast that could be used for offshore aquaculture, in this work, we intend to compare some physico-chemical water parameter values on the water column (up to 50 metres) with the ideal growth parameters of some fish species with economic interest and potential to be produced in offshore aquaculture.

Materials and methods

This study was conducted with field surveys on the Portuguese Coast in 5 areas (Area A: between Viana do Castelo and Oporto; Area B: between Aveiro and Figueira da Foz; Area C: Peniche; Area D: between Setúbal and Sines; Area E: Algarve region) and 4 different periods: October, 2018; April, 2019; October, 2019 and March, 2020. Temperature (ºC), salinity, pH, dissolved oxygen (mg-O_2 L^{-1}), total oxidized nitrogen (also known as nitrate+nitrite, μmol L^{-1}; NO_x^-) and ammonia (μmol L^{-1}; NH_3) were analysed in 3 different depths (5 m, 25 m and 50 m). Also, the mean monthly temperature data were collected from the NASA GHRSST (Group for High Resolution Sea Surface Temperature, Level 4) platform to evaluate the surface monthly temperatures in the studied areas. The optimal and maximum and minimum limits of the previous parameters tolerated by some potential fish species (*e.g. Argyrosomus regius*, *Sparus aurata*, *Dicentrarchus labrax, Seriola dumerili, Salmo salar* and *Sardina pilchardus*) that can be produced in these locations were compiled and these data were compared with the physico-chemical water parameters data determined in each field survey, area and depth.

Results

During the field surveys of 2018, 2019 and 2020, the parameter that changed significantly throughout the water column was the temperature. Overall, the area that presented the most extreme mean temperatures were area E, with a mean maximum of 22.75 ºC in the 2018 survey at 5 m deep, and area A, with a mean minimum of 13.38 ºC in the October 2019 survey at 50 m deep. There have been some variations of pH, dissolved oxygen and salinity values in the water column. The mean values of pH varied from 7.93 (area C; 5 m; October, 2019) to 8.14 (area D; 5 m; April, 2019); dissolved oxygen mean values varied from 6.43 (area A; 50 m; October, 2019) to 9.26 (area A; 5 m; April, 2019) and salinity mean values varied from 35.35 (area A; 5 m; April, 2019) to 36.71 (area E; 5 m; October, 2018). Total oxidized nitrogen, nitrites and ammonia values were consistently below the respective limits of quantification. All parameters analysed are within limits tolerated by the potential species that can be produced except temperature.

Discussion

Comparing the ideal temperature growth values of the most economical interesting species that can be produced in mainland Portugal it is possible to highlight the areas where it is achievable to implement submerged sea cages for each species. The meagre *Argyrosomus regius* can withstand a wide range of temperature values (13 – 29 °C) with optimal values ranging from 24 ºC to 29 ºC (Stavrakidis-Zachou et al., 2021) and can be produced in south of Portugal to depths up to 50 m. The gilthead sea bream *Sparus aurata* and the sea bass *Dicentrarchus labrax* have similar ideal growth values between 20 ºC and 25 ºC (Zhang *et al.,* 2021) which make them species that can also be considered for deep farming in southern Portugal. For the greater amberjack *Seriola dumerili* the information available suggests that this species has an optimal growth at warmer temperatures and the southern area would also be the most suitable. On the other hand, salmon *Salmo salar* needs lower temperature being able to withstand values from 14 ºC to 18 ºC (Johansson *et al.,* 2009) that makes it potentially promising for the central and northern area of Portugal. For new species under investigation that are not yet commercially produced as sardine *Sardina pilchardus* the information available is scarce and more studies are needed to understand which areas would be the most promising for its rearing. Submerged sea cage aquaculture is an intricate process that has multiple variables, such as feeding routines, monitoring, storm prevention structures, net material, currents, depth deployment and anchor weights that need to be considered. Nevertheless, there is potential to insert new depth structures in Portugal but further studies are needed to reduce the risks associated with its implementation.

ASSESSING THE ROLE OF ULVAN EXTRACTS AS FUNCTIONAL INGREDIENTS IN AQUACULTURE

M. Ponce*, V. Anguís and C. Fernández-Díaz

IFAPA Centro El Toruño. Camino Tiro de Pichón s/n, 11500 El Puerto de Santa María, Cádiz, Spain
E-mail: marian.ponce@juntadeandalucia.es

Introduction

Aquaculture industry is one of the fastest growing food production sectors becoming generalized intensive and semi-intensive practices and therefore, increasing the susceptibility to infectious diseases. The use of antibiotics has been generalized, not only as therapeutic measure to control bacterial pathogens but also as growth promoters despite the side effects that these practices involve (Lulijwa et al., 2020). For this reason, the scientific community has focus on the research of bioactive compounds with immunostimulatory properties and be able to conduct preventive strategies. Ulvans are marine derived polysaccharides extracted from green macroalgae of the genus *Ulva* that possess immunomodulating, antioxidant, anticoagulant, anticancer, antiviral and antihyperlipidemic activities (reviewed in (Kidgell et al., 2019)). Recently, the role of ulvan extracted from *Ulva ohnoi* as bioactive compound with immunomodulatory activity in *Solea senegalensis*, a species of great interest in aquaculture, has been reported (Ponce et al., 2020). However, the purification grade is an important issue to consider as well as the administration method. The aim of this study was to investigate the effects on the immune system of *S. senegalensis* fed diets with the inclusion of the functional ingredient ulvan. For this reason, the influence of the purification grade on the structure and chemical composition of ulvan extracts and therefore, on their biological activities throughout *in vitro* assays in *S. senegalensis* macrophages was evaluated. Thereafter, *S. senegalensis* juveniles were fed diets with the selected ulvan extract with potential properties to enhance the defence system at ratios 0, 1 and 2% for 30 days. Finally, juveniles were challenged with *Photobacterium damselae* subsp. *piscicida*, an important fish pathogen, and the mortality rate was determined.

Material and methods

Macroalgae *U. ohnoi* was supplied by Huerta Marina Huelva S.L. (Spain). The sulfated polysaccharide ulvan was extracted following the method described by (Fernández-Díaz et al., 2017) without the use of sodium oxalate during the extract process. Three ulvan extracts with different purification grade were obtained referred as: CUE (crude ulvan extract); UE (precipitation of ulvan with ethanol) and UU (ulvan obtained by ultrafiltration). For *in vitro* assays, macrophages from head kidney of *S. senegalensis* juveniles were extracted and cultured as described by Secombes and Fletcher, (1992). A total of 40 juveniles (average weight 85.63 ± 24.91 gr) were obtained from facilities of IFAPA Centro El Toruño (El Puerto de Santa María, Spain) and head kidney was sampled under aseptic conditions. The cell suspension was loaded on a 34%51% discontinuous Percoll (Sigma-Aldrich) gradient. Cells were distributed into 24-well cell culture plates at 2 x 10^6 cells ml^{-1}. After 24 h of incubation with ulvan extracts (0.05, 0.5 y 1 mg ml^{-1}), cells were collected. Three replicates were used per treatment and the experiments were performed three times. Total RNA was isolated using the RNeasy® Mini Kit (Qiagen) and treated twice with DNase I using the RNase-Free DNase kit (Qiagen). Total RNA was reverse transcribed using the iScript™ cDNA Synthesis kit (Bio-Rad). Expression analyses of a set of genes related to the antioxidant and immune system were performed by RT-qPCR using specific primers. For *in vivo* assays, *S. senegalensis* juveniles (average weight 33.16 ± 6.64 gr) were provided by Cupimar S.A. (Cádiz, Spain) and they were acclimated for 14 days. Three groups of fish in triplicate were fed the diets with UE at rates of 0, 1 and 2% for 30 days. The feeds were developed by LifeBioencapsulation S.L. (Almería, Spain). At 30 days post treatment, spleen was sampled, transferred to RNAlater™ Stabilization Solution (Invitrogen) and store at -80ºC until use. Expression analyses were performed as described above. Blood was drawn from the caudal vein, plasma was collected and stored at -20ºC until further análisis. Lysozyme Detection Kit (Sigma-Aldrich) was used to determine the lysozyme activity in plasma. *S. senegalensis* juveniles were challenged with the strain Lg41/01 of *Phdp* and mortality was monitored daily.

(Continued on next page)

Results and discussion

In order to investigate the effects of the purification grade on the biological activities of ulvan, the expression level of a panel of genes related to the antioxidant and immune system was evaluated. The selected genes were as follows: superoxide dismutase 1 (*sod1*), catalase (*cat*), glutathione peroxidase 1 (*gpx1*), thioredoxin (*txn*), lysozyme g (*lyg*), interferon regulatory factor 1 (*irf1*), interleukin 1b (*il1b*), interleukin 6 (*il6*), interleukin 10 (*il10*), complement C3 (*c3*) and complement C7 (*c7*). In relation to the expression pattern of genes related to the antioxidant system, no significant differences in the expression levels of *gpx1* and *cat* were observed in any case. Expression levels of *txn* were significantly higher in the case of CUE and UU treated macrophages than in the control groups. However, mRNA levels of *sod1* were only significantly higher in the case of CUE treated macrophages. Regarding genes related to the immune system, only the mRNA level of *c7* was significantly higher in macrophages treated with CUE extracts than in the control groups. Nevertheless, a significant coordinate increase in the mRNA levels of *lyg*, *il1b*, *il6*, *il10* and *c7* were observed in macrophages incubated with both, UE and UU extracts with respect to the controls at concentrations of 1 mg ml^{-1}. Based on these results, UE extract was selected to be incorporated into the functional feeds for the evaluation of the effects in the immune system of Senegalese sole juveniles. All the results obtained in this study will be presented and discussed in depth during the oral presentation.

Introduction

Ulvan is a marine sulphated polysaccharide obtained from green seaweeds of the genus *Ulva* that has a wide range of bioactivities including immunomodulating, antioxidant, anticoagulant, anticancer, antiviral and antihyperlipidemic activities (Reviewed in Kidgell et al. (2019)). Proposed methods to extract ulvan include hot water extraction, hot water with sodium oxalate, acidified ammonium oxalate or hydrochloric acid, among others. The extract is separated from the residual biomass by filtration and/or centrifugation being the isolation of ulvan performed by precipitation, evaporation or concentration by ultrafiltration followed by lyophilisation. Extraction conditions as well as the purification methods influence the composition of the extracted ulvan and thereafter, their biological activities (Wahlström et al., 2020). Further research is needed to have a deep understanding of the general trends in physicochemical properties and biological activities of ulvan relative to its structural features. The aim of this study was to assess the effects of the extraction method of ulvan and the purification grade on their structural and biological properties. Acidic and hot water extraction methods were compared as well as the isolation and purification grade of the extracted ulvan. The antioxidant and immunostimulant activities and the protective effect induced by the different types of ulvan on *S. senegalensis* macrophages were evaluated.

Material and methods

Macroalgae *U. ohnoi* was supplied by Huerta Marina Huelva S.L. (Spain). The sulfated polysaccharide ulvan was extracted following two methods: one extraction with hydrochloric acid (HCl) as described by Yaich et al. (2014) and another one by an aqueous extraction protocol as described by Fernández-Díaz et al. (2017) but without the use of sodium oxalate. Crude ulvan extracts were referred as CUE-HCl and CUE-H_2O, respectively. From each extraction method, ulvan were obtained by ultrafiltration and they were named as UU-HCl and UU-H_2O, respectively. Antioxidant activity of ulvan was evaluated by determining their DPPH and superoxide anion radicals scavenging abilities according to (Chen et al., 2016). Macrophages from head kidney of 30 juveniles *S. senegalensis* juveniles (average weight 88.85 ± 27.41 gr) obtained from facilities of IFAPA Centro El Toruño (El Puerto de Santa María, Spain) were extracted and cultured as described by Secombes and Fletcher, (1992). After 24 h of incubation with ulvan extracts (0.05, 0.5 y 1 mg ml^{-1}), cells were collected. For the H_2O_2 challenge, macrophages were isolated from 36 Senegalese sole juveniles (average weight 74.16 ± 9.30 gr) and treated with ulvan extracts as described before. Afterwards, the medium was removed and new medium containing 1 mM H_2O_2 was added and cultivated for another 1 h. Three replicates were used per treatment and the experiments were performed three times. Total RNA was isolated using the RNeasy® Mini Kit (Qiagen) and total RNA was reverse transcribed using the iScript^{TM} cDNA Synthesis kit (Bio-Rad). Expression analyses of a set of genes related to the antioxidant and immune system were performed by RT-qPCR.

Results and discussion

The scavenging rate on superoxide anion radical of ulvan obtained after aqueous extraction was 9.73-fold higher than that of ulvan obtained from HCl extraction. All of them showed lower scavenging activity than ascorbic acid (AA). No significant differences were observed between DPPH scavenging rates being 12.70, 12.22, 13.39 and 13.59 % respect to the AA for CUE-HCl, CUE-H_2O, UU-HCl and UU-H_2O extracts, respectively. To deep investigate the effects of both, the extraction method and the purification grade of the ulvan extracts on the biological activities, the expression level of a panel of genes related to the antioxidant and immune system was evaluated. The selected genes were as follows: superoxide dismutase 1 (*sod1*), catalase (*cat*), glutathione peroxidase 1 (*gpx1*), thioredoxin (*txn*), lysozyme g (*lyg*), interleukin 1b (*il1b*), interleukin 6 (*il6*) and interleukin 10 (*il10*). In relation to the expression pattern of genes related to the antioxidant system, no significant differences in the expression levels of *cat* were observed in any case. Expression levels of *gpx1* were significantly lower in the case of UU-HCl and UU-H_2O treated macrophages than in the control groups, whereas no significant differences were observed between crude extracts treated groups. In the case of *sod1*, mRNA levels were only significantly higher in the

(Continued on next page)

case of both CUE treated macrophages. Expression levels of *txn* were significantly higher in the case of all ulvan extracts treated macrophages than in the control groups at concentrations of 1 mg ml^{-1}. Regarding genes related to the immune system, a significant increase in *lyg*, *il1b*, *il6* and *il10* mRNA levels were observed only in UU-H_2O treated macrophages at concentrations of 1 mg ml. In order to further investigate the antioxidant properties of the ulvan extracts, a H_2O_2-induced injury cell model was performed, and gene expression patterns were evaluated. A significant decrease in mRNA levels of *sod1* and *gpx1* were observed in H_2O_2 treated macrophages with respect to the control groups whereas no significant differences were observed in the case of macrophages preincubated with the four types of ulvan. Changes in the structure of ulvan during the extraction procedure may reduce or enhance its functionality. These results indicate that the biological functions of CUE and UU ulvan are more related to antioxidant and immunomodulating activities, respectively.

Introduction

Aquaculture industry is a strategic development sector of the blue economies, considering the huge amount of seafood consumption in the EU, but only 20% comes from EU farms (EUMOFA, 2018). Indeed, the sector is stagnating due to different problems, such as administrative, environmental, and technical criticalities. In order to promote a sustainable, innovative and competitive aquaculture, a spatial planning should be carried out to highlight the most suitable areas to this activity. In this framework the identification of the Allocated Zones for Aquaculture (AZAs), areas where aquaculture has priorities over other uses (Sanchez-Jerez et al., 2016), can booster this sector. An AZA is a planning system that considering the environmental, social, and economic components, allowing to highlight the most suitable areas to specific farming activities.

In 2020, in Sardinia, started a project about the AZA identification (EMFF PO 2014-2020), with 3 main objectives: (i) improve the aquatic ecosystems knowledge; (ii) prepare the AZA regional plan; (iii) develop a Geoportal for managing and consulting data. Based on the regional resolution (Sardinian Region resolution 3/26 of 22/01/2020), the AZA have to be classified as follow: ZONE 1, areas suitable for aquaculture activities; ZONE 2, areas suitable for aquaculture activities subjected to regulation/limitation; ZONE 3, areas not suitable for aquaculture activities.

In this paper we present a framework for supporting the AZA identification in three aquatic ecosystems: at sea, in lagoons, and in lakes.

Methods

The AZA plan pertained to the Sardinian territorial sea waters (SW), lagoons (LG) and lakes (LK). A tiered approach was developed that first assessed the availability of the three aquatic ecosystems for aquaculture. Following this, in the areas considered to have good availability for aquaculture, the suitability for different species was estimated. In these ecosystems data about chemical-physical water characteristics, habitat distribution, and current uses were collected. Data were extracted from regional agencies database (*in situ* data), remote sensing database (*i.e.*: CMEMS), and cartographic data gathered from different sources (e.g.: Sardinian Geoportal and EMODnet).

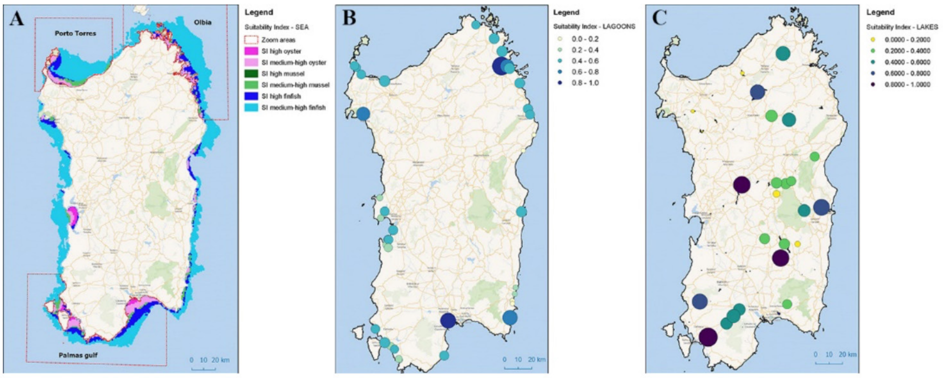

Figure 1. Aquaculture suitability index (SI) estimated for the three aquatic ecosystems: sea (A), lagoons (B) and lakes (C).

(Continued on next page)

In the three aquatic ecosystems, the species considered were: European seabass (SW, LG), gilthead seabream (SW, LG), Mediterranean mussel (SE, LG), Pacific oyster (SW, LG), flathead grey mullet (LG), grooved carpet shell (LG), rainbow trout (LK), brown trout (LK), carp (LK), perch (LK), tench (LK), largemouth bass, and striped bass (LK).

At sea, the AZA were identified applying the Spatial Multi-Criteria Evaluation methodology (Brigolin et al., 2017; Porporato et al., 2020), considering 4 criteria: potential growth, distance to harbour, significant wave height, bottom typology. Protected habitats distribution, sea uses, and potential conflicts, with their specific buffer zone, were also considered. Subsequently, in 3 different zoom areas, namely Porto Torres, Olbia, and Palmas gulf (Fig. 1A), a dispersion index for finfish farms was estimated. Finally, the Cumulative Effect Assessment and the Maritime conflict analysis tools, based on the Tools4MSP Modelling Framework (Menegon et al., 2018), were applied in the Porto Torres area.

In lagoons and lakes, firstly the aquaculture suitability was estimated combining 2 methodologies, the fuzzy logic classification and the factorial analysis. In these systems biological (*e.g.*: temperature, oxygen) and logistic criteria (*e.g.*: site accessibility and facilities) were considered. Subsequently, depending on these first results, in depth analyses in 3 lagoons and in 2 lakes were carried out. Pacific oyster carrying capacity in the three lagoons was calculated using data on water movement and food availability. In the lakes, the suitability of Sardinian reservoirs for rainbow trout aquaculture was evaluated through seasonal field samples of temperature and oxygen at different locations and depths.

In parallel to the previous described analyses, in order to draft a participatory AZA plan, and to select the zoom areas, different stakeholders, including local authorities, farmers, the scientific community, and the general public, were involved in different events.

Results and discussion

The main results of the aquaculture suitability estimated for the 3 aquatic ecosystems are show in Fig. 1. A Geoportal based on GeoNode, containing data and tools was developed (www.waterspatialplanning.eu). Our research was aimed at identifying the environmental, social, and economic conditions that allow the development of a sustainable aquaculture, guaranteeing the environmental protection, and the reduction of potential conflicts between different uses, facilitating synergies and co-uses.

The obtained results will be used to draft the AZA Sardinian plan which will be instituted by the competent authority. Spatial planning and the choice of areas has been based on the use of scientific, environmental, legal, technical and socio-economic evidence, to guarantee the conservation and protection of the environment and territories, maintaining a good ecological status, and preventing habitat and ecosystem degradation.
Our approach, thanks to the generality and transferability of the applied methodology could be applied to the AZAs identification in other case studies.

STAKEHOLDERS INVOLVMENT IN THE ALLOCATED ZONES FOR AQUACULTURE (AZAs) IDENTIFICATION PROCESS: THE SARDINIAN EXPERIENCE

E.M.D. Porporato[1*], D. Grech[1], D. Trogu[1], M. Baroli[1]

Introduction

The aquaculture development needs to improve spatial planning process in order to ensure socio-economic sustainability, effective preservation of protected habitats, food security and employment generation. The Allocated Zones for Aquaculture (AZAs; Sanchez-Jerez et al., 2016) identification should be carried out in synergy with all the stakeholders through a participatory approach in the planning process (Corner et al., 2020). Indeed, aquaculture growth depends on a complex value chain influenced by different societal and governmental factors that can determine the successful, or the failure, of the AZA identification and planning. Moreover, multiple uses and users of spaces, including coastline and lagoons, can coexist or, frequently, have conflicting interests and needs.

In 2020, in Sardinia, started a project about the AZA identification (EMFF PO 2014-2020), which since the beginning has foreseen the direct involvement of different stakeholders, including the decision makers, farmers, fishers, researchers and academics, and the general public. In this paper we present the results of stakeholders' involvement in the AZA identification carried out in Sardinia (Italy).

Methods

Two online meetings were organised, one restricted with the decision makers, public institute and agencies, and one public. In the first meeting were involved 4 regional departments, 2 regional agencies, and the institute responsible for the veterinary and public health. The second meeting involved the general public, farmers, fishers and researchers and academics.

Subsequently, in order to define the current state of aquaculture in Sardinia, collect necessary data to estimate the suitability, and to stimulate the involvement of some stakeholders' categories, semi-structured questionnaires were produced and distributed to all the farmers operating in Sardinia, both in lagoons and at sea. The structure of the questionnaire was conceived in four sections: (i) characteristics of the farming site, services and facilities present, (ii) species reared and breeding cycle, (iii) economic information, (iv) environmental pressures.

Results and discussion

During the two online meetings we collected few feedbacks about the AZAs identification, both by the decision makers, farmers and the general public which have not a proactive involvement. The interactive involvement was established with the researchers and academics which asked details about the process, but not giving advices about the selected areas. In our opinion, the participation and direct involvement of the stakeholders was affected by the COVID-19 restriction. Indeed, the meeting held online and not in presence not allowing us to involve properly and in a more active way the stakeholders.

Concerning the questionnaires, 39 responses from farmers, operating both at sea and in the lagoons, were collected. The farming site characteristics, services and facilities highlighted that the majority of farms have different facilities specific for aquaculture activities, such as rearing tanks, equipment for sorting and packaging live bivalves, and enclosed spaces in the lagoons. The farmed species resulted mainly seabream (64%), seabass (59%), mullets (49%), mussels (33%), oysters (33%), and clams (33%). Concerning the economic section, the results highlighted a varied situation, with a total annual turnover that exceeds 65 million euros, of which more than half, however, derives from a single cooperative. The marketing channels are linked to wholesaler (96.9%), direct sales (43.8%) and retail sales (37.5%). As regards the destination of the product, 35.9% is commercialised at local level, 43.6% regional level and 28.2% at national level.

Regarding the last section of the questionnaire, the environmental pressures at the farmer sites perceived by the farmers themselves, the results are reported in the figure 1. As one can see, the most frequent pressure is related with the damage from fish-eating birds (*i.e.*: cormorants).

(Continued on next page)

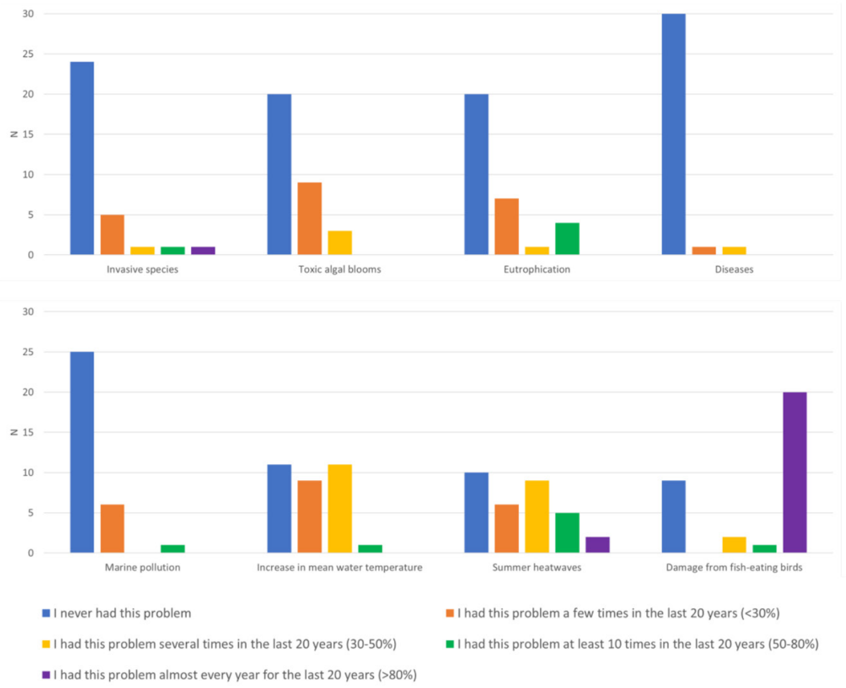

Figure 1. Frequency of the environmental pressures in the farming sites perceived by the farmers.

The results of the stakeholders' involvement in the AZA identification process underlined the initial reluctance within the participatory process, related also to the online meetings. In the next months, different strategical events in presence will be organised in order to present the draft of the AZA plan for the Sardinian region, and to inform properly the stakeholders about the project outputs, as well as asking again possibile useful feedbacks and suggestions for the AZA plan implementation.

AN EMERGENCY CALL TO DEVELOP "ACTION PLAN FOR CONSERVATION OF STURGEON FROM THE CASPIAN SEA"

M. Pourkazemi,

Guilan University, Caspian Sea Water Basin Research Institute
POB: 41996137776,Tel. +98-13-33690274,Rasht, Guilan – IRAN
Email: mpourkazemi17@yahoo.com

The Caspian Sea was the main basin for the world sturgeon resources in 3 decade ago, where produce more than 28000 tons of sturgeon meat and 3000 tons of caviar. Illegal catch, poaching, destruction of living or spawning sites, pollutions and lack of appropriate coordinated management of Caspian littoral states for unique shared stocks were the main reasons to lose sturgeon species to close to extinct level. Despite having a zero quota for commercial catch and export to international market, based on CITES agreement all sturgeon catch should allocated for rehabilitation and restocking as well as for research purposes. The objective of this paper is to demonstrate the critical situation of sturgeon resources in the Caspian Sea and call for collaboration, sharing the knowledge and experience to save the sturgeon in the Caspian basin before this unique species become extinct.

Since 1997, The Convention on International Trade in Endangered Species of Wild fauna and Flora (CITES), beginning from COP-10 to COP 14, tried to save the wild sturgeons resources by adopting several decision and resolution to allocate the catch and export quota for the Caspian Sea and all sturgeon basin, however no success were achieved for sturgeon conservation. It clearly demonstrated that sturgeon conservation and sustainable use can be solved by appropriate management of shared stocks. In other words regulation the catch or banning of international trade will only shift the market from international to national or regional trade!

In recent years in 2020 and 2021, the lowest number of sturgeon brood stocks were cached, other crises such as the climate change, shortage of rainfall and running water in rivers and remains very limited area for natural spawning caused that natural and artificial spawning reached to its minimum level close to zero for some sturgeon species. Totally less than 10 specimens of Ship (*Acipener nudiventris*) and Beluga (*Huso huso*) were cached last year and getting lower and lower by years.

Since 2011 a self-moratorium of sturgeon commercial catch and caviar export was established by the Caspian littoral states, unfortunately no progress have been observed on the status of sturgeon stock resources. It indicates that still illegal catch is on the place and market shifted mostly into the domestic level. As it proposed by CITES, the Caspian Sea littoral states should conduct a reliable stock assessment and share the information in order to evaluate the impact of fishing ban and trade control!. At present before the complete extinct of rare sturgeon an establishment of sturgeon live gene bank is necessary in order to develop a genetic bases for conservation and restocking program as well as for aquaculture extension.

In conclusion, before it become late it is needed to act immediately by 5 Caspian Sea littoral states to develop an standard joint Action Plan similar to sturgeon action plan established in Europe, and North America sturgeon species. To support for such initiative it should call for national, regional and international communities to join in to this long term management program for sturgeon conservation in the Caspian Sea. It is clearly approved that development of Action Plan is the first steps towards the resource management, It need strong political wishes and financial support as well as all necessary tools to implement the Action Plan.

There are excellent experiences by FAO for the Sustainable management of shared resources, IUCN guideline for Action Plan as well as the World Sturgeon Conservation Society (WSCS) published Decelerations on global sturgeon conservation (Ramsar, 2005 and Vienna 2019).These documents can be used to develop appropriate Action Plan and its implementation.

LONG-TERM CHARACTERIZATION OF ENVIRONMENTAL CONDITIONS AND MICROBIAL POLLUTION IN SHELLFISH GROWING AREAS OF EMILIA-ROMAGNA, ITALY

A. Pourzangbar[1*], T. Petochi[1], A. Bruschi[1], S. Rubini[2], M. Munari[2], M. P. Campolunghi[2], G. Marino[1]

[1] ISPRA Italian Institute for Environmental Protection and Research, Rome, Italy
[2] IZSLER Istituto Zooprofilattico Sperimentale della Lombardia e dell'Emilia Romagna, Italy

Introduction

Shellfish aquaculture is a vulnerable sector to climate change (Zgouridou et al., 2022). There is a clear evidence of climate change (e.g. temperature rise, extreme events) in the Emilia-Romagna region (AdriaClim, 2021) where 145 growing areas for shellfish are based (23% of total national shellfish areas). Monitoring of shellfish areas is routinely carried out by competent authorities to ensure environmental quality in transitional and marine waters and seafood safety.

In this study, historical dataset of *Escherichia coli* measured in harvested shellfish and growing waters of ER, were analyzed for cross correlations with environmental parameters and for implementation of a microbial diffusion model under climate change scenarios.

Materials and Methods

Field data collected between 2005 and 2021 from 24 nearshore stations in Emilia-Romagna have been analyzed for β-glucuronidase positive *Escherichia coli* (*E. coli*) in the shellfish and the growing waters (respectively ShellEcoli, WatEcoli). Statistical analysis has been carried out to characterize the frequency of noncompliance in the classified shellfish area and relationship with environmental conditions, focusing on water salinity (Sal), dissolved oxygen (O2), pH and surface temperature (T_w). Environmental data were collected *in situ* at the same shellfish sampling time. The frequencies have been calculated for ShellEcoli thresholds (MPN/100g) set by European Regulation 627/2019: 230 (class A, direct human consumption), 4.600 (class B, consumption after purification or relaying) and 46.000 (consumption after relaying over a long period) and WatEcoli (MPN/100ml).

The relationships between ShellEcoli and WatEcoli, and environmental parameters measured during official monitoring campaigns have been calculated. For each sampling station, temporal averages of ShellEcoli, WatEcoli, salinity, O2, pH and water temperature have been evaluated. Then, the cross-correlation coefficient (CC, aka Pearson correlation) has been calculated on the resulting set of data (temporal mean values for each station) to evaluate the relationship between ShellEcoli and WatEcoli and with respect to environmental parameters.

Results

The average of ShellEcoli at stations located in zone "A" is 79.97 MPN while it is 994.21 MPN for stations in zone "B". The maximum of ShellEcoli at various stations ranges between 1.300-9.200 MPN in zones "A" and 3500-54.200 MPN in zones "B". The mean percentage of measurements whose ShellEcoli exceeded 230, 4.600 and 46.000 MPN resulted 7%, 0% and 0% respectively in zones "A", and 42%, 5% and 0% respectively in zones "B".

Given WatEcoli, the average at stations in zone "A" is 1.1 MPN while it is 14.29 MPN for stations in zones "B". The maximum of WatEcoli at various sampling stations ranges between 48-230 MPN in zones "A" and 26-2.400 MPN in zones "B". Regarding CC values, the ShellEcoli and WatEcoli parameters do not show a significant CC (0.14).
A significant negative CC between ShellEcoli and salinity, O2 and pH (-0.71, -0.80 and -0.68 respectively) was found. While water temperature does not show a significant CC (-0.29). CC between WatEcoli and salinity, O2 and pH show similar results but with a weaker relationship (-0.72, -0.65 and -0.52 respectively), while water temperature does not show a significant CC (-0.15).

(Continued on next page)

Discussion and conclusion

Results proved that a robust classification procedure has been done in agreement with legal framework and limited noncompliance events were observed in shellfish A and B zones. Significant relationships between environmental (Sal, O2, pH) and microbial parameters were found. The absence of a clear correlation between WatEcoli and ShellEcoli may be related to a delay in the absorption of WatEcoli by shellfish. Data analysis also highlight the expected effect of salinity, dissolved oxygen and pH on *E. coli* concentration (both ShellEcoli and WatEcoli). The absence of CC between *E. coli* with temperature may be explained as even if WatEcoli is affected by environmental parameters, its concentration also depends on the actual quantity of *E. coli* discharged in the sea that is not constant. Hence, in order to carry out a clear analysis of the importance of the different environmental parameters it is necessary to follow *E. coli* pollution from its source of release. To overcome this challenge, historical dataset together with further near real-time *in situ* data will be used for the implementation of a microbial diffusion model. This represents an operative tool for regional authorities and industry sector to estimate the extension of shellfish growing areas potentially influenced by fecal pollution from point sources in present and climate change scenarios in order to develop adaptive strategies for the long-term sustainability of shellfish farming.

Introduction

Live feed is essential in marine aquaculture. Among the most important are the cultures, which are generally used in larval stages. Phytoplankton cultures have a significant bacterial load, including beneficial and necessary bacteria. Unfortunately, however, they can also harbour vibrios, including species potentially pathogenic to the organisms they are fed to (Prado et al., 2017, 2019a, 2019b).

In the case of bivalve mollusc hatcheries, the entire diet is based on phytoplankton, which is supplied to broodstock, larval cultures and seed. It is therefore a transversal compartment of the installation and influences all stages of the bivalves cultured.

This report presents the results of monitoring the presence of presumptive vibrios in the phytoplankton cultured in a batch system in a bivalve hatchery, to assess the risk of potential pathogen contribution by the feed pathway.

Materials and methods

The batch culture (BCS) is developed in the greenhouse of the Centro de Cultivos Mariños-CIMA (Ribadeo. Xunta de Galicia), in transparent polyethylene bags with a capacity of 40 l. The seawater used is filtered down to 1μm. The nutrient medium is Cell-Hi F2P Varicon Aqua, based on Guillard F/2 medium with trace elements, N, P and vitamins. The system has constant aeration and natural lighting, supplemented with LEDs to achieve a day:night photoperiod of 18:6. The microalgae grown are *Isochrysis*, *Diacronema*, *Tetraselmis*, *Phaeodactylum*, and occasionally benthic species. At times of peak demand, the required volume can be supplemented with a natural bloom obtained in the same facility.

Routine microbiological monitoring revealed the regular presence of suspected vibrios in the BCS mixture, to a greater or lesser extent, throughout the year. To verify this and identify the vibrios present, a specific control protocol was designed, sampling the mixing tank weekly, but also the monospecific ones. Temperature and pH data were collected for each sample to evaluate the possible influence of these parameters.

The samples were immediately processed on site, spread on plates of Thiosulphate-Citrate-Bilis-Bilis-Sucrose (TCBS), selective for vibrios, following Prado et al. (2014).

Results and discussion

Sampling was carried out during the year 2020, although unfortunately confinement and restrictions due to COVID-19 prevented us from obtaining the complete series.
In the first stage, January-February, *Vibrio splendidus*-like (VSL) was recurrently isolated. VSL bacteria have been linked to episodes of larval mortalities in hatcheries, although with an as yet unidentified pattern, different from the usual pathogens. The occasional detection of *Vibrio tapetis*, a known pathogen of adults but not of larvae, should also be noted.

At the beginning of the second stage, after containment by COVID-19, the pathogen *Vibrio alginolyticus* was already present. This species had been detected as predominant at times of high temperatures in the course of previous work. Initially, it was accompanied by VSL. During the summer, *V. alginolyticus* (/*V. parahaemolyticus*) persisted. Occasionally *V. mediterranei* and *V. harveyi* were detected.

In the September samples *Vibrio europaeus* was detected together with *V. alginolyticus*. It is likely that this pathogen was present previously, but overgrowth of *V. alginolyticus* at high temperatures may mask other species. Since its emergence, *V. europaeus* persisted together with *V. alginolyticus* until October. During September-October, the presence of *Vibrio neptunius* and, occasionally, the crustacean pathogen *Vibrio penaeicida* was also observed.

(Continued on next page)

Of the monospecific cultures, *Tetraselmis* and *Phaeodactylum* had the highest vibrio load, quantitatively and qualitatively, with a predominance of *V. alginolyticus*. The bacterial load in the cultures of *Isochrysis* and *Diacronema* with growth was generally low, although it should be noted that in addition to *V. alginolyticus*, *V. europaeus* was detected in these cultures.

A separate mention should be made of the occasional samples of natural bloom (August-October.) In all cases, the load was high or very high, and with a great diversity of potentially pathogenic vibrios for marine aquaculture, despite the small number of samples: *V. alginolyticus*, *V. neptunius*, *V. penaeicida* and *V. mediterranei*.

In summary:

- Monitoring shows that phytoplankton cultures carry vibrios, including potential marine aquaculture pathogens, which needs to be taken into account in the management of the facilities.
- In general, VSL is associated with the winter months (temperatures < 20ºC), while *V. alginolyticus* has a very important presence in the summer months (temperatures > 20ºC). *V. europaeus* was also detected.
- The pathogens described do not affect the microalgae, which act as "asymptomatic carriers".
- The load of vibrios in the phytoplankton is highly variable during the year, but also over the course of a week, probably related to factors such as cleaning protocols.
- It was observed that it was not uncommon to find a higher load in the distribution tube than in the mixing tank from which it started, indicating a possible point of bacterial persistence, probably related to the ability of many pathogens to form biofilms (Prado et al., 2019a).

Introduction

The Centro de Cultivos Mariños-CIMA (Ribadeo. Xunta de Galicia) specialises in the development of bivalve molluscs from spawning to the appropriate size for outdoor cultivation. They have been diversifying the bivalve species, so that the facility is active throughout the year, combining clam and solenid cultures, taking into account the most appropriate season for each of them.

The USC-CIMA group has been developing microbiological control protocols for the facility, which include the transversal compartments (seawater circuit and microalgae cultures), as well as the larval, post-larval and spat cultures. Controls of larval cultures are of particular relevance, and are mainly aimed at detecting possible pathogens that may condition their development.

In this scenario, an outbreak of a pathogen that has not been detected so far in the hatchery, in the past years of microbiological controls, has arisen and seems to affect all the species cultivated at the time of its appearance, and to persist in the system.

Materials and methods

The known aetiological agents of hatchery mortalities are almost all bacteria of the genus *Vibrio*. Considering this, and that sampling in a hatchery must be a simple and quick process that does not interfere with the work of the personnel, the Thiosulphate-Citrate-Bilis-Sucrose (TCBS) medium, selective for vibrios, was used in the samples taken in routinary controls. Recently, it has been decided to incorporate the general medium Marine Agar (MA) as a standard, in order to broaden the spectrum of bacterial detection. Samples were taken and immediately spread on plates in the hatchery and further processing was carried out by the USC-team. Bacterial isolation, preservation and identification of isolates followed the methodologies described in Prado et al. (2014).

Results and discussion

Results showed the occurrence of *Vibrio pectenicida* (Lambert et al., 1998; Nicolas et al., 1996) in samples from the spawning of the growing carpet shell clam in May. Since then, this pathogen has been detected in all the developing cultures during June-July, both carpet shell clam, *Ruditapes decussatus*, and wedge shell clam, *Donax trunculus*, as demonstrated by 16S rDNA sequences obtained for the isolated strains.

The extent to which the cultures have been affected is being assessed, but there were problems in any case. To our knowledge, this is the first detection of *V. pectenicida* in hatchery cultures of carpet shell clam and wedge shell clam.

The addition of the MA medium to the microbiological controls has allowed the detection of a pathogen that does not grow in TCBS, and is therefore outside the routine controls in this bacteriological medium.

Since its initial detection, its presence has been recurrent, regardless of the bivalve species and the different spawns obtained. This fact seems to point to the facility in some way as the origin. It is not likely that different batches of broodstock of different species would carry the same pathogen simultaneously. Hypotheses point to an entry of the pathogen via seawater or phytoplankton and perhaps subsequent persistence through mechanisms such as surface biofilm formation. In other works, we demonstrated the recurrent presence of vibrios in the phytoplankton, as well as the ability of aquaculture pathogens within the genus to survive in this specific environment (Prado et al., 2019a, 2019c). We have also experimentally demonstrated the ability of many pathogenic vibrios to form biofilms on surfaces under hatchery conditions (Prado et al., 2019b), which makes them highly resistant to many of the treatments commonly used in these facilities.

Introduction

All aquatic crustaceans are susceptible to Vibrio infection and the diseases associated with these pathogens may cause substantial production losses (de Souza and Wan, 2021). However, within crustaceans, some groups have been more deeply studies, while about others the literature is scarce. This is the case of the European clawed lobster, *Homarus gammarus*, clearly less well understood than their American counterpart, *H. americanus*.

Within the framework of the educational activities for aquaculture technicians of the IGaFA (Instituto Galego de Formación en Acuicultura), a lobster culture was developed using two different techniques. The sudden mortality of a batch led to microbiological sampling, especially aimed at identifying the vibrios presente, in order to gain a first insight into the microbiota associated with this species, with was little known until now.

Materials and methods

This report describes the microbiological sampling of a *Homarus gammarus* culture carried out at IGaFA's facilities in October 2020 using two different techniques. The classic method uses open flow, high water renewal and frozen food (Artemia). The alternative method is in stagnation with seawater renewal every two days, live food (Artemia) and phytoplankton (*Isochrysis galbana*). Both use seawater filtered to 1μm and sterilized by UV (Richards and Wickins, 1979, Uglem et al., 2006; Browne et al., 2009).

A massive mortality was observed in the alternative culture, close to the moult from stage II to III, not directly attributable to culture conditions. Samples were then collected for microbiological analysis from the alternative but also the traditional culture, as both were made with larvae from the same batch.

Samples were immediately processed in situ: larvae, gills, culture seawater, Artemia and *I. galbana*. Bacteriological media Marine Agar (MA) and Thiosulphate-Citrate-Bile-Sucrose (TCBS) were used. Bacterial isolation, preservation and identification of isolates followed the methodologies described in Prado et al. (2014).

Results and discussion

The bacterial load (TCBS, presumptive vibrios) of L4 larvae (alternative technique) was much higher than that of K1 (traditional system) larvae in larvae, gill and culture water samples.

In the TCBS samples of L4 larvae, *Vibrio rotiferianus-campbellii* and *Vibrio alginolyticus* grew as the major colony types. *Vibrio chagasii*, *Shewanella* and *V. rotiferianus-campbellii* were detected in gills. *Vibrio rotiferianus-campbellii* is also present in the culture seawater. In all cases, the same type of the Splendidus clade appears too.

In the K1 larval samples the bacterial load was lower and the diversity higher, sharing with the L4 larvae the presence of *V. chagasii*. It is interesting the presence of two potential pathogens, *Vibrio penaeicida* and *Vibrio alginolyticus,* both in the larvae and in the gill samples.

Looking for the origin of the vibrios, UV-treated seawater, microalgae and open-circuit seawater can be ruled out, with no growth in TCBS medium.

(Continued on next page)

As for the Artemia samples, the bacterial load (TCBS) of Artemia+cysts was too high, even in the 1 μl seeding, to differentiate specific colonies. In the sieved Artemia samples, *V. rotiferianus-campbellii* was isolated as a clearly dominant type, which points to this being the origin. *V. alginolyticus* was also detected, although in low concentrations. There was no growth in TCBS medium from the open-circuit water sample.

This is a first approach to the knowledge of the vibrios (and other bacteria) in hatchery cultures of *H. gammarus*, with the report of the presence of known aquaculture pathogens associated to mortalities, as well as a first attempt to elucidate the route of entry.

Introduction

In response to population growth and its effects on the environment and natural resources, there is a global need to exploit nutrient sources. Aquaculture is the fastest growing food production sector and accounts for 50% of the produced fish used for food (FAO, 2020). European catfish, *Silurus glanis*, has been farmed in Central and Eastern Europe for over 100 years. Absence of scales and of intramuscular bones and its favourable taste makes it an important species in the European aquaculture industry (Linhart, O et al., 2002).

Phosphorous (P) is an essential element involved in several life processes of fish such as energy transport and bone mineralization (Lall et al., 1979) In modern fish feeds, P is a limiting nutrient and supplementary mineral phosphates have to be added to the diet. The excretion of indigestible P leads to an accumulation of P in closed water systems, like recirculation aquaculture systems (RAS). Previous studies show that freshwater tilapia species can absorb P from the water through the gills and gastrointestinal tract (Al-Kholy et al., 1970; Urasa et al., 1987) and in other species, it has even been shown that the accumulation of this mineral in water can be beneficial for growth and normal skeletal development (Strauch et al., 2019; Van Bussel, C et al., 2013).

The objective of this study is to quantify the impact of water-borne P and dietary P at different concentrations on P-retention in juvenile European catfish. The final goal is to find an equivalence ratio to reduce the dietary phosphorus content by recycling the P accumulated in water. Differences will be assessed by quantifying fish growth, P-accumulation in the whole body and opercula and comparing the skeletal development and the total fat content.

Materials and methods

Juvenile *Silurus glanis* with an average starting weight of 1.79±0.17g were divided equally among 12 tanks of four independent RAS. The four RAS were set to contain four different freshwater phosphorous concentrations using mono-sodium phosphate (MSP): <10mg P/L, 40mg P/L, 80mg P/L, 120 mg P/L. In each system four different diets were tested with supplemental MSP: a control diet with 0.5% of total P (D1) and 3 increasing levels of dietary total P: 0.55%P (D2), 0.60% P (D3), 0.65% P (D4). Each diet was tested with three replicates per system at 23.4±0.7ºC in freshwater. Growth performance of each treatment was assessed after 21-days and 42 days. At trial end, fish were sampled and analysed for P in opercula, and whole-body P. Samples were also taken for skeletal development analysis by x-ray images (Fig.1).

Results (after 21 days)

Weight (g) of fish in different feeding and water treatments showed no significant difference after a 21-day growth period at either water P levels (P0, P40, P80, P120), or dietary P levels (D1, D2, D3, D4) (Fig. 2).

Discussion

At the end of the trial, data will be collected on whole body-P and operculum-P, fat content, skeletal development and final weight. An equivalency factor will be calculated which allows to reduce dietary P supplementation in relation to any given concentration of water-borne P.

Introduction

Koi herpesvirus disease (KHVD) can cause severe mortality in farmed carp populations causing major economic losses and is listed as a notifiable disease by the World Organization for Animal Health (Taylor et al., 2010; OIE, 2018). In the past years, the genetic architecture of resistance to KHVD has been widely studied (**Ødegård** et al., 2010; Tadmor-Levi et al. 2017; Palaiokostas et al., 2018, 2019; Zhao et al., 2020). Genome-wide SNP markers generated by RAD sequencing revealed significant QTL affecting resistance to KHVD (Palaiokostas et al., 2018) and led to optimizing genomic prediction of host resistance to KHVD in Amur mirror carp - AMC (Palaiokostas et al., 2019). The aim of this study was to assess the heritability estimates and the genomic prediction accuracy of such resistance using only a subset of SNP markers selected based on the previous genetic association to KHVD resistance (Palaiokostas et al., 2018; 2019) in two AMC populations.

Materials and methods

Two populations of AMC were created using a partial factorial design of 20 dams and 40 sires (Pop 1) and 27 dams and 29 sires (Pop 2). One-year fish (Pop 1 = 1,259 ind.; Pop2 = 1,325 ind.) were pit-tagged, phenotyped, fin clipped, and challenged to KHVD resistance as described in Palaiokostas et al. 2018. Restriction-site associated DNA sequencing (RAD-seq) generated 15,615 genome-wide SNP markers (RAD) on Pop 1 (Palaiokostas et al., 2019) from which 216 SNPs (LAB) with the strongest association to KHVD resistance were selected and genotyped on Pop 2. Genetic parameters and estimated pedigree (EBV) and genomic (GEBV_RAD and GEBV_LAB) breeding values were calculated and evaluated on Pop 1 using either pedigree, RAD or LAB markers and on Pop 2 using pedigree and only LAB markers. The heritability estimates and breeding values were estimated using the software package BLUPf90 (Misztal et al., 2014) and rrBLUP (Endelman, 2011). Moreover, 50 replicates of Monte Carlo 'leave-one-group-out' cross validation test was run to evaluate the accuracy of (G)EBVs on Pop 2.

Results

The percentage of total mortality was 66% for Pop 1 and 56% for Pop 2. After quality control (QC) of LAB markers, 183 SNPs (Pop 1) and 165 SNPs (Pop 2) were used for further statistical analysis. The heritability of KHVD resistance (Pop 1) as measured by survival on the underlying scale was estimated to be 0.61 using pedigree and 0.50 (RAD) and 0.36 (LAB) using genomic markers. On Pop 2, heritability estimates were 0.96±**0.09** (pedigree) and 0.68±**0.09** (LAB), and 0.78±0.25 (pedigree) and 0.55±**0.16** (LAB) with a model containing a random maternal effect. The phenotypic correlations (Pop 1) between EBV vs. GEBV_RAD, EBV vs. GEBV_LAB and GEBV_RAD vs. GEBV_LAB were very high: 0.91, 0.81 and 0.86, respectively. The phenotypic association between EBV vs. GEBV_LAB on Pop 2 was 0.79 and on average, GBLUP accuracy (0.66) was 7% higher than pedigree-based BLUP accuracy (0.62).

Discussion and conclusion

Heritability estimates were very high regardless of the challenge-tested populations of AMC and regardless of using the pedigree or the genomic relationship matrix. It repeatedly suggests that resistance to KHVD is a highly perspective trait to be genetically boosted by a selection program (**Ødegård** et al., 2010; Tadmor-Levi et al., 2017; Palaiokostas et al., 2018; Zhao et al., 2020). On the other hand, genomic heritability (Pop 1) using reduced LAB markers decreased (0.36) in comparison to the full density RAD markers (0.50). Still, it suggests that the selected subset of SNP markers captured a significant part of genetic variation for resistance to KHVD. Furthermore, the implementation of a subset of LAB markers into a genomic selection would allow a gain in accuracy of 7% compared to PBLUP selection on Pop 2, and with only

(Continued on next page)

a minor loss of accuracy when compared to GEBV_RAD (Palaiokostas et al., 2019) using a full SNP panel on Pop 1. It may be concluded that selected subset of SNP markers previously associated with KHVD resistance might be used for more accurate prediction of breeding values for KHVD resistance in different populations of AMC. Hence, it might be an interesting strategy to achieve the optimal balance between economic cost (number of SNPs to be genotyped per fish) and selection accuracy, as also recently investigated by e.g., Kriaridou et al. 2020 and Griot et al. 2021.

Introduction

Peptides are considered advantageous for larvae improving physical properties (Piggot et al. 1982) and nutritional value of the diet (Carvalho *et al*. 1995). Reported to have a beneficial effect in fish performance (growth, survival) and skeletal development in several species (Szlaminka *et al*. 1993, Cahu and Zambonino 1995, Zambonino *et al*. 1997), they allow effective and early substitution of live with inert diets, reducing production cost. Raised hypotheses suggest protein hydrolysates' potential to enhance better absorption of the protein intake or fulfillment of amino acid requirements during the early larval stages (Cahu *et al*. 2003). Recently, a correlation of hydrolysate incorporation in fishmeal and regulation of skeletogenesis procedures has been described (Gisbert *et al*. 2012). Simultaneously, myogenesis can be affected by similar diets (Canada *et al*. 2018), in terms of muscle growth, degree of muscle fibers recruitment and hypertrophy activation.

Given the clear effect of peptides on musculoskeletal structure and activity in fish, the goal of the present study is to answer whether and how dietary peptides can prevent or reduce the occurrence of lordosis in a model fish species undergoing a swimming challenge at early juvenile developmental stage.

Materials and methods

Two experimental (P6, P12) and one control (C) diets were tested in triplicate, from the stage of yolk-resorption up to early juveniles in zebrafish (Fig. 1). Two feeding regimes were followed, with the incorporation (A) or not (B) of a short live feed period at the beginning. To evaluate bones' integrity against haemal lordosis induction, early juveniles with normal skeletal development were subjected to swimming challenge test (SCT) according to Printzi *et al*. (2021). Samples were collected immediately after the end of the SCT. Study of juvenile quality and the outlining of bone changes were succeeded through means of whole mount staining, histology and gene expression analysis of selected targets.

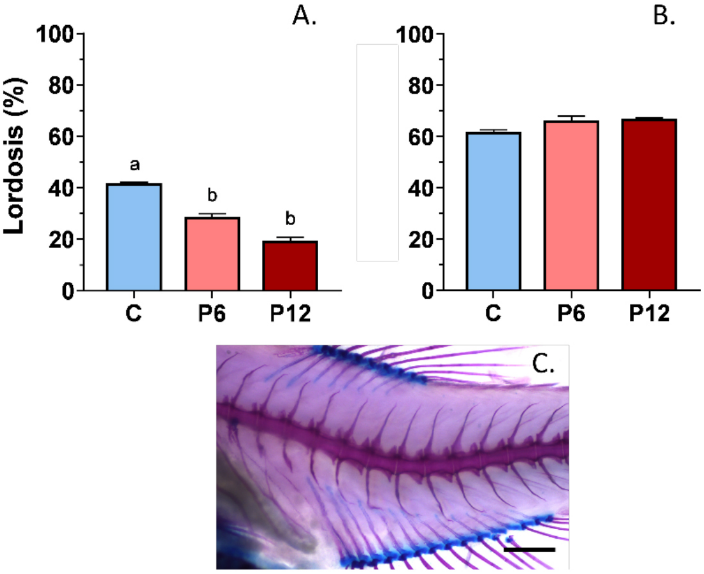

Figure 1. Lordosis frequency after SCT among the experimental diets on zebrafish juveniles, reared with (B) or without (A) live food incorporation. Lack of common letter indicates statistically significant differences.

(Continued on next page)

Results and Discussion

Peptide diets can alter the frequency of exercise-induced lordosis (Fig. 1C) observed after the end of the SCT regardless of the feeding regime. Exclusive supply of the dry diets (Fig. 1A) led to a decreased frequency of lordosis ranging from 41.9 ± 0.2 at group C to 28.6 ± 1.3 and 19.4 ± 1.2 at P6 and P12 respectively. In contrast, incorporation of live feed resulted in a common increased presence (61.8, 66.4 and 67.1%) of lordotic incidents between the diets (Fig.1B).

The correlation of harmonious axial development with incorporation of small peptides in fish diets seems to be coincident with the up to now findings of the present study. Understanding potential mechanisms through which peptides affect the musculoskeletal system is raised as a target. Direct beneficial effect for aquaculture will be integration of peptides in larval diets to maintain the optimum product quality. In addition, a possibility of skeletal deformities recovery (Fragkoulis et al. 2019) through proper nutritional handling will arise on a vertebral model species.

Introduction

Over the last decades, harmful algal blooms (HABs) have increased in frequency, duration, and severity worldwide, in association with storm events, changes in upwelling dynamics, climate change, and anthropogenic activity (i.e., animal waste inputs, agricultural runoff, growing aquaculture industry in coastal areas) (Grattan et al., 2016; Hallegraeff, 2010). Bivalve molluscs, by ingesting large amounts of phytoplankton, during HABs could become unsafe for human consumption. Dinoflagellates blooms of the genus *Dinophysis*, which produce okadaic acid (OA) causing Diarrhetic Shellfish Poisoning (DSP), are endemic to the Mediterranean coasts of Europe. To protect the consumers, European Union established mandatory monitoring of shellfish production areas on a weekly basis (EU Commission, 2019). Whenever the OA concentration in shellfish exceeds the established legal limit (equal to 160 µg kg-1 of OA equivalents, EU Council, 2004), shellfish harvesting activities are compulsorily suspended. The mussel farming areas along the Italian coasts of the Northern Adriatic Sea are affected by recurrent DSP events, in particular the Gulf of Trieste (France et al., 2006) and the marine area facing the Po River Delta (Veneto, Italy) (Pistocchi et al., 2012). In these areas, the main detected toxic species are *D. acuminata*/*D. sacculus* in spring-early summer, and *D. fortii*/*D. caudata* in late summer/autumn, associated with a predominance of OA in mussels. The impact of *Dinophysis'* blooms is expected to increase in the future, together with the expansion of mariculture. Mitigation of such phenomenon should prioritize research on the genetic regulation of toxin uptake pathways, absorption, and elimination mechanisms, and on predictive models for OA accumulation in bivalve molluscs.

This study aimed at developing a machine learning predictive model for OA accumulation in farmed Mediterranean mussel (*Mytilus galloprovincialis*) in the coastal area off Po River Delta (Veneto, Italy), based on oceanographic data measured by means of remote sensing. The results of the predictive model will be integrated into an online early warning tool available to shellfish farmers within the framework of AQUACULTURE2020 and VALUESHELL projects, funded by the Italian Ministry of Agriculture (MIPAAF).

Materials and methods

The data deriving from the official monitoring activities carried out from 2016 to 2020 to verify the accumulation of OA in the shellfish production sites located in the marine areas overlooking the Po River Delta were evaluated and analyzed. In this study, offshore sampling stations were considered those with the highest satellite coverage. The following physical and chemical parameters relative to the 6-weeks before each mussel sample (weekly mean, minimum, maximum, variance, skewness, and kurtosis) were associated with each OA essay: chlorophyll concentration (Chl, mg m^{-3}), Dinophyta contribution to total [Chl] (mg m^{-3}), eastern and northern components of wind direction (m s^{-1}), thickness of water column mixed layer (m), NH_4 concentration ([NH_4], mmol m^{-3}), NO_3 concentration ([NO_3], mmol m^{-3}), dissolved O_2 concentration ([O_2], mmol m^{-3}), PO_4 concentration ([PO_4], mmol m^{-3}), nitrates/phosphates ratio, daily precipitations (mm day^{-1}), salinity (psu), surface water temperature (°C), eastern and northern components of sea current (m s^{-1}), wind pressure on sea surface (Pa), solar radiation (Wh m^{-2}).

Data were classified according to a binary system: "1" for samples with a toxin value above the limit of quantification of the analytical method (LOQ = 40 µg kg^{-1}), "0" for samples with a toxin value below the LOQ. Data were divided into 1) train set, consisting of 1057 samples, collected before 2019 (of which 155 in class "1"); 2) test set, consisting of 429 samples, collected after 2019 (of which 89 in class "1"). Given the unbalanced dataset (dominance of the class "0"), the "1" category was oversampled using SMOTE (Synthetic Minority Oversampling Technique, Chawla, 2002). Different machine learning algorithms were evaluated with a cross-validation procedure, leading to define the LightGBM algorithm as the most suitable (Ke, 2017).

(Continued on next page)

Results and Discussion

The results of the classification algorithm on the test set showed an accuracy of 85%. Further analyses showed that false negatives were mainly associated with relatively low levels of toxins (< 100 µg kg^{-1}), while true positives had higher mean values of toxins: the algorithm tended to classify low concentrations of OA as negative samples. Since exact toxin concentrations for negative samples were not available (the LOQ of the analytical method was 40 µg kg^{-1}), it was not possible to analyze trends in false positives (e.g. concentrations just below the LOQ value, classified as positive). However, they tended to occur in August.

Further steps to improve the performance of the model will be: 1) to increase the number of available data, mainly of positive samples (class 1); 2) to correlate data on OA accumulation in mussels with data on *Dinophysis* spp. concentrations in the water column; 3) to include data on mussel physiology (e.g., dietary preferences depending on the structure of the phytoplankton community) in the model.

Once optimized, the predictive model will be integrated into the AQUAX online platform (https://gis.aquaexploration.com) as an early warning system capable of alerting mussel farmers 2/3 days before a highly probable OA accumulation event.

EFFECT OF DIFFERENT STUNNING METHODS ON THE SHAPE OF *Salmo carpio* (L. 1758) FILLETS DURING *Rigor mortis* AND ICE STORAGE

Introduction

There is growing interest among producers and consumers in ethical practices that safeguard fish welfare. Poor management during the stunning/slaughter phase can represent a stress condition, greatly compromising fish fillet quality during storage [1,2]. This has led aquaculture to adopt a comprehensive approach to ensure humane stunning and slaughtering practices and preserve fillet quality [3,4]. Slaughter-related stress generates H^+ ions associated with a high production of lactic acid. Consequently, pH diminishes in the early *post-mortem* stage, affecting fillet quality, *e.g.*, water holding capacity and texture [5-7]. Fish response to slaughter-related stress is species-specific. Thus, one of the most ambitious challenges is to find the best-performing stunning/slaughtering procedure for each species. Further studies are needed, especially for species poorly studied but with a high market value. This study was focused on "carpione del Garda" (*Salmo carpio* L.), an endemic salmonid of Lake Garda (Italy), which has been inserted as "critically endangered" into the Red List of Threatened Species [8]. Local farmers made several attempts to rear this species, whose fillets have a high market value (35-40 €/kg), but *S. carpio* is still considered a not domesticated species, and the farming protocols follow those of rainbow trout, including stunning/slaughtering procedures. To increase useful knowledge on *S. carpio*, this study aimed at evaluating the effects of two stunning methods commonly utilized for salmonids (i.e., electrical stunning and immersion in iced water) on fillets' shape, during *rigor mortis* in refrigerated storage. An automatic image analysis protocol for the evaluation of fillet shape changes was developed to that end.

Materials and methods

The experiment was carried out at the Experimental Fish Center of Fondazione Edmund Mach (San Michele all'Adige, IT) (Min. Aut. n. 22/2019-UT) and the protocol was approved by Ethics Committee. A total of 81 individuals (347.4±68.9 g) were randomly sorted into three experimental groups of 27 fish each (9 fish per replica). The stunning methods tested were: 1) a lethal dose of anesthetic (AN; 400 mg L^{-1} of MS-222), used as control; 2) electrical stunning in an EG100 Fishkill (ES; 24 V, 4 seconds; Scubla, UD, Italy); 3) cold shock by immersion in iced water (ICE; tank 240 L, -3°C). After stunning, all fish were killed by percussion by trained personnel. From each group, 6 fish (2 for replica) were allocated to *rigor index* (RI) evaluation until *rigor* resolution [9]. The right fillets of 9 fish for each group (n=27, 3 for replica) were photographed at different time points (0, 3, 6, 9, 12, 15, 21, 48, 72, 96, 168 and 192 h *post-mortem*). Fillet images were captured with a 12 M-pixels camera, in a lightbox and illuminated with a 6000 K lamp covered with a light diffusor. All the images (n=324) were calibrated using a 24-color patch Color Checker. Using "auto-threshold" and "analyze particles" functions of ImageJ [10], binary images were obtained, and the following geometric features were measured: area, perimeter, length, height, and circularity of the fillet [$(4\pi \text{ Area})/(\text{Perimeter})^2$]. RI data were analyzed using a Generalized Additive Model (GAM) [11], using treatments (AN, ES, ICE) and replicates (*i.e.*, tanks) as factors, and time and individuals as smoothers. Two-way PERMANOVA [11] was carried out to test for significant differences among treatments during the time. Multivariate analysis of variance (MANOVA) was used to test the differences in shape parameters means between groups at each time. Analyses were performed in R-4.2.1 environment.

Results and Discussion

RI evolution (onset, duration, and strength) was significantly different among treatments (t=3.51, p<0.01), but not among replicates (t=0.64, p=0.52), being faster in ES and ICE than in AN, and achieving the highest intensity after 21 and 28 h *post-mortem*, respectively in ES and ICE. Shape features changed accordingly to RI evolution, with a slight delay. Significant differences in shape geometric features were evident among stunning methods (F=5.82, p<0.001), but not in time (F=1.23, p<0.21), nor interaction between the two factors (F=0.75, p=0.999). The main shape changes were linked

(Continued on next page)

to the *rigor* onset and resolution, associated with a contraction phase followed by a relaxation one. During the contraction phase, in all groups, a reduction of the fillets' area (*i.e.*, shrinkage) was observed, while during the second phase fillets tended to recover their initial area in all treatments. In any case, fillets recovered their initial area with a more marked reduction in AN (-5.88%) and ICE (-5.70%). Perimeter experienced a reduction, not recovered in the relaxation phase, more evident and significant in ICE (-7.73%, $p<0.05$) and ES (-7.52%, $p<0.05$) than AN group. A fillet shortage was also observed, more evident in ICE (-9.89%), and lengths did not recover their initial values ($p<0.05$) in all the groups. Height and circularity had an opposite trend, both increasing during the contraction phase and decreasing in the relaxation one. In all groups, initial height was almost recovered at the end of the period considered, as variation was not significant between T0 and T192. On the opposite, initial circularity was recovered only in AN, while ICE (11.29%) and ES (13.11%) showed significantly different values between T0 and T192.

Introduction

Being sessile filter feeders, sponges have developed a wide range of unique chemical defences to deter pathogens and fouling organisms, representing a great reservoir of chemodiversity (Di Cesare Mannelli et al., 2021). The interest of the scientific community for this group as a source of bioactive compounds have raised exponentially over the past decades, leading to a critical decline of sponge populations worldwide (Webster, 2007) due to its uncontrolled harvesting together with the more and more frequent disease outbreaks (Di Camillo & Cerrano, 2015).

Chondrosia reniformis is a peculiar sponge species containing a high abundance of collagen, a protein of great interest for the pharmaceutical and nutraceutical industries. Effective cultivation methodologies are under development in several international laboratories. The implementation of cost-effective marine culture plants of the species could provide the opportunity to develop local blue economies, while protecting *C. reniformis* wild stocks.

Material and methods

Experimental plants for the cultivation of *Chondrosia reniformis* were set at 20 m depth using old artificial reefs along the coast of Alassio (Ligurian Sea, NW Mediterranean). Each module consists of a concrete cube of side 2 m, and the modules are organised in groups of five blocks, forming a pyramidal system. In total, 80 fragments were transplanted on 16 horizontal faces of the blocks (Fig. 1).

Structure from Motion (SfM) photogrammetry allowed the creation of three-dimensional (3D) digital reconstructions from a series of overlapping images using Agisoft software. This technique was applied to estimate sponge volume, and to monitor regeneration of the sponge cuts for a period of 9 months. From volume data, annual increment of sponge biomass (expressed as grams of dry weight per year per initial volume of sponge) and collagen production (grams of collagen per year per initial volume of sponge) have been estimated, using the approaches applied by Morganti et al. (2019) and Pozzolini et al. (2018), respectively.

Results

From the 80 *C. chondrosia* fragments transplanted, 40 were used to estimate yearly changes. 92.3% of the 40 cuts successfully attached to the substrate and all of them showed an increment in volume of 120% ± 63.14% per annum. Which means an estimated production of 125 ± 90 gDW year^{-1} dm^{-3} in terms of biomass, and an estimated production of 37.3 ± 27 g collagen year^{-1} dm^{-3}, considering the average yield established by Pozzolini et al., 2018.

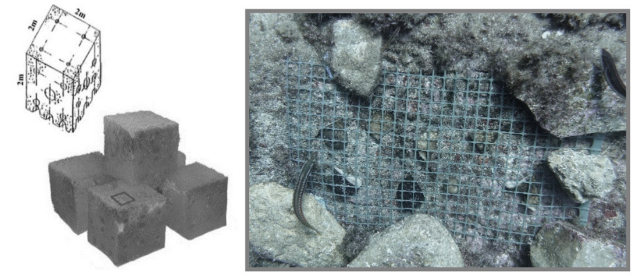

Fig. 1. Artificial structures used as substrate for mariculture implants of *Chondrosia reniformis*.

(Continued on next page)

Discussion and conclusion

The mariculture of *C. reniformis* has been repeatedly identified as a challenge in the literature, especially over horizontal substrates given its high motility (Gökalp et al., 2022). Our mariculture approach on artificial substrates highlighted once again the potential of this species as a source of marine collagen, by obtaining high re-attachment, survival and growth rates from the sponge explants.

The application for the first time of SfM-photogrammetry to monitor the growth of this species resulted in a complete success. Thanks to this technique, volume and surface fluctuations through time could be recorded along the experiment. The application of non-invasive 3D monitoring tools is therefore crucial to understand possible seasonal changes and growth patterns of this species over long-term series.

Our results showed that fragments of this sponge can double their volume in one year, suggesting the feasibility of the tested cultivation technique. Nonetheless, environmental data still need to be better analysed to evaluate the best local conditions to guarantee long-term investments in *C. reniformis* aquaculture.

ALTERNATIVE PROTEINS OR ACTIVE INGREDIENTS? COMPARISON OF DIFFERENT DIETS ON *Dicentrarchus labrax* FILLET QUALITY AND OXIDATIVE STABILITY

L.F. Pulido-Rodríguez*, G. Secci[1], E. Tibaldi[2], G. Parisi[1]

Department of Agriculture Food Environment and Forestry (DAGRI), University of Florence, Via delle Cascine 5, 50144 Firenze, Italy
E-mail: linafernanda.pulidorodriguez@unifi.it

In recent years, aquaculture has proven to be the fastest growing sector in the agri-food industry. The use of non-conventional protein source responds to the need of the aquafeed sector to replace conventional dietary protein sources with eco-friendly and nutritious ones potentially acting also as functional ingredients. Considering the recent researches, *Hermetia illucens* meal (HM) and poultry by-product meal (PBM) can be considered valuable alternative protein sources fitting the ecological transition towards a circular bio-economy (Pulido-Rodriguez et al., 2021). Recently, dried marine microalgae biomass (MA) and red swamp crayfish meal (RCM) have also been seen as interesting supplements due to their valuable profile in n-3 polyunsaturated fatty acids (PUFA) and content in vitamins, minerals, and natural antioxidants (Zarantoniello et al., 2022). Due to this, the aim of the present trial was to evaluate the effects of five experimental diets contained the aforementioned protein sources on European sea bass fillet quality and oxidative stability during 60 days of frozen storage.

Material and methods

Two-hundred and seventy European sea bass (*Dicentrarchus labrax)* were equally and randomly distributed in 15 tanks (300 L) and maintained under controlled conditions during the whole experiment (T 23.6 ± 0.70 °C; salinity 30 ± 1.4 g/L; dissolved oxygen 6.1 ± 0.38 mg/L). Five grossly isoproteic (45%), isolipidic (20%) and isoenergetic (22 MJ/kg) diets, deprived of fish meal, were formulated starting from a vegetable protein-based feed and distributed to fish in 3 different tanks for each diet. The diets were prepared by partially replacing the plant proteins with MA (10%, 2:1 *Tisochrisis lutea* and *Tetraselmis suecica*; MA10), RC (10%, RC10), PM (20%, PM20) and HM (20 or 40%, HM20 and HM40, respectively). Fish were fed the experimental diets twice a day for 21 weeks. At the end of the trial, 8 fish per group were slaughtered by trained personnel and fully characterized during a storage trial. Immediately after death, the fish were filleted and the right-side fillets were analyzed at 0 day of storage (S0), while the left-side fillets were individually inserted into plastic bags and stored at -10 °C for 60 days (S60) in order to observe possible variation on lipid oxidation during the storage period at sub-zero temperature. Analyses of color (CIE, 1976)colour difference equations and metric colour terms","type":"article-journal"},"uris":["http://www.mendeley.com/documents/?uuid=56c606e1-e157-4327-a159-73e33dc10bc8"]}],"mendeley":{"formattedCitation":"(CIE, 1976, lipid content (Folch et al., 1957), fatty acid profile and lipid oxidation (Bruni et al., 2021) were assessed on the S0 and S60 fillets. A two-way ANOVA (main effects: diet, D; storage, S and their interaction, D×S) was applied for data analysis, followed by a Tuckey post-hoc test to compare the mean values considering a significant difference at $p<0.05$.

Results and discussion

Microalgae and red crayfish are rich in carotenoids which are responsible for flesh pigmentation (Pulcini et al., 2021). The analysis showed that the yellowness index (a^*) was increased by MA diet ($p<0.0001$), while the other diet did not affect any of the considered parameters, analogously to those found by Pulido-Rodriguez et al. (2021). The diets also modified both lipid content and the fatty acid profile of fillets. The HM40 fillets were fatter than fillets from MA10 and RC10 groups and they had the highest SFA content. The MA10 had the highest value of n-6PUFA and not different n-3PUFA level, but the n-3 fatty acids were singularly affected. For instance, HM20 and MA10 fillets were the richest in C18:3n-3 while HM40 in C20:5n-3. In this trial, it was found that the carotenoids present in the MA diet were able to preserve the fillets from lipid oxidation during the 60 days storage at -10 °C. In contrast, fillets from E. sea bass fed RC diet reached the highest value of lipid oxidation at the end of the storage. Hence, while the level of RC inclusion did not seem to preserve the quality characteristics of the fillets, the microalgae mixture could be taken into consideration in the case of fish intended for preservation or handling rather than for consumption as fresh.

Introduction

Senegalese sole (Solea senegalensis) have good aquaculture potential. However, sustainable development has been hindered by a reproductive failure of cultured broodstocks, hatched and reared in captivity (Duncan et al., 2019). Cultured males exhibit a behavioural dysfunction and do not participate in courtship to fertilise eggs. A behaviour termed the "Follow", behaviour where sole follow each other in a procession and that is unique to the courtship has been associated to successful spawning. High participation in the "Follow" behaviour appears to indicate spawning success. The aim of the present study is to automate the identification of the "Follow" behaviour in videos of Senegalese sole broodstocks and to track individual sole involved in the behaviours.

Materials and Methods

The videos used for the behavioural analysis were taken from a broodstock tank that contained both wild and cultured breeders, formed with 2 wild males, 5 wild females, 5 cultured males and 4 cultured females (mean weight 1,192.61 ± 170.70 g). The broodstock had been held together during 4 years under natural photoperiod and simulated temperature conditions, fed daily and water quality was maintained optimal with a recirculation system (IRTAmar®). Video recording was during April at the peak of the reproduction season. The videos were recorded with cameras installed just below the water surface in the corner of the broodstock tanks and connected to a video recorder. The period recorded was during the night (19:00-20:00) with night illumination (Carazo et al., 2013) and when the locomotor activity of fish was highest, due to the reproductive behaviour. For the purpose of this study, five video clips of the fish participating in the "Follow" behaviour were randomly selected from 30 video clips of the "Follow" behaviours taken from days with spawning that had been previously identified and analysed. As control videos, a further five video clips were selected that were of the same group of fish and recorded during the same time period. These control video clips had fish swimming individually that were not participating in the "Follow" behaviour.

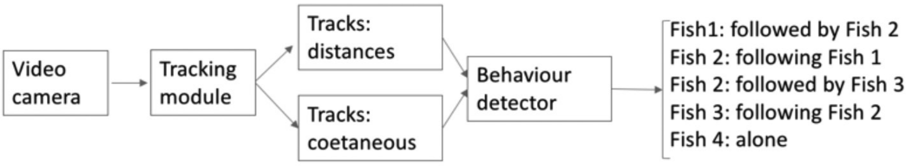

Figure 1. Main scheme of the tracking system.

Figure 2. Two shots from the fourth video. The video tracker has detected four fish.

(Continued on next page)

Results and Discussion

The main scheme (Fig. 1) of the tracking system included a tracking module that keeps the information of the tracks of all the fishes, which is updated with each frame. Tracks are composed of a vector that each element keeps the current position (x,y), the time and the fish identification. Note that the camera does not visualize the whole tank and for this reason, tracks have a beginning (when the fish appears in the visual field) and an ending (when the fish disappears from the visual field).

Ideally, the position has to be the centre of the fish. Note that this position is represented in 2D-camera coordinates. The track distances were computed using the algorithm called Dynamic Time Wrapping (DT) (Petitjean et al., 2011). This algorithm deduces a distance between vectors or discretised functions. Speaking in a plain language, the idea is to deduce the cost of transforming a vector into another considering that elements in the vectors have to keep the same order. It is based on three main edit operations, viz, substitution of local elements, deletion of elements in the first vector and insertion of elements in the second vector. In our case, we have only considered the 2D position of the tracks and the time has been discarded in this stage. Moreover, since tracks can have very different lengths, the final distance is normalised by the average length of the two involved tracks. The time information in the tracks is taken into consideration to deduce if tracks are coetaneous. We consider that two tracks are coetaneous if the beginning of both tracks are inside a specific temporal window TW.

The final output of the system depends on the track distances and also on the information if both tracks are coetaneous. We consider Fish 2 follows Fish 1 if they are coetaneous, the track of Fish 2 begins later than the track of Fish 1 and the distance between tracks is smaller than a threshold DT. On the contrary, we say that a Fish has an "alone" behaviour if the distance between it´s track and the rest of tracks that are coetaneous to it is larger than the threshold DT. Therefore, a DT lower $DT < 40$ indicated a fish was considered to have a "Follow" or "Follower" behaviour and contrarily, larger or equal to $DT \geq 40$ indicated an "alone" behaviour. Two shots from the fourth video in which there is a "Follow" behaviour, show that Fish 1 is followed by Fish 2 and Fish 3. Moreover, Fish 4 stays alone the whole video and does not relate to the other fish. Thus, we consider the four fish have different behaviours. Fish 1 is a "Followed", Fish 2 is a "Follower" and a "Followed", Fish 3 is a "Follower" and Fish 4 is an "Alone". The DT values for Fish 1, 2 and 3 in relation to each other ranged from 15.9 to 25.3, while distances between Fish 4 and Fish 1, 2 and 3 ranged from 85.6 to 97.2.

These promising results demonstrate a simple computer vision system to identify different behaviours related to courtship that can be used to detect and predict spawning behaviour in Senegalese sole. This system can be further developed to automatically detect the behaviours in real time without the need to make video recordings.

ESTIMATION OF BIOFILM ACTIVITIES ON BIOFILTER CARRIERS FROM RECIRCULATING AQUACULTURE SYSTEM BY RESPIROMETRY

Wanhe Qi*, Peter Vilhelm Skov, Kim João de Jesus Gregersen, Lars-Flemming Pedersen

DTU Aqua, Section for Aquaculture, Technical University of Denmark, Willemoesvej 2, DK-9850
E-mail: waqia@aqua.dtu.dk

Introduction

Biofilm, the aggregates of microbial layers that are attached on the surface of biofilter carriers, plays a central role in nutrients removal in recirculating aquaculture system (RAS) to achieve high degree water reuse for fish production (Chen et al., 2006). The bacterial activities in biofilm are of great importance for surveillance and management of RAS biofilter, but cannot easily be measured. Moreover, a biofilm detachment process and laboratory equipment are required for current methods to characterize the biofilm, which seem unsuitable for on-site application in a RAS facility. The present study was conducted with an aim to develop a simple and reproducible method that allows *ex-situ* estimation of biofilm activities without destroying biofilm integrity.

Materials and methods

Three different types of biocarriers, extruded polypropylene (EPP), injection molded polypropylene (IMPP) and polymeric foam (PF) from biofilters connected to the same RAS were tested in our tailor-made respirometry system. The oxygen consumption rates of biofilm in respirometric chambers packed with biocarries were measured after intermittent spiking with either ammonium, nitrite or acetate. The standard substrate degradation batch kinetics tests for evaluating biofilter performance were also conducted to confirm the feasibility of our proposed method as a means to assessing biofilter performance.

Results

Results showed that the method allowed estimation of endogenous respiration rates, as well as respiration of ammonia-oxidizing bacteria (AOB), nitrite-oxidizing bacteria (NOB) and heterotrophic bacteria (HB) in biofilm. The highest activities, calculated and standardized as volumetric oxygen consumption rate (VOCR), were found in PF with values of 764, 677 and 166 g $O_2 \cdot m^{-3} \cdot d^{-1}$ for AOB, NOB and HB, respectively (**Figure 1**). Furthermore, substrate degradation batch tests matched respirometric tests well for all three tested carriers to evaluate biofilter performance (**Figure 2**).

Discussion and conclusion

The higher activities of AOB, NOB and HB in biofilm of PF carriers suggest that PF carriers could achieve more effective removal of ammonia, nitrite and organic matter in RAS water treatment. This is in support of findings from Shitu et al., (2020) that found PF carriers achieved higher nitrification performance than plastic media in MBBR treating RAS wastewater. The deviation between the predicted and observed values for biofilter performance for PF carriers may be the result of different factors, such as that i) respirometric tests and nitrification batch kinetic tests were performed separately, ii) differences in hydraulic conditions in reactors (closed respirometric chamber vs. open beaker) might have an influence on oxygen and substrate diffusion, iii) a part of ammonia, as well as small amount of electrons from TAN oxidation and nitrite oxidation processes are used for cell synthesis, which has a lower oxygen demand than predicted by the theoretical oxygen demand (Liu and Wang, 2012). In conclusion, the proposed method allows estimating activities of biofilm attached on biofilter carriers from a freshwater RAS by measuring oxygen consumption rates following substrate spikes. The designed intermittent respirometer platform achieved replicated and non-invasive oxygen measurement without disturbing biofilm integrity. This method allowed complete estimation of metabolic activity of endogenous respiration, NOB, AOB and HB in biofilm within less than five hours. Comparison study with standard substrate degradation kinetic batch tests for assessing biological processes in biofilter confirmed the feasibility of our proposed method to evaluate the biofilter performance. Our study provides a potential tool of monitoring and diagnosis for RAS biofilter and a better understanding of biofilm on the carriers, which would benefit biofilter design and water quality management in RAS.

Introduction

The REMEDIA Life Project (REmediation of Marine Environment and Development of Innovative Aquaculture: exploitation of edible/not edible biomass) funded by the European Community foresees, for the first time in Europe, the use of an integrated multi-trophic aquaculture system (IMTA) where a new set of bioremediator organisms, such as polychaetes, porifera, mussels and macroalgae, are reared/cultivated in addition to fish breeding. Macroalgae, in particular are included in the set of bioremediator organisms because some species are able to reduce the nitrogen and phosphorus load produced by fish farming. The project aims to demonstrate that the bioremediation technologies developed can be successfully applied to an industrial mariculture plant in an confined environment with positive effects in the specific sector and with the aim of the exploitation and the zero-kilometer marketing of the biomass produced. In particular, the biomass of macroalgae produced can be used for the extraction of active compounds or as food useful in the dietetic field. In order to verify the safety of macroalgae to be used as food the present work was aimed to verify the presence and potential removal of microplastics (MPs), which are among the most hazardous emerging pollutants (Sharma and Chatterjee, 2017), in *Chaetomorpha linum* (O.F Müller) Kützing (Chlorophyta, Cladophorales), one of the seaweeds collected in the Mar Piccolo of Taranto (Northern Ionian Sea, Mediterranean Sea) and then transferred to the aquaculture farm to be cultivated in the IMTA system.

Materials and Methods

Chaetomorpha linum, was collected during the season of maximum growth. Three replicates of about 500 g of fresh material were harvested by a rake at a depth of 50 cm. Before the placement of macroalgae in the plant, the presence and removal of MPs, from the thallus was evaluated by performing three extractions with a sodium chloride (NaCl) hypersaline solution (salinity of 38.00 ‰ and density of 1.20 g/cm^3) as reported by Thompson et al., (2004). Algae were placed in a beaker with a magnetic stirrer at 400 RPM for 20 minutes in the hypersaline solution and then let to settle for 2 hours. After that period the microplastics floated by virtue of their low density, the supernatant was filtered on a glass microfiber filter (GF/F, 47mm, 1μm) using a vacuum pump, then dried in the oven at 40 °C for 24 hours. Filters were inspected primarily using a stereomicroscope, each particle considered microplastic was photographed with a camera attached to the stereomicroscope. The particles were classified and catalogued on the basis of their shape and colour following the categories suggested by Hidalgo-Ruiz et al., (2012). To assess the chemical nature of the particles found, the samples were analyzed by ATR-FTIR spectroscopy. For this purpose, a Perkin Elmer Spectrum One Spectrometer was employed. The assignment of absorption bands in the output spectra was accomplished by comparison with spectra of standard polymer materials found in the literature (Jung et al., 2018). After the procedure of three times washing with NaCl solution algae were analyzed under a stereomicroscope in order to check the absence of MPs.

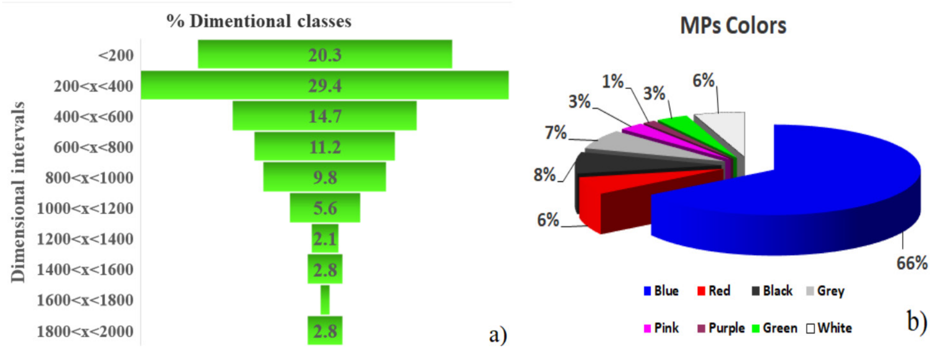

Fig 1 - Percentages of the different recorded MPs: a) dimensions; b) colours.

(Continued on next page)

Results and Discussion

Up to now information on the status of MPs accumulation in marine autotrophic organisms is scant even though they have been recently reported in macroalgae (Li et al., 2020). This is noteworthy taking into account that macroalgae serve as animal feed and human food (Gao et al., 2018). Our data suggest that in *C. linum* several kinds of MPs are present. Out of the total of 143 MPs found, 141 were fibers while only two were fragments. The average particle size was found to be 555 μm. The size class with a major number of MPs was between 200 μm and 400 μm (Fig. 1a). Among the various colours, the predominant was blue (65.7%), while the remaining colours had considerably lower percentages (Fig. 1b).

ATR-FT-IR spectra related to the relevant fibers were assigned to polypropylene, polypropylene plus calcium carbonate filler, polystyrene, polyethylene, and polyester reinforced with calcium carbonate (E.Quarta unpublished data). In conclusion, our findings highlighted the presence of MPs in *C. linum* and the possibility to remove them with simple procedures thus encouraging the exploitation of this species in an aquaculture scenario where it is cultivated in the realized IMTA system. Finally, the strong trapping capacity of MPs by *C. linum* indicates this seaweed as a potential material to remediate MPs-polluted seawaters

Introduction

Skeletal anomalies are rather frequent in Senegalese sole (*Solea senegalensis*) aquaculture. Particularly, vertebral deformities may impact physiological processes and welfare, affecting swimming, growth or even the susceptibility to other diseases, as well as slowing weight gain. Although several diagnostic techniques have been used for the assessment of skeletal deformities in Senegalese sole, the molecular mechanisms underlying the vertebral deformities are still poorly understood. In this context, the present multidisciplinary research aims at deepening the knowledge of the genetic basis and molecular pathways of osteogenesis processes and the development of vertebral anomalies in *S. senegalensis*.

Materials and methods

For this study, an experimental trial was carried out in the Marine Research Centre ECIMAT (Vigo, Spain). A commercial batch of Senegalese sole fertilized eggs was split into two groups subjected to two different incubation temperatures (18 ºC and 22 ºC). Hatched eggs were then placed in separate tanks, with three replicate tanks for each condition. Random samples of 300 postlarvae (30 days after hatching, dah) and 311 juveniles (130 dah) were taken to evaluate the prevalence of vertebral anomalies by stereomicroscopy. Stereomicroscopy, digital radiography, and digital imaging methods were performed to assess the vertebral anomalies at 30 and 130 dah, classify the main types of vertebral anomalies and support sampling collection for further transcriptomic analyses. Vertebral bone tissues from unaffected and anomalous vertebral phenotypes were collected for RNA extraction at 30 and 130 dah. Muscle and fin tissues were also sampled in the latter juvenile stage. An RNA-seq analysis including three replicates per condition was performed after quality-filtered reads aligned against the Senegalese sole genome. Reference mRNA and miRNA transcriptomes of vertebral bone were obtained for functional evaluation of bone homeostasis and spinal pathologies in the conditions tested.

Results and discussion

The data obtained from the stereomicroscopic study, focused on the count of vertebrae and the skeletal alterations present, showed significant differences between the incubation temperatures. At 22 ºC, both postlarvae and juvenile Senegalese sole presented a higher number of total vertebrae in the column, and the prevalence of vertebral anomalies was higher, especially the number of vertebral fusions. Regarding the transcriptomic analysis, sets of differentially expressed genes (DEGs) were detected between control and malformed vertebral phenotypes across tissues and life-stages under different incubation temperatures, providing insights into the functional mechanisms regulating vertebral development and growth in Senegalese sole. These results on DEGs revealed long-lasting effects of early incubation temperature on the spine, and regulatory insights on vertebral bone health and growth. Among these, defective extracellular matrix, osteogenesis, chondrogenesis, mineralization, bone remodelling and inflammation. Muscle and fin DEG profiles also correlated with cartilage and bone related genes associated with the spinal skeleton health.

Conclusion

This study shows the imprint of the environmental conditions of egg incubation on the bone tissue, which is manifested on the prevalence of skeletal malformations until juvenile stages. On the other hand, the transcriptomic study is useful for the identification of mRNA and miRNA biomarkers that may be applicable to aquaculture industry and to the comparative pathology of bone tissue.

Introduction

A high frequency of skeletal anomalies can represent a multilevel problem for the aquaculture sector, especially if they repercuss in the general appearance of the fish sold as a whole, causing rejection by consumers. Despite the high relevance of turbot (*Scophthalmus maximus*) in European aquaculture, there are few studies addressing vertebral anomalies at commercial size cultured fish. Reports at early stages of development, detected the presence of skeletal anomalies in around 50 % of the turbot larvae/post-larvae (Tong *et al*. 2012). Conversely, only 2.3 % of fish at 0-47 days after hatching (dah) showed spinal deformities in Lv *et al*., 2019. This work aimed to characterize the main vertebral body anomalies and spinal deviations on the last stage of turbot rearing, close to market size, by means of computed radiography. The relationship between deformities and biometric measurements of the fish was assessed.

Material and methods

For this study, 51 farmed turbot at commercial size were radiographed in latero-lateral (LL) projection using a Philips Super 80 CP X-ray equipment and a mammography film (FCR Fuji IP cassette type CH). Exposure parameters ranged from 40 kV to 45 kV and 25 mAs, depending on the fish size. Computed radiographic images were analysed with a RadiAnt DICOM Viewer 2020.2.3 software. External biometric measurements were taken as standard length (StL; cm) and maximum body width (BW; cm), and StL/BW ratio was calculated. Vertebral bodies were assessed for the presence of anomalies, according to Witten et al., 2009. To check the relationship among fish biometrics and deformities, individuals were distributed in three groups ("D1-5", "D6-10", "D>10") according to the number of deformed vertebrae. The first group "D1-5" included fish with 1 to 5 deformed vertebrae; the second group "D6-10" included fish with 6 to 10 deformed vertebrae; and fish with more than 10 deformed vertebrae were allocated in group "D>10". Group differences in StL, BW and StL/BW ratio were analysed using one-way ANOVA test. Normality and homogeneity of variance of the data were previously checked using Shapiro-Wilk and Levene's tests, respectively. Tuckey's pairwise comparison tests were performed in case of finding significant differences ($p < 0.05$).

Results and discussion

One-sided compressions, complete fusions, and compression and fusion were the most common vertebral body anomalies found. The distribution of the anomalies along the vertebral column varied according to the malformation type. Mainly two vertebral segments were affected: the first and the last caudal vertebrae. Different types of compressions in the vertebral bodies were predominant in the transition between the abdominal and caudal regions. This region may have a high mechanical load due to the swimming musculature and flexion of the vertebral column in different fish species (Fjelldal et al. 2021). As suggested by Witten et al., 2005, the combination of disuse and mechanical overload may contribute to the development of compressed vertebrae. Complete fusions affected mainly the caudal-most vertebrae. According to the number of deformed vertebrae, turbot that presented more than ten deformed vertebrae were slightly shorter or wider, although not significantly. However, they had a significant smaller mean ratio StL/BW (1.22) compared to D1-5 (1.31) and D6-10 (1.30) groups ($p<0.001$); although such differences in the proportions of the animals may be sometimes difficult to assess with the naked eye.

Conclusion

The results of this study highlight the presence of vertebral body anomalies in farmed turbot with a very particular distribution along the vertebral column, depending on the malformation type. The presence of several anomalies in the same turbot seems to maintain the external biometric values, except the ratio StL/BW in fish with more than ten deformed vertebrae. Besides, the anomaly profile may have a low impact on turbot marketability. This work could be useful to compare with studies on the anomaly profiles of other flatfish species, for which malformations still represent a problem for its intensive production.

Abstract

The reproductive management of two mullet species (*Chelon labrosus* and *Liza aurata*) is assessed from its capture (2018 for *Liza aurata*, 2019 for *Chelon labrosus*) to the final obtention of viable spawns 4 and 3 years later, respectively. From 60 *Liza aurata* broodstock, acclimated in 3 tanks of 1 m3, 11 natural spawns were obtained from November 2021 to January 2022. From 54 *Chelon labrosus* broodstock acclimated in 3 tanks of 10 m3, 3 induced spawns were obtained in April 2022. From each species, viable eggs and larvae have been obtained under controlled conditions, opening new perspectives to increase the culture of these species.

Introduction

The Mugilidae family presents a great potential for the sustainable diversification of aquaculture due to their eurythermal, euryhaline, and low trophic nature. However, the culture of these species continues depending on fry collection from the wild, which produces high mortalities (Crosetti and Blaber, 2015). In this respect, establishing adequate protocols for wild broodstock collection, acclimatization, and reproductive management is the first step to successfully closing the biological cycle in captivity.

Materials and methods

Fishing and acclimatization

Adult animals were fished and transferred to open sea-water system tanks in the GIA-Ecoaqua facilities (Canary Islands, Spain). One month after acclimatization, animals were anaesthetized with clove oil (50 ppm) and individually pit-tagged. Species genetic corroboration was carried out from caudal fin samples through Polymerase Chain Reaction (PCR) of the 5s-rDNA gene and by subsequent sequencing analyses according to Imsiridou et al. (2007).

Reproductive management

Sex identification of broodstock was carried out before the beginning of the natural spawning season of each species. Males were identified through abdominal massage, while animals negative for this test were gonadally biopsied using a 1.3-mm-internal-diameter catheter, to later visualized the sampled material under a stereoscope. For all the period, both species were fed daily with a commercial organic feed for marine fish (Aller Blue organic, Aller Aqua Group, Denmark). Fish were maintained under natural photoperiod and temperature.

Liza aurata broodstock was maintained untouched through the spawning season, while the spawning of *Chelon labrosus* was hormonally induced in mature specimens following the protocol described by Vallainc et al. 2021.

Table I. Culture conditions and mean weight of mullet broodstock.

	Liza aurata	*Chelon labrosus*
Male/Female ratio	2:1	1.4:1
Stocking density (Kg/m^3)	7	3
Mean female weight (g)	525±90	1626±530
Mean male weight (g)	366±79	1357±250

(Continued on next page)

Results

Fishing and acclimatization

After trying various fishing techniques, *Liza aurata* adults were fished by fishing nets at sunset, while *Chelon labrosus* adults were fished with a fishing rod during the daylight.

As acute haemorrhagic and ulcerative lesions were observed (>50% of the population) during the first week after capture, at arrival the animals were subjected to a preventive enrofloxacin treatment (10 mg/Kg in single intramuscular injection), and to a formaldehyde bath the next day (100 ppm, one hour bath).

Reproductive management

From *Liza aurata* broodstock, 11 natural spawns were obtained 4 years after acclimatization, from November 2021 to January 2022. From *Chelon labrosus* broodstock, 3 hormonally induced spawns were collected in April 2022. The fertilization rate ranged from 0-57.5% in *Liza aurata* spawns, and from 0-5.35% in *Chelon labrosus*.

Discussion and conclusions

Both mullet species are sensitive to the stress of capture and transport, so acute skin damage and ulcerative processes were observed during the first weeks of acclimatization. For these reasons, careful handling and preventive treatments such as formol baths are strongly recommended at arrival. After this period, mullet broodstock adapted well to captivity and dry feed, even obtaining natural spawns in the case of *Liza aurata*, in concordance with previous experiences with this species (Quirós-Pozo et al., 2022, unpublished results). For *Chelon labrosus*, despite achieving the state of final oocyte maturation (FOM) naturally, no spawns were obtained spontaneously, in concordance with previous experiences with this species (Besbes et al., 2020), so hormonal induction treatment was applied as described by Vallainc et al. (2021) with successful results. Although the low fertilization rates, robust larvae and juveniles have been obtained, suggesting the feasibility of culturing both species under controlled conditions.

Introduction

At present, there are approximately 24 000 fishponds in the Czech Republic. Decades of inappropriate management at the watershed, excessive erosion of arable land and increased fish production have led to the accumulation of sediments in ponds. In the Czech Republic, a third of ponds show an excessive load of sediments. Accumulation of sediment can lead to a reduction in depth, depletion of dissolved oxygen, accumulation of nutrients, and thus limiting biological, ecological functions, and fish production. The removal of sediment from ponds is necessary for fishpond maintenance. One of the options is the mechanical removal of sediment. However, due to economic reasons, people are looking for other methods of reducing the excessive accumulation of sediments.

In our study, we used the PTP Plus (Baktoma Ltd.), a mixture of bacterial spores and enzymes that should decompose the organic content of sediments in ponds. It is a concentrate of spores and endospores of specially selected and targeted breeding strains of native soil bacteria. Shortly after the introduction of the product into the aquatic environment, spores and endospores should revive and feed the organic sediment. According to the manufacturer, this should result in the reduction of organic deposits, phosphorus and chlorophyll–*a* content in water, while oxygen concentration should increase.

Materials and methods

Monitoring of the physical and chemical parameters of both the water and sediments took place from April to October 2016 and 2017 in three fishponds: BOH I (1 ha), BOH II (0.8 ha) and BOH III (0.6 ha) in the Olomouc Region (Czech Republic). In two of the ponds, bacterial product PTP Plus (Baktoma) was repeatedly applied from May till October 2017 according to the instructions from the supplier - BOH II (recommended dosage) and BOH III (doubled dosage). Basic hydrochemical parameters (dissolved oxygen concentration, water temperature, pH, conductivity and transparency) were measured once a month. Water samples were collected, and the following parameters were analyzed: COD, BOD, total nitrogen and phosphorus, ammoniacal nitrogen, nitrites, nitrates, phosphates, chlorides, acid neutralizing capacity, calcium and chlorophyll–*a*. The surface layer (0–15 cm) of the sediment was collected using an Ekman-Birge grab. The dry mass of the sediment samples was determined and aqueous leachates from fresh samples of sediment were prepared. Basic available nutrients (N, P), COD and organic substances were determined in aqueous leachates. Soil extracts were prepared from dried samples of the sediment using Mehlich III and aqua regia. Amount of the available phosphorus and calcium was determined using the extracts.

Results and discussion

In order to evaluate the possible effects of the PTP Plus preparation, the water and sediment quality in 2016 (before the PTP Plus application) and in 2017 (after application) were compared. Significant difference and increase in conductivity, and the amounts of calcium and chlorides in the water were recorded. In the case of the sediment, a significant difference between years was recorded in some of the parameters (COD, nitrogen, phosphorous, calcium), but not in every pond. Different climatic conditions of each year probably had a major impact on the significant changes in water and sediment quality during the particular years of monitoring. The occurrence of submerged and free-floating macrophytes in 2017 could also have affected the difference in water and sediment parameters between the studied years. Results of the non-metric multidimensional scaling of ponds based on physico-chemical parameters of sediment showed differences among ponds, but did not show year-on-year changes, indicating different sediment conditions of each pond. The expected reduction of the share of organic matter in the sediments after the application of the product was not confirmed in our study. Our results confirm the findings of other authors who state that the effect of the addition of bacterial mixtures into ponds on the improvement of the water and sediment quality is low.

Introduction

Eurasian perch (*Perca fluviatilis*), a temperate but eurythermal (CT_{max} 30-32°C) fish species, is a potential candidate for freshwater aquaculture diversification in Europe. It is a freshwater, carnivorous (piscivore, insectivore, facultative planktivore) fish species, that have evolved feeding on primary consumers of the aquatic food web. As such, their nutritional bioenergetics, e.g., relatively poor carbohydrate tolerance, low endogenous EPA/DHA biosynthesis, higher amino acids, and long-chain >C20 PUFA requirement, closely resembles that of higher trophic level fishes like salmonids. Over the past, there has been some good progress in Eurasian perch broodstock maturation and seed production – including studies on sperm/egg quality, handling, storage condition, etc. Albeit some previous nutritional characterization (mostly fatty acids, and nucleotides) of their gametes, their basic cellular nutritional bioenergetics mechanisms (*i.e.,* relative stoichiometries or turnover of nutrients and energy) have not been fully understood. Here, we have taken *P. fluviatilis* spermatozoa as a model to elucidate some probable mechanisms behind a short burst of motility. Elucidation of these mechanisms is even more important for temperate percids like Eurasian perch, which reproduce (maturation → external fertilization) in metabolically difficult, cellular thermal environments (cold water around 12-14°C). Understanding the strategies in such conditions might help in tailoring captive broodstock nutrition in a better way and open novel biotechnological applications.

Materials and Methods

Pond reared Eurasian perch *Perca fluviatilis* adults (body weight 172.1 ± 16.2 g; age 3+) fed on natural food were obtained from Nove Hrady region (541 m asl), Czech Republic. Harvested fish were transported to an indoor RAS facility in Ceske Budejovice (7°C) and captive maturation was induced by a combination of photo-thermal and hormonal manipulation in April [1]. Males were stripped and selected (initially 15 then 10 hand-picked fulfilling >90% sperm motility). Sperm was collected using 5 ml syringes and avoiding urine or blood contamination. Received sperm in centrifugation tubes were always handled in ice slurry bath (4-6°C). Sperm concentration was assessed in Bürker cell hemocytometer and sperm kinematics were assessed using negative phase-contrast microscope equipped with 20x lens, and uEyecockpit software, set at 25 frame per second [2]. Fresh samples from 10 good males were divided into batches: (a) freshly frozen at −80°C ('control'), (b) test-tube activation around 10°C and freezing −80°C ('treatment'). Treatment was done (1 sperm: 39 diluent) by an activation solution [3]. Biochemical analyses included fatty acids (n=21, C14-C22), peroxidation products (malondialdehyde), nucleotides (IMP, AMP, ADP, ATP, hypoxanthine, inosine, adenosine), and lactate [4]. Fresh sperm were analyzed as original matter. Whereas frozen treatment' was thawed and centrifuged (4°C, 8000 rpm, 10 min) to extract sperm pellet (used for analyses). Relative stoichiometries of fatty acids and nucleotides were derived from the quantitative data (fatty acids and nucleotide content per unit weight of sample) and then also verified from semi-quantified data (relative percentage of total fatty acids and nucleotide per billion spz). Apparent desaturase and elongase activity were estimated by product-to-precursor ratio [5]. Metabolic losses or nucleotide degradation was assessed by K-value change [4] and cellular bioenergetics by established nucleotide balances [6].

Results

Motility parameters: Among studied males, sperm concentration was variable 37.7±8.3 × 10^9 spermatozoa ml^{-1} (CV 22%). Representative results from 10 hand-picked males fulfilling a motility percentage of 90-100% suggest an average motility duration of 30.6±3 seconds (CV<10%). Timepoint of 60 seconds ensured termination of sperm motility. The active spermatozoan had a curvilinear velocity of 168.8±33 $\mu m\ s^{-1}$ (CV 19.7%), straight-line velocity 76.4±33.6 $\mu m\ s^{-1}$ (CV 44%), average path velocity 115.5±41.9 $\mu m\ s^{-1}$ (CV 36.3%), and linearity 62.8±5.9% (CV 9.4%).

Fatty acid metabolism: Like in higher vertebrates and nervous (brain) tissues, spermatozoon at its entirety is mainly composed of a ω-3 LC-PUFA docosahexaenoic acid (DHA, C22:6n3 ~31% of total fatty acids) followed by saturated fatty acid, palmitic acid (PA, C16:0 ~18% of total fatty acids); making up half of the sperm lipidome. While DHA is known to impart structural flexibility and fluidity required to achieve sperm kinetics, the PA serve as an energy source. The palmitic acid: PUFA ratio changed ($p<0.05$) at quiescent versus exhausted stage; suggesting at quiescent state PA served as energy substrate while post-activation PA were desaturated and elongated to PUFAs to supposedly reinforce the sperm kinetics. Apparent activities of Δ9 desaturase (*scd2* gene), bi-functional Δ5/Δ6 desaturase (*fads2*), Δ4 desaturase (*fads2* or purported *degs2*), elongases (*elovl6*, *elovl5, elovl2*) were hinted in both quiescent and post-activation state.

(Continued on next page)

There might be a gear-up mechanism (1st gear: 'SFA → MUFA' to 2nd gear: 'MUFA → PUFA') supposedly involved when spermatozoon activates from quiescent state. Expression of *scd2* and *elongase6* switched opposite to each other ($p<0.05$), when going from quiescent to post-activation state. *Elovl5* (responsible for C18 to C20 elongation) and Δ4 desaturase (responsible for EPA to DHA conversion) suggested the highest apparent activity in perch spermatozoa, with a higher average expression in post-activation. DHA relative to other fatty acids in exhausted spermatozoa was ~14% higher than in quiescent state. There was no significant change in malondialdehyde content (lipid peroxidation product) between quiescent and post-activation state; values were as low as in fresh fish flesh (internal standard).

Energy metabolism: As expected, degradation (metabolization) of nucleotide increased ($p<0.05$) from quiescent to post-activation stage. Net retention of nucleotides (100- Kvalue %) in quiescent stage was ~63% (pre-store) while it dropped ($p<0.05$) to almost half (~31%) in post-activation. Indeed, the nucleotide degradation was not via free radicals or lipid peroxidation, as malondialdehyde were almost unchanged (above). ATP:ADP ratio was low (0.21: 1; indicating glycolytic cellular metabolism) in quiescent stage and high post-activation (0.71: 1; indicating a switch to oxidative cellular metabolism). It also suggests suppressed mitochondrial function in quiescent stage and higher during post-activation. Higher mitochondrial function corresponded with higher 'adenylate energy charge' post-activation. Adenylate kinase reaction ($2ADP \rightleftharpoons ATP+AMP$), which occur in mitochondria and flagellar axoneme, occurred almost close to equilibrium (0.5-1.0: 1.0) in quiescent stage; but equilibrium was lost, and forward reaction occured post-activation (1.3-3.9: 1.0). Glycolytic metabolism was suggested to be suppressed in post-activation, while fatty acid synthesis continued. These mechanisms fit well with achieving a short burst of motility in cold water.

TOWARD SEA CUCUMBER PRODUCTION AND IMTA APPLICATIONS IN EUROPE: PROGRESS, PROBLEMS AND OPPORTUNITIES

A. Rakaj*, A. Fianchini, L. Grosso, D. Pensa, M. Scardi

Experimental Ecology and Aquaculture Laboratory, Biology Department of Rome Tor Vergata University, Via Cracovia 1, 00133 Rome, Italy
E-mail: arnold.rakaj@uniroma2.it

Introduction

There is an increasing focus on the effects of organic wastes produced by intensive aquaculture, and on solutions to reduce the polluting impacts of European marine farms worldwide. Integrated Multi-Trophic Aquaculture (IMTA) is a new generation aquaculture that allows for the reduction of environmental impacts, higher profits and the diversification of commercial production. This integrative approach, in fact, offers a natural means of encouraging nutritional recycling within aquaculture farms, simulating a natural community through the employment of extractive species with a low trophic level and high market value. In this context, sea cucumber as deposit feeders species could represent promising candidates for co-culture in IMTA, considering their feeding habits and their high market value. However, although their ecological role in many marine habitats and their feeding behaviour seems highly promising compatible with extensive integration, there are only few investigations available regarding the co-culture of European sea cucumbers in productive systems (MacDonald et al., 2013; Tolon et al., 2017; Neofitou et al., 2019; Grosso et al 2021; Bastien Sadoul et al., 2022; Cutajar et al., 2022).

In this context, aquaculture could offer a sustainable alternative to the exploitation of the wild population, to meet current market demand and at the same time could promote the waste bioremediation nearby productive areas. With regard to European sea cucumber species aquaculture, a consistent body of research literature has been produced in the last few years, paving the way for the artificial reproduction of many European species by developing a spawning induction methodology and larval rearing protocol (Domínguez-Godino et al 2015; Domínguez-Godino et al 2018; Rakaj et al 2018; Rakaj et al., 2019; Laguerre et al., 2020; Magdy et al.,2021; Schagerström et al., 2022). Nevertheless, there are still some challenges facing sea cucumber aquaculture that need to be overcome for future aquaculture development. This brief keynote present the up-to-date research progress and problems and future opportunities for European sea cucumbers in aquaculture.

Introduction

Atlantic salmon (*Salmo salar*) is a major species produced in world aquaculture [1] and an important vertebrate model organism for studying the process of rediploidization following whole genome duplication events (Ss4R, 80 mya) [2]. The then current *Salmo salar* transcriptome was largely generated from genome sequence based in silico predictions supported by ESTs and short-read sequencing data [3]. However, recent progress in long-read sequencing technologies now allows for full-length transcript sequencing from single RNA-molecules. A full-length protein coding transcriptome from a species (the CDS as well as the 5'- and 3' UTRs) and its repertoire of splice variants is an essential resource to reliably annotate protein coding transcripts and understand how such structural variants impact disease and economical important traits in farmed animals [4]. The aim of this study was to generate a high-quality full-length transcriptome resource for Atlantic salmon, based on sequencing of samples from tissues and conditions of broad interest to salmon research.

Material and Methods

Trandcriptome sequencing was carried out in liver, head-kidney and gill materials, sampled before and during smoltification as well as after sea-water transfer. Head-kidney from fish challenged with a viral infection was also included. RNA extraction was performed using the Qiagen RNeasy Mini Kit according to the manufacturers protocol. All samples were sequenced both with PacBio long-read SMRT sequencing and Illumina 150bp paired-end sequencing. A pipeline for data-analysis was developed based on Iso-seq sequencing of long-reads on the PacBio platform (HQ reads) [5] followed by error-correction of the HQ reads by short-reads from the Illumina platform using the LoRDEC algorithm [6]. This was followed by in-house developed filtering steps, and multiple clustering steps using cDNA_Cupcake, Cogent and CD-hit. Finally, functional annotation and classification of transcripts (splice variants or different genes) was performed based both on the reference genome and Blast searches against other chordates using the SQANTI [7] and OmicsBox [8] software package respectively.

Results

The pipeline successfully processed more than 1.5 million long-reads and more than 900 million short-reads into error-corrected HQ reads. A surprisingly high percentage (32%) represented expressed interspersed repeats, while the remaining were processed into 71 461 full-length mRNAs from 23 071 loci. Each transcript was supported by several single-molecule long-read sequences and at least three short-reads, assuring a high sequence accuracy. On average, each of the 23071 genes were represented by three isoforms (splice variants). More than 80% of transcripts were assigned Gene Ontology terms. Comparisons to the current Atlantic salmon transcripts in the RefSeq database showed that the long-read transcriptome validated 25% of all known transcripts (current GenBank reference mRNAs), while most of the remaining full-length transcripts were novel isoforms of known genes, with 566 transcripts putatively stemming from novel genes. A comparison to the current genome assembly indicates that the long-read transcriptome greatly improves transcript annotation and may provide long-read linkage information useful for improving the genome assembly. Thousands of transcripts were from genes or splice-variants expressed in an organ-specific manner demonstrating that hybrid error-corrected long-read transcriptomes may be applied to study genes and splice-variants expressed in certain organs or conditions (e.g. challenge materials).

Conclusion

At time of writing, this study represents the single largest contribution of high-quality full-length mRNAs in Atlantic salmon. The results will be of great value to salmon genomics research, and the pipeline outlined may be applied to generate additional de novo transcriptomes from other tissues in Atlantic Salmon or be applied for similar projects in other species.

CHARACTERIZATION AND INCLUSION OF VEGETABLE BY-PRODUCTS IN SUSTAINABLE AQUAFEEDS. THE EXAMPLE OF BANANA BY-PRODUCTS

Introduction

The evolution of the different raw materials used in animal feed production over the last 30 years indicates an increase in the use of cereals, with soya, corn and wheat leading the way, following the 2001 crisis, and a reduction in the use of the animal meal. One of the utilities of by-products from crops have been to use them for animal feed (Federici *et al*., 2009), as fodder.

In the case of bananas, this traditional use has been naturally occurring throughout the world and in the Canary Islands (Padam *et al*., 2014).

However, since the early 2000s, authors have been pointing out the potential of by-products from the agro-industrial sector as functional ingredients for the human and animal food industry (Schieber *et al*., 2001). This has led to the search for new uses of by-products from other industries, be it food, alcoholic beverages or bioethanol production, especially in the last twenty years.

Material and Methods

Biochemical and functional characterisation of two banana by-products, pseudo-stem (BP) and flower (BF) were carried out. Based on these results, consecutive trials were developed for the global valorisation of both products in juveniles of two species of high interest in aquaculture, tilapia and sea bass. Three studies were performed for each of these species, one trial with BP, a second with BF and a third with organic extracts and BF residue, in which the bioactives responsible for the beneficial effects of banana blossom would be present. Different growth parameters, biochemical and histopathological characteristics, oxidative status and immune parameters of both species were evaluated.

Results & Discussion

Treated BP reduced the lipid content in tilapia and modified the fatty acid profile, while in sea bass the lipid content was not affected. BF increased the amount of n-3 fatty acids in tilapia, while it did not affect sea bass. BP improved the oxidative status of the seabass liver and BF improves stress response parameters and the cellular response to simulated infection in seabass. Therefore, it should be noted that both BP and BF are both novel by-products of banana production, with potential for inclusion in feed for aquaculture and species of different trophic levels, with a high content of non-extractable polyphenols in BF, which positions it as a functional ingredient of interest (Ramírez-Bolaños *et al.,* 2021). Further studies on the effect of different processes on raw materials, mainly on BF, to increase the percentage of inclusion in feed would be of interest based on these first studies with pre-processed products.

Based on the results, treated BP can be included in tilapia diets for up to 5% and untreated BP can be included for up to 8% in sea bass. Untreated BF can be included at 3% and 6% in tilapia and sea bass diets, respectively.

Introduction

In order to achieve optimal performance in aquaculture, it is important to maximize growth while reducing costs and ensuring the sustainability of production activities. To do so, feeding strategies need to be optimized through careful daily estimation of the total biomass. Due to the impracticality of daily measurement of fish biomass, it is crucial to understand in an objective and practical way, the growth patterns and their underlying mechanisms, to enable (for example) biomass estimation between measurements. Traditionally, empirical mathematical models (e.g. RGR, TGC, FCR) have been used in aquaculture to predict growth due to their simplicity and ease of parameter determination. However, such models often ignore important aspects, such as feeding information (e.g. feed quantities properties), and/or lack clear physical/biological support, being inadequate as general context-independent prediction models. In academic contexts, other alternatives have been suggested, such as the use of bioenergetic models or nutritional models (e.g., energy-protein models). These types of models take into consideration feed quantities and (at least some) properties, which allows them to provide more precise growth predictions, as well as other important information (e.g., environmental impact due to waste and excretion losses). However, there is still some scientific and technical questions regarding the implementation of these models, which perhaps hampers their more widespread adoption in commercial settings.

In this work, tilapia growth data were collected and used to compare different combinations of models and calibration methods, using objective criteria based on cross-validation, to determine the best combination for this species.

Materials and methods

Nile tilapia growth data were collected from 27 publications, covering sizes from 0.51 g to 457 g. Primarily, an exploratory analysis of the data was performed to see how relevant responses were affected by different factors (e.g. body weight, temperature, feed intake, digestible protein intake, digestible energy intake). Bioenergetic and energy-protein flux models were then developed and tested with different calibration methods. Several “model + calibration method” combinations were evaluated through different cross-validation methods (leave-one-out cross-validation, repeated k-fold cross-validation with k=10, k=5 and k=2), to objectively evaluate their predictive capacity. This evaluation was performed considering both qualitative (diagnostic plots) and quantitative aspects (calibration and cross-validation RMSE, MAPE and CRM).

Results

Exploratory analysis of the data suggests a linear relationship between digestible protein intake and protein gain, and between energy intake and energy gain.

Considering the results of cross-validation, nutritional models, like the EP model (energy-protein flux), appear to provide better predictions than the simpler bioenergetic models, with the EP models showing cross-validation errors (e.g. MAPE) on the order of ≈ 8 % and ≈ 14 %, whereas the bioenergetic model had ≈ 13 % and ≈ 14 %, for the body weight and body composition predictions, respectively (in a 5-fold cross-validation). Regarding the calibration methods, an important finding was that models have better growth predictions when calibrated assuming the standard body weight exponents of 0.8 and 0.7 for maintenance costs (energy and protein, respectively), than when the estimated exponents are used.

(Continued on next page)

Discussion and Conclusion

The results regarding the linear relation between digestible energy intake and energy gain are consistent with what has been previously demonstrated by Lupatsch et al. (2003) for gilthead seabream, but in disagreement with the quadratic relation that Van Trung et al. (2011) reported for the specific case of Nile tilapia. The relation between digestible protein intake and protein gain was also linear, which disagree with the quadratic relation that Van Trung et al. (2011) suggested for Nile tilapia.

The fact that EP models have a better predictive ability than bioenergetic models shows that protein intake is an important component to consider when estimating growth in Nile tilapia. Perhaps, at least in part, this effect can be explained by the generally low protein content in tilapia feeds, which suggests that growth is protein-dependent.

The energy and protein maintenance costs exponents for body weight seem to show better results when they are fixed, using the standard values of 0.8 and 0.7, respectively (Clarke & Johnston, 1999), or assuming isometry (exponents equal to 1), rather than estimated from the data.

Overall, in this study, the use of evaluation methods that consider cross-validation error metrics enabled the clarification of important scientific (e.g., best model to predict growth) and technical (e.g., best calibration method) questions, providing a meaningful contribution to a more widespread adoption of highly-predictive nutrient-based fish growth models.

THE HORIZONTAL INTEGRATION OF A SHELLFISH FARM IN A BROADER BUSINESS MODEL

Perry Raso*

Matunuck Oyster Farm
Wakefield, RI, 02879 USA
perryraso@gmail.com

The demand for Eastern oysters over the last two decades has increased year after year. This steady continuous growth has created opportunity not only for oyster farmers and other businesses immediately supporting the shellfish aquaculture industry, such as gear and transportation, but it has also created opportunities just outside the shellfish aquaculture market. Opportunities to reach retail markets, such as restaurants and open-air markets, with their product and integrating into establishing those market on their own.

In order to meet those markets directly Matunuck Oyster Farm has horizontally integrated in each stage of the cycle of the eastern oyster (Crassostrea virginica). Matunuck Oyster Farm was established in 2002 as a 1-acre oyster farm with one employee. Now, 20 years later, that business has expanded to five additional businesses with over 200 employees, each business having the farmed Eastern oyster being a central, integral part of the business. Each of the new businesses support the farm, and the farm supports each business, creating more financial stability for the oyster farm.

The growth of Matunuck Oyster Farm into the six other sectors has been organic and determined by company needs. In addition to selling oysters to wholesalers, we expanded by offering different products such as Bay Scallops. We then started selling oyster seed to other farmers, selling at open air markets, and established Matunuck Oyster Bar, a popular restaurant overlooking the shellfish farm. This led to the establishment of Matunuck Organic Vegetable Farm, Matunuck Marina, Matunuck Shellfish Hatchery Research and Innovation Center and most recently a retail market in our adjacent downtown area of Wakefield, Rhode Island.

Perry Raso, Founder and Owner of these businesses, will discuss synergies between each of the businesses and how each business has strengthened and added value to each other.

THE EFFECT OF CLIMATE CHANGES IN SURVIVAL AND BEHAVIOUR OF EUROPEAN CLAM (*Ruditapes decussatus*)

Introduction

Climate changes represent a potential limiting factor to aquaculture, directly interfering with survival and behavior of bivalves. Severe fluctuations in temperature along with periods of heavy rainfall or periods of drought that significantly change the salinity[1], can promote physiological stress of bivalves, resulting in changes in physiological and behavioral responses and, in extreme cases, leading to high mortalities[2,3].

European clam (*Ruditapes decussatus*) represents one of the most relevant emergent bivalve species from the aquaculture sector in Europe with high economic value. Considering the predicted climate changes and given the economic and ecological importance of *R. decussatus*, the current study was designed to evaluate the effects of different combinations of salinities (0-40) and temperatures (5-35°C) on mortality and feeding behaviour of juveniles and adults of *R. decussatus*.

Material and methods

Juveniles and adults of clams *R. decussatus,* captured in Ria Formosa lagoon, were exposed to combined ranges of temperature and salinity. Considering the annual temperature and salinity variations in this coastal area over the last years, it was established a control temperature range between 15°C and 23°C, inclusive, and salinity 35.

Three and two trials of 120 h were performed for adults and juveniles, respectively.

Mortality and feeding behaviour were evaluated and registered every 24 hours. Individuals were considered dead every time they were unable to close their valves after mechanical stimulus[4], being then removed from the beakers. Feeding behaviour was evaluated through the absence or presence of faeces, scored as 0 or 1, respectively. Median lethal time (Lt50) and median lethal temperature (LC50) were calculated.

Results

Low salinities and high temperatures caused higher mortality rates, in both juveniles and adults, after 120 hours of exposure. In the control temperature range (15°C - 23°C), juveniles revealed to be more sensitive to the salinity variations. As salinity increased, juveniles' mortality decreased. In adults, the mortality rate reached 60% of the individuals at salinities lower than 15. Above the upper limit of the control temperature range (23°C) and salinities inferior to 15, the observed mortality was almost always extremely high, for both size classes. In more saline waters, juveniles seemed to be more resistant than adults, mainly at extreme temperatures (32°C and 35°C), where occurred 100% of mortality of the adult population. For salinities equal or below 15, LC50 varied between 20.28°C and 22.29°C for juveniles and adults, respectively, for salinities higher than 15, LC50 was set at 31.08°C for juveniles and 30.08°C for adults. In temperatures higher than 23°C and salinities less or equal to 15, Lt50 substantially decreased as temperature increased, with juveniles more sensitive to higher temperatures (32°C and 35°C). At higher salinities, juveniles seemed to be more tolerant than adults, however, the mortality of 50% of adults' population would never be expected to occur below 30 hours of exposure.

Feeding behavior seemed to be highly influenced by salinity, regardless the temperature, for both juveniles and adults. At salinities lower than 15, it appeared that individuals did not feed. From this point and at control temperature range, the feeding behavior of juveniles and adults was maximum. Out of this range, juveniles were less active at lower temperatures and more active at extreme temperatures. On the other hand, adults showed the opposite pattern. Mortality revealed a positive correlation with temperature while salinity had a strong positive influence on feeding behaviour.

(Continued on next page)

Discussion

Our results suggested salinity 15 as “turning point” below occurred a change in mortality and feeding behavior, which is in accordance with previous studies for venerid species [5,6]. Salinity fluctuations have a direct impact on feeding behavior, while temperature has a major impact on survival of clams. Low salinities and high temperatures are lethal to *R. decussatus.* Juveniles are less resistant to the increase of temperature in less saline environments, however, more resistant than adults to extremely high temperatures under more saline conditions.

Considering the predicted climate changes scenarios, juveniles will die faster when exposed to low salinities and high temperatures, consequences of heavy rainfall and heatwaves, never reaching the adult stage, thus compromising reproduction and consequently, bivalve recruitment. The failure in bivalve recruitment will have a strong negative impact on the economic sector due to the decrease in the available biomass for harvesting.

Introduction

Chemical communication is essential in several aspects of the life cycle of aquatic organisms. In the case of broadcast spawning species, such as oysters, pheromones play a crucial role in spawning synchronization. It is well known that oysters can be induced to spawn by thermal shock, however, females usually need an additional stimulus to trigger spawn. In general, this is achieved by adding conspecific sperm to the water. This way, sperm carries a chemical signal that stimulates/induces spawning in females: a spawn-inducing pheromone (SIP) (Galtsoff, 1938; Taylor et al., 2018). In this study, we investigated the chemical nature of male SIP in the Pacific oyster, *Magallana gigas* through an electrophysiological technique, the 'electro-osphradiogram'.

Material and methods

Oysters were induced to spawn by thermal shock (15°C - 29°C, at intervals of 1h). Once males started to spawn, they were transferred to a beaker with 200 ml of charcoal-filtered seawater to obtain natural spawning sperm (NS). After 15-20 minutes, males were opened, and sperm was obtained through incisions in the gonad – stripped sperm (S). In a first approach, "NS" sperm and "S" sperm from each male were centrifuged (10 min, 7200 rpm). The chemosensitivity of the oyster osphradium to total sperm and sperm fractions (supernatant and pellet) of both "NS" and "S" sperm (fresh and frozen) was assessed through electro-osphradiogram (EOsG), a D.C. field potential. Then, fresh and previously frozen (-20°C) NS and S sperm pools, were centrifuged (30 min, 2500 rpm, 4°C). Each supernatant was extracted through solid-phase extraction (SPE) C18 cartridges, and filtrate (aqueous fraction) and eluate (elution with methanol) were collected. Afterwards, filtrate and eluate were assessed for 'olfactory' activity by EOsG. The voltage signal was amplified (x2000 - x20 000) with the low-pass filter set at 30 Hz. The signal was then digitised and recorded on a PC running Axoscope TM software. L-cysteine (10^{-3} M) was used as a positive control (or standard) whereas the natural filtrated seawater was the blank or negative control. The EOsG peak amplitude was measured in millivolts. All recorded responses were blank-subtracted and normalized to the standard (10^{-3} M L-cysteine).

Results and discussion

The method of sperm collection affected the amplitude of the EOsG response; the stripped sperm (S) was more potent than sperm obtained through natural spawning (NS). This may be due to sperm emulsion containing some remains of gonadal tissues resulting from the incisions in the gonad and/or the sperm collected at higher density.

Similarly, when comparing fresh with frozen sperm, the latter evoked a higher EOsG amplitude. This can be explained by the cellular rupture associated with the freezing process releasing additional odorants from the spermatozoa.

In general, the supernatant evoked greater EOsG amplitude than the pellet, and similar to those of total sperm. After SPE extraction of the supernatant, the eluate fraction did not evoke any EOsG response whereas the aqueous fraction – the filtrate – evoked the highest amplitude responses, similar to that of total and supernatant; the majority of pheromonal/olfactory activity is in the aqueous fraction of the supernatant.

As in other marine invertebrates, such as polychaetes (Zeeck et al., 1998a, 1998b, 1998c), the pellet appeared to be pheromonally inactive whereas pheromonal activity was mostly contained in the supernatant and, in the case of this oyster species, is contained in the aqueous fraction of the supernatant. In contrast, in the pearl oyster (*Pinctada maxima*), it has been suggested that the pheromone is a proteinaceous multi-component associated with the sperm membrane (Taylor et al., 2018).

(Continued on next page)

Therefore, these results suggest that the male pheromone consists largely of (a) polar compound(s). Future work will focus on isolation and identification of the polar compound(s) that trigger females, and other males, to spawn. A successful identification will be an important step towards a future where it is possible to induce oysters to spawn, without the need to sacrifice individuals to obtain sperm emulsions.

Introduction

Over the last decades, the trend in the aquafeed formulation has been characterized by the reduction of fish meal (FM) and fish oil (FO) in favor of more sustainable alternatives. Insect meal has emerged as one of the most promising new aquafeed ingredients. More specifically, the black soldier fly (*Hermetia illucens*) represents an encouraging and increasingly studied insect species for aquafeed formulation due to its proper protein content and an essential amino acids profile similar to that of FM. Furthermore, the *Hermetia illucens* prepupae meal (HM) contains different bioactive molecules like chitin, antimicrobial peptides and lauric acid known for their immunostimulant and/or anti-inflammatory activity. The inclusion of full fat HM in fish diets is still limited by its unbalanced fatty acid profile (rich in saturated fatty acids and poor in polyunsaturated ones); however, it has been widely demonstrated that the HM fatty acid profile can be modified enriching the prepupae rearing substrate with potential sources of polyunsaturated fatty acids (PUFA). In this context, the addition of Spirulina (*Arthrospira platensis*) dried biomass to the insects' growth substrate may represent an interesting way to improve the nutritional value of the prepupae and, thus, of HM. Spirulina is the most common cultured cyanobacteria being produced at commercial scale and it contains high-quality protein and several bioactive components, such as vitamins, minerals, carotenoids, and tocopherols with antioxidant properties. In light of this, the present study was aimed to: (i) improve the nutritional value of HM in terms of PUFA and bioactive molecules by adding *A. platensis* to the insect growth substrate (15% w/w), (ii) formulate two experimental diets characterized by two different dietary inclusion levels (3 and 20%) of "enriched" HM, (iii) investigate the physiological effects of the experimental diets in rainbow trout (*Oncorhynchus mykiss*) juveniles during a 42-days feeding trial.

Materials and Methods

Two experimental diets characterized by 3 and 20% of HM inclusion levels in replacement of FM (named HM3 and HM20, respectively) were prepared starting from a control diet (HM0) formulated with marine (FM and FO) and vegetable ingredients. The three diets were formulated to be grossly isoproteic (50% on dry matter), isolipidic (23% on dry matter) and isoenergetic (25 MJ/kg).

Five hundred forty rainbow trout juveniles (initial weight: 15.28 ± 2.20 g) were randomly divided into nine square fiberglass tanks (in triplicate). Fish were hand-fed on the three experimental diets at apparent satiety for 6 weeks. At the end of the trial, fish were individually measured and liver, pyloric caeca, and distal intestine or whole fish were sampled. Final survival rate was calculated by daily recording of dead fish. For zootechnical performance, weight gain, specific growth rate and Fulton's condition factor (K) were calculated. Histological analyses were performed on liver samples to assess the integrity of liver parenchyma and the degree of fat accumulation, and on distal intestine to investigate the gut health status by means of morphometric evaluation and histopathologic indexes. Molecular analyses were performed to analyze the relative expression of genes involved in stress response, fish growth, fatty acid biosynthesis and inflammatory response. To determinate the macromolecular composition of liver samples, FTIRI measurements were performed. Gut microbiota analysis was performed on whole digestive tract by amplifying and sequencing the V3-V4 region of the bacterial 16S rRNA and sequences were analyzed.

Finally, the effectiveness of enriching insect substrates with bioactive compounds was also evaluated by analyzing fillet fatty acid profile by gas-chromatography.

(Continued on next page)

Results and Discussion

At the end of the trial, the survival rate of fish was 100% in all the experimental groups and fish growth did not show significant differences among the experimental groups. This result was fully supported by the molecular analysis and was in accord to most of the literature. In the present study, the dietary fatty acids analysis revealed an increasing percentage content of total PUFA, ω3-PUFA, DHA and EPA from HM0 to HM20 diets. As a consequence, in fish, the expression of genes related to lipid metabolism did not show significant differences among the experimental groups. Even carotenoids and total tocopherols showed the same increasing trend.

Interestingly, the fatty acid profile of HM20 trout fillets was the richest in ω3-PUFA, especially in C18:3-ω3, while HM3 contained higher level of DHA only compared to the control group. According to the literature, the dietary inclusion of HM was highlighted by the increasing content of lauric acid (C12:0) revealed in fish fillet.

Intestine plays a key role in nutrient absorption and therefore, evaluating the intestine micro-anatomy and inflammatory markers represents a proper and useful approach when new ingredients are tested. Histological analysis showed that the mucosal fold height was significantly reduced in fish fed HM20 diet respect to control diet; however, no sign of intestinal inflammation was detected in all the experimental groups probably because of the presence of specific bioactive molecules (lauric acid, tocopherols and carotenoids) with anti-inflammatory and antioxidant properties of which the HM20 diet was particularly rich. However, most of the genes involved in the immune response showed an upregulation in HM20 group respect to HM3 and HM0; this result can be related to a possible upcoming intestinal inflammation, not yet macroscopically detectable, or to the decrease in microbiome phylogenetic richness (dysbiosis) observed in fish fed HM diets. Regarding the liver, no differences in the histological architecture and macromolecular composition were observed among groups. In addition, stress markers gene expression did not show differences among the experimental groups. In conclusion, the present study evidenced that lipids (particularly PUFA) from *A. platensis*, tocopherols and carotenoids, were successfully transferred to the fish diets by enriching the insects' growth substrate, demonstrating the suitability of the enrichment procedure proposed. As regards fish fatty acids profile, a dose dependent ω3-PUFA increase was observed from H0 to H20 group. Furthermore, fish welfare was not negatively affected by the experimental diets, while a reduction of mucosal fold height in distal intestine was observed only in HM20 group. Finally, an increased immuno-related gene expression was detected only in HM20 group; this result requires further studies in order to understand if this is a precocious sign of an upcoming intestinal inflammation.

Introduction

The giant freshwater prawn (*Macrobrachium rosenbergii*) is a widely farmed decapod species worldwide due to its nutritional value, good meat quality and high growth rates. To ensure proper growth and constant productivity, aquafeeds commonly used for this species contain high percentages of unsustainable and expensive marine-derived protein sources like fish meal (FM). To increase aquafeed sustainability, great attention has been given to alternative ingredients like insect meal, that has been shown to be able to replace high amounts of FM in diets intended for farmed aquatic species. Some insect species, such as the black soldier fly (*Hermetia illucens*), beside the proper protein tenor and amino acid profile and the appreciable content of bioactive molecules (i.e. lauric acid, chitin, and antimicrobial peptides) with antioxidant, antimicrobial and immunostimulatory features are able to modulate their nutritional profile, especially in terms of fatty acids, in relation to the growth substrate. On this regard, enriching the *H. illucens* growth substrate with microbial biomass of *Arthrospira platensis* (spirulina), rich in essential amino acids (methionine, cystine, and lysine), polyunsaturated fatty acids, vitamins, minerals, and pigments with antioxidant properties, can represent an efficient method to exploit the beneficial properties of both ingredients. The use of aquafeeds that include ingredients with antioxidant and immune-boosting properties could be of primary importance for species that are frequently subjected to infectious diseases with consequent economic losses, like *M. rosenbergii*.

The present study was aimed to improve the nutritional value of full-fat *Hermetia illucens* meal (HM) by adding 15% w/w of *A. platensis* to the larval growth substrate and then to include (3 and 20 % respect to FM) the "enriched" HM in diets for *M. rosenbergii* juveniles. To further improve the prawns culture sustainability, the 60-day feeding trial was conducted in an aquaponic system (MjEnergy, Treia, Macerata, Italy).

Materials and Methods

Three test diets were formulated to be grossly isoproteic, isolipidic and isoenergetic. A control diet (HM0) containing FM, vegetable ingredients and fish oil was used as basal formulation for the test diets characterized by 3 and 20 % of HM inclusion levels respect to FM (named HM3 and HM20, respectively). At the beginning of the trial, 1971 giant freshwater prawn juveniles were randomly divided into nine aquaponic systems according to the three dietary treatments (in triplicate). Each system consisted of a hydroponic unit for plants cultivation and a prawn tank (total volume of water: 720L). In each hydroponic unit, 15 lettuce (*Lactuca sativa*) seedlings were planted one day before the introduction of prawns. Feeding trial duration was 60 days during which prawns almost triplicated their weight and were hand-fed the experimental diets, at apparent satiety. At the end of the trial, prawns were sacrificed by thermal shock for individual measurements and for excision of the cephalo-thorax for collection of hepatopancreas samples. For zootechnical performances, survival rate, weight gain, percentage of weight gain, and specific growth rate were calculated. Histological analyses have been focused on the middle portion of each hepatopancreas tubule (called B cells zone) since this part includes the mature stage of B and R cells. The relative abundance of B and R cells, as well as the lipid droplets abundance in R cells (as indication of the degree of lipid accumulation), tubule diameter, and the height of the epithelium were measured on 20 randomly selected tubules per section (3 sections per prawn, 15 prawns per dietary treatment). Molecular analyses were performed on hepatopancreas samples to analyze the relative expression of genes involved in prawn molting regulation (*jheh*), enzymatic hydrolysis of chitin (*chit3*), protein digestion (*catL*), stress response (*hsp90*), and immune response (*α2m*).

(Continued on next page)

Results and Discussion

All the experimental diets were well accepted by the prawns leading to the absence of significant differences among the experimental groups in terms of zootechnical performances. The suitability of the different experimental diets was confirmed also by the histological and molecular analyses on the hepatopancreas, the largest organ in the digestive tract of Decapoda, involved in absorption, digestion, and storage of nutrients as well as in immune response. In the present study, lipid absorption and storage were not affected by the provision of HM diets, as demonstrated by the comparable frequency of R cells and the high lipid droplets abundance among the dietary treatments. In particular, the massive presence of lipid droplets in R cells in all the experimental groups can be associated to the necessity of juvenile prawns to sustain energy-demanding processes like molting. Accordingly, the absence of significant differences in *jheh* gene expression confirms that molting processes were not affected by the different dietary treatments.

This positive *scenario* was evident despite the increasing dietary content of chitin in HM3 and HM20 diets that could impair nutrient absorption due to its complex matrix. On this regard, prawns possess specific chitinases (*chit3*) able to digest chitin since insects are part of the natural diet of *M. rosenbergii*. However, it should be pointed out that, in crustaceans, a reduced bioavailability of dietary nutrients is usually associated to an increasing in B cells population in the hepatopancreas, which are involved digestive processes at cellular level. Accordingly, in the present study, significant differences were evident in terms of B cell relative abundance in HM3 and HM20 groups compared to HM0. This result was fully supported by the expression of *catL* that codifies for the cathepsin L, a protease stored in the digestive vacuole of B cell.

Finally, considering the hepatopancreas health status, no structural alterations were highlighted by the histological analyses and no significant differences were evident in terms of expression of genes involved in stress (*hsp90*) and immune (*α2m*) response, confirming the suitability of the experimental diets used in the present study for prawns' culture.

In conclusion, the present study represents an example of how *M. rosenbergii* culture can be implemented with more sustainable dietary formulations and farming techniques like aquaponic.

*eapper@lallemand.com

Introduction

Lactobacillus species are among the most widely used probiotics. Despite a plethora of evidence advocating their beneficial effects, there are a number of practical limitations to their industrial application in animal feed. Besides, a growing body of literature examines the nutraceutical potential of inactivated microbial fractions ('postbiotics') processed from specific strains of *Lactobacillus*. Those products are supposed to exert a crosstalk with the host cells and to have positive impact on intestinal barrier and intestine-organs axis. However, only few *in vivo* evidence are available.

The study tested the dietary supplementation with a single proprietary *L. helveticus* HA122 strain with known specific parietal features supplemented either live (probiotic, LHPro) or inactivated (postbiotic; LHPost) as well as with a *L. paracasei* HA-108 postbiotic (LPPost) on the mucosal barrier function of zebrafish used as vertebrate model.

Materials and Methods

The 5-week trial (Plymouth, UK) tested 4 dietary groups in triplicate using wild-type adult zebrafish ($BW_i = 0.52 \pm 0.06$ g; 25 fish/tank) and a basal diet formulated to NRC requirements for cyprinids (36% protein, 8% lipid). Treatment consisted of 1] non-supplemented basal diet (Control), and basal diet supplemented with 2] LH probiotic (LHPro; 20 mg/kg), 3] LH postbiotic (LHPost; 60 mg/kg) or 4] LP postbiotic (LPPost; 350 mg/kg). All microbial products were supplemented at 1×10^6 cells/g feed and consisted of proprietary microbial strains provided by Lallemand SAS (France). Diets were fed at fixed rate of 4% biomass daily over 3 daily rations. At the end of the trial, intestinal and skin histomorphometry (n = 9 fish/ treatment) as well as the intestinal immune response using ELISA, flow cytometry and gene expression analysis (n = 6 fish/ treatment) was assessed. Differences between control and experimental groups were assessed by non-parametric permutation test with significance accepted at $p < 0.05$.

Results

The intestinal lysozyme level (by ELISA) was significantly higher in the LHPost (+38.7%, $p < 0.005$) and LPPost (+33.3%, $p < 0.05$) groups compared to the control; (**Fig 1A**) in line with a significant up-regulation in the expression of *lyz* in the intestine (LHPost: +70.2%, $p < 0.05$; LPPost: +63.2%, $p < 0.05$; **Fig 1B**). The expression of *catL* (coding for cathepsin L) was significantly up-regulated in all treatment groups compared to the control ($p < 0.0001$).

Compared to the control, goblet cell coverage (GCC) was significantly increased in the LPPost group (intestine: +39.8%; skin: + 54.0%; $p < 0.05$; not shown) and goblet cell density (GCD) was increased in the LHPost group (intestine: +23.1%; $p < 0.05$, not shown). In the intestine, the abundance of intraepithelial leukocytes (IEL) was also significantly higher in all supplemented diets (LHPro: + 23.1%; LHPost: + 43.4%; LPPost: + 23.1%; $p < 0.001$; **Fig 2**).

Flow cytometry analysis of the intestinal tissue (**Fig 3**) revealed healthy (> 0.9) and consistent ratios of $CD4^+$ to $CD8^+$ cells across all treatments; alongside with significant elevations of $CD4^+$ (+ 62.9%, $p < 0.05$) and $CD8^+$ (+ 63.7%, $p < 0.01$) cells in the LPPost group compared to the control.

Conclusions

The study identifies the potential of postbiotics to strengthen barrier functions at two levels. Firstly, by promoting the goblet cell population that could lead to better antigen sensing via formation of goblet cell-associated antigen passages (GAPs). Indeed, actively secreting goblet cells can take up antigenic material for further processing by dendritic cells and tissue specific macrophages for presentation to mobilise adaptive T-cell and B-cell responses (Johansson and Hansson, 2016). Secondly, by stimulating innate humoral defences and increasing the presence of innate immune cells in the submucosa of the intestine as shown by elevated levels of lysozyme and IELs, CD4+, CD8+ cells respectively. Together these findings demonstrate the potential of bacterial postbiotics to support intestinal and skin immunity and warrant further research on their application in target species.

LOW-COST DENITRIFICATION IN BRACKISH WATER AQUACULTURE PRODUCTION

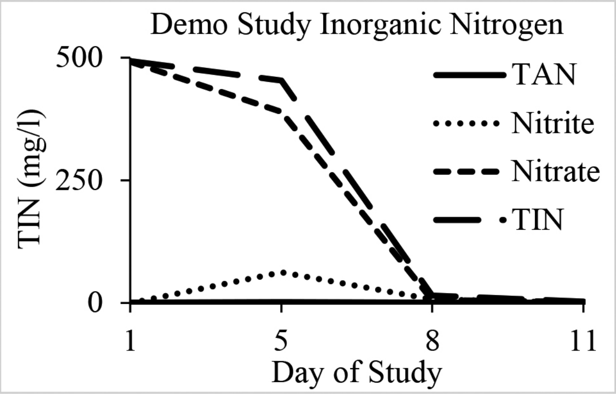
Andrew J. Ray*, Mark E. Johannemann, Leo J. Fleckenstein

School of Aquaculture and Aquatic Sciences
Kentucky State University Land Grant Program
Frankfort, KY 40601 USA
andrew.ray@kysu.edu

Nitrate accumulation is a primary limiting factor of water reuse in many recirculating aquaculture systems (RAS). Water reuse is critical in inland marine RAS, as expensive artificial sea salts are often used to create salt water. Denitrification, a process in which facilitative anaerobic microbes reduce nitrate to dinitrogen gas, may allow producers to reuse water for extended periods of time. This may result in significant cost savings for producers and may have positive environmental impacts by reducing wastewater discharge. This presentation will cover several past and ongoing trials investigating simple, low-cost denitrification methods in brackish water aquaculture systems.

Three studies and a demonstration project were conducted to examine different denitrification strategies. The first study examined the effectiveness of simple, external denitrification chambers containing different media types. The treatments included plastic bio-media (BM), expanded clay pellets (EC), woodchips (WC), and a control (CO) using no media. A second study examined the addition of ethanol at a 2:1 carbon: nitrogen ratio to 4 different treatments filled with water from an active shrimp production system. The treatments were aerated with ethanol, aerated with no ethanol, no aeration with ethanol, and no aeration with no ethanol (AWE, ANE, NAWE, and NANE). The third project examined denitrification in used aquaculture water using different carbon: nitrogen ratios (1:1, 3:1, 5:1, 0:1) created through ethanol additions in systems with no aeration. The demonstration project tested a denitrification method using ethanol at an active shrimp farm in a 17 m^3 shrimp tank.

The first study showed that all media types and the control (no media) can denitrify to some extent, which led to further investigations using low oxygen/low ORP environments in bodies of water without an external denitrification chamber. The second study showed a significant amount of partial denitrification in the NAWE treatment, but this treatment also had a large amount of nitrite accumulation, indicating insufficient carbon or insufficient time. The third study showed over a 95% reduction of nitrate in the 1:1 and 3:1 treatments over the course of 27 days. The demonstration study showed a significantly faster rate of denitrification, likely due to temperature. Nitrate fell from 495 mg/l to 2.9 mg/l in 11 days and only required 35 L of ethanol to denitrify 17 m^3 of water. This has important implications for shrimp producers, as a rapid and low-cost denitrification method may significantly increase the longevity of water reuse and greatly reduce water discharge and salt use.



NON-HALOPHYTE PLANT SPECIES IN BRACKISH-WATER AQUAPONICS

Andrew J. Ray*, Jill C. Fisk, Leo J. Fleckenstein

School of Aquaculture and Aquatic Sciences
Kentucky State University Land Grant Program
Frankfort KY 40601 USA
andrew.ray@kysu.edu

Brackish-water aquaculture producers often face challenges with nitrate accumulation to the point it becomes toxic to animals. Disposing of high-nitrate water wastes both water and salt, can be toxic to terrestrial crops, and often cannot be discharged into municipal sewer systems. Using aquaponics to reduce waste discharge while producing marketable plants is gaining popularity globally; however, brackish water producers are typically thought to be limited to halophytes, or salt-tolerant plants only. Although halophytes grow well and remove nitrogen in brackish water systems, the plants are often unknown to consumers, or are not palatable. Finding non-halophyte species that are tolerant of salt and better known to consumers may allow producers to utilize aquaponics and reduce water and salt use.

Over 10 different plants have been tested at KSU to determine their suitability for brackish water aquaponics. Each plant is evaluated for salinity tolerance by growing plants in 0, 5, 10, 15, and 20 salinity. Plants that show high survival and growth at elevated salinities are used in further trials that examine plant performance in situations representative of shrimp farming conditions. Variables such as varying nutrient concentrations, plant age, acclimation strategies, decoupled versus coupled aquaponics with shrimp, and the effects of supplemental iron on chloride tolerance have been tested.

Kale has been a standout performer with 100% survival even at 20 salinity. Mustard has also shown high survival while only showing moderate growth reduction at higher salinities. A primary finding is the importance of an acclimation period. This acclimation process involves germinating plants in freshwater, then increasing salinity over a two-week period. Many plants show survival at 5, 10, and even 15 salinity when using this acclimation period. Changes in nutrient uptake and tissue concentrations have been noted, particularly replacement of Ca and K by Na, while Mg seems to be unaffected. Some plants appear to store excess Na in leaf tissue, while other plants (notably kale), appear to have lower amounts of Na in the leaves and can reduce Na uptake at the roots or have a Na transport/evacuation ability. Nitrate uptake rates tended to decrease as salinity increases across all plants, however significant amounts of nitrogen were removed from the water, even at 15 and 20 salinty. Other findings are the increased necessity of dosing certain nutrients at high levels compared to freshwater, particularly iron. This line of research has opened potential opportunities for brackish-water aquaculture producers. Further research will include human sensory profiles of the plants and consumer acceptance studies.

EXPERIMENTAL HANDLING CHALLENGES AFFECT THE MONOAMINE SYSTEM, PHAGOCYTIC CAPACITY AND TRANSCRIPTOME OF MARAENA WHITEFISH (*Coregonus maraena*)

Introduction

Maraena whitefish *Coregonus maraena* responds to stressors in a more sensitive fashion[1] than salmonids that are better adapted to husbandry conditions, such as rainbow trout or Atlantic salmon. There are only limited reports on the physiological reactions of maraena whitefish to unavoidable aquaculture procedures. However, the response to environmental challenges is reflected on multiple physiological levels (Fig. 1a). A comprehensive panel of biomarkers provides a reliable source of information for evaluation of the actual immune status and the impact and severity of such a challenges. We analysed the monoaminergic response in the brain, the phagocytic capacity of myeloid head kidney cells and the transcriptomic response of the head kidney to acute and repeated exposure to handling of maraena whitefish.

Material & Methods

Maraena whitefish with a start weight of about 200 g were subject to a single handling challenge followed by sampling after 3 h (n = 8) and 24 h (n = 8) or repeated daily handling over a period of 10 days (n = 8); an equal number of untreated control animals were included. For the single handling challenge, a total of 16 fish were intermittently chased and netted for 1 min. They were then lifted separately from the tank and transferred into a secondary tank, where they were kept until the 3 h or 24 h post-handling time point. The repeated handling procedure was applied on a daily basis for a 10 day period, and the eight treated fish were sampled at 24 h after the last handling treatment. Cohorts of control fish (24 fish in total) were kept in parallel under identical conditions but not exposed to the handling challenge. The plasma cortisol concentrations were quantified using a competitive enzyme-linked immunosorbent assay. Microarray-based gene-expression analysis of head kidneys was performed on 8×60 K AgilentSalmon Oligo Microarrays following the Agilent 60-mer oligo microarray processing protocol. RNA isolated from brain was used for expression profiling of panel of relevant genes. A suspension of head-kidney cells was incubated with or without fluorescein isothiocyanate-labeled *Aeromonas salmonicida*. The cell suspension was then analysed by fluorescence activated cell sorting using a MoFlo XDP high-speed cell sorter.

Results

Brain neurochemistry responded to a single episode of handling with increased serotonergic activity 3 h post-challenge. This was accompanied by a modulated expression of monoaminergic receptor genes in the hindbrain (Fig.1b) and a significant increase of plasma cortisol (Fig.1c). Microarray analysis of head-kidney samples from the challenged and control fish revealed 12 and 70 differentially expressed genes at 3 h and 24 h, respectively, after the single handling episode. Only 12 genes were found differentially expressed after 10 days of repeated daily handling (Fig.1d). The identified genes were assigned to numerous stress- and immune-relevant functional pathways, including “glucocorticoid receptor signaling” (3 h post challenge), “HIF1A signaling” (24 h post challenge), or “complement system” (10 days of repeated challenge).

The phagocytic capacity of myeloid cells from maraena whitefish was significantly decreased by 37% at 3 h after handling compared with the undisturbed control fish (Fig.1e).

Discussion and conclusion

Our data indicate that relatively short handling procedures have a measurable impact on the physiology of maraena whitefish and should be minimized as much as possible to prevent increased disease susceptibility. Our data also show that habituation may decrease the activation of the stress axis and subsequent immune suppression. Therefore, close monitoring of the wellbeing of fish in aquaculture is essential to establish a balance between challenges that cause distress and subtler challenges that can lead to habituation.

(Continued on next page)

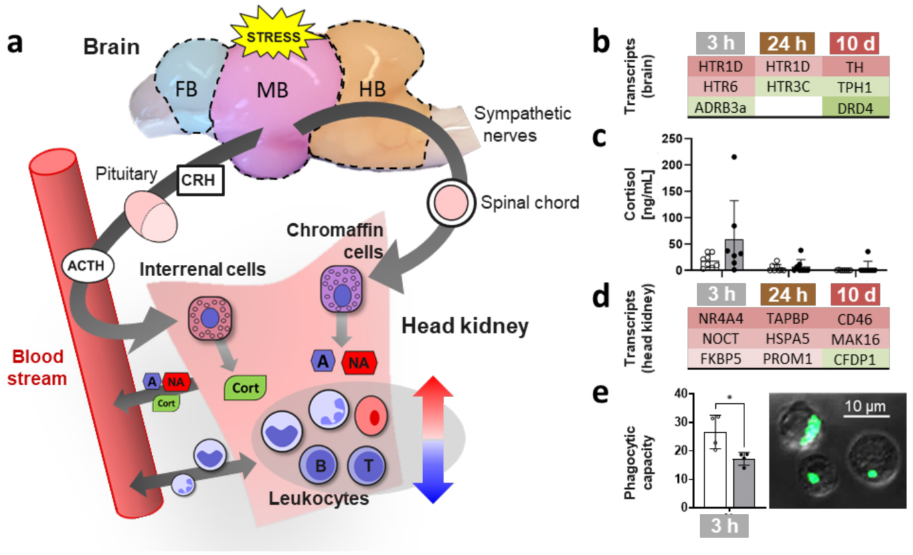

Fig.1 **Graphical summary** about (**a**) the three levels of the stress response in teleost fish and (**b-e**) major results of the present study. (**a**) The primary response activates the brain-sympathetic-chromaffin axis transferring the stress signals to chromaffin cells in the head kidney, which releases the catecholamines adrenaline (A) and noradrenaline (NA) into the bloodstream. In parallel, the activation of the hypothalamic–pituitary–inter-renal axis stimulates the release of corticotropin-releasing hormone (CRH) and adrenocorticotropic hormone (ACTH) into the blood. ACTH, in turn, induces the inter-renal cells in the head kidney to release cortisol (CORT) that promotes the secondary response of reorganizing the availability of energy resources. The tertiary response includes the reprograming of the immune system, behaviour, growth, and reproduction. (**b**) The most differentially expressed genes in brain 3 h and 24 h after single handling and 10 days after repeated daily handling. (**c**) Plasma cortisol concentrations in the treated (grey bars) and control (white) maraena whitefish. (**d**) The most differentially expressed genes in head kidney 3 h and 24 h after single handling and 10 days after repeated daily handling. (**e**) Phagocytic capacity of myeloid cells from treated (grey bar) and control (white) maraena whitefish 3 h after a handling challenge; confocal microscopy was used to validate the phagocytosis of labelled bacteria by myeloid cells.

INCLUDING FAR-FIELD IMPACTS AND LOCAL CONTEXT IN THE ECO-CERTIFICATION OF MARINE SALMON FARMS

M. Rector[1]*, R. Filgueira[1], J. Grant[2]

[1] Marine Affairs Program, Dalhousie University, Halifax, Nova Scotia, B3H 4R2, Canada

Email: megan.rector@dal.ca

The overall production of marine salmon aquaculture and the production of eco-certified marine salmon aquaculture have increased significantly over the past 20 years. Increasing demand for eco-certified seafood indicates that eco-certification has been successful in creating a market for sustainable seafood, but the potential for eco-certification to produce positive sustainability outcomes is less certain (Jonell et al., 2013; Tlusty, 2012; Tlusty & Thorsen, 2017). Two limitations of eco-certification in improving salmon farming sustainability are: (1) the application of global eco-certification criteria in specific and unique local contexts, and (2) the risk of excluding far-reaching impacts of aquaculture in the farm-scale application of eco-certification schemes (Amundsen et al., 2019; Amundsen & Osmundsen, 2019; Bush et al., 2019). Therefore, the goal of this study is to explicate the role of local context and the far-field impacts of aquaculture in the eco-certification of marine salmon farms.

Interviews with industry professionals who have experiential knowledge in the application, auditing, and/or design of eco-certification criteria took place over a year-long period. Conversational interviews consisted of open-ended questions about the role of eco-certification in marine salmon aquaculture. Additional materials identified through interviews and review of eco-certification scheme websites were also used to explore the role of farm location and far-field impacts of aquaculture in the application and outcomes of the eco-certification of salmon farms. Thematic coding of interview transcripts, eco-certification criteria, and variance requests were used to identify common challenges in the application of eco-certification in local contexts and how far-field impacts are considered and evaluated in the application of eco-certification criteria.

Preliminary results indicate that differences in auditor approach, training, and experience play a role in resolving conflict between local context and eco-certification criteria. Although eco-certification is a farm-scale approach to sustainability, some eco-certification schemes incorporate an ecological perspective by including criteria that reference regulatory requirements such as environmental assessment and participation in area-based management plans.

COMPARATIVE STUDY ON EPA AND DHA CONTENT AND FATTY ACID PROFILING OF CERTAIN MARINE BY-CATCH FISH SPECIES AVAILABLE IN INDIAN WEST-COAST WATERS WITH COMMON INDIAN FOOD FISHES

Steffi Reji[1]*, Aldon Baby[2], R. Anandan

The University of Nantes, Nantes, France
*Email: steffireji97@gmail.com

Introduction

The estimated level of capture fisheries in India is about 5.4 million tonnes. Of these 3.8 million tonnes is contributed by marine sector. The by catch landings in India is about 58000 tonnes which constitutes nearly 2% of the total landings. Among the by-catch, deep sea fishes constitute a good quantity of discards from deep sea trawlers operating at off south west coast of India. Harvesting of under-utilised fish resources is one of the effective methods to increase the capture fish production. Moreover, it also allows the recovery of over exploited conventional fish resources. Under exploited marine fishes caught are a found to be a hopeful potential resource. An attempt has been done to compare the chemical composition and fatty acids profiling of three mesopelagic fish species found in Indian west- coast waters *viz Canthidermis maculata, Gephyroberyx darwinii* and *Satyrichthys adeni* with three commonly available Indian food fishes *viz Sardinella longiceps, Rastrelliger kanagurta* and *Stolephorus commersonii*.

Materials and methods

The fish species were filleted, skinned and the homogenized fish samples were used for nutritional analyses. The samples were determined by AOAC method (2005) for moisture content, total nitrogen, crude fat an ash content. Analysis of fatty acid methyl esters of lipid extracted by the method of Folch et.al (1957) were analysed with Gas Chromatography equipped with Elite-225 capillary column (60m length and 0.25 ID) and Flame ionizing detector using nitrogen as carrier gas. Calibration of GC was done using standard FAME mixtures (Supelco Germany). Analyses were repeated three times and the results were expressed as mean ± standard deviation.

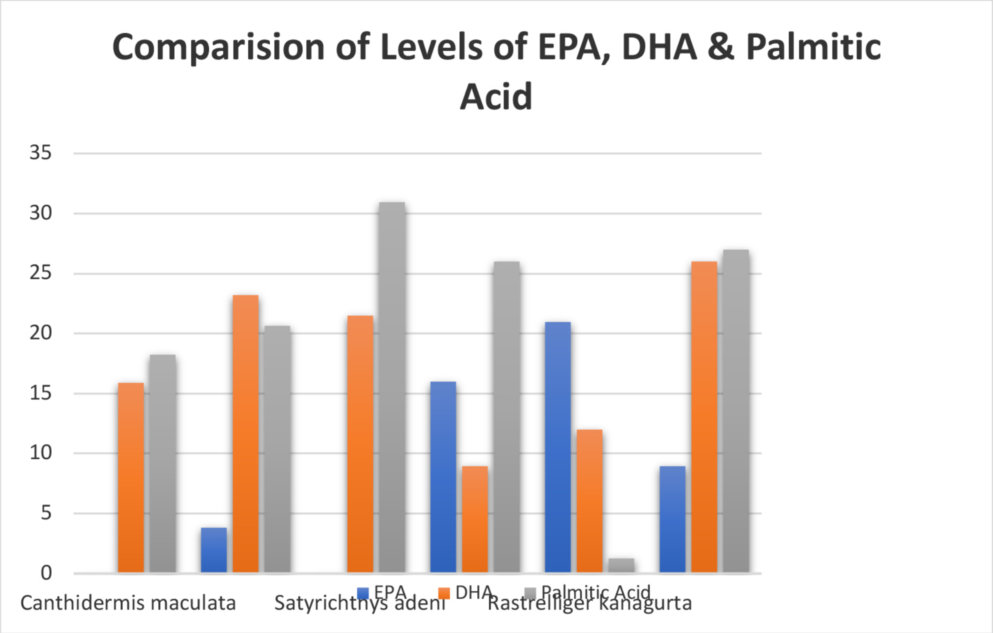

Fig 1: Comparison of levels of EPA, DHA and Palmitic Acid in *Canthidermis maculata, Gephyroberyx darwinii* and *Satyrichthys adeni* with *Sardinella longiceps, Rastrelliger kanagurta and*

(Continued on next page)

Results

Nutritional profiling has revealed a good amount of protein in all by-catch fish species *viz Canthidermis maculata* (21.99%)*, Gephyroberyx darwinii* (19.97%) and *Satyrichthys adeni* (20.99%) than the food fishes *viz Sardinella longiceps, Rastrelliger kanagurta* and *Stolephorus commersonii*. Substantial level of docosahexaenoic acid (DHA) is found in marine species viz *Canthidermis maculata* (15.94%), *Gephyroberyx darwinii* (23.23%) and *Satyrichthys adeni* (21.52%) is higher than the levels in food fishes. Furthermore, the species *Canthidermis maculata* (18.26%), *Gephyroberyx darwinii* (20.68%) and *Satyrichthys adeni* (30.98%) has considerable amount of palmitic acid as that of food fishes *Sardinella longiceps* (26%)*, Rastrelliger kanagurta* (1.24) and *Stolephorus commersonii* (27%). Of the three mesopelagic fish species, only one species *Gephyroberyx darwinii* (3.87%) showed remarkable levels of eicosapentaenoic acid (EPA). The presence of caproic acid in significant level is also evident in *Canthidermis maculata* (59.70%) and *Satyrichthys adeni* (14.64%). The results of this study show that these marine species can be considered as a potential nutrient resource in the formulation of fish-based products, pharmaceuticals and also in animal feeds.

The blue bar depicts the EPA, orange shows the level of DHA and palmitic acid in species is shown in ash bar.

GENETIC VARIABILITY WITHIN AND ACROSS SEA CUCUMBER POPULATIONS FROM DIFFERENT MEDITERRANEAN SITES

Introduction

Sea cucumbers (class Holothuroidea, phylum Echinodermata), also named holothurians, are widespread all over the world seas and play an important ecological role for their bioturbation and alkalinization activities of the seabed. These species are also considered economically relevant for Asian luxury food (e.g. trepang) and traditional medicine markets, as well as for the production of pharmaceutical and cosmetic bioactive compounds. Their economic relevance has caused an over-exploitation of holothurians to supply these specific markets, especially in the Mediterranean area where the excessive fishing is a quite recent phenomenon. The massive withdrawal of sea cucumbers from the Mediterranean Sea (hundreds of tons of holothurians per year) has been demonstrated to have a negative impact on the marine benthonic ecosystem and caused a biodiversity loss among populations and in some places their complete extinction. For these reasons, few initiatives are recently evaluating sea cucumbers as novel aquaculture species.

The aim of this study was to evaluate the level of genetic diversity within two Mediterranean sea cucumber species, *Holothuria polii* and *Holothuria tubulosa*, across different Mediterranean areas, before considering the implementation of conservation actions and as a first step in establishing cultivated stock populations. We analyzed portions of *cox1* and *16S* mitochondrial gene sequences because of their informativeness both for species identification across the genus *Holothuria* and for genetic variability estimations within and across different populations.

Materials and methods

A total of 240 holothurians, 120 belonging to *H. polii* and 120 to *H. tubulosa*, have been sampled from three sites across the Mediterranean Sea in a range of depth from 8 to 22 meters, on different substrates seabed typologies (sand, rock, *Posidonia* meadows). Total DNA was extracted from the integument of all specimens, then amplified with specific primer pairs targeting *cox1* and *16S* genes of mtDNA of both species and Sanger sequenced. A Neighbour Joining (NJ) phylogenetic tree has been generated using 1000 bootstrap replicates from a reduced dataset of 34 *cox1* sequences, including six samples per species per site and two outgroups (*H. scabra* and *H. forskali*). Then, genetic divergence (*p-distance*) within and between species have been calculated using the Maximum Composite Likelihood model assuming the rate variation among sites with a Gamma distribution (shape parameter = 1).

Results and discussion

The estimation of genetic diversity shows that the average *p-distance* is similar between and within species (0.10 and 0.09, respectively; Table 1).

Figure 1 shows the phylogenetic tree derived from of the holothurian mtDNA *cox1* gene. A clear differentiation between the two species is evident, confirming the informativeness of this mtDNA gene region, which can be also applied also for authentication purposes of sea cucumber derived food products. Moreover, the NJ tree shows no differentiation within species between site populations, indicating the existence of active gene flows among Mediterranean sites populations.

Finally, evidence of heteroplasmy in mtDNA sequences of a total of five holothurians of both species have been identified, suggesting that some hybridization events might have occurred between these two sympatric species, as already reported in other studies. Figure 1 shows two of the five animals in which heteroplasmy was detected: their position in the tree is nested to the cluster of their respective species.

(Continued on next page)

Genetic diversity	Average	Standard Error
Inter species diversity (p-distance)	0.10	0.03
Intra species diversity (p-distance)	0.09	0.02

Table 1. Genetic diversity (p-distance) between and within *Holothuria polii* and *Holothuria tubulosa.*

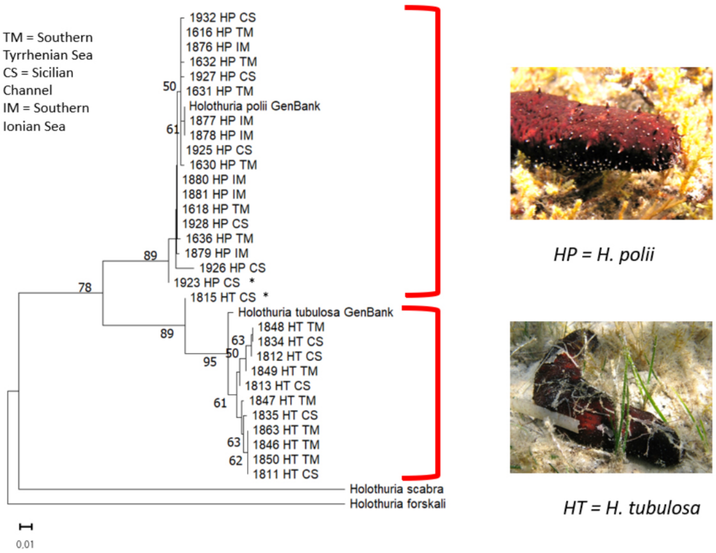

Figure 1. Neighbour-Joining phylogenetic tree of three populations of *H. polii* (HP) and *H. tubulosa* (HT) in Mediterranean Sea (TM = Southern Tyrrhenian: CS = Sicilian Channel; IM = Southern Ionian). The percentage of replicate trees in which the associated taxa clustered together in the bootstrap test (1000 replicates) are shown next to the branches. * Samples in which evidence of heteroplasmy have been identified. For these sequences, the possible two mtDNA haplotypes were not inferred.

Conclusions

The results of this study provide genetic markers useful for holothurian species identification and an overview of the genetic variability existing in three populations of *H. polii* and *H. tubulosa* in the Mediterranean Sea. Further studies are needed to disentangle the origin of the mtDNA heteroplasmy reported in a few samples. These data will be useful to establish cultivated stocks with high level of genetic variability.

Acknoledgements

Introduction

Fish and aquatic foods are associated with numerous health benefits not just as a source of protein, but also as an exceptional and diverse provider of essential omega-3 fatty acids and bioavailable micronutrients. Aquaculture is the fastest growing agri-food sector globally and has huge potential to feed and nurture the world's growing population (FAO 2022). However, aquaculture of carnivorous fish is highly dependent on fishmeal (FP) and fish oil (OP) from wild fish stocks, creating an urgent sustainability challenge. The partial replacement of FP and OP by plant ingredients is already a common practice in the industry. However, concerns arise about the effects of FP and OP substitutions on the nutritional value of fish muscle and on the content of concomitant beneficial nutrients for humans, as plant ingredients used instead are devoid of the aforementioned n-3 LC-PUFA. Since one of the goals of aquaculture is to promote health guaranteeing the supply of omega-3s to the consumer, recommended by the World Health Organization, it is essential to investigate strategies to overcome this problem. That is what OmegaPeixe project aims at: the production of differentiated fish with a high content of omega-3 LC-PUFA, focusing on species of great relevance and value in Southern Europe - European seabass and turbot. In order to have real impact, this innovative product must be viable on the market, meaning that the increase in costs per kg of fish produced should be lower to the price increase that the consumers are willing to pay for a high-quality product, rich in omega-3s. A comprehensive consumer survey was carried out nationally and in the relevant European countries to evaluate the market's acceptance of differentiated aquaculture products, considering the general consumer segment and also the Organic products sector.

Objectives

To carry out a comprehensive consumer survey, both nationally and in relevant European countries, a questionnaire was developed with the main purposes of:

1. Assess the consumer's willingness to pay for omega-3 fortified aquaculture fish.
2. Assess the level of consumer confidence in aquaculture products.
3. Identify trends in fish consumption.

Material and methods

The online questionnaire was designed and adjusted, considering the multivariate analysis carried out on the pre-test to allow for the collection of information on the target audience - socio-economic characterization data, consumption data of fish and aquaculture products, willingness to pay for value added products, level of trust and preference for aquaculture products. The questionnaire was disseminated by the project promoters, through their commercial and institutional contact networks, as well as through social networks. Additionally, relevant consumer entities from the aquaculture sector and NGOs were approached to participate in the dissemination of the questionnaire to make it as comprehensive as possible. Responses were collected over a 5-month period from September 16, 2021 to February 16, 2022. The information collected was statistically treated in IBM SPSS Statistics 28.0 program applying Multivariate Analysis so that hypotheses and relationships between variables could be assessed.

Results

In this study 1349 valid questionnaires were obtained, with respondents aged 18-82 years, 61.7% living in Portugal and 30.9% living in Spain. 75.7% of the respondents live less than 20 km from the coast and 84% in urban areas; 80% are active, the average monthly household income is over 3000 € for 21.1% of the respondents and 33.4% spend more than 400 € monthly on food. Additionally, 88.3% have never worked in the aquaculture sector and 97.4% are fish consumers. The most reported consumed fish is salmon (60.9%, 800 responses), followed by cod (52.2%, 689) and tuna, with similar values of preference (51.7%, 680). 35% consume sea bass and 2.6% consume turbot. 45% of the fish consumers prefer fish of national origin, with only 2.5% preferring fish from outside the European Union. The respondents are well informed, as 88.9% know what omega-3s are. About 50% of fish consumers and more than 45% of those who do not usually consume fish would be willing to pay at least 1€/kg more for fish fortified in omega-3. 37.1% of respondents that do not consume fish would consider eating it if they knew that it was an enriched food and that it provided an extra health benefit.

Introduction

The monogenea parasites are responsible for the majority of stock losses, leading to economic losses in aquaculture, affecting several species (Doan et al, 2020). In Mediterranean aquaculture, sea breams are also produced, as are *Sparus aurata* and *Dicentrarchus labrax*. This is the case of *Diplodus cervinus*, which is produced in land-based tanks, notably in polyculture with other species. Most bream are more sensitive to ectoparasites than other commonly produced species such as sea bream, sea bass and meagre. The aim of this paper is to describe how the monogenea *Microcotyle* spp. affects the gills of *D. cervinus* and to analyze the level of infection.

Methods

An anomalous behavior of reared fish was observed in a earthen pond of a semi-intensive production system at the Aquaculture Research Station of Olhão. Thus, six *D. cervinus*, were collected for pathological analysis, microbiology, external and internal parasites observation. Firstly, the animals were sacrificed with a spin column insition and the four left-sided gill arches were removed and the presence of parasites was verified and counted under an optical microscope. After that, the first two gill arches on the right side were collected for histology, placing them in 4% buffer formalin for 48 hours and transferred to 70% ethanol. The slides were sectioned and stained with haematoxylin and eosin. Finally, the mounted slides were scanned with Hamamatsu NanoZoomer C13140-01 and the images visualized with the NDP. The level of lesions was classified according Poleksic & Mitrovic-Tutundzic (1994).

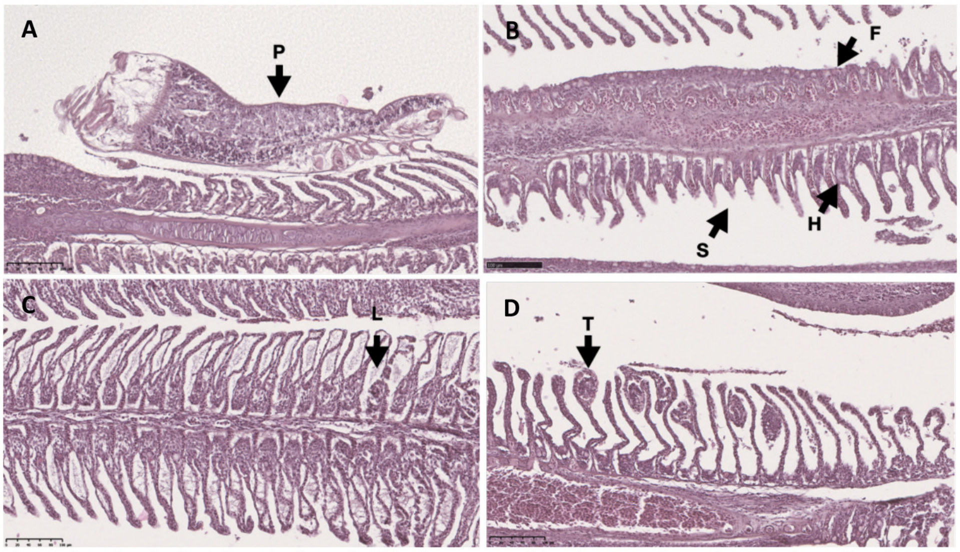

Figure 1 - Histological description of gill lesions caused by the parasite *Microcotyle sp.* in *Diplodus cervinus*, A) P - part of the parasite *Microcotyle sp.*; B) F - fusion; H - hyperplasia; S - shortening of the secondary lamella; C) L - lifting of filaments; D) T - lamellar telangiectasis

(Continued on next page)

Results and Discussion

Water temperature in ponds was 19,5 ± 1°C. *D. cervinus* exhibited swimming near the surface. Thus, a pathological analysis was performed revealing the presence of monogenean *Microcotyle sp.* in the gills and its mean intensity was 1,83 (1-6) parasites per gill arch in each fish. Concerning other pathogens, there was growth of *Pseudomonas* sp. on plate . However, no other external and internal parasites were observed in the remaining fish.

With the presence of the parasite, observed in histological sections, the gills presented some alterations, the most recurrent were hypertrophy and hyperplasia of gill epithelium, lifting of epithelium cells, rupture lamellar, fusion and shortening of secondary lamellae, filament blood vessels enlargement, thinning or thickening of respiratory epithelium, lamellar telangiectasis and in some places degradation of the epithelium may occur (Figure 1). In general, the severity of lesions was classified as moderately to heavily, However, many of these changes belong to the first phase, in which there is not a high severity in the tissue, managing, through appropriate environmental conditions, to recover the normal structure of the tissue.

In conclusion, the monogenea *Microcotyle sp*. causes some lesions on the gills of the host *D. cervinus,* and it is necessary to implement prevention and mitigation measures for this parasite, so that infections decrease in aquaculture.

Introduction

Plastics are ubiquitous pollutants found in marine, freshwater, and terrestrial environments. Microplastics (MPs) are defined as plastic particles ranging from 1μm to 1 mm in diameter, whereas nanoplastics (NPs) have a particles size range of 1-1000 nm. One of the main risks deriving from MPs and their nanoscale forms is their bioaccumulation along the food chain, which potentially represents a threat not only for the environment but also for human health. There are evidences of MPs accumulation in the digestive system of fish causing various adverse effects, such as damage to the gastrointestinal tract, cytotoxicity, and dysbiosis (Montero et al., 2022). The translocation of MPs from feed to fillet has been also detected in two of the most important commercial fish species: gilthead sea bream (*Sparus aurata*) (Jovanović et al., 2018), and European sea bass (*Dicentrarchus labrax*) (Zeytin et al., 2020). As a consequence, humans may be exposed to high MP and NP levels by seafood consuming.

The MPs and NPs identification are becoming an emerging issue for consumer health, and recently a new analytical method of identification in complex matrices based on *μ*-Raman spectroscopy has been developed (Valsesia et al., 2021). The present research represents one of the first attempts to evaluate the presence of MPs and NPs in a commercial raw material used for aquafeed formulations, such as meal from black soldier fly (*Hermetia illucens*) larvae, which is considered a valid and sustainable alternative to fishmeal. Insects for aquafeeds are generally produced in a frame of circular economy, as agri-food wastes are commonly used as rearing substrate for their larvae.

Materials and Methods

Sample preparation. An aliquot of commercial insect meal was digested overnight with 10% (wt/vol) KOH at 60°C. Two sequential vacuum filtration steps of digested sample were performed on polycarbonate filter membranes (12 μm) and then, on a pore size filter of 2 μm.

Confocal Raman microscopy (CRM) analysis of 2-12 μm plastic fraction. Analysis of filter was performed using an inVia™ Confocal Raman microscope (Renishaw). Optimization of Raman signal was set as follows: 1 s, 10% laser, 10 accumulations, range 1700-3000 cm^{-1}. Extended analysis of spectrum (200-3500 cm^{-1}) was performed on more interesting objects setting the Raman signal at 5 s, 10% laser, 5 accumulations.

Scanning electron microscopy (SEM) analysis of < 12 μm and < 2 μm plastic fractions. An aliquot of digested sample was filtrated on 12 μm pore size polycarbonate filter membrane and the eluate was manually spotted on a silicon (Si) Teflon-coated wafer and dried under nitrogen flux before imaging. To analyze plastic particles of less than 2 μm, filtrate from 2 μm pore size filter was firstly concentrated using an Amicon Ultra 2 mL Centrifugal Filter Unit (30,000 MWCO) and then, manually spotted over a rough superhydrophobic surface (Si wafer coated with polydimethylsiloxane). The presence and distribution of small plastic particles was performed by spotting sample on a positively charged surface to immobilize the particles in random separated positions thus permitting SEM counting and Raman identification. Scanning Electron Microscopy of samples was performed using a Nova 600i Nanolab equipped with an Energy Dispersive X-Ray spectroscopy (EDS) system for elemental analysis.

Transmission Electron microscopy (TEM) Analysis of < 2 μm plastic fraction: TEM coupled with Energy Dispersive X-Ray spectroscopy (EDX) was used at 120 kV in both TEM and STEM modes to characterize primary size, morphology and elemental composition of plastic-like particles, in the nanosize range dimension. The elemental analysis was done in STEM, bright field, and hypermap mode (Quantax software, Brüker, Italy) to identify the carbon content.

(Continued on next page)

Results

The KOH treatment efficiently digested the organic matter of lipid-rich insect meal sample eliminating a large part of the biological matrix. Six different areas of filter corresponding to 0.01% of the whole filtering surface were analyzed with Renishaw CRM. A total of 328 objects were manually recognized and mapped. Among them, seven were recognized as polymers of polyethylene (PE) with a size < 10 µm. Considering the volume of sample filtered and the fraction of area of the filter analyzed at best resolution, the potential hit of polymer objects in the whole sample was calculated. In this case we found a concentration of 7 x 10^5 particles in 0.5 g of insect meal.

SEM counting and Raman identification performed on sample (< 2µm fraction) spotted on positively charge surface confirmed the presence of nanoparticles of PE in insect meal. Accordingly, the same analysis performed on sample spotted on superhydrophobic silica surface established the presence of aggregates of PE particles.

TEM coupled with EDX confirmed the presence of plastic-like morphology structures inside the digested insect meal sample. The corresponding EDX analysis in STEM mode displayed that these objects contained carbon in higher concentration consistent with PE plastics.

Conclusions

In conclusion, our results demonstrated the presence of MPs and NPs in commercial insect meal. The method used was suitable even for the extraction of nano size particles. A combination of Raman microscopy, SEM/EDS, TEM/EDX led to a successful detection of both micro and nanoplastics in a complex organic matrix such as insect meal with a reliable estimation of their concentration.

Introduction

Plastics are a ubiquitous source of marine pollution, especially in the form of microplastics (MP). Exposure and contamination of fish and other seafood products by MP is a major concern worldwide and brings two types of risks to fish culture: 1) disruption of fish growth and reproduction thereby impacting operational capacity and 2) possible adverse health effects on consumers of fish products contaminated by MP. Culturing of fish in onshore recirculating aquaculture systems (RAS) can on the one hand potentially reduce exogenous MP contamination, i.e., from seawater, via water filtration, but on the other hand may expose fish to endogenously generated MP, i.e., from within the RAS plastic components, or even be contaminated through fish feeds derived from marine sources. Aiming for two major objectives: 1) knowing whether MP contamination in RAS-cultured fish is higher, lower, or equivalent to fish grown in open sea cages or wild-captured fish, and 2) knowing if MP characteristics (particle size and chemical composition, including plasticisers and other additives) are different for RAS-grown fish in comparison to fish obtained from other sources; a consortium formed by SEAentia (RAS meagre producer) and 2 research institutes, IPMA and SINTEF, implemented the project "Minimizing microplastic contamination in onshore (RAS) meagre farming" – MP-RAS, funded by EEA Grants. The aim of this study was to investigate if the RAS water contains differences in the quantity and characteristics of MP content when compared to raw seawater used to fill up the system.

Materials and methods

Over a course of four months, water samples were collected at four sampling points along a newly loaded RAS, used for the growth of meagre (*Argyrosomus regius*). The system has 2 distinct filtration systems: 1) intake water before the recirculation and 2) RAS water inside the recirculation loop. The four sampling points include the seawater inlet, collected from the seashore (SP1), after the intake water filtration and before filling the RAS with water (SP2); Inside the RAS loop, water coming from fish tanks and before entering the filtration system (SP3); and after exiting the filtration components of the recirculation and before re-entering the fish tanks (SP4). Water samples of 10 litres were collected in MP-free glass containers and filtered through 1.2-micron glass-fibre filters. The glass-fibre filters were treated with filtered hydrogen peroxide (30% solution H_2O_2) as an oxidizing agent to digest organic matter. The resulting solutions were filtrated using 20 µm stainless-steel filters and washed repeatedly with ultrapure water. These filters were then put into concentrated NaCl solutions for density separation. To detach the sediments from the filters, sonication was used for 10 min. After 10 min centrifugation at 3000 rpm, the upper part of the solutions was decanted. Lastly, both the upper and lower parts were filtrated using a Whatman Anodisc25 filter. Three successive extractions of the stainless-steel filters were carried out. The glass-fibre and Anodisc25 filters were analysed by optical microscopy using an Olympus DSX100 digital microscope. The amount of particulate matter including MP and microfibres (MF) on the Anodisc25 filters was estimated by image analysis using a Matlab script developed in-house. FT-IR microscopy (Agilent Cary 620/670) was used to assess the material type of some representative MP on the Anodisc25 filters.

Results and Discussion

The seawater used to supply the RAS contained large amounts of particulate matter including MP and MF (Figure 1). These amounts varied over time due to changes in water currents and weather events. The amount of MP and MF was reduced after the first filtration (SP2) but increased again at SP3. Since the fish tanks have no cover on top, particles and fibres from the facility's environment can enter the RAS, which might contribute to the observed increase. The filtration after the fish tanks (SP4) did not reduce the level of MP and MF significantly. A reason might be that this filter system is mainly designed to remove fish and feed-related biological waste but not necessarily MP and MF.

FT-IR analysis of the Anodisc25 filters revealed that the material types of the MP included the most common plastics, such as polyethylene, polypropylene, polyester, and polyamide (Figure 2). Whether some of these MP can be associated with certain components within the RAS is still under assessment. Many of the MF were natural fibres, such as cotton, which indicates that they most likely originate from the facility's environment.

(Continued on next page)

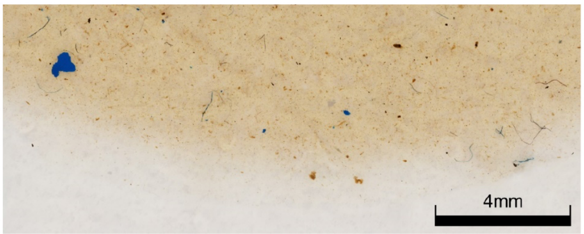

Figure 1 - Microscopy image of a glass-fibre filter from the seawater inlet (SP1).

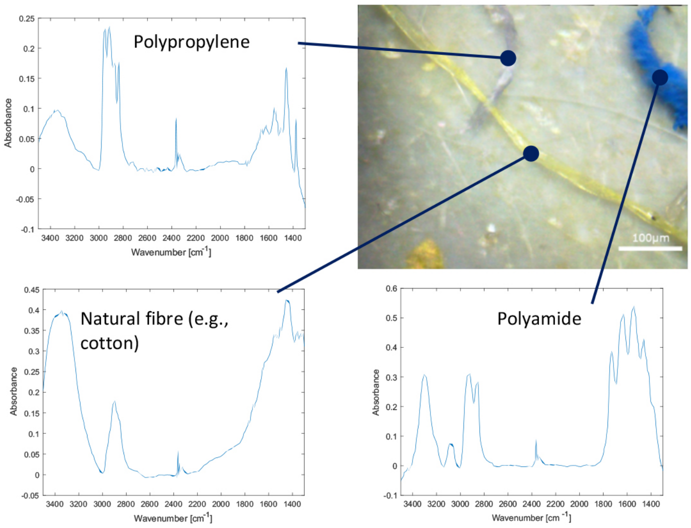

Figure 2 - Microscopy image of an Anodisc25 filter from SP3 showing MP and MF as well as FT-IR spectra of the respective items.

Conclusion

Water samples were collected at four sampling points along a new RAS. These samples were filtered and characterised by optical and FT-IR microscopy, which identified MP and MF from possibly endogenous and exogenous sources. The filtration system at the inlet of the RAS seems to significantly reduce the amount of particulate matter whereas the filtration after the fish tanks is less effective in removing MP and MF.

Introduction

Microplastics (MP) in the marine ecosystem are relentlessly growing, becoming a threat to food safety. This contamination will increase over the foreseeable future with MP already present in the major finfish species harvested for food (2017, FAO Technical paper 615). In aquaculture, fish exposure to MP can: 1) impair growth and reproduction, thereby affecting operational capacity, and 2) cause adverse health effects on consumers of fish products contaminated by MP. Culturing of fish in recirculating aquaculture systems (RAS) may diminish MP contamination through ultra-filtration of the water used to stock the system. However, the system might expose fish to endogenously generated MP, or through fish feed derived from marine sources. To determine the efficacy of RAS in minimizing MP levels of cultured fish, a consortium formed by SEAentia (RAS meagre producer) and 2 research institutes, IPMA and SINTEF, implemented the project "Minimizing microplastic contamination in onshore (RAS) meagre farming" – MP-RAS, funded by EEA Grants. The project will assess the efficacy of the RAS water conditioning system in MP clearance and will compare MP levels of meagre cultured in this system with meagre from wild-capture and cultured in open-sea cages. Detailed knowledge of MP levels and composition in farmed fish coupled with the deployment of technological solutions for minimizing MP contamination will provide added value to the fish product and will have a wider societal benefit by raising awareness of MP pollution while stimulating more widespread use of MP mitigation strategies among fish producers.

Materials and Methods

Analysis of water-borne MP in the RAS

Water samples were collected at four sampling points of SEAentia's pilot RAS. The system has 2 distinct filtration systems: 1) intake water before the recirculation and 2) RAS water inside the recirculation loop. The sampling points were immediately before and after of each of the filtration system. Water samples, after being filtered and processed, were analysed by optical microscopy to assess quantities of particulate matter and also by FT-IT microscopy to determine the material type of MP.

Comparison of MP and related contaminant levels in tissues of RAS-cultured meagre *versus* meagre harvested from open sea cages and by wild-capture

Fish were collected at the beginning and after 12 months of growth in SEAentia, representing RAS-culture meagre population. This approach enables the evaluation of MP content in fish tissues through time and its comparison with wild and sea cage-produced individuals. All the MP obtained from the samples were quantified by colour and shape, and the plastic polymer identified using a Fourier Transform Infrared spectrometer coupled with a universal attenuated total reflectance accessory (ATR-FTIR). MP are usually associated to other contaminants, such as organic pollutants, toxic metals, and plasticizers. The determination of these contaminants was performed applying a specific protocol optimized for this species. With all this information it will be possible to conduct a modelling study to identify the main drivers of the different MP, as well as the correlations between the contaminant content and MP and the nature and strength of such correlations.

Results and Discussion

Results will be presented and discussed with detail, when all the analyses and data treatment are completed.

AMPLICON SEQUENCING REVEALS DIFFERENT NITRIFYING BACTERIA IN RAS BIOFILTERS WITH DIFFERENT SALINITIES

Irene Roalkvam* and Mark Powell

Marineholmen RASLab, Thormøhlensgate 41A, 5006 Bergen, Norway
Email: irene.roalkvam@ilab.no

Recirculating aquaculture system (RAS) operating at a high degree of water recirculation depends on an array of water purification technologies to maintain good water quality, including an active biofilter with high capacity of microbial nitrification for ammonia removal. However, detailed knowledge on microbial colonization, development and influencing factors on these bacteria is still deficient today, despite the use of biofilter technology in aquaculture for decades.

At Marineholmen RASLab, research and development on aquaculture species and technologies are conducted in small-scale RAS units. These units are equipped with 1000L tanks and have microbial biofilters adapted to either fresh water (0ppt NaCl), brackish water (15ppt NaCl) or sea water (34ppt NaCl). The biofilters were inoculated with commercial enrichment culture in May 2020, and have developed to specific biofilters for the 3 different salinities (0ppt, 15ppt or 34ppt NaCl) over the last 2 years. In order to obtain detailed information about the nitrifying bacteria in biofilms from all 3 types of biofilter, targeted 16S rRNA genes from the entre microbial communities were amplified and sequenced using Illumina sequencing technology.

The results revealed great differences in microbial communities present in the specific types of biofilter. Overall, the diversity in the biofilter for brackish water was much lower compared to the biofilters for fresh water and sea water. In addition, the number of common bacterial taxa, i.e. bacteria present in all 3 biofilter types, was only 64, while the number of unique bacterial taxa were 238-335. Within the nitrifying community, brackish water biofilters at Marineholmen RASLab were dominated by the ammonia oxidizing *Nitrosomonas* and nitrite oxidizing *Nitrospira*. In contrast, the fresh water biofilters were dominated by the ammonia oxidizing *Nitrosospira,* which was also present at high relative abundance in the sea water biofilter. Furthermore, the fresh water and sea water biofilters had lower relative abundances of *Nitrospira* compared to the brackish water biofilter, which was also represented by a different species in the latter biofilter type.

In all biofilters, bacteria involved in both steps of nitrification were detected, but different species of nitrifying bacteria were associated with the process in each biofilter. Hence, different salinities seemed to enrich different nitrifying species. These had different growth requirements or responses to changing conditions, but still served a similar function in the biofilters. This clearly indicates that different RAS can contain different biofilters, depending on type and management, which could make it difficult to have standardized protocols on how to operate an RAS biofilter and which response to expect from changing conditions.

TOTAL FISH OIL SUBSTITUTION BY DATE PALM SEED OIL IN *Liza aurata* LARVAE

Y. García[1], R. Quirós-Pozo[1], S. Ramírez-Bolaños[1], J. Roo[1], L. Robaina[1*].

E-mail: lidia.robaina@ulpgc.es

Introduction

Aquaculture has become a fundamental tool to meet the growing demand for seafood, to serve an increasingly demanding consumer in the variety and quality of their food. While diversification of aquaculture production is not a new issue (Abellán & Basurco, 1999; Espinós *et al*., 2011), it is accompanied by the need to supply differentiated, economically profitable, and sustainable products, and in sufficient quantity to meet a global demand that is growing exponentially (FAO, 2022). On the other hand, the search for alternative and scalable raw materials, bioresources or co-products of vegetable origin for feed, to reduce conventional raw materials, primarily meals and oils of marine origin, is essential. This is generally accompanied by difficulties in meeting the requirements of marine fish(Tocher, 2015).

Material and Methods

Four experimental diets with 0%, 50%, 75% and 100 % substitution of marine oils with *Phoenix dactylifera* seed oil were formulated and tested in *Liza aurata* larvae (29 dph) for 25 days.

Afterthe feeding trial,proximal composition, growth, survival, stress resistance and gene expression of Fads2 (fatty acid desaturase) and Elov5 (fatty acid elongase) were evaluated.

Results and Discussion

The results found in the larvae during the 25 days of feeding showed no negative effects on growth, survival and resistance to stress up to 100% substitution of marine oils. Regarding the fatty acid profile in larvae, a decrease in EPA (20:5n-3), ARA (20:4n-6) and DHA (22:6n-3) was found, related to the increase of date seed oil in the diets. On the other hand, gene expression results of Elov5 and Fads2, showed promising trends in larvae fed with the microdiets containing date seed oil, although the values were not sufficient to improve the fatty acid profile.

Therefore, larvae at 54 dph did not show essential fatty acid biosynthesis capacity to the extent reported for the same species in its juvenile stage (Quirós-Pozo *et al*., 2021). Being the first results in this line reported for *Liza aurata*, they open the door to new studies covering the development of the animal between 54 dph and its juvenile stage. Determining the evolution of the ability to biosynthesize long-chain fatty acids contributes to the development of specific feeds for mugilids throughout their culture cycle and the expected overall sustainability of commercial-scale production of these low trophic level species.

Introduction

The growth of the aquaculture industry and high cost of fishmeal and fish oil has resulted in a shift within the feed sector to utilise alternative protein and lipid sources[1]. However, gastrointestinal health must be maintained and/or improved to ensure growth and robust immune responses against disease outbreaks. Currently, *in vivo* testing is the best means of determining digestibility and assessing feed quality. However, *in vivo* testing is both time-consuming and expensive, prohibitively so for many smaller producers[1,2]. *In vitro* digestibility methods have potential as a rapid and reliable way to calculate nutritional values and rank ingredients regarding suitability for inclusion in aquafeeds[2]. Recently, we have adapted the *in vitro* gastrointestinal simulator of cultivated Atlantic salmon known as SalmoSim®[3,4] to assay protein digestibility and absorption to compare against *in vivo* methodology. Here, we aim to test how well SalmoSim®-Digest predicts matching *in vivo* digestibility trial data.

Method and Materials

SalmoSim-Digest consists of bioreactors where pH and temperature parameters are maintained to simulate two different Atlantic salmon's gut compartments (first stomach, then pyloric caecum). At each compartment phase, appropriate enzymes cocktails and bile salts are added to simulate the digestion of proteinaceous aquafeed ingredients over 90 hours. Dialysis was conducted over the same period to allow the transfer of amino acids across a semipermeable membrane. Samples of dialysate were taken at 4-time points (18, 42, 66 & 90 hours) in triplicate for each bioreactor.

One millilitre of dialysate (in triplicate) was analysed for amino acid concentration by Phthalaldehyde amino acid assay with absorbance read at 340 nm with Multiskan Spectrum Spectrophotometer. Data were corrected using the absorbance of seawater (pH7) to calculate zeroed amino acid concentration. Raw ingredients were also analysed using an industry-standard pepsin assay. Apparent digestibility coefficients (ADCs) were calculated by comparing crude protein concentrations (Kjeldahl method) of undigested vs digested feed for both *in vivo* and *in vitro* assays.

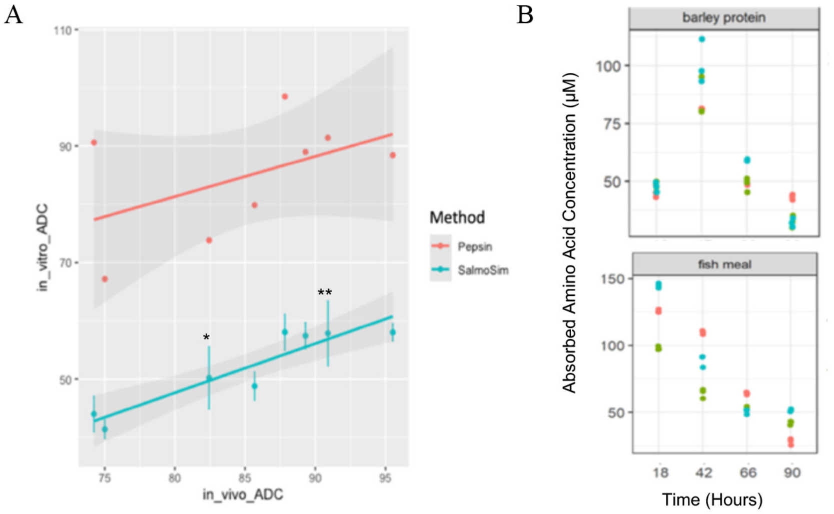

Figure 1: (A) SalmoSim-Digest comparison with *in vitro* trial data by Alltech-Coppens Ltd for *Oncorhynchus mykiss* (Rainbow trout). SalmoSim-Digest, $R^2 = 0.86$ (Blue). Pepsin digestibility assay, $R^2 = 0.23$ (Red). Based on eight feed ingredients (Barley protein * and Fishmeal **) including four different single-cell proteins. (B) SalmoSim-Digest amino acid absorption (µM) for two protein ingredients (Barley Protein and Fish meal) over 90 hours (colours indicate replicates).

(Continued on next page)

Results

The use of SalmoSim in assessing *in vitro* against *in vivo* digestibility revealed that SalmoSim-Digest can accurately predict *in vivo* digestibility trial data in salmonids ($R^2 = 0.86$), compared to ($R^2 = 0.23$) for industry-standard pepsin digestibility assays (Fig. 2A). Concentration of absorbed amino acids accumulated in the dialysate could also be reproducibly estimated at desired time points during digestion revealing distinct temporal patterns of absorbance (Fig 2B) that correspond with ADC profiles of distinct ingredients.

Discussion

We assessed the accuracy of SalmoSim-Digest in predicting *in vivo* salmonid protein digestibility and absorption. Our analysis revealed that we can accurately predict *in vivo* digestibility for proteins in salmonids *in vitro*. In this respect, our assay outperforms the current *in vitro* industry-standard pepsin digestibility assay. Alone, SalmoSim-Digest represents a rapid, cost-effective and ethical tool to assay ingredient digestibility, avoiding *in vivo* trials. Combined, SalmoSim-Digest (digestibility) and SalmoSim (gut microbial communities) offer a powerful tool to explore the link between gut microbes and ingredient digestibility in the Atlantic Salmon gut.

LYSOPHOSPHOSLIPID SUPPLEMENTATION IMPROVES FEED INTAKE AND GROWTH OF TILAPIA (*Oreochromis sps.)* REARED AT LOW TEMPERATURE

R. Robles-Arozarena*[1], L. Bermúdez[1], , A. Girons[2] ,W.G. Nuez-Ortín[3]

Tilapia was the third most farmed fish species globally in 2018 according to FAO 2020 report. Although the species has an optimum temperature range of 26-30ºC, tilapia is cultured at suboptimal temperatures in many countries around the world. The negative impacts of this practice are reflected in feed intake, growth and at last, in an impaired organ and immune system functioning. At low temperatures, several fish species go under the so called homeoviscous adaptation, which is the process to increase the fluidity and permeability of the cell membranes by increasing the fatty acid unsaturation of their phospholipids.

In the last years, lysophospholipids are coming to the scene of aquafeed formulations since they play an important role as emulsifying agent and improve the absorption of lipids and lipid-soluble compounds among other metabolic actions.

In the present work, tilapia fingerlings with an average individual weight 42,02 ± 0,34 g were stocked in 24 tanks of a freshwater recirculating aquaculture system (RAS) during11 weeks at 18ºC temperature (10ºC below optimal temperature for the species). The trial was divided in two periods with different feeding management (7 weeks automatic feeding and 4 weeks manual feeding). Lysophospholipids (Aqualyso, Adisseo) were included in the diet at different levels of inclusion.

Lysophospholipid incorporation in the feed had a positive effect on feed intake (Figure 1), feed conversion and growth of tilapia grown at 18ºC. Somatic indexes were also positively affected by the use of lysophospholipids. Results also showed a relevant role of feeding management on the tilapia culture performance.

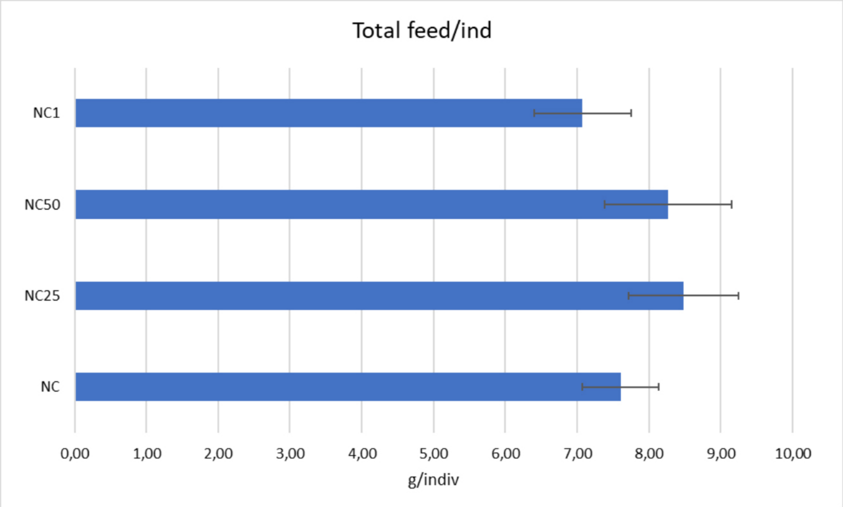

Figure 1. Feed intake, expressed as g/individual, of tilapia fed the four experimental diets (NC, NC25, NC50 and NC1).

UNDERSTANDING OFF-FLAVOUR IN WATER AND FISH OF RECIRCULATING AQUACULTURE SYSTEMS: FROM THE ECOLOGICAL SIGNIFICANCE OF GEOSMIN TO FLAVOR DECRYPTION THROUGH TRADITIONAL AND NOVEL ANALYTICAL APPROACHES

Introduction

Recirculating Aquaculture Systems (RAS) allow for raising fish in a land-based and controlled environment to minimize the direct interactions between production processes and the environment (Ahmed & Turchini, 2021). Even though RAS farms can produce high-quality fish, "musty" and "earthy" off-flavours often taint fish, which can cause significant financial losses for fish farmers (Podduturi et al., 2021). The main volatile compounds that impart those flavours in fish are geosmin and 2-methylisoborneol, besides many other compounds that may additionally play a role in fish off-flavour (Moretto et al., 2022). Traditional procedures to deal with these problems in RAS include oxidation processes, such as ozonation, or fish depuration in cleaner water. The last approach causes weight loss and fish stress, and is also energy- and water-demanding (Podduturi et al., 2021). Scientific and industrial efforts have been applied to minimize these problems, and it has been considered of great importance to use accurate tools for early detection of the presence of microorganisms producing off-flavours, such as highly sensitive molecular biology and advanced sensory analytical techniques to avoid expenses associated with the purification process (Moretto et al., 2022). In a newly established European network project (RASOPTA), novel instrumental and microbiological approaches are combined to help alleviate the present off-flavour issues in RAS production of commonly farmed fish within the EU.

Methods

A workflow developed by four PhD students aiming to comprehend odour issues in RAS is presented. It covers geosmin production ecology and degradation dynamics, influence of fish feed, sensory analytical characterization and quantification of odour-active compounds and consumer acceptance. Specifically, the present work will apply microbiological assessments, such as genetic engineering to study the regulation of the geosmin synthase gene, and bioinformatic tools to identify genes needed for biological degradation of geosmin. In addition, sensory analytical methods (e.g. gas chromatography-mass spectrometry/olfactometry (GC-MS/O), proton transfer reaction-time-of-flight mass spectrometry (PTR-TOF-MS)) will be applied for the characterization and determination of factors that influence off-flavour formation in RAS. Organoleptic properties of the fish and its acceptance will be analysed through sensory evaluation and consumer testing. Furthermore, the impact of fish feed formulation on off-flavour formation will be explored by means of sensory analytics and experimental feed trials with off-flavour free and non-fishmeal-based ingredients.

Expected Results

The expected outcomes of this cluster of projects include identification of dominant off-flavours in water and fish from RAS; application of PTR-ToF-MS technology for off-flavour monitoring ; knowledge on which biotic and abiotic factors up- and downregulate the geosmin synthase gene; test of conventional and new prototypes of fish feeds for off-flavour modulation; identification of off-flavour degrading bacteria; and the analytical characterization of fish and it is relation to sensory perception and consumer acceptance.

(Continued on next page)

Discussion

Recirculating water in RAS may favour bacterial growth and the accumulation of the substances they produce, often including off-flavours with earthy and musty notes. Little is known about occurrence and biology of off-flavour producing bacteria, chemical characterization of the off-flavours and to which extent consumers accept tainted fish. RAS are extremely productive seafood farming systems that can operate throughout the year, in a variety of locations, such as next to major seafood markets, and without being affected by seasonality and environmental variables (Ahmed & Turchini, 2021). On the other hand, RAS are expensive and complex systems that require substantial and multidisciplinary knowledge. Moreover, the management of off-flavours must be eco-friendly, efficient and low-cost. The nutrition and culture environment are critical factors affecting volatile profiles of aquatic animals and are the variables that can be controlled by aquaculture producers (Jones et al., 2022). Hence, it is of great importance to holistically understand the system (biological, chemical and nutritionally) to develop robust methods that can efficiently prevent or manage the presence of off-flavours in RAS. In this project, innovative procedures to mitigate the prejudice of the tainting of RAS fish will be developed by identifying biological and chemical processes leading to production of the off-flavours. Solving off-flavour issues is key for the aquaculture industry, since consumers avoid buying fish products with an unacceptable taste. This approach could ensure high quality of fish products, which would lead to a higher consumer acceptance, in turn benefiting the entire RAS industry.

Introduction

Fish have daily rhythms synchronised mainly to the light/dark (LD) cycle. However, food may be a stronger synchroniser than light for some peripheral organs such as the liver. In aquaculture, nutrition is a major problem, mainly regarding lipid and protein sources and metabolism. Regarding the lipids, their metabolism seems to display daily rhythms in some species such as the zebrafish (*Danio rerio*) and the gilthead seabream (*Sparus aurata*). However, little is known about the existence of daily rhythms in lipid metabolism in other species and, moreover, the effects of the season and feeding time have not yet been studied in fish. The aim of the present research was to investigate the existence of daily rhythms in lipid metabolism (both mRNA expression and enzyme activity) and the lipid profile in the liver of the European sea bass (*Dicentrarchus labrax*). In addition, we tested the relative strength of two synchronisers, LD and feeding cycles, and whether these rhythms present seasonal differences.

Materials and methods

To this end, two samplings were carried out, the first one in December and the second one in June. For each sampling, fish were divided into two groups: one fed in the middle of the light phase (ML) and the other one fed in the middle of the dark phase (MD). Throughout the experiment, fish were kept under natural photoperiod and temperature conditions. After 30 days under the feeding regimes, samples were collected at different time points over a 24-h cycle (ZT0.5, ZT4, ZT7.5, ZT12, ZT16, ZT20 and ZT24.5 h), with ZT0 h belonging to light onset.

Result and discussion

The existence of daily rhythms in the expression of genes from lipogenesis and lipolysis processes was detected in both ML and MD groups and in both seasons. In general, the rhythms were more pervasive in December than in June. In addition, the expression levels were higher in December than in June in both groups. Different important fatty acids such as EPA and DHA displayed rhythms in both groups in December and June, with the amount of lipids being higher in June than December. The present study shows the existence of daily rhythms in lipid metabolism in the European sea bass and the influence of both feeding time and the season of the year on them. In addition, the results highlight the importance of considering circadian rhythms and the environmental factors influencing them when working with processes such as lipid metabolism and nutrition.

Introduction

The animals synchronize their activity to light or darkness, showing daily rhythms in their activity pattern, so they are classified as diurnal or nocturnal. However, several fish species, like the European sea bass (*Dicentrarchus labrax*), can display either diurnal or nocturnal behaviour, which is called dualism. In the wild, European sea bass usually displays nocturnal feeding behaviour in winter and returns to diurnal feeding behaviour in spring and summer. In aquaculture, nutrition is a major problem, mainly regarding lipid and protein sources and metabolism. To date, the effects of the feeding time on lipid metabolism and composition have been little studied, especially considering also feeding patterns of dual behaviour as displayed by sea bass. The aim of the present research was to investigate the differences in the lipid profile in liver, plasma, muscle and perivisceral fat in European sea bass fed at two different feeding times and in two different seasons of the year, winter and summer.

Material and methods

Two samplings were carried out, the first one in December and the second one in June. For each sampling, animals were divided into two groups: one fed in the middle of the light phase (ML) and the other one fed in the middle of the dark phase (MD). Throughout the experiment, fish were kept under natural photoperiod and water temperature conditions. After 30 days under the feeding regime, samples of plasma, liver, muscle and perivisceral fat were collected and frozen immediately. The lipid profile was analysed by gas-liquid chromatography.

Result and discussion

The statistical analysis revealed significant differences in several fatty acids such as oleic, linoleic, α-linolenic, ARA, EPA and DHA between groups (ML and MD), season (December and June) and the interaction between both factors in muscle, liver, plasma and perivisceral fat. In muscle and liver, Total n6 and Total PUFA are higher in MD of December than in the other groups. In addition, in perivisceral fat the % of oleic, linoleic and α-linolenic is higher than in other tissues and the % of EPA, ARA and DHA are lower. In general, the % PUFA is higher in December MD and June ML. The change in activity must be taken into account in aquaculture and nutrition for a better accumulation of fatty acids and an increase in product quality.

BEYOND BINDING – A DEEPER LOOK INTO MYCOTOXINS MITIGATION STRATEGIES FOR AQUATIC SPECIES

Rosen, R. [1*], Mueller A [2], Hofstetter, U [2]., Schatzmayr, D.[1]

[1]DSM-BIOMIN Research Center, Technopark 1, 3430 Tulln, Austria
[2]Competence Center Mycotoxin Risk Management DSM, Erber Campus 1, Getzersdorf, Austria
Roy.Rosen@dsm.com

Mycotoxin related pathologies in aquatic species have been constantly and globally described in scientific literature since the 1960's.

In recent years a shift towards increased use of plant origin materials and reduction of the animal components in aquatic feeds created a 'more-than-ever' risk of mycotoxicoses in aquaculture systems, which is now a globally growing and fast developing industry.

As their chemical structures vary considerably, mycotoxins cannot be classified as one group according to their mode of action, toxicology or metabolism (Gonçalves, et al., 2019). Moreover, the chemical and thermal stability of these molecules allows them to pass through the feed manufacturing procedures without reducing their toxic potential.
These characteristics together with the increasing wide range of cultured aquatic species create great challenges in development of modern mycotoxin mitigation strategies for aquaculture.

Aflatoxins (AF) were the first and most described mycotoxins in aquaculture. AF, to various extent, can be effectively adsorbed to suitable binders due to their planar molecular structure. The capacity, selectivity and specificity of the toxin binder are the main differentiating factors distinguishing these compounds from one another.

Other toxin groups cannot be bound in this manner as effectively and require different detoxification solutions such as biotransformation. Among these are trichothecenes (such as T-2 toxin and deoxynivalenol), zearalenone, and fumonisins (FUM), the last being one of the most commonly found mycotoxins.

FUM pose a major global concern, particularly in the Asian and Latin American regions where their prevalence in aquatic raw materials and compound feeds reaches levels of over 80% (Biomin, 2019). Li et al. (1994) described fumonisin B1 (FB1) as causing mortality in fish either by direct tissue damage, or by immunosuppression that results in higher sensitivity to infection. Chronic effects of FB1 include a decrease in body weight gain changes to haematological blood parameters decreased feed consumption, feed efficiency ratio, and impaired sphingolipid metabolism(Matejova, et al., 2017),.
Biotransformation by enzymes is one of the most modern forms of mycotoxin detoxification. Other biotransforming components include specific yeast and bacterial strains, some of these biological components have been proved to effectively detoxify specific mycotoxins.

In addition to toxins binding and biotransformation, specific plant and algal bioprotective compounds and extracts designed to support immunologic and metabolic processes demonstrated abilities to restore performance parameters when combined in the anti-toxin treatment.

The ubiquity of mycotoxins and their toxic potential to animal and humans calls for an evidence-based preventive solution. Important aspects such as antibiotic reduction, animal welfare and sustainable-economic aquaculture system all can be directly improved by choosing and applying the correct mycotoxin mitigation strategy.

Introduction

Many fish populations are under pressure due to overfishing and environmental deterioration. They are frequently supported by release of cultured individuals. These releases are common practice in fisheries management, especially in waters that are subjected to angling pressure and for stock enhancement for instance in ocean ranching. Furthermore, in species conservation practices where the reproductive population is declining steadily, and effective population size has become critically low, *ex situ* practices are utilized to safeguard the remaining genetic diversity until the adverse impacts that led to the decline of the populations have been overcome, while hatchery release of progeny can be needed to allow self-sustaining populations to reestablish.

While the general suitability of the introduction of captive reared or transplanted fish has been increasingly questioned due to poor survival and adverse impact upon native populations, conditions exist where no alternatives for releases are available, and must be employed (for instance in reintroduction measures).

Results

The adverse impacts of confined rearing on post-release fitness and survival can strongly influence morphological, genetic, behavioral and physiological responses. Fish fitness as the ability to survive and reproduce in the harsh natural environment does not develop in the well-protected (disease and predator-free) culture environment. The monotonous nature of traditional hatchery practices, including high stocking densities, and predictability in feeding regimes, often results in a lack of environmental variability depriving behavioral responses linked to behavioral and neural deficits. As a result the fish reveal reduced survival in novel conditions. This has been exemplified in Gulf sturgeon (*A. oxyrinchus desotoi*) where survival following release reached only 20% of the fish that were originating from natural recruitment.

Over the past years, the adverse effects of such release practices have been the target of research and several means for the improvement of the rearing practices as well as the adaptation of release strategies have been considered wherever the releases have been determined as indispensable. For sturgeons, a first guideline to improve culture methods for release has been suggested.

Fish exhibit plasticity in neurogenesis depending upon the environment that they are reared in. While brain size is reported to be a result of the early life experiences with regard to the diversity of the environmental stimuli the neuronal interlinkage and brain structure adapts constantly. As such, transfer from monotonous environments into diverse ones even later in ontogeny has the potential to alter their cognition and adapt their physiological responses to challenges. Consequently, fish are sensitive to changes in environmental conditions and social interactions and thus are able to adopt skills to develop coping mechanisms provided by previous experience, i.e. do learn.

Discussion

Strategies to cope with behavioral depreviation - or even better - to prevent it at an early phase of development are strategies that have shown promising results in laboratory tests and following release. Such prevention or mitigation strategies can be applied as early as during reproduction, allowing mate choice and near natural incubation to optimize the resulting offspring. Among the mitigation strategies applied during embryonic development and rearing, streamside hatcheries are applied utilizing river water from the release site which are providing near natural conditions with regard to the environmental fluctuations while at the same time preventing excessive mortalities through predation. Alternatively, training schools prior to release have been shown to increase the adaptability of juveniles. Here, different stimuli or a combination of these can be used over a period of some 10 days to enhance the responsiveness of the fish to changing environments. It has been shown in Baltic sturgeon *A. oxyrinchus* that moderate environmental fluctuations such as temperature or light during the training phase alter the response of the fish with regard to the expression of heat shock proteins and increase the swimming performance. In current research it was shown that enhanced rearing conditions result not only in significant differences in behavior in laboratory experiments but also produce a significant difference in performance habitat choice and migration patterns) following release.

(Continued on next page)

As such the adaptation of rearing conditions to near natural variability or even the short-term exposition to environmental fluctuation improves the performance of the fish by enhancing their responsiveness and as such have the potential to increase effectiveness of releases and subsequent survival. Further studies are needed to develop methodologies to prepare hatchery-reared juvenile fish for fitness for survival in a highly competitive world, such as early recognition of potential predatory and effective escape reactions as well as early measures to support the development of the immune defense against pathogens known to occur in the natural habitat.

THE CONCEPT OF BALANCED FISH NUTRITION IN TEMPERATE EUROPEAN PONDS TO TACKLE EUTROPHICATION

Koushik Roy*, Jaroslav Vrba, Lenka Kajgrova, Jan Mraz

University of South Bohemia in Ceske Budejovice, Faculty of Fisheries and Protection of Waters
South Bohemian Research Center of Aquaculture and Biodiversity of Hydrocenoses

Introduction

Large fishponds (IR: 4.4–64 ha area, 1.3–3 m depth), predominant standing-waters in the land-locked central Europe, resemble temperate, shallow-lake ecosystems with immense contribution to regional eco-services (~74.5–100.6 million € country^{-1}), food security (≥50% aquatic protein/PUFA). Latest fitness check of EU-WFD revealed >70% of these waters failed to achieve good ecological status. Their *status quo* nutrient management are debated for eutrophication concerns, with focus on N:P-cycling (Roy et al. 2020a, 2020b). Till now, ecologists have mostly seen the problem of fishpond eutrophication through various perspectives. In line with the ecological nutrients stoichiometry theories predicting nutrient assimilation efficiencies, we show how in-vivo nutritional bioenergetics can strongly modulate nutrient translocation in aquatic systems. Especially how imbalanced stoichiometry of amino acids, digestible fractions of P, and carbohydrate energy (in fishponds) aggravate 'autochthonous' nutrient loading by carps.

In CEER fishponds, carps endure a counter-moving stoichiometry of food sources (natural food down; cereals up). As a result, strong shifts in nutrients reaching their gut per unit of ingested mass (e.g., digestible N or amino acids, bioavailable versus non-bioavailable P, digestible carbohydrate energy). Our core hypothesis was that such changing dietary scenarios across vegetative seasons have implications on carp's nutritional bioenergetics and raised the following questions: (a) is there a pattern in nutrient retention, faecal and metabolic excretion with the seasonally shifting diet components? (b) what are the deeper nutritional anomalies that aggravate or suppress nutrient losses from fish, making them source or sink nutrients? (c) is it possible to achieve a balanced diet and suppress fishes pumping out nutrients in reactive forms? – the central question.

Materials and Methods

A 11-month long experiment were conducted with lab-trained *Cyprinus carpio* (120-400 g) in a 12 tank (120 L tank^{-1}) Guelph system (19-21 °C, >4 mg L^{-1} DO, 6.8-7.3 pH) with provisions of 3-6 replicates per trial. Experiments were conducted in 2 phases: (a) digestibility trials (5 kg carp tank^{-1}) on cereals (corn, wheat, triticale; commonly used in fishponds) and lyophilised natural prey dry matter (daphnia, cyclops, chironomids; freshwater origin) @30% diet replacement method (basal diet = Skretting Carpe-F), 1% Y_2O_3 inert marker and passive faeces collection (every 4 h); (b) based on digestibility results (formula, NRC 2011), innovative diet formulations (compounded feed = wheat + natural prey @1Da:1Cy:1Ch 'by weight' + inert marker) were made on 'relative FCR basis' (calculated) simulating different scenarios of food availability for carps in regional fishponds (3 diet scenarios = 'BALANCED (cereals 2: natural prey 0.3)', 'LOW natural food, abundant cereals (2:0.1)', 'HIGH natural food, relatively low cereals (2:0.5)') – another round of digestibility trial (estimated digestible losses) + 5-week growth trial (2 kg carp tank^{-1}) was ran (estimated metabolic/ non-faecal losses, retention from initial and final whole body compositions of representative carps; thermal growth coefficient of stock). All feeds were cold-extruded (sinking) and fed 2% body weight basis.

Results

We show aggravated N, P loading by fish may occur both under high (≈beginning of the vegetative season) and low (≈end of season) zooplankton-zoobenthos availability. At beginning-season, the following phenomenon occurs in feeding fish: (a) high bioavailable P (P-homeostasis and digested-P urinated), (b) high PPR (renal stress≈ urinary PO_4^{3-} excretion), (c) renal EAA biosynthesis, e.g., arginine from abundant precursor NEAA proline (by-product≈ PO_4^{3-}), (d) low protein-sparing by low digestible carbohydrates (more protein catabolized≈ NH_4^+ excreted). Fish exhibit high but 'inefficient' N and P-retention under beginning-season diets. At end-season, the following phenomenon occurs: (a) insufficient, poor-quality protein (limited in lysine, isoleucine; rich in glutamic acid) results in poor N-deposition and aggravated NH_4^+ disposal, (b) highest P losses (poorest digestibility and discarding of already-digested P) in tandem with poorest N-deposition, (c) *de-novo* lipogenesis due to excessive starch, limitation of branched-chain amino acids for carbohydrate metabolism,

(Continued on next page)

obesity-inducing high omega-6: omega-3 fatty acids ratio in digested lipids. Protein accretion or growth almost ceases, fishes become fatty, and worst environmental loading of N, P happens in algae-reactive forms (NH_4^+, and PO_4^{3-}), under end-season diets. These novel observations were successfully validated against field metadata. We conclude highest ecosystem resource utilization efficiency and least N, P loading by fish are related to a balanced nutrition and managing fishes' satiety to graze (or spare) zooplankton-zoobenthos, enabling maintenance of clear-water phase and ecosystem services.

The present study provides a deep understanding how fish nutrition shapes excretion and eventually eutrophication in temperate shallow lake ecosystems like most large-sized European fishponds. We point out that improved ecosystem resource utilization efficiency (RUE) and tackling eutrophication may be achieved by 'bio-manipulating' temperate shallow lake ecosystems like large European fishponds towards a balanced fish nutrition (≈proposed approach). Besides extrinsic factors, the highest ecosystem RUE, highest ecosystem services and least internal N, P loading depends much on nutrition availability for fish in fishponds.

Discussions

Present supplementary feeding strategy in fishponds reflect a rather traditional, not very scientific practice of Central and Eastern Europe; not tuned towards improved resource (nutrient) use efficiency and nutrient bioeconomy. The managerial implication of this study is to improve present carp farming (feeding) practices for improved resource (nutrients) use efficiency, minimized N, P footprint and uncompromised production in CEER fishponds. The applied side of our proposed concept is in line with the state-of-the-art understanding of fish (animal) nutrition and in line with the plankton ecology group (PEG) principles to tackle eutrophication in shallow lake ecosystems, e.g., maintenance of clear water phase by zooplankton dominance. Large-bodied zooplankton (especially big daphniids) are the keystone group or species in shallow-lake ecosystems suppressing the eutrophication risks. Findings of 'nutritious pond' concept and present study hint that better retention efficiency and bioeconomy of food web derived N and P can be achieved simultaneously in fishponds through balanced "pond feeds" to complement the fluctuations in natural food base across distinct vegetative season windows. The idea is to also satiate the carps and spare natural food from being over-grazed; suppressing top-down and bottom-up effects.

Introduction

In a context of climate change changes in abiotic factors are taking place, among them. Oxygen that is a limiting factor both in the environment and in production systems, so reduction may become a stressor. In addition, climate change will increase the frequency of environmental hypoxic situations. The effects induced by hypoxic situations depend on the intensity of hypoxia, the duration of the stress event, or whether it is acute (short duration) or chronic (long duration). Under a stressful situation fish activate the hypothalamic-pituitary-interrenal axis (HPI) which triggers the release of cortisol that induces secondary and tertiary responses. The recovery of individuals subjected to stressors depends on their ability to modulate physiological, biochemical, and behavioural responses in order to maintain metabolic functions ans homeostasis.

The aim of this study is to determine the physiological response of rainbow trout under repeated hypoxic stress in different time points and different matrices, measured as cortisol levels. Sampling were 1, 6, 24 hours post stress, and samples were taken from plasma, skin mucus, water and scales.

Materials and methods

Rainbow trout juveniles were acclimated to AQUAB fish facilities (Universitat Autònoma de Barcelona, UAB), subjected to a 12L:12D photoperiod and 14ºC in a closed recirculation system. Fish were fed ad libitum with a commercial diet (Skretting). After the acclimation period, trouts reached a final body weight of 62,89 ± 11,10g and body length of 17,59 ± 1,09 cm. Fish were randomly divided in 5 different treatment groups, 2 control groups (absolute control and manipulated control) and 3 hypoxia groups: H1 that only received 1 hypoxic exposure, group H2 which received 2 hypoxic exposures and group H3 which received 3 hypoxic exposures.

Every exposure to hypoxia consisted in reducing the water oxygen level in the tanks from 8-9 mg/L to 2 mg/L by removing the aeration pumps and bubbling N_2 into the system. Then fish were left in the tanks for 1 hour and sample subsequently. Water oxygen levels were continuously monitored during the experiment. After the challenge, 9 fish per treatment, and time-point were euthanized with an overdose of Tricaine metanosuphonate (MS-222). Samples of blood, skin mucus, scales and water from the recovery tank were collected to analyse cortisol levels by ELISA. Plasma was isolated by centrifugation (10 min, 5000 rpm) and stored at -20ºC until analysis.

Results

Figure 1 shows the physiological response of cortisol levels at the different matrices analysed. Regarding plasma and skin mucus, the same pattern was observed, i.e., 1 hour post stress showed the highest levels in all groups. Regarding plasma, the difference between treatments was observed only with respect to the absolute control. On the other hand, with respect to skin mucus, greater differences can be observed between treatments, particularly between treatments. In the scales, when comparing the absolute control group with those that have undergone 3 hypoxic exposures, no significant differences could be established (Figure 1D). Finally, in terms of the cortisol values in the water, it is where more differences were observed between the different groups (Figure 1C). In addition, it should be added that the absolute control follows the same pattern between time-points as the plasma and skin mucus (Figure 1A and 1B), but the rest of the groups follow a different pattern.

Discussion

The data shows the typical physiological acute response to stress. It should be noted that the highest cortisol levels in all matrices were found 1 hour after stress. Furthermore, the results seem to indicate a circadian pattern of cortisol that can be observed in both plasma and mucus as previously observed in other experiments such *as Rance et al., 1982* and *Boujard et al., 1992,* among others. In contrast, this pattern could not be observed in water and scales. As far as the scales are concerned, no significant differences were observed, probably because deposition of cortisol in this matrix normally takes a longer time period. In terms of the physiological response to repeated exposure to hypoxia a progressive decrease in cortisol values was observed which may indicate an habituation of fish to this type of regular repeated stress.

Biofloc technology is a system that reduces water consumption, and energy consumption and has the capacity to recycle the waste products into high-quality food that can be used by the species in production. In the current work, different carbon sources were tested at different proportions in a species of great commercial value such as the white shrimp (Penaeus *vannamei*), observing that molasses with C/N ratios of 14:1 and 18:1, provided the best survival results and growth, likely, thanks to a differential microbial community.

Introduction

The production of white shrimp (*Penaeus vannamei*) is the most important sector of aquaculture with a production in 2020 of 4,966 million kg and a commercial value of 28,782 million U$. Traditionally, shrimp has been produced in semi-intensive systems, however, intensive and super-intensive systems in RAS and biofloc (TBF) technology are increasing, with much higher densities (250-500 shrimp/m^2). TBF is based on the principle of recycling waste nutrients, particularly nitrogen, into microbial biomass that can be used *in situ* by the animals produced or collected and processed into feed ingredients.

Material and Methods

A classic biofloc system requires external contributions from an exogenous carbon source, both its composition and its proportion in relation to nitrogen (C/N ratio) being important. In the current work, 3 experimental groups were designed according to the carbon source used: molasses, brewer's yeast plus a source mainly of di- and polysaccharides (77%), and a polymer (1,4-butylene succinate; PBS) plus a source of carbon formed mainly of monosaccharides (68%). Within each source, 5 different C/N ratios have been tested: 26/1, 22/1, 18/1, 14/1, and 10:1. Each ratio had 4 replicates, so a total of 20 tanks per carbon source.

Once the shrimps reached the average weight of 0.5 g, they were introduced into the tanks at final densities of 350 shrimp/m^2 (super-intensive production conditions). The animals were housed in 90 L tanks at a salinity of 21±0.14 g/L, temperature of 28 ºC, pH 7.5-8.5, oxygen >5 mg/L, and alkalinity >150 mg/L. Ammonium, nitrite, nitrate, alkalinity, or phosphate values were measured weekly using colorimetric kits in a spectrophotometer (Hanna instruments). Settleable solids were analysed using the Imhoff cone and total suspended solids (TSS) after filtering 80 ml of water through a microfiber filter. In order to have a better understanding of the C/N ratio, the total carbon and nitrogen of the biofloc particulate matter were analyzed weekly by direct combustion, using a Leco CN628 Elemental Analyzer. In addition, to evaluate the evolution of the biofloc bacterial community in the different experimental groups, microbial counts (culturable and cytometric) were performed at different points of the experiment: initial and intermediate (1.5 g mean weight). To carry out the microbial diversity analysis, Shannon index, functional richness, and metabolic characterization (AWCD) were performed. All experimental groups were fed with a standard formulation feed for an intensive production system, which includes 35% crude protein (CP) and 10% fat. Every two weeks shrimp were sampled to assess both, survival and weight gain (Kuhn et al., 2010).

Results and discussion

The values of temperature, oxygen, pH, salinity, and alkalinity were found within the pre-established values. Higher C/N ratios were registered when the carbon source was molasses, followed by yeast and polymer. About the evolution of nitrogenous compounds, as expected, the ammonium, nitrite, and nitrate peaks followed each other, being generally higher in the molasses group (Figure 1A-1B). Nevertheless, the highest final weight was reported in molasses, without significant differences concerning survival (Figure 1D-1E). Consequently, despite the higher nitrogen toxic level in the water, molasses biofloc was able to provide a better growth performance. Regarding the ratios, the intermediate values from 14/1 to 22/1 provided the best results, both for production values and water quality.

(Continued on next page)

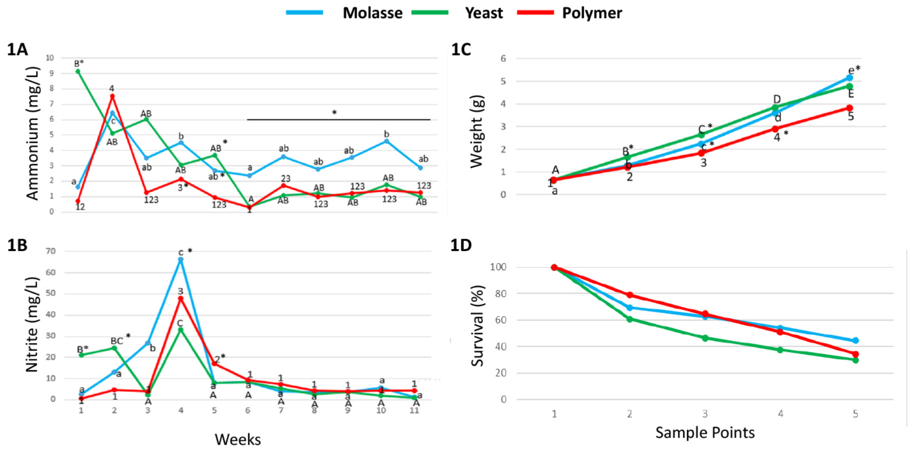

Figure 1. Evolution (mg/L) of ammonium (NH_4+), 1A; nitrite (NO_2-), 1B; average weight (1C) and survival (1D) by carbon source. Lower case letters represent significant differences through the experimental period for the molasses group, capital letters for yeast group, and numeration for polymer group. Asterisk (*) represents differences among carbon sources at the same time point.

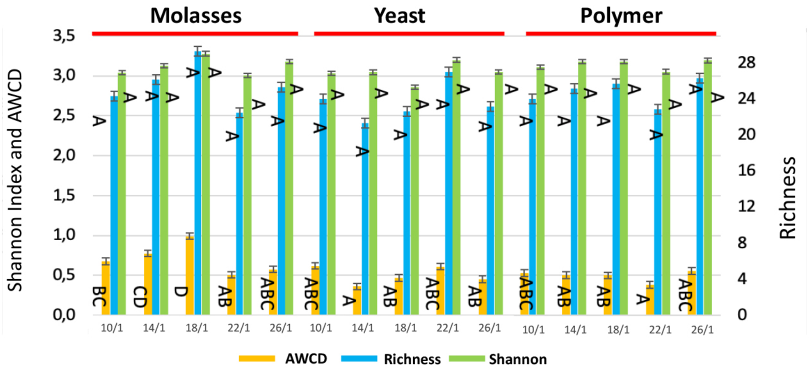

Figure 2. Shannon index, functional richness, and metabolic characterization (AWCD) of different experimental groups. Letters represent significant differences at 45 days of experimentation.

The results of the studies of the bacterial populations indicate a predominant marine heterotrophic microbiota in all the experimental groups, which was expected because the tanks were kept in the dark. Regarding the total and nitrifying bacteria counting, the molasses group registered the highest values of total bacteria at 45 days, although without differences regarding nitrifying bacteria. Concerning microbial diversity, no differences at 45 days of experimentation were found respect richness and Shannon index, but the microbial community of molasses group showed a more diverse metabolism, especially the intermediate groups (Figure 2). These results could explain the best growth performance for the intermediate ratios of molasses group, despite the highest levels of ammonium and nitrite.

An efficient integrated multitrophic aquaculture (IMTA) requires species capable of effectively converting particulate waste into biomass (Chopin et al., 2012). These species, called detritivores help mitigate the benthic impacts of aquaculture farms, once extracted of the system, and represent, ideally, an additional income to the production. Sea cucumbers are interesting candidates for IMTA due to their prevalence in the marine environment, their diversified diet and their economic value (Zamora et al., 2018). Yet scarce information is available regarding the capacities of European species to be stocked and reared underneath aquaculture cages. There is therefore a growing scientific effort in Europe, including in France, to get more insight on the biology, the reproductive physiology, the embryonic development, the feeding behavior, and on their growing capacities in captive environments (David et al., 2020; Laguerre et al., 2020; Sadoul et al., 2022)to date little is known about the nutritional requirements of East Atlantic and Mediterranean species. In this study, we propose a "natural population"-oriented approach to characterize food sources, digestive efficiency and resources allocation based on the composition of pigments and fatty acids (FA. Two French projects (EPURVAL2 and HOLOFARM) have thus investigated possibilities of using local deposit-feeding sea cucumber species, *Holothuria forskali* and *Holothuria tubulosa*, for bioremediation of aquaculture particulate waste. This presentation aims at sharing to the aquaculture community the failures, successes and perspectives highlighted by both projects. Among others, difficulties with escapees, high mortalities, reduced growth in captive conditions, and biometrics will be shared along with possible solutions. Both projects have allowed significant breakthrough in the use of these species for bioremediation and estimation of their growing capacities using bioenergetic modeling. Also, we have made substantial advances in our capacities to reproduce and raise juveniles, which seem to be, as a conclusion of both projects, the key to efficiently bioremediate aquaculture waste. Research perspectives regarding stocking densities, repeatable reproduction, and identification of geographically effective sites for their use will also be discussed.

E-mail: bastien.sadoul@institut-agro.fr

Oysters have been cultured for millennia all around the world, and represent now the leading molluscan species produced in volume (Botta et al., 2020). While France is still the leading European country for oyster production, annual production has generally decreased over the last two decades ("Graph'Agri," 2021). The use of innovative technologies adapted for our rearing conditions can help improve rearing efficiencies, quality of the product and therefore favor sustainability of the production. Here, we investigated the potential benefits of 1) a co-culture of Pacific oyster, *Crassostrea gigas*, with the grazing gastropod *Littorina littorea* vs a monoculture of *C. gigas*, 2) offshore compared to classic intertidal culture and/or 3) oyster basket compared to oyster mesh bag. We tested all conditions in a full cross factorial study over three months of rearing. Effects on growth, aspect, flesh percentage, and fatty acids profiles were investigated. We also compared the total fouling between conditions. Results show that off-shore rearing is greatly beneficial for getting the best quality of the final product, in terms of aspect, survival and flesh content. The association with *L. littorea* showed great potential for reducing fouling and ultimately potentially favoring growth. Fatty acids analyses highlighted the amazing contents in omega-3 (n-3) long-chain polyunsaturated fatty acids, particularly important for human nutrition, in all products but more importantly in oysters reared off-shore. Altogether these results, show the great potential of these techniques for increasing the efficiency and quality of oyster products while reducing work load of professionals.

EFFECTS OF ALGAE-BASED DIETS ON SHELF-LIFE EXTENSION OF TURBOT (*Scophthalmus maximus*) FROZEN FILLETS

Introduction

Turbot (*Scophthalmus maximus*) is an emerging fish candidate for diversifying the aquaculture in the Southern Europe. This flatfish can be commercialised both fresh and frozen owing to its leanness, since high lipid content in other fish species is considered a major constraint for freezing. Moreover, the presence of polyunsaturated fatty acids in fish fillets contributes for increasing susceptibility of lipids to oxidative processes, decreasing both shelf-life and sensorial quality. Therefore, the prevention of lipid oxidation constitutes an effective approach for delaying fish spoilage, being one of the major current challenges for the seafood industry. Algae are rich in a wide variety of bioactive compounds, such as carotenoids and polyphenols among others, which provide remarkable antioxidant and antimicrobial activities (Nakagawa *et al.,* 2012). Thus, several studies have broached the application of algae as natural preservatives for fish products. However, to date the potential effects of algae on objective quality parameters in turbot remains scarcely explored. In this context, this study explores whether the administration of *Ulva rigida* meal or a blend of microalgae at low dietary inclusion level could influence the objective quality parameters of *S. maximus* frozen fillets as well as extend their shelf-life during cold storage.

Materials and methods

Experimental diets were elaborated at the Ceimar-Universidad de Almería facilities (Service of Experimental Diets, https://bit.ly/3wdO03h, Almería, Spain). Three iso-nitrogenous (50.5%, DW) and iso-lipidic (16.5%, DW) experimental feeds were formulated: **U5** containing 5 % of *U. rigida* meal, **M5** containing 5 % of a blend of freshwater and marine microalgae, and a free-algae diet used as control (**CT**). Additionally, a commercial aquafeed specific for this species (**COM**) was tested. Turbot juveniles were randomly distributed in 12 tanks, and fed at a rate of 2% of the total biomass during a 180-d period. At the end of feeding trial, 30 specimens per dietary treatment were withdrawn. After slaughtering, specimens were gutted, filleted and packed in transparent sterile polyethylene bags. These bags were directly stored at -20 ºC for an extra period of 150-d with the aim of evaluating changes in objective quality parameters throughout the frozen fillet shelf-life. Samples were extracted from each lot at 1, 3, 6, 8 and 10 days post-thawing (dpt), and hardness, pH, water holding capacity (WHC), skin pigmentation and lipid oxidation were determined at each sampling time. In addition, at the initial sampling point muscle proximal composition was determined.

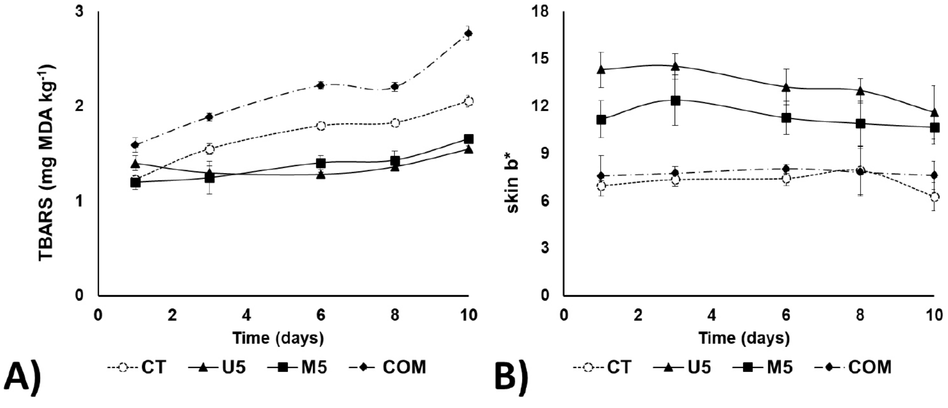

Figure 1. Time-course of A) TBARS muscle content and B) skin b* parameter of turbot frozen fillets. Dietary codes: CT: control; U5: 5% *U. rigida*; M5: 5% microalgal blend; COM: commercial turbot aquafeed. Values are expressed as mean ± sd (n=6).

(Continued on next page)

Results and discussion

The chemical composition of fillets was influenced by dietary treatments (P≤0.01), showing an increase of muscle lipid content in specimens fed on COM diet. U5 and M5 fillets tended to show slightly lower lipid values compared to CT, but without significant difference (P=0.17). Overall, algae inclusion in diets (U5 and M5 batches) decreased muscle lipid oxidation during cold storage time, extending frozen fillet shelf-life (P≤0.01, Figure 1.A). This protective effect is extremely useful considering that freezing and thawing processes accelerate fish deterioration, shortening fillet shelf-life. Regarding skin pigmentation, results obtained evidenced that a* and b* parameters were modified by dietary treatments (P≤0.01 and ≤0.01, respectively). In general, the skin of algae-supplemented fed fish, compared to CT and COM batches, was greenish (a*) and yellowish (b*), mostly due to differences in b* parameter observed after *U. rigida* dietary inclusion (Figure 1B).

Aside from skin pigmentation and oxidative status, textural parameters represent a crucial feature of fish muscle, both in terms of consumer's acceptance and shelf-life. In this context, algae inclusion in aquafeeds did not affect neither hardness nor WHC parameters of muscle. However, cold storage time caused a decrease of the percentage of water retained in the muscle in COM and M5 batches (P≤0.01). Regarding pH parameter, values increased significantly during 10 dpt in all experimental batches, owing to the emergence of alkaline compounds from amino acid bacterial degradation (Masniyom *et al.,* 2002). Despite this fact, significant lower pH values were observed in U5 and M5 fillets compared to CT and COM (P≤0.01) during post-thawing period.

Conclusions

The results confirmed either microalgae or *Ulva rigida* administered at low inclusion level (5%) in grow-out aquafeeds has positive impact on different aspects related to antioxidant activity and skin pigmentation in turbot. In addition, these functional effects could be key on consumer acceptance and the shelf-life extension of frozen fillet.

Introduction

Fillet quality attributes and commercial shelf-life heavily rely on fish species-specific factors, but also on the utilization of commercial additives aimed at delaying deterioration of fish. Both microbiological and biochemical phenomena jeopardize the quality of the final product, and therefore, they represent the target of most of the food additives. However, the use of chemically synthesized substances on the final product is limited both by legal regulations and by the low acceptability by consumers of this strategy. The consequence is that a limited array of such preservatives is available for the seafood industry, while processed fish formats are increasing in the market, not least those involving extended storage periods. In this regard, frozen fish involve long-term storage, in which biochemical deterioration is still possible. Namely, lipid peroxidation and protein degradation are among the most known phenomena that can alter fillet quality. Scarce research has been conducted aimed at controlling oxidative deterioration in fish during frozen storage based on dietary strategies, and therefore, there is considerable room for innovation in this field. In this regard, a promising strategy is represented by the utilization of functional aquafeeds enriched with bioactive additives included at low percentage (less than 10%). An emerging application for these innovative feeds is their administration at the end of the production cycle (finishing feeds), since variations in diets are rapidly reflected in fillet quality (Grigorakis *et al.,* 2002). Among the potential additives with this aim, plant extracts, prebiotics, and microalgae stand out, all of them with potentially valuable physiological effects on fillet pigmentation or oxidation of fillet lipids. However, a possible disadvantage associated with the use of prebiotics and microalgae as functional additives consists in the existence in some cases of a thick cell wall, which can limit the bioavailability of the potential bioactive inner compounds. The use of biotechnological treatments, such as enzymatic hydrolysis with fibrolytics enzymes, could overcome this limitation.

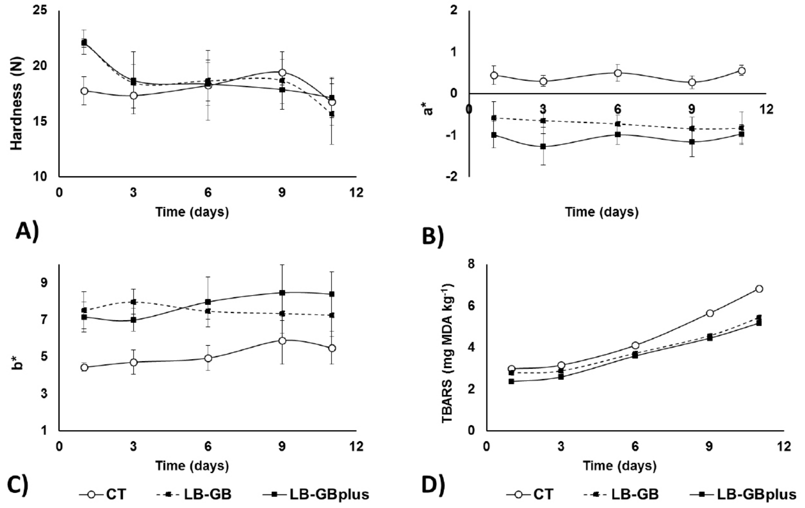

Figure 1. Time course of A) hardness, B and C) a* and b* skin colour parameters, and, D) lipid oxidation in frozen seabream fillets. Values are mean ± sd (n=4).

(Continued on next page)

Materials and methods

Three iso-nitrogenous (42.5%, DW) and iso-lipidic (17.5%, DW) experimental feeds were formulated at the CEIA3-Universidad de Almería facilities (Servicio de Piensos Experimentales, http://www.ual.es/stecnicos_spe; grants EQC2018-004984-P and EQC2019-006380-P). LB-Gb diet contained a 10% of LB-Goldbream, a commercial microalgae-based additive provided by Lifebioencapsulation S.L. This product consists of a blend of microalgae and prebiotics. A second diet, designed as LB-Gbplus diet, was also prepared; similar to LB-Gb diet, except for the fact that the blend of microalgae and prebiotics was hydrolysed enzymatically. In addition, a third diet, additive-free, was used as the control batch (CT). A feeding trial was carried out at the aquaculture facilities of "Servicios Centrales de Investigación en Cultivos Marinos" (SCI-CM, CASEM, Universidad de Cadiz, Spain). Gilthead seabream specimens (180.0 ± 10 g b.w.) were randomly distributed in 9 tanks, and the experimental diets were offered at 2% of the biomass during a 41-d period. At the end of feeding assay, 15 fish per treatment were withdrawn. Immediately after slaughtering, specimens were gutted, filleted, packed in transparent sterile polyethylene bags, and stored at -20 ºC for six moths. Afterwards, fillets were thawed, and then transferred into a cold chamber (4 ºC) for an extra 11-d period. Samples were withdrawn from each lot at 1, 3, 6, 9 and 11 days post-thawing, and texture profile analysis (TPA), pH, water holding capacity (WHC), skin pigmentation and lipid oxidation were determined at each sampling time.

Results and discussion

During post-thawing cold storage, hardness decreased markedly in all experimental lots ($P<0.01$); however, at the beginning of the trial additive-enriched diets were responsible for fillets with significantly higher hardness than controls ($P<0.01$, Figure 1A). Roughly, gumminess, chewiness and WHC followed a tendency similar to that observed for hardness, whereas springiness, cohesiveness and resilience, and well as muscle pH. On the other hand, skin colour (pigmented fillet side) showed significant differences for a* (redness) and b* (yellowness) parameters attributable to the inclusion of the commercial additives in diets ($P<0.01$ and $P<0.01$, respectively). Roughly, LB-Gb and LB-Gbplus fillets displayed lower a* and higher b* values than CT fillets up to 6 days post-thawing (Figure 1B and C). In addition, significant differences between both additive-enriched diets were found in a* parameter (lower values for LB-Gbplus than for LB-Gb batch). Regarding storage time, a* and b* values remained stable from the beginning to the end of the assay ($P=0.36$). Lipid oxidation depended clearly on storage time in all experimental groups, as evidenced by the significant increase of TBARS throughout the storage period ($P<0.01$, Figure 1D). However, although the most contributing factor to TBARS concentration was storage time, additive-enriched diets decreased significantly ($P<0.01$) fillet lipid oxidation at any sampling time, compared to CT batch.

Conclusions

Overall, the results obtained in the present study showed that the incorporation of LB-Gb and LB-Gbplus in finishing aquafeeds yielded favourable effects on *S. aurata* frozen fillet quality, namely on textural, pigmentation and oxidation parameters.

Introduction

Vegetable acid oils (AO), by-products from the edible oil refining industry are characterized by having a similar fatty acid (FA) composition to that of their corresponding crude oil, free fatty acid (FFA) being the major component (> 40 % of lipid classes) (Varona et al., 2021). Its high energetic value makes them promising candidates as energy sources into aquaculture feed, enabling an upcycling of these by-products. The effect of inclusion of AO in fish feed on growth and digestibility has scarcely been studied (Trullàs et al., 2016 a,b; Verge-Mèrida et al., 2022). The aim of the present study was to investigate the histological effects of the inclusion of soybean and olive pomace AO on hepatic and intestinal tissue in European seabass (*Dicentrarchus labrax*).

Materials and Methods

A total of 300 individuals (101.5 ± 0.4 g, initial weight) were distributed into 15 tanks. Five were fed for 100 days, differing in the added fat source (25% fish oil, 75% experimental oil): S (crude soybean oil), SA (soybean-sunflower acid oil), O (crude olive pomace oil) or OA (olive pomace acid oil) and a control diet containing with only fish oil (FO diet). At the end of experimental period, samples of the liver and anterior part of intestine were collected from 4 fish/tank (3 tanks/experimental diet; 12 fish /treatment) and processed using a routine histological procedure in paraffin. Serial sections were stained with hematoxylin-eosin. In liver, also the size and the degree of vacuolization of hepatocytes were analyzed according to Kowalska et al. (2011) and Figueiredo-Silva et al. (2005) using a five-degree semi-quantitative scale. In anterior intestine, a morphometric evaluation was carried out, giving attention to the enterocyte height (300 measurements/treatment; 10 folds/fish), the goblet cell number (10 folds/fish; 120 folds/treatment) and the widening degree of lamina propria (LP) in the intestinal folds using a semi-quantitative system adapted from Úran (2008) and Millán-Sorribes et al. (2020). Data were statistically treated using a one-way ANOVA and analyzed for statistical significance using Tukey's multiple range test ($P<0.005$).

Results and Discussion

No significant differences in hepatic morphohistology and hepatocyte size were observed among the different treatment groups ($P>0.05$) (Table 1). However, lipid accumulation observed tended to be higher in the soybean oil diets (S and SA) similar to that described for this specie and rainbow trout (Figuereido-Silva et al, 2005). None of these changes were considered pathological due to the lack of extensive hepatic necrosis (Saraiva et al, 2015)

Table 1. *Hepatic and intestinal parameters of European seabass fed experimental diets.*

Parameter	FO	S	SA	O	OA	SEM	P-value
Liver							
Hepatocyte area (μm^2)	16.63	19.14	21.73	18.92	18.19	±1.62	0.274
Vacuolization degree	2.11	2.81	3.23	2.48	2.16	±1.46	0.226
Anterior intestine							
Enterocyte height (µm)	4.56^{b}	4.92^{ab}	3.78^{c}	5.20^{a}	5.22^{a}	±0.145	<0.001
Goblet cell number(/100µm)	4.76^{ab}	4.30^{b}	5.68^{a}	3.96^{b}	3.79^{b}	±0.299	<0.001
Widening degree of LP	2.02^{ab}	2.18^{a}	2.12^{a}	2.05^{ab}	1.79^{b}	±0.085	0.016

Absence of superscript letters indicates no significant difference between treatments ($P>0.05$). FO: Fish oil diet; S: Soybean oil diet; SA: Soybean acid oil diet; O: Olive pomace oil diet; OA: Olive pomace acid oil diet. LP: Lamina propia. SEM: Standard error of the mean (n=12).

(Continued on next page)

In anterior intestine, no pathological changes in the epithelium were observed among treatment. When crude oil diets (S and O) are compared with FO diet only statistically differences were obtained for enterocyte height, being higher for O diet (Table 1). Although a higher enterocyte height had been related to a higher absorption of nutrients, no differences in lipid apparent digestibility was obtained of using the same diets (Verge-Mèrida et al, 2022). When S was replaced by SA, lower enterocyte height and a higher globet cell number was observed, which would point to a lower absorption and a general gut inflammation (Torrecillas et al, 2019), respectively. In contrast, no significant differences were obtained for these histological parameters when OA replace O. These results agree with the differences in saturated fatty acid digestibility observed when SA replace S, but not in olive pomace oils (O and OA), although a lower total lipid digestibility was obtained for AO compared to its corresponding crude oils (Verge-Mèrida et al., 2022). No effect of crude and experimental oils has been obtained in the widening of the LP which can indicate the absence of a non-infectious sub-acute enteritis due to an infiltration of inflammatory cells (Urán, 2008).

From the results, it can be concluded that the effect of the inclusion of acid oils in the diet of European seabass on liver and intestinal histology differs between the two fat sources used (soybean oil and olive pomace oil), although their inclusion does not appear to compromise intestinal and liver integrity.

Introduction

Fish feed is the principal operating cost in the production of fish and the main protein and energy source has traditionally been fish meal and fish oil. Research has concentrated on replacing fish meal and fish oil with cheaper ingredients of either animal or vegetable origin. Knowledge of the apparent digestibility coefficients (ADCs), of these various ingredients is a basic requirement for formulating diets. ADCs, provide estimates of nutrient availability in foods, and can be used to select ingredients that optimize the nutritional value and cost of formulated diets (Lupatsch *et al.*, 1997). Therefore, this study designed to compare the digestibility of a series of diets and ingredients when fed to Gilthead seabream, Sobaity bream and Barramundi under the Red Sea environmental conditions.

Materials and Methods

The diet-substitution digestibility method was used in this study (Glencross et al. 2007). ADCs were determined for dry matter (DM), crude protein (CP), crude lipid (CL), gross energy (GE), and amino acids of the available local ingredients in KSA. A basal diet (diet 1; 500 g kg^{-1} DM protein, 200 g kg^{-1} DM lipid) and test diets (of 14 different diets consisting of 70% basal diet and 30% of the feedstuff) were used with 1% Yttrium oxide as an external marker. The composition details of each diet is presented in (Table 1). The experimental fishes, averaging 150 to 300 g, was stocked in 850 L tanks at a density of up to 30 fishes per tank, under Red Sea conditions; seawater with salinity of 42 ppt; dissolved oxygen 7.33 ± 0.18 mg L^{-1} and water temperature at around 28ºC to 30ºC. Feces were collected in triplicate by stripping based on best timing for digestion.

Results

There were several significant differences among the digestibility parameters of the experiment diets (Table 1). Diet dry matter digestibility was poorest in the FM-TUNA diet (0.439) when fed to Gilthead seabream, and best recorded results for the same diet when fed to barramundi (0.606). Dry matter digestibility was highest in the WHEAT-GLUTEN diet when fed to barramundi (0.743), though this was significantly higher when fed to Gilthead seabream (0.684) and Sobaity bream (0.642). Diet protein digestibility was poorest in the FM-TUNA diet with (0.809) when fed to Gilthead seabream, while it was highest in the WHEAT GLUTEN diet when fed to Barramundi as shown (0.934), though this was not significantly differed when same diet fed to Gilthead seabream and Sobaity bream as (0.930) or (0.919), respectively. Diet energy digestibility was poorest in the WHEAT MEAL diet (0.668) when fed to Sobaity bream, which was significantly poorer when fed to Barramundi (0.727) and Gilthead seabream (0.754).

Different presuperscripts within columns indicate significant differences between means among the same digestibility parameters between fish species, but not between different digestibility parameters or between different ingredients ($P < 0.05$). Different postsuperscripts within rows indicate significant differences between means among ingredients, but not between digestibility parameters or diet type ($P < 0.05$).

(Continued on next page)

Ingredient protein digestibility was poorest in the WHEAT MEAL (0.401) when fed to barramundi and highest in the WHEAT GULTEN diet when fed to Gilthead seabream as (0.985), though this was not significantly differed when fed to Barramundi (0.952) and Sobaity bream (0.966). The overall range in ingredient protein digestibility values was higher for Barramundi (0.841) than Gilthead seabream (0.834) and Sobaity bream (0.832). Also, the overall range in ingredient energy digestibility values was higher for Gilthead seabream (0.736) than Sobaity bream (0.727) and Barramundi (0.576).

Discussion

Evaluation of apparent digestibility coefficient for dietary diets and ingredients in fish nutrition is contribute better to assess their potential nutritional value and nutrients availability through short term digestibility trials which help in optimum diet formulation. In this regard, chemical composition and quality of meals differ considerably depending on raw materials and processing methods. Energy content of the feed is considered to be the main factor controlling feed consumption in finfish (Boujarda et al., 2004). In this study, there was a strong correlation between Gilthead seabream and Sobaity beam and Barramundi for diet DM digestibilities as well as protein digestibilities. This provided responses of different species when subjected to same type of diets and feed.

Conclusions

These findings may put on the table a new emerging evidence considering the Red Sea environmental condition specifically higher salinity and temperature as an issue considering different digestibility responses based on the behavioral nature of all the species tested being carnivores. Diets then could be formulated on the basis of digestibility of individual ingredients and protein could be recommended to use as alternative protein source in all diets tested for the species.

EFFECT OF DIETARY NANO-CURCUMIN ON GROWTH, IMMUNITY, HEAT STRESS RESISTANCE AND STRESS INDICATORS OF NILE TILAPIA (*Oreochromis niloticus*)

Mohamed El-S. Salem*, Heba M. Abdel-Ghany, Doaa M. El-Sisy

*National Institute of Oceanography and Fisheries, NIOF, Cairo, Egypt
Salem_200080@yahoo.com

Heat stress is one of the consequences of climate change which has devastating effects on fish farming especially in intensive systems, resulting in huge economic losses. The aim of this study was to evaluate whether dietary supplementation with free- or nano-form of curcumin improves growth performance, immune status, and heat stress resistance in Nile tilapia (*Oreochromis niloticus*).

\Seven diets were prepared, six of which contained 3 levels of curcumin nano-sphere (50 (CN50), 100 (CN100) or 200 (CN200) mg kg^{-1}) or free curcumin (50 (C50), 100 (C100) or 200 (C200) mg kg^{-1}), and one diet contained no addition (CON). Fish (13.54±0.32 g) fed the experimental diets for 65 days and then they subjected to the acute heat stress by gradually raising the water temperature from 25 to 40° within 3 h. Results revealed that dietary curcumin has enhanced growth performance with superiority to nano-curcumin over the free form. The optimum growth performance was obtained at CN100 (Fig.1). Heat stress rather than diets increased platelets, mean corpuscular volume (MCV), mean corpuscular hemoglobin (MCH), leukocytes and neutrophils counts while lymphocytes decreased. CN50 and CN100 reduced the activity of liver enzymes (Alanine Aminotransferase (ALT) and Aspartate Aminotransferase (AST) more efficiently than the other diets and C200 gave the highest activity of these enzymes. CN100, CN200, C100 and C200 had higher immunoglobulin (IgM) levels than CN50 while C50 and CON gave the lowest values. C200 showed a higher level of complement C3 and C4 than the other treatments while C50 and CON gave the lowest values (Table 1). CN50 and CN100 have efficiently eliminated cortisol levels compared to the other treatments. All curcumin-supplemented diets, except for C200, produced lower glucose values compared to CON. After heat stress, ALT, AST, IgM, C3, C4, cortisol and glucose have been increased. Thus, curcumin nano-sphere has better ability than its free form to increase the ability of farmed fish to withstand heat stress, enhance growth rates and thus increase fish productivity.

Introduction

One of the challenges of science in disease prevention is optimizing drug and vaccine delivery. Until now, many strategies have been employed in this sector, but most are quite complex and labile. To overcome these limitations, great efforts are directed to coupling drugs to carriers, either of natural or synthetic origin. Among the most studied cell carriers are antigen-presenting cells (APCs), however, red blood cells (RBCs) are positioned as attractive carriers in drug delivery due to their abundance and availability in the body. Furthermore, fish RBCs have a nucleus and have been shown to have a strong involvement in modulating the immune response. In this study, we evaluated the binding of three peptides to rainbow trout RBCs, two lectin-like peptides and another derived from Plasmodium falciparum membrane protein, in order to take advantage of this peptide-RBCs binding to generate tools to improve the specificity, efficacy, immunostimulatory effect, and safety of the antiviral therapeutic or prophylactic administration systems currently used.

Material and Methods

In order to evaluate the binding of the peptides to RBCs, we carried out a dose-response assay using a concentration range of Rhd-labeled peptides. The binding of the peptides was evaluated by means of flow cytometry. Moreover, an *in silico* evaluation of the peptides' physicochemical descriptors was carried out. Also, we investigated whether the treatment with the three peptides could generate an antiviral immune response in RBCs, *in vitro*, by means of examining the expression profile of some genes related to antiviral activity.

In order to track *in vivo* the binding of the peptides to RBCs, we examined the peripheral blood of rainbow trout individuals injected with the Rhd-labeled peptides, and blood was analyzed by means of flow cytometry and fluorescent microscopy.

Results

Our results demonstrated the binding of peptides to rainbow trout RBCs, with a higher affinity of two of them *in vitro* and *in vivo*. Additionally, peptide-RBC binding was confirmed by confocal microscopy which showed the presence of all the peptides inside the cell. In general, gene expression analysis showed that these peptides were capable of modulating the expression of genes related to the antiviral immune response.

Briefly, our results showed that two of these three peptides bind to rainbow trout RBCs and they are good candidates for linking up to new delivery systems and enhancing the antiviral immune response during treatment.

SOFT X-RAY CRYO-TOMOGRAPHY REVEALS THAT ENDOPLASMIC RETICULUM PLAY AN ACTIVE ROLE IN RAINBOW TROUT ERYTHROCYTES ANTIVIRAL IMMUNE RESPONSE

Introduction

Fish nucleated red blood cells (RBCs) play an active role in the homeostasis of the fish immune system as they can modulate the expression of different proteins in response to various stimuli, including the attack of a virus. These functions include the activation of pathogen elimination mechanisms and the activation of autophagy and genes related to the immune response. Furthermore, when rainbow trout RBCs are exposed to the viral haemorrhagic septicaemia virus (VHSV), in addition to generating an antiviral immune response, these cells appear to undergo intracellular changes and, in the end, RBCs halt VHSV infection. In this work, cryo soft X-ray tomography (cryo-SXT) has been used to elucidate the structural changes induced in rainbow trout red blood cells exposed to UV-inactivated VHSV and we have focused on studying the involvement of endoplasmic reticulum stress in the antiviral response in RBCs.

Material and methods

First, rainbow trout RBCs were purified by ficoll density gradient centrifugation. Then, RBCs were exposed to UV-inactivated VHSV and samples under cryogenic conditions were transferred to Mistral beamline (ALBA light source) at ALBA synchrotron, to obtain the X-ray tomography data sets.

In addition, time course of ER stress-related genes expression was carried out on RBCs and rainbow trout gonad-2 cell line (RTG-2) exposed to VHSV or UV-inactivated VHSV. Also, RBCs and RTG-2 cells were incubated with a stress inhibitor both post-exposure and pre-exposure to VHSV. ER-stress was evaluated by means of immunofluorescence and RT-qPCR.

Results and conclusions

Cryo-SXT images showed remarkable cellular modifications. One of them was the increment of the endoplasmic reticulum (ER) in RBCs exposed to UV-inactivated VHSV, which was related to the stress of the ER and the activation of the unfolded protein response (UPR) pathway. Another one was the production of extracellular vesicles (EVs) in RBCs exposed to UV-inactivated VHSV.

On the other hand, the expression of ER stress-related genes was increased in RBCs and RTG-2 cell line in response to UV-inactivated VHSV and there was a direct effect between ER stress inhibition and VHSV replication levels in both cell types.

These results open a new line of investigation related to the role of ER stress, UPR, and EVs in the immune response induced by RBCs in response to viral vaccines.

DAILY RHYTHMS IN THE STRESS RESPONSE OF THE EUROPEAN SEA BASS (*Dicentrarchus labrax*): EFFECTS OF SEASONALITY AND FEEDING TIME

Introduction

Fish in aquaculture facilities must cope with different stressors like handling that involve air exposure. This operation can elicit a high stress response due to manipulation and a strong oxidative reaction due to air exposure followed by reoxygenation. The stress response starts in the hypothalamus and culminates with cortisol secretion. The antioxidant system responds with a different regulation of its principal factors like catalase (*cat*), superoxide dismutase (*sod1*), glutathione reductase (*gsr*) and glutathione peroxidase (*gsh-px*) (Scandalios et al. 2005). Mitochondria are involved as well in maintaining the balance between the oxidative and antioxidative processes and encode for genes considered as mitochondrial biomarkers for fish welfare like uncoupling protein (*ucp*), peroxiredoxins (*prdx*) and cytochrome c oxidase 4 (*coxIV*). *Fish* are subjected to environmental variables that act as *zeitgebers* or synchronizing factors in the natural environment. These *zeitgebers* follow a predictable pattern based on cyclicity. They have promoted the development of the circadian system based on input signals, pacemakers, and output pathways, coordinated by a self-sustainable clock at the molecular level that relies on positive and negative feedback (Pando and Sassone-Corsi 2002). A molecular connection between the circadian system and physiological stress response has been proved in several species (Cowan et al. 2017), with a species-specific pattern, but nothing is known about this subject in the European sea bass (*Dicentrarchus labrax*). Moreover, the components of the antioxidant system have been described in fish, but only a few studies focused on the time-dependent response of the genes involved (Vera et al. 2014). Additionally, seasonal variations in basal cortisol levels have been described in the sea bass (Planas et al. 1990), making it reasonable that other components of the stress response could display differences based on the season of the year. This study aimed to clarify if the European sea bass presents variations in the stress and antioxidant responses to air exposure depending on the time of the day or season of the year. For this purpose, fish were exposed to air for 1 minute in two moments of the year (December and June). Physiological stress indicators in plasma, genes of the hypothalamus-pituitary-interrenal (HPI) axis, genes involved in the oxidative response and mitochondrial oxidative biomarkers were analyzed for this scope.

Materials and method

The European Sea bass specimens (N = 196 for each seasonal trial) were placed into 14 tanks, randomly divided into two groups (CTRL and STRESS - 7 tanks each group) and fed once a day in the mid-light phase (ML). They were kept under natural seasonal conditions of photoperiod and water temperature in an open recirculatory system. Fish were maintained under these conditions for one month prior to sampling in December (10:14 LD; 19,47 ± 0,17 °C) and June (14:10 LD; 22,13 ± 0,13 °C). CTRL and STRESS groups were sacrificed during a 24-h cycle, in 7 sampling points, respectively at ZT 0.5, 4, 7.5, 12, 16, 20 and 24.5 h. Fish from the CTRL group were sampled directly, while fish of the STRESS group were exposed to air for 1 minute and sampled 1 h later. Samples of plasma, liver and hypothalamus were collected.

Results

The plasmatic levels of cortisol, glucose, and lactate displayed a significant increase in the STRESS group in both seasons. Surprisingly, the hypothalamic gene *crh* showed a different pattern, and the stress group had not consistently higher expression levels, while *crh-bp* presented more differences between control and stress. Genes involved in the antioxidant system (*cat, sod1, gsh-px* and *gsr*) analyzed in the liver responded significatively to air exposure in both the season. In these genes, an effect of the season was observed as higher differences between the CTRL and STRESS groups were detected in June. Concerning the mitochondrial biomarkers (*ucp1, prdx3* and *coxIV*), they responded to stress with different patterns depending on the season. In this study, we also investigated the existence of daily rhythm in the parameters analyzed. It was confirmed for most of the physiological parameters analyzed but with significant differences between the control and stress groups and between the seasons studied, December and June. For the genes with a daily rhythm confirmed, the acrophases were predominantly nocturnal, both in December and June. Additionally, the season seems to influence the appearance of a rhythm since a significant part of the biological parameters that displayed rhythms in December seemed to lose it in June.

(Continued on next page)

Conclusions

In the present study, the physiological response to air exposure was evident, especially in the plasmatic levels of cortisol, glucose, and lactate. In the liver, the response of the antioxidant genes was clear as well. Additionally, the season seems to play an important role since in the antioxidative response is markedly different compare December and June. The study of the daily rhythms revealed that they are present in most of the physiological parameters studied, both in control and stress with a nocturnal acrophases. In this case, again, the contribution of the season is relevant since in June only a few of them continued to display rhythmicity. Taken all together, these data suggest that the stress response is not only species-specific but also time-dependent and influenced by the season of the year.

HOW FEEDING TIME AFFECTS CLOCK AND EPIGENETIC MECHANISMS IN LIVER AND BRAIN OF EUROPEAN SEA BASS (*Dicentrarchus labrax*)

E. Samorì*[1], I. Rodríguez[1], F. J. Sánchez-Vázquez[1] J. F. López-Olmeda[1]

Introduction

In response to an environment based on the 24-hour light-dark (LD) cycle, fish have evolved circadian systems based on a 24-hour periodicity and synchronized by different *zeitgebers*, like the photoperiod and feeding. At the molecular level, a circadian rhythm is created by a self-sustainable molecular clock formed by positive and negative feedback loops. The positive feedback is represented by *clock* and *bmal,* which heterodimer promotes the transcription of *cry* and *per*, also known as the negative feedback since their product will translocate into the nucleus to inhibit the transcription of *clock* and *bmal* (Pando and Sassone-Corsi 2002). The mechanism and the rhythm established at different physiological levels are controlled by the intersection of the positive and negative loop, but the epigenetic mechanisms of deacetylation and methylation are also involved (Reszka & Zienolddiny 2018). In the deacetylation process, *sirt1* plays a crucial role (Nakahata et al. 2009). Concerning methylation, DNA methyltransferases could be involved in controlling the positive loop and *dnmt3* might be responsible for the methylation of *bmal's* promoter (Satou et al. 2013). Moreover, different processes are involved in the erasing of the methylation, pointing out that the contribution to the molecular clock could come from different levels. Additionally, both sirtuins and DNA methyltransferases are linked to nutrient availability (Su et al. 2016), suggesting that feeding time can act on the clock mechanism also through the epigenetic way. This study aimed to understand if feeding time can affect the rhythms of expression of clock genes and genes from the epigenetic machinery in the liver of the European sea bass (*Dicentrarchus labrax*), and a possible connection between the two systems. Additionally, clock genes were also analyzed in the hypothalamus to understand if feeding time affects the central pacemaker.

Materials and method

Fish were kept in an open recirculatory system in a 14:10 L:D cycle and fed with 1% of the fish body weight, once a day at fixed times. To understand how feeding time can affect rhythms of expression of clock genes and genes from the epigenetic machinery, fish were divided into two groups, fed at mid-light (ML) or at mid night (MD) respectively. During the sampling, fish were sacrificed in a 24-h cycle during seven sampling points, respectively at ZT 0.5, 4, 7.5, 12, 16, 20 and 24.5. Samples from hypothalamus and liver were collected for gene expression analysis. In hypothalamus, the analysis focused on the clock genes (*clock, bmal1, per1, per2, cry1* and *cry2*), while in the liver, clock genes and genes of the epigenetic machinery (*sirt1, dnmt1, dnmt3a, gadd45aa, mbd4* and *tet2*), were analyzed.

Results

All the clock genes analyzed in the liver (*clock, bmal1, per1, per2, cry1* and *cry2*) displayed rhythms in the ML group, while only *per2* displayed a rhythm in the MD group. Concerning the epigenetic genes analyzed (*sirt1, dnmt1, dnmt3a, gadd45aa, mbd4* and *tet2*), their rhythm was confirmed in the ML group, while only *dnmt3a* displayed a rhythm also in the MD group. Additionally, all the rhythms found in epigenetic genes had their acrophases during the night. Finally, rhythms were found in the hypothalamus for the clock genes both for ML and MD groups, except *cry2*, where no rhythm was found.

Conclusions

In the liver, rhythms were present in all clock genes analyzed in the ML group but not in the MD group with the exception of *per2*. This suggests that the feeding time has a strong impact since, when fish are fed in MD, the rhythm seems to disappear. Additionally, in most of the genes, the differences between ML and MD gene expression are significant, underlining the fact that the feeding time also influences the levels of transcription. Concerning the deacetylation mechanism, *sirt1* displays rhythm at least in ML. In most of the ZT points, a significant difference between both groups (ML vs. MD) is found in the transcriptional level, which could depend on the availability of NAD+ that it uses as cofactor, and it's related to the energy status. Additionally, its acrophases is similar to the one of *clock*, which counteract its acetylase activity. In the methylation process, *dnmt1* seems to be more affected by the feeding time than *dnmt3a*, suggesting that the maintenance of the pattern of methylation in the cells could be impacted by the energy status. The genes involved in the demethylation process presented rhythms only in ML but not MD, revealing their sensitivity to feeding time. Moreover, differences between ML and MD are present in several ZT points, with the value of MD group usually higher, suggesting an increase of the demethylation potential. In the hypothalamus, most of the clock genes analyzed displayed rhythm both in the ML and MD

(Continued on next page)

groups, confirming that the feeding time is not the first synchronizer in the central pacemaker. However, comparing ML and MD groups, significant differences are present between the same ZT point, so even if feeding time cannot be the major synchronizer, it can affect at least the expression, especially of the positive loop. To better understand the contribution of the epigenetic process to the clock genes, our research is currently focusing on the analysis of the methylation of *bmal1* promoter.

HOW FEEDING TIME AFFECTS THE DAILY RHYTHMS OF FOOD INTAKE CONRTOL AND DIGESTIVE FACTORS IN THE EUROPEAN SEA BASS (*Dicentrarchus labrax*)

E. Samorì*[1], I. Rodríguez[1], J.A. Paullada-Salmerón[2], J.A Muñoz-Cueto[2], F. J. Sánchez-Vázquez[1], J. F. López-Olmeda[1]

elisa.samori@um.es

Introduction

The regulation of food intake is a complex process where central and peripheral endocrine factors act to stimulate or inhibit feeding. Specifically, the hypothalamus plays a central role in integrating circadian and metabolic information and neuroendocrine signals. Additionally, it produces neuropeptides that can be divided into orexigenic and anorexigenic based on their action on feed intake (Volkoff 2016). As a peripheral organ, the liver is implicated in the regulation of feeding since it produces hormones that give information on the energy status. In addition, the digestive system of fish produces and secretes enzymes that are involved on nutrient digestion. All these factors, hormones and enzymes, are under the control of the circadian system and feeding time in fish (Kulczykowska & Sánchez Vázquez 2010). Moreover, the light-dark cycle represents one of the most important signals that can entrain the hypothalamus and its circadian clock, but for peripheral clocks feeding time seems to exert a significant influence (Montoya et al. 2010). The result is a system where the circadian mechanisms affect the metabolic pathway but at the same time the circadian system is affected by metabolism as well (Delgado et al. 2017). This study aimed to understand how feeding time can affect the daily rhythm of the factors involved in appetite control and digestion in the European sea bass (*Dicentrarchus labrax*).

Materials and method

Fish were kept in an open recirculatory system in a 14:10 L:D cycle and fed with 1% of the fish body weight, once a day at fixed times. To understand the importance of feeding, fish were divided into two groups, one group fed at mid-light (ML) and the other at mid-dark (MD). The sampling was performed in a 24-h cycle with seven sampling points at ZT 0.5, 4, 7.5, 12, 16, 20 and 24.5. Samples from hypothalamus and liver were collected and stored at -80ºC until analysis. Gene expression analysis was performed to evaluate the expression of genes involved in the regulation of feeding both in the hypothalamus (*neuropeptide Y*, *agouti-related protein, orexin* and *melanin-concentrating hormone*) and liver (*trypsinogen2, trypsinogen3, chymotrypsinβlike, carboxypeptidase* and *phospholipase*)

Results

In the hypothalamus, the rhythm was found in the MD group for the expression of *npy*, *agrp* and *orexin*, while no rhythm was found in the expression of *mch*. For all the genes that displayed rhythms, the acrophases were nocturnal. In the liver, *trypsinogen3, chymotrypsin-β-like* and *carboxypeptidase* displayed rhythms in the ML and MD groups, and the acrophases were nocturnal with a shift in the acrophases between ML and MD that varies between 3 and 7 hours. For *trypsinogen2* and *carboxypeptidase*, the only rhythm found was in the ML group, again with nocturnal acrophases.

Conclusions

No rhythm has been confirmed in the hypothalamus for the ML group, but only in the MD group for *npy, agrp* and *orexin*. These data suggest that feeding time can impact the rhythm in the brain, but the fact that ML feeding seems not to affect the hypothalamus in terms of rhythm could suggest that another part of the brain could participate in integrating the signals and displaying the rhythm of some genes analyzed. To clarify this hypothesis, a possible candidate for the analysis in the brain would be the telencephalon, where genes involved in the regulation of food intake are expressed like in the hypothalamus. The analysis revealed a clear rhythm in the liver for the genes analyzed in the ML group, suggesting a synchronization due to feeding time. In the genes where the rhythm is present also in the MD group, a shift in the acrophases is present but does not match the 12 hours of differences between the two feeding time, suggesting both light and feeding time interact to determine the acrophases of the rhythm.

E-mail: luisandresampaio@gmail.com

Introduction

Temperature has a strong influence on fish metabolism, which is correlated with fish growth and ultimately survival (Boltaña et al., 2017). Temperatures outside the optimum range of the species can induce oxidative stress in fish, a condition caused by the imbalance between prooxidant and antioxidant defenses (Nitz et al., 2020). This work aimed to evaluate the effect of temperature on survival, growth performance, and oxidative stress responses of juvenile Southern black drum *P. courbina*.

Materials and Methods

Juvenile *P. courbina* (450 fish, initial weight 0.58±0.19g) were exposed in triplicate to 23, 26, and 29°C for 25 days. The experiment was carried out in 300 L tanks attached to RAS. Photoperiod was set to 12 h light per day, salinity was maintained at 30±1‰, pH was equal to 8.01±0.1, and nitrogen compounds were within acceptable levels.

Fish were fed four times a day, with a formulated diet containing 55% crude protein and 13% lipids. At the end of the trial, weight and length were measured, six fish from each tank were killed and samples of gill, liver, and muscle were frozen in liquid nitrogen for analysis of total antioxidant capacity against peroxyl radicals (ACAP), lipid peroxidation (TBARS), and protein thiols (P-SH).

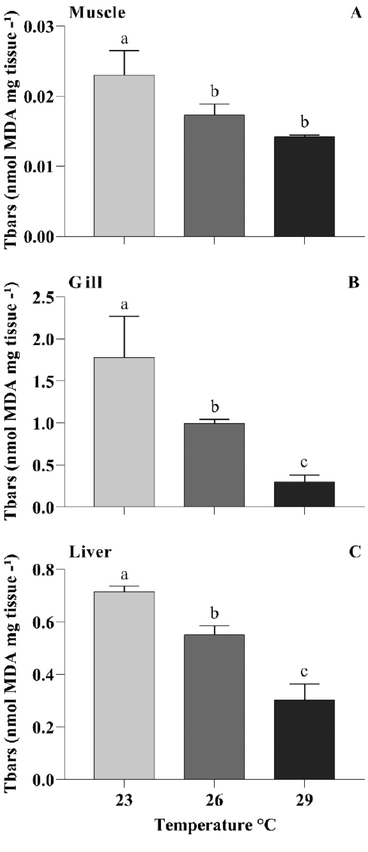

Figure 1 – Lipid peroxidation of muscle, gill, and liver of juvenile *Pogonia courbina*, reared for 25 days at different temperatures.

(Continued on next page)

Results

Survival was not influenced by temperature, it was above 98% in all treatments. The fastest growing fish were those reared at 29°C. Their final weight (8.94±0.56 g) was significantly higher ($P<0.05$) than fish maintained in any other treatment. Even tough fish reared at 23°C had the lowest SGR (7.38±0.30 % day^{-1}), their final weight was 6.3 times larger than the initial weight. Furthermore, weight gain of fish reared at 29°C was 2.7-fold higher than fish reared at 23°C. The total amount of food consumed was smaller for fish kept at 23°C, and the apparent feed conversion was poorest at the smaller temperature. Regarding responses on oxidative stress parameters on muscle, gill, and liver, cold exposition (23°C) led fish to higher lipid peroxidation (TBARS) in all tissues analysed (Figure 1). The lowest temperature triggered upper regulation on the total antioxidant capacity against peroxyl radicals (ACAP) in gill and liver if compared to 29°C. Fish protein thiols (P-SH) were higher in the liver of organisms kept at 29°C than 23°C.

Discussion and conclusion

The best performance of fish kept at 29°C may be related to the increased total feed intake, coupled to better apparent feed conversion, along with lower lipid and protein damage, plus lower investment in antioxidant capacity. Based on this, we concluded that among the tested temperatures, 29°C is the best temperature for *P. courbina* production

AN INNOVATIVE APPROACH FOR THE ENVIRONMENTAL ASSESSMENT IN INTEGRATED MULTI-TROPHIC AQUACULTURE: ASTRAL PROJECT

Sanchez, I ; Armengol, J.; Checa, D; Escamilla, M.;

LEITAT Technological Centre C/ de la Innovació, 2 · 08225 Terrassa (Barcelona)
isanchez@leitat.org

Introduction

Given the rapidly increase of the aquaculture sector, it is of relevance to provide the industry with solutions that ensure the sustainability and profitability. However, the monitoring of the sustainability of the aquaculture is challenging due to the diverse of production methods that hamper the development of standardized procedures tailored to all systems: from open to close or from extensive to intensive.

ASTRAL is a European project that aims at developing and providing innovative techniques and species combination to improve Integrated Multi-Trophic Aquaculture (IMTA). Specifically, the project is oriented to the full implementation of strategies to increase the sustainability, profitability, and resilience in four IMTA labs: open offshore (Ireland, Scotland), flow-through inshore (South Africa) and recirculation inshore (Brazil) systems, with a regional challenge-based perspective, including fish, mollusc, echinoderm, crustacean, and algae species.

IMTA systems represent a good alternative production method combining the farming of multiple and complementary species from different trophic levels, where extractive species take nutrients otherwise would be wasted affecting the natural environment (Chopin, 2018). Nevertheless, the environmental assessment of IMTA systems is an emerging topic that has not been extensively explored. In this sense it seems of relevance to elaborate on an innovative approach to address, under an environmental perspective, the complexity not only of nutrients recycling routes but also feeding regimes and infrastructure elements.

ASTRAL demonstrates the sustainability of the selected IMTA chains from an economic, social, and environmental perspective, where the latter approach incorporates a life cycle thinking in the assessment, together with the evaluation of practices toward zero waste and the study of circularity attributes associated to the innovative practices.

This work entails the description of how the LCA, circularity and zero waste approaches are employed to provide a comprehensive evaluation that allows the identification of the best IMTA configuration, while provideing recommendations for the development of production methods towards zero waste and consequently more sustainable business models.

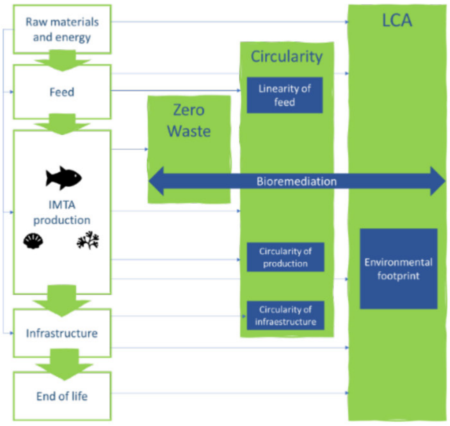

Figure 1. The integrated framework for the environmental assessment of IMTA systems.

(Continued on next page)

Material and methods

The Zero Waste approach aims at assessing the potential nutrients bioremediation rates in closed IMTA systems, where water and solids are collected and recirculated through the different trophic levels. In open systems, dissolved and suspended solids are released to the environment, so the circularity assessment integrates mass balance analysis to calculate fish emissions, while the nutritional content of extractive species is taken as a proxy to estimate the bioremediation efficiency.

Not limited to the bioremediation, the circularity analysis incorporates a wider perspective where the use of resources and the end of life of materials are considered as well. On the one hand, the development of novel feeds with alternative ingredients sourced from valorisation routes are assessed through circular indicators that inform the linearity of the feed. On the other hand, the infrastructure materials are evaluated in terms of the circularity embedded in plastic and steel elements with recycled components. Both analysis, feed, and production materials, complement the circularity assessment that enables the implementation of an innovative framework to analysis how diverse IMTA systems operate under the principles of the circular economy.

Moreover, and following the recommendations for a more sustainable aquaculture (COM (2021)), the environmental assessment is also materialized with the implementation of a Life Cycle Analysis, that permits the evaluation of the environmental impacts under a cradle to gate perspective. All inputs and outputs needed for the co-production of aquaculture species are gathered and transform into environmental impacts in line with ISO 14040 and 14044 standards. Complementary to zero waste and circularity, the LCA study provides the assessment of eutrophication impact category as a key indicator that represents the efficiency of the IMTA systems in terms of bioremediation (Figure 1).

Conclusions

Having identified the need to harmonise and adapt the methodologies for the aquaculture sector, ASTRAL project brings together the different approaches to create an integrated framework that allow farmers to obtain valuable indicators for decision making to increase the environmental performance of the processes. With a new assessment of circularity and zero waste indicators, ASTRAL develops a LCA study complemented with an IMTA-specific dimension which enables the development of greener business models.

IFISHIENCI PROJECT: THE ROLE OF NUTRIENT ASSIMILATION IN THE CIRCULAR ECONOMY

Checa, D; Escamilla, M.; Sanchez, I

LEITAT Technological Centre C/ de la Innovació, 2 · 08225 Terrassa (Barcelona)
dcheca@leitat.org

Introduction

Optimization of feeding is a driver to achieve the circular economy in aquaculture. This will enable the enhanced utilization of nutrients and benefits the farming industry through improved production yields with reduced feeding cost, while minimizing the environmental impact of undigested and uneaten feed. Key criteria for the success and continued growth in aquaculture will be to accelerate innovations that can improve sustainable fish feeds, optimize the feeding efficiency, and provide advanced management control for different species in different rearing environments.

The challenge is to find alternative sources at a reasonable cost with the same or similar nutritional value, comparable palatability and digestibility and the potential to substitute fish meal entirely without any negative effect on growth and filet quality. To date, technological developments and commercial applications have mainly focused on algae as a micro-feed ingredient,. Moreover, there is a promise of much higher available quantities of algal biomass in the future (due to its development for use as biofuels), potentially serving the need as a bulk alternative to today's feed ingredients for aquaculture.

Feed, being one of the major costs in fish production is also one of the major constraints for industry growth due to limited sources of sustainable raw materials. Further reduction of fish meal in feed for high value species (e.g. salmon, sea bass) and total replacement in diets of mass produced lower value species (tilapia, carps, African catfish) is necessary to make the world aquaculture more circular and sustainable. The increase of circularity of the production system will be achieved by qualifying methods to obtain new and functional feed ingredients from algae and validating processes for optimal valorisation of waste and sludge from aquaculture production systems.

iFishIENCi is a European project that aims at delivering breakthrough innovations supporting sustainable aquaculture, based on enabling technologies and circular principles, thereby providing the European aquaculture industry with the competitive advantage and growth stimulation needed to be a mover in revolutionizing global efficiency in fish production and meet society's needs for food from the ocean. The project targets circular principles and zero waste by qualifying new and sustainable organic value chains for feeds, and valorisation of by-products. In that sense, in the iFishIENCi project framework, the waste water and sludge collected from the fish growth are used for algae cultivation, reducing those waste streams and growing algae for the production of new feed ingredients. Moreover, the project has actively contributed to the recommendations to incorporate the circularity into the aquaculture sector *(Policy Recommendations For a More Circular Aquaculture*).

Material and methods

In iFishIENCI, the circularity associated to the use of waste streams from aquaculture to produce new feeds are addressed. To do so, available methodologies for circularity assessment are firstly reviewed and later adapted to measure the circularity along the value chain, focusing not only on feed production but also on the farming operation, where the nutrient assimilation plays a relevant role. With regard to feed formulation, ingredients sourced from waste valorisation routes are considered as recycled feedstock. The farming operation is also addressed since the efficiency of feeding is a key element in determining the functionality of the new formulations.

Three main indicators are defined for the circularity assessment of the new feed. Linear flow index (LFI), Material circularity indicator (MCI) and Nitrogen waste indicator (NWi) are the indicators that represents the circularity within the innovative aquaculture systems. The study considers nitrogen, as the principal nutrient involved in the bio recovery cycle.

Material Circularity Indicators of feed is defined in accordance with the Linear Flow Index of nitrogen together with a factor F(X) that is built as a function F of the utility X.

$$MCI = 1 - LFI\ x\ F(X)$$

(Continued on next page)

The utility reflects the extent to which a product is used to its full capacity. In the context of IFishIENCi, digestibility is addressed in the circularity assessment though the ratio that represents the Nitrogen assimilation efficiency (NE), calculated as follows:

$$N\ assimilation\ efficiency\ (NE) = \frac{N\ assimilated}{N\ ingested}$$

The increase on digestibility, that means the assimilation of nitrogen in feed, results in a more efficient use of any resources that take a linear path in the material flow. Therefore, the higher NE, the higher utility. It is calculated as the ratio between the NE of the new feed formulation obtained in the project in comparison with the NE average of the industry for conventional feeds and not-improved feeding systems.

In the example below, MCI is 58,93% higher when increasing nitrogen assimilation by 50%; MCI is 35,36% higher when increasing nitrogen assimilation by 30%; MCI is 15,69% higher when increasing nitrogen assimilation by 10%. Therefore, notable variations are observed when applying the nutrient assimilation principle to the method and taking different NE ratios when performing the calculations, MCI increases value when the assimilation of nutrients increases.

Conclusions

Improving digestibility, nutrient excretion is minimized, increasing the circularity associated to the feeding systems. Moreover, digestibility and sustainability are linked under the circularity perspective as nutrients are used in a more efficient way, facilitating the incorporation of the circular economy principles in the feed manufacturing process and farming operation.

Introduction

Aquaculture has become one of the most important practices for the food industry. Management, health, water quality and pathogen control are determining factors for the success of aquaculture. The search for alternatives for crop improvement and protection against pathogens is of utmost importance to avoid production losses and use of antibiotics. In traditional medicine, plants have been used ancestrally for therapeutic purposes, which is why their antimicrobial potential is recognized. The need for surfaces to provide enough plant tissue for crops can be avoided if aquaponics is implemented. Probiotics have proven to be an effective and safe alternative, not only to limit the development of both bacterial and viral pathogens, but also to improve the general performance of aquaculture crops. When live food is administered in culture systems, it will also be affected by the antibacterial additive, so it is necessary to evaluate said effect, hoping that it benefits the growth of live food or, at least, does not modify it, allowing the administered bacteria generate its probiotic effect in the cultivated organism. The aim of this work is to develop an integral proposal for aquaculture systems to improve farming efficiency through eco-friendly and sustainable strategies.

Material and Methods

The inhibitory capacity of bacterial growth and development was evaluated using extracts of *Ocimum basilicum L* (Basil), *Rosmarinus officinalis* (Rosemary) and *Origanum vulgare* (Oregano). For *O. basilicum*, plants in aquaponic system were also tested.

For the preparation of the extracts, the leaves of each plant were used. The extraction methods were: maceration and rest in ethanol (70 and 96%, 24 h and 15 days), infusion. and decoction in distilled water, stripping with steam and resin. For the growth inhibition tests, Gram (-) microorganisms associated with the culture of the American bullfrog (*Lithobates catesbeianus*), white shrimp (*Litopenaeus vannamei*) and oyster (*Crassostrea* sp.), were used, as well as a strain of *Vibrio parahaemolyticus* (from CIBNOR´s collection) to demonstrate the benefit of extracts for aquaculture. Other marine products (macroalgae and sea urchin extract) were evaluated for their antimicrobial potential.

To evaluate the effect of probiotic bacteria on secondary culture organisms for live food, this study assessed *in vitro* interaction between *Bacillus* bacteria and microalgae and their posterior *in vivo* effect on rearing Kumamoto oyster *Crassostrea sikamea*. The probiotic strains *Bacillus licheniformis* (MAt32), *B. subtilis* (MAt43), and *B. subtilis subtilis* (GAtB1) were individually inoculated in triplicate into 250 mL flasks containing 1×10^4 colony forming units (CFU) mL^{-1} of bacteria and 4.5×10^4 cell mL^{-1} of microalgae (*Isochrysis galbana* or *Chaetoceros calcitrans*) to evaluate their growth during a 7-day culture. Single cultures of microalgae or bacilli served as control. Additionally, *C. sikamea* spat was treated for 28 days with four single/combined bacillus treatments in triplicate at a concentration of 1x106 CFU mL-1 as follows: (a) Control, without treatments; (b) Combination of two antibiotics (10 mg L^{-1}); (c) *B. licheniformis*; (d) *B. subtilis*; (e) *B. subtilis subtilis*; (f) mixed bacilli.

Both bacteria and plant extracts were added to white shrimp cultures in experimental treatments. The administration of the extracts in the form of microencapsulates was also evaluated.

Results

The aquaponic system provided sufficient plant material for the extractions at a density of 1:5.3 with *Oreochromis niloticus*. Visually, there were no differences between the plants on land and in the aquaponic system. Inhibition tests *in vitro* (Bauer *et al.*, 1966) showed a higher inhibition halo with the extract obtained by steam dragging. The highest inhibition halo was obtained with oregano extract and to a lesser extent with basil (Table I).

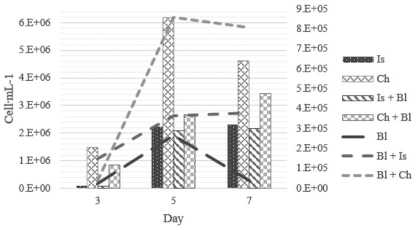

Figure 1.- Microalgae and bacterial growth in co-cultivation. Bars correspond to microalgae and lines to bacterial growth. **Is** = *Isochrisys galvana*, **Ch** = *Chaetoceros calcitrans*, **Is + Bl** = *I. galvana* in co-culture with *Bacillus licheniformis*, **Ch + Bl** = *Ch. calcitrans* in co-culture with *B. licheniformis*, **Bl** = *B. licheniformis*, **Bl + Is** = *B. licheniformis* in co-culture with *I. galvana*, **Bl + Ch** = *B. licheniformis* in co-culture with *Ch. calcitrans*.

The results showed a significantly ($P < 0.05$) increased growth of *Bacillus* strains co-cultured with microalgae while the growth of *I. galbana* co-cultured with bacteria was not reduced significantly ($P > 0.05$) compared with the control group (Fig.1). *C. sikamea* spat treated with *Bacillus* showed significantly ($P < 0.05$) higher growth and survival than the control group. In this study, *C. calcitrans* microalgae were susceptible to the presence of probiotic bacteria. Nonetheless, this reduction in microalgal growth observed *in vitro* increased growth and survival of *C. sikamea* spat exposed to probiotic bacteria compared to spat without probiotics.

To test plant tissues, experimental white shrimp *P. vannamei* cultures were used added with oregano and basil. No significant differences were found in growth with respect to the controls, but a slight difference was observed in terms of survival, decreasing in the treatments due to the toxicity of the plant even mixed with the food, therefore, the addition of the extracts as microencapsulated was evaluated.

Conclusions

With the results obtained, it will be possible to evaluate the inclusion of medicinal plants and probiotic bacteria in the feeding of cultured organisms. The incorporation of plant extracts requires fine-tuning the mode of administration, through microencapsulations. Use of natural additives in aquaculture can contribute to increased growth and survival, and improve the immune response, giving greater resistance to pathogens in a sustainable manner.

Introduction

Aquaculture bacterial outbreaks are responsible for huge annual economic losses worldwide, remaining a major challenge for sustainable aquaculture expansion. Although antibiotics are an important tool for disease treatment, their damaging effects on the environment and public health have led to increased restrictions on their use in aquaculture. Thus, new biological measures are emerging to control the occurrence of bacterial diseases in aquaculture, assuring advanced and integrated health care for humans, animals, and the environment. Over the last years, fish-gut-associated microorganisms have been exploited as an effective approach to face the challenges of modern aquaculture. Among these, *Bacillus* spp. have recognizable biotechnology applications including the production of Natural Antimicrobial Compounds (NACs) that may constitute a barrier against pathogens' proliferation by targeting their growth, biofilm formation, and Quorum-Sensing and the stimulation of the host immune system.

After validation of the *in vitro* bioactivity of three promising *Bacillus* spp. secondary metabolites (1, 2), here we evaluate their potential protective effects and established the best course of treatment using an *in vivo* model when challenged with *Edwardsiella tarda*.

Materials and Methods

Zebrafish experiments and handling were approved by the Animal Welfare Committee of the Interdisciplinary Centre of Marine and Environmental Research (CIIMAR), performed by trained scientists (with FELASA category C), and carried out in a registered installation (N16091.UDER), in compliance with the European directive 2010/63/EU for the care and use of laboratory animals.

In this work, we used three Fish isolates (*B. subtilis* FI314, *B. vezelensis* FI436, and *B. pumilus* FI464) previously isolated from the gut of different fish species (*Sparus aurata*, and *Dichentrarchus labrax*) and selected for their *in vitro* bioactivities (1, 2).

Before evaluating the *in vivo* protection, we determined the maximum non-toxic extract concentration (MNTC) of each FI following the Organisation for Economic Co-operation and Development (OECD) Guidelines. Further, we establish the *Edwardsiella tarda* infection model by immersion using 10 dpf zebrafish larvae. Larvae were distributed into 6-well plates containing 10 larvae/well in 5 mL of Egg water and inoculated with $5x10^7$, $1x10^8$, and $3x10^8$ CFUs mL^{-1} of *E. tarda*. After inoculation, larvae were fed, and the plate was incubated at 28 ºC. The *E. tarda* inoculum was kept in the water for 24 h. Cumulative mortalities were registered for 48 h and dead larvae found during the assay were removed.

Finally, to evaluate the best course of treatment for *Bacillus* spp. secondary metabolites, zebrafish larvae were treated with the FI extracts once before mouths' opening, once three days before the bacterial challenge, once one day before the challenge, and every day after the mouths' opening and until the bacterial challenge. Thus, 10 healthy larvae were distributed into each well of a 6-well plate, containing 5 mL of Egg water and treated accordingly with the extracts for 2 h at 28 ºC and then transferred to new 5 mL egg water. The treated 10 dpf larvae were challenged by immersion with *E. tarda*

(Continued on next page)

1×10^8 CFUs mL^{-1}. After inoculation, larvae were fed, and the plate was incubated at 28 ºC for 24 h. Cumulative mortalities were registered between 16 and 48 h and dead larvae were removed and discarded. Control groups were included: (i) non-treated larvae inoculated with *E. tarda*; (ii) non-inoculated larvae; (iii) larvae inoculated with 1xPBS. The experiment was independently performed 3 times.

Survival data were analysed using Kaplan–Meier, and group differences were analysed by the log-rank, using the GraphPad Prism 9 software.

Results

The first step of this work was to determine the maximum non-toxic extract concentration of each FI extract to be employed in protective assays using zebrafish larvae. The results showed that extracts from the three FI induced toxicity in zebrafish when administrated at concentrations above 250 μg mL^{-1}. Secondly, we established the *E. tarda* infection model by immersing 10 dpf zebrafish larvae with three different concentrations of *E. tarda* for 24 h. Larvae exposed to 3×10^8 CFUs mL^{-1} started to show mortality at 10 h post-infection (hpi) and rapidly progressed until 18 hpi, with 100% mortality. In larvae exposed to 1×10^8 CFUs mL^{-1} mortalities began at 17 hpi and progressed through time, reaching ~60% at 24 hpi. From these results, we selected 1×10^8 CFUs *E. tarda* mL^{-1} as the bacterial concentration for the challenge experiment.

Finally, the protective effects and best course of treatment of the FI metabolites were determined using the *E. tarda* infection model and the FI extract maximum non-toxic concentration. Larvae treated once before the mouth's opening and once one day before the challenge did not exhibit any effects on zebrafish survival upon bacterial challenge, when compared to non-treated larvae challenge with *E. tarda*. Zebrafish larvae treated every day with the FI metabolites after the mouth's opening until the bacterial challenge induced higher mortalities when compared to the non-treated and challenge larvae ($p<0.01$), causing 100% mortality after 24h of infection, which might indicate a potential overstimulation of zebrafish's innate immune system. On the other hand, when zebrafish larvae were treated only once three days before the bacterial challenge, we observed a significant increase in larvae survival rate up to 50%, when compared to the non-treated zebrafish larvae infected with *E. tarda* ($p<0.001$).

Conclusions

Taken together, our experiments revealed that the three promising fish-gut *Bacillus* spp. produce extracellular molecules that protect zebrafish larvae from *E. tarda* infection only when administrated once three days before the bacterial challenge. Thus, the metabolites produced by FI314 (*B. subtilis*), FI436 (*B. vezelensis*) and FI464 (*B. pumilus*) may be promising tools for disease control in aquaculture.

DOMESTICATION AND WELFARE IN FARMED FISH

João L. Saraiva*, Maria F. Castanheira, Pablo Arechavala-López, Jenny Volstorf and Billo Heinzpeter Studer

FishEthoGroup, Olhão, Portugal
Email: joao@fishethgroup.net

The domestication of fish species is still in its early stages when compared to terrestrial animals. Although the gap between the time domestication has been underway in terrestrial farm animals and in farmed fish is enormous, there has been a considerable effort towards fish domestication in recent times (Duarte et al 2007). However, the main component in the domestication process is the generation interval (i.e. the average age of the parent animals at the birth of their offspring—note that this is *not* the age at maturity). A comparison between land animals and fish may be found in Figure 1.

Comparison between the generation intervals in terrestrial farm animals (white bars) and fishes (grey bars).

Generation intervals may be in the same order of magnitude in terrestrial animals and fish, but they vary immensely for different species in aquaculture, adding a biological layer of complexity to the implementation of welfare standards for such a diverse group of animals.

The effects of domestication on welfare of farmed fishes are complex to study because fish differ from livestock in genetics, physiology and behaviour, and experience different sensory worlds. Consequently, empathy with fish and understanding of their needs becomes more problematic than with land animals. Additionally, the acknowledgement and study of mental dimensions of fish existence is very recent (Brown 2015). We discuss that higher levels of domestication in fish do not necessarily correspond to better welfare because (1) artificial selection by the aquaculture industry is mostly focused on production-related traits such as growth, and this selection process may have unknown effects on welfare-related traits; (2) the number of fish species presently farmed (circa 400) is 10-fold higher than land animals, rendering the establishment of general welfare guidelines extremely complicated, even because there is immense diversity among fishes in what regards their welfare needs; (3) the current paradigm of the Five Freedoms guiding welfare is out-dated, was designed for livestock and largely considers animals passive with regards to their environment; and (4) there are still severe knowledge gaps in the biology of farmed fishes, especially in welfare-related traits (Saraiva et al 2019). The implementation and regulation of humane fish farming systems should acknowledge the challenges and specificities of farmed fishes (Saraiva et al 2022), integrating industry, academia, advocacy groups and policy makers in a constructive dialogue.

MAPPING TEMPERATURE STRESS IN RED SEA CUCUMBER *Parastichopus tremulus* USING NON-INVASIVE RESPIROMETRY

E. Schagerström* H. Lindgren K.S. Sundell

Department of Biological and Environmental Sciences, University of Gothenburg
Kristineberg 566, 451 78 Fiskebäckskil, Sweden
Email: ellen.schagerstrom@bioenv.gu.se

In order to develop IMTA systems with sea cucumbers, a supply of animals in large quantities is needed. The red sea cucumber *Parastichopus* tremulus is found in the northeast Atlantic Ocean, mainly along the Skagerrak and North Sea coast of Norway, Denmark and Sweden, but also Iceland, the Faroe Islands and British Isles, with recorded occurrences down to the Canary Islands. The species can occasionally be found from 18 m down to 4000 m but is most frequent found at 50–500 m on soft sediment bottoms. Fully grown specimens of *P. tremulus* can reach 50 cm in length, 10 cm in width and a wet weight close to 300 g, but the average size and wet weight is around 25 cm and 200 g, respectively Commercial trawling, where sea cucumbers are often caught in large numbers as bycatch, is both destructive to their deep sediment bottom habitat as well as lethal to the animals. By farming red sea cucumber, the development of sustainable aquaculture can proceed, and natural populations be protected from overfishing.

To be able to rear the species on a large scale, it is necessary to know the effect of salinity, ammonium, pH and temperature on its physiological performance in order to be able to optimize the cultivation conditions. We have adapted and developed respirometry equipment for use with sea cucumber *P. tremulus.* We intend to measure the effect of the four mentioned parameters on the animals' oxygen consumption through respirometry studies. Here, we present results on the effect of different temperatures. Oxygen consumption in an organism is an accepted way of non-invasively measuring stress in animals with as little impact as possible.

The focus of our research is to investigate basic physiology and the physiological boundaries regarding environmental biotic and abiotic factors of *P. tremulus.* This will build the knowledge base for developing breeding, hatching and farming guidelines with a focus on animal health and welfare along with productivity for farming new sea cucumber species.

Based on adaptations of several existing protocols for spawning and rearing sea cucumbers, we have also developed a hatching and larval rearing protocol for this species (Schagerström et al 2022). This enabled us to successfully produce the first captivity-bred juveniles of this species in Sweden during 2020.

EX-SITU AQUACULTURE TRIALS FOR BIOMASS PRODUCTION OF MEDITERRANEAN SPONGES

K. Schiefenhövel*, M. Schiffer-Harms, W. Schatton, C. Cerrano, M.J. Slater and J. Henjes

Alfred Wegener Institute, Marine Bioeconomy, Aquaculture Research
Am Handelshafen 12, 27570 Bremerhaven, Germany
*Email: karin.schiefenhoevel@awi.de

Introduction

Marine sponges gaining increasing importance as sources of bioactive compounds for application in medicine, pharmacy, industry and as nutraceuticals. Mediterranean sponge species like *Chondrosia reniformis* and *Axinella polypoides* are of special interest due to their antiviral and antibiotic activities and high amount of *Chondrosia*-collagen (Swatschek et al., 2002). Large amount of sponge biomass is required to obtain a high yield of desired compounds. To avoid overharvesting of natural resources and guarantee a sustainable production, alternative strategies have to be found. The market interest has stimulated research on alternative methods for sponge biomass production such as in situ and ex-situ aquaculture. Although the sponge genus *Axinella* is known to be a source of a variety of metabolites (Menna et al., 2012), so far no attempt has been made to cultivate this species within aquaculture systems. Other than, assessments of in situ mariculture show high growth and survival rates of the marine sponge *C. reniformis* (Gökalp et al. 2019). But it seems to be economically viable production of the respective species is not feasible due to their photophobic characteristics and substrate requirements. *C. reniformis* is being able to de-attach and move around, especially when using common culturing structures, such as pins, lines and net grids (Van Treek et al., 2003). In addition, selecting sites for culturing of this species depending on turbidity and depth respectively sun aversion (Gökalp et al., 2020). Independent of location and weather conditions, ex-situ aquaculture represents a promising alternative as required species-specific conditions can be customized (Nickel and Brümmer, 2003).

Aquaculture trials shall determine optimal conditions for a sustainable sponge biomass production in land-based recirculating aquaculture systems, in special high attachment, survival and growth rates of sponge fragments with triggered compound production.

Materials and methods

Sponge specimen were obtained from either Adriatic or Aegean Sea and subsequently raised in a recirculation aquaculture system at the Alfred Wegener Institute, Bremerhaven, Germany. In various experiments sponges were cut into fragments and placed on different substrate types like artificial substrate (pebbles, quartz sand, cement), clay bowl, clay pot, PPE plate or oyster shell for *C. reniformis* and accordingly clay pot and long line for *A. polypoides*. Tests with different feed types and feeding strategies were conducted. Sponge fragments were fed with either a commercial liquid diet for filter feeders, a self-formulated diet, shrimp-faeces or living microalgae. In parallel approaches sponges were fed once a day or with increased feeding frequency. The effect of nutrient content, temperature, light source (440nm/365+440nm) and current (tank drain bottom/surface) on sponge attachment and survival were examined during the course of the experiment. Fragment growth were measured photographically and the wet weight was determined at the beginning and end of the experiment.

Results

In all experiments the survival rate of sponge (both species) explants were quite high with 80 to 95%. Best survival rates were detected for *C. reniformis* under blue light (440nm) and tank drain at the bottom. Increased algae growth under UV-light (365nm) had no effect on the health status of sponge explants. A further test on temperature increase up to 22°C to enhance metabolism and growth resulted in soaring death rates. Fragments of *C. reniformis* attached easily to any of the substrate types, whereas *A. polypoides* did not attach at all to either clay pot or long line. Statistical tests revealed no significant differences for survival, attachment and growth rates between the different feed or substrate types for both species. But on average increased feeding frequency led to a higher collagen content in *Chondrosia*-fragments fed with self-formulated diet. In general, growth varied greatly among fragments (-35 to 135%).

(Continued on next page)

Discussion and conclusion

To avoid sudden death of sponge specimen short after arrival at the aquaculture facility, efficient transportation conditions as high water volume and cooling are essential. Running-in of culture tanks with water retreatment processes need to give stable nutrient values. Fluctuation of ammonia- and nitrite-contents in the culture tanks has a negative impact on sponge health status. A land-based cultivation of any sponge species could not be implemented yet due to sponge sensitivity to transportation and high demands on aquaculture conditions (Nickel and Brümmer, 2003). Water temperature varies from 17 to 25°C in native environments. Here is a tendency of soaring death rates of fragments with increasing water temperature in connection with unfavourable water parameters. In addition, for reactivation of metabolism and intake of food, sponge fragments need to reorganise their body structure from fragmentation and physical adapt to present flow patterns in the culture tank. Subsequently, any movement of fragments during the experiment has a negative impact on the fitness and formation of a new pumping system. Hence, measurements of growth gives only two values, start and end of experiment.

As sponges are effective active filter feeders with a filtration rate per day of 24,000l/kg sponge biomass (Henchel et al., 2002), optimal feed supply is essential, but in addition high loads of feed can lead to blockage of the ostia whereas low feed supply in starving of sponge fragments (Wilkinson, 1983). It can be assumed that better survival rates are achieved with a special current setting, because the drain at the bottom ensures improved homogeneity of the water body in the tank and thus feed materials are better distributed and waste particles are moved more easily away.

In summary, first attempts to a successful land-based production of sponge biomass have been made, feeding, attachment, survival rates and fitness give reliable values and can be replicated. But for enhanced sponge biomass production there is still further research needed to get more information about the species-specific growth needs and characteristics of sponges.

Background

Collagen plays a major role in healthcare and well-being and has many potential applications such as in drug delivery, cosmetics and food industries. Thus, the market for collagen is growing rapidly worldwide. Marine sponges are a highly valuable source of marine collagen. Among them, *Chondrosia reniformis* is of particular interest due to the high concentration (> 30%) of type I collagen in the sponge biomass (Ghosh et al. 2019) and the absence of any inorganic components (spicules).

A major constraint regarding the industrial application of sponge collagen is the sufficient supply of sponge biomass. Promising efforts have been made in the mariculture of *Chondrosia reniformis* targeting sustainable production of sponge biomass needed for collagen production (Gökalp et al, 2020; Orel et al, 2021). Land-based aquaculture represents an interesting alternative for the culture of marine sponges, as it allows species-specific conditions and, as a result, maximized collagen production.

Materials and methods

C. reniformis were obtained from the sampling area in the Mediterranean Sea near Ancona/Italy and subsequently reared in a recirculation aquaculture system at the Centre for Aquaculture Research, Bremerhaven/Germany. In different approaches, sponge specimens were cut and sponge fragments were allowed to attach to different substrates (oyster shells, concrete, PVC plates, clay pots and clay plates). In addition, different feeding regimes (feeding duration, feeding frequency) and different food (shrimp faeces, living algae, commercial food for filter feeders, self-designed powder feed) were tested. Sponge collagen was isolated (Swatschek et al, 2002) and collagen content was determined.

Results

The collagen content of *Chondrosia reniformis* was not significantly affected by the substrate they grew on. While *Chondrosia* attached to PVC plates had a mean collagen content of 22%, cultivation on a clay pot and a combination of a clay pot and PVC plate resulted in mean collagen contents of 20% and 24%, respectively. *Chondrosia* growing on clay plates, however, showed a collagen content ranging from 23% to 37% in different experimental approaches.

The diet of the sponges had a significant effect on the collagen content of *Chondrosia*. Sponges fed with shrimp faeces or a combination of shrimp faeces and living algae had a collagen content of 22% and 23%, while feeding them with a self-designed powder feed resulted in 33% and 39% in different experimental approaches. However, food quantity played a significant role to reveal this effect.

Conclusion

Land-based aquaculture of *Chondrosia reniformis* is a promising approach to grow marine sponges and increase their collagen content. In our studies, we found collagen contents of up to 80% in some specimens. This is a clear indication that a systematic increase in the amount of sponge collagen in a closed recirculating aquaculture system is possible. Further studies need to focus on the specific requirements that trigger collagen production in marine sponges.

Introduction

Development of All-female Walleye broodstocks could improve angler satisfaction in Midwestern U.S. states while creation of a YY Male Broodstock could assist with exotic Walleye eradication in Western states *via* the Trojan Y Chromosome of YY Male approach.

Material and Methods

During this pilot study effort, we fed fry feed top-coated with either Estradiol (E2) or Methyltestosterone (MT) at the Rathbun and Meade Hatcheries in Iowa and Kansas. Fish were killed by anesthetic overdose

Results

At 171-176 dph, 255 and 181 fish were euthanized and necropsied from the Meade and Rathbun facilities, respectively. Phenoypic sex ratios for control groups were 53.1% Female, 43.8% Male (1 unknown) from Meade and 57.4% Female and 41% Male (1 unknown) at Rathbun. Preliminary phenotypic sex calls suggest successful recipe development for sex-reversal in both directions. The proportion designated phenotypic or intermediate females in the three E2 treatment trials at 171-176 dph ranged from 96.3 to 98.4%. The number of fish designated as either males or presumed males in the two MT trials at that time were 94.0 and 98.4%. Remaining study fish from both hatchery facilities were subsequently transferred to the Milford Hatchery in Kansas to be reared further to confirm the above sex ratios. At 332dph, a total of 32, 29 and 35 surviving fish from three E2 treatment groups were killed and examined histologically yielding 100% female sex ratios for all three groups (Table 1). The appearance of histological samples was quite clear-cut with readily observed oocytes (Figure 1). Based on both the early phenotypic and the subsequent confirmatory histological results, the study yielded two recipes for highly successful feminization of male walleye. At two years of age, the MT80 and MT100 MT groups were 75 and 80% male based on necropsy, though these results were hindered by small sample size.

TABLE 1: Results of histological examinations from three treatment groups at 332 dph in the estradiol trials at two hatchery facilities

Hatchery	Treatment	Male	Female
Rathbun IA	Control	16	23
	E2 84	0	32
	E2 100	0	29
Meade KS	Control	5	5
	E2 84	0	35

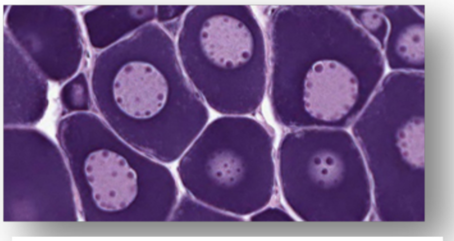

Figure 1. Typical oocyte appearance in 100% of E2 treated Walleye in all three treatment groups.

(Continued on next page)

Discussion

Based on both the early phenotypic and the subsequent confirmatory histological results, the study yielded two recipes for successful feminization of male walleye. The masculinization results were less clear-cut. However, subsequent full-scale studies yielded highly effective sex reversal protocols for both feminization of male Walleye in North Dakota and masculinization of females in Iowa. We conclude that combining existing fish culture and sex reversal experience from multiple agencies/entities is an efficient approach for development of desirable monosex broodstocks for both commercial aquaculture settings and fisheries management.

FROM AQUACULTURE TO AQUACULTURE: PRODUCTION OF THE FISH FEED ADDITIVE ASTAXANTHIN AND OTHER VALUABLE CAROTENOIDS FROM AQUACULTURE SIDESTREAMS IN *Corynebacterium glutamicum*

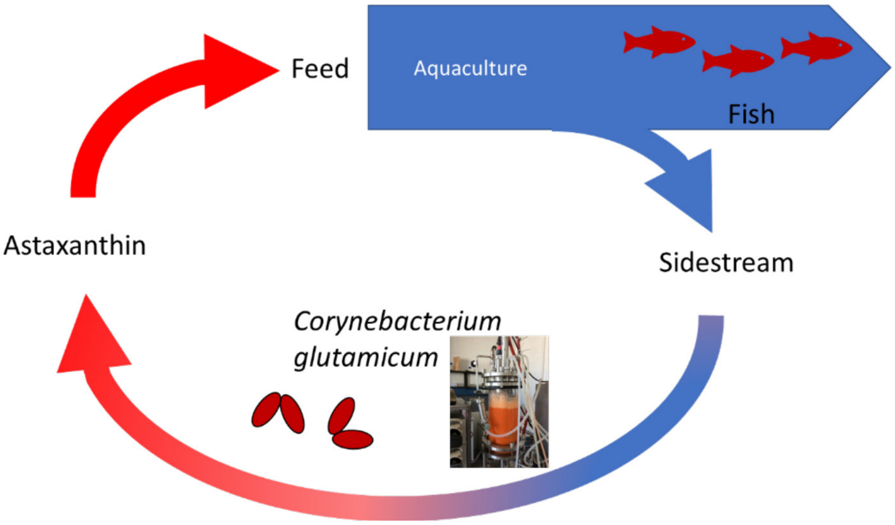
Ina Schmitt*, Florian Meyer, Nadja A. Henke, Petra Peters-Wendisch and Volker F. Wendisch

Genetics of Prokaryotes, Faculty of Biology & CeBiTec, Bielefeld University, Bielefeld, Germany
E-Mail: ina.schmitt@uni-bielefeld.de

Circular economy holds great potential to minimize the use of finite resources and reduce waste formation by the creation of closed-loop systems. Turning biotechnological production chains into sustainable, circular processes offers the possibility to contribute to climate protection and global waste reduction.

Aquaculture generates nutritious side streams from residual fish feed and fish excrements that may be used for bacterial fermentation processes. Fermentation processes are established in the biotechnological industry creating value from products such as food and feed amino acids or non-animal protein.

Corynebacterium glutamicum is used in the million-ton-scale fermentative amino acid production (Wendisch, 2020), but has also been engineered for production of functionalized amines, diamines, organic acids, alcohols or isoprenoids (Mindt et al., 2020). C. glutamicum naturally synthesizes the yellow C50 carotenoid decaprenoxanthin and was engineered for the production of the red C40 carotenoid astaxanthin (Henke et al., 2016; Henke & Wendisch, 2019). Furthermore, it was engineered for the production of lycopene and β-Carotene (Henke et al., 2017), and the C50 carotenoids bisanhydrobacterioruberin (BABR) (Taniguchi et al., 2017), 2,2′-bis-(4-hydroxy-3-methylbut-2-enyl)-β,β-carotene (C.p. 450) and Sarcinaxanthin (Henke et al., 2017). Carotenoids exhibit antioxidative and ROS quenching properties. They are used as supplements for animal feed in salmonid and shrimp aquaculture, in poultry farming and as food colorants. C. glutamicum grows on a number of carbohydrates and has been engineered to utilize several alternative growth substrates to enable a flexible feedstock concept (Wendisch et al., 2016). C. glutamicum is a very suitable production host for the circular bioeconomy as large scale processes are established and can be scaled and due to its flexibility regarding utilization of various feedstocks and the ease of metabolic engineering towards a broad spectrum of target products.



(Continued on next page)

In this study, we aimed to utilize an aquaculture side stream (AQ) for production of astaxanthin and other valuable carotenoids. Previously, we have engineered *C. glutamicum* for overproduction of astaxanthin (Henke et al., 2016; Henke et al., 2018; Henke & Wendisch, 2019). Here, we studied if *C. glutamicum* can utilize components present in AQ. First, AQ did not inhibit growth of *C. glutamicum.* Second, AQ could replace a number of components of the mineral salts medium used to support growth of *C. glutamicum*, e.g., phosphorus, calcium, chloride, magnesium and sulfate ions as well as biotin and trace elements. Third, we could show that the standard growth medium supplemented with AQ even enhanced production of astaxanthin. Fourth, the AQ improved astaxanthin production was scaled-up to 2 L bioreactor fermentations. Fifth, this strategy was transferrable and we showed that supplementation with AQ also improved production of the native lycopene and decaprenoxanthin as well as the non-native carotenoids such as β-carotene, zeaxanthin, canthaxanthin, BABR, C.p.450 and sarcinaxanthin.

Thus, we have gained a proof-of-principle for production of astaxanthin from aquaculture sidestreams for use as feed additive in aquaculture, e.g. of salmonids or shrimp. We will discuss the potential and limitations of this aquaculture based approach to circular economy.

Introduction

To transition towards a bio-based society, there are efforts to increase seaweed cultivation in the North Sea, especially within areas of offshore windfarms. Seaweed takes up nutrients during winter, grows during spring and is harvested in early summer. Should seaweed cultivation increase on a large scale, the additional uptake of nutrients through seaweed could decrease the availability of nutrients needed for the growth of protists.

Protists are unicellular eukaryotes and they form the base of aquatic food webs. Protist communities consist of phytoplankton, mixoplankton and protozooplankton. Phytoplankton perform photosynthesis and use dissolved nutrients to grow, while protozooplankton acquire nutrition from prey via phagotrophy. Mixoplankton combine photosynthesis with phagotrophy, so mixoplankton can access nutrient and carbon sources that phytoplankton and protozooplankton cannot.

As phytoplankton, mixoplankton and protozooplankton employ different trophic strategies, the additional uptake of nutrients through seaweed could impact the trophic structure of protist communities. A decreased availability of dissolved inorganic nutrients could favor mixoplankton as they do not rely solely on dissolved inorganic nutrients as their source of nutrients.

Material and Methods

To gain insight into the possible impacts of seaweed cultivation on the protist community, a 3D numerical model of the North Sea was modified to simulate the growth of seaweed as well as the growth of phytoplankton, protozooplankton and mixoplankton. Figure 1 illustrates the conceptual ecological model that was applied. Two scenarios were run with (seaweed scenario) and without (reference scenario) taking the growth of seaweed into account. For the seaweed scenario, seaweed was seeded in 25% of all designated offshore windfarms in the Dutch North Sea (i.e. 790 km^2). The two model scenario simulations were run for 12 months from September 2016 to September 2017 and thus covered one growth period of seaweed cultivation.

The reference scenario was quantitatively compared to in-situ measurements of nutrient concentrations and biomass of the protist community. Then, the reference scenario and the seaweed scenario were compared to each other in terms of nutrient concentrations and biomass of phytoplankton, protozooplankton and mixoplankton. Furthermore, the trophic composition of the protist community resulting from the seaweed scenario was qualitatively compared to mesocosm experiments.

Results

Preliminary model results show that the reference scenario manages to capture the timing and magnitude of the nutrient and chlorophyll peak concentrations well compared to in-situ observations. A preliminary comparison between the reference and seaweed scenario show a relative decrease of dissolved inorganic nitrogen and phosphate concentrations as well as a relative shift of the trophic composition of the protist community towards diatoms and mixoplankton. Thus, seaweed aquaculture has the potential to change the trophic composition of protist communities. The comparison of the trophic composition of the protist community resulting from the seaweed scenario to mesocosm experiments is still ongoing research.

Conclusion

The preliminary model results show that seaweed aquaculture has the potential to impact the trophic composition of protist communities. As many harmful algal bloom species are mixoplankton, and diatoms (due to their high nutritional value) are the preferred diet of many higher trophic levels, changes to the trophic composition of protist communities could impact marine ecosystems. In the future, seaweed cultivation will interact with other types of aquaculture, e.g., mussel aquaculture, and potentially with fed aquaculture in an integrated marine trophic aquaculture (IMTA) setting. 3D ecosystem models provide a tool to analyze the effect these scale-dependent anthropogenic changes can have on the trophic composition of protist communities.

(Continued on next page)

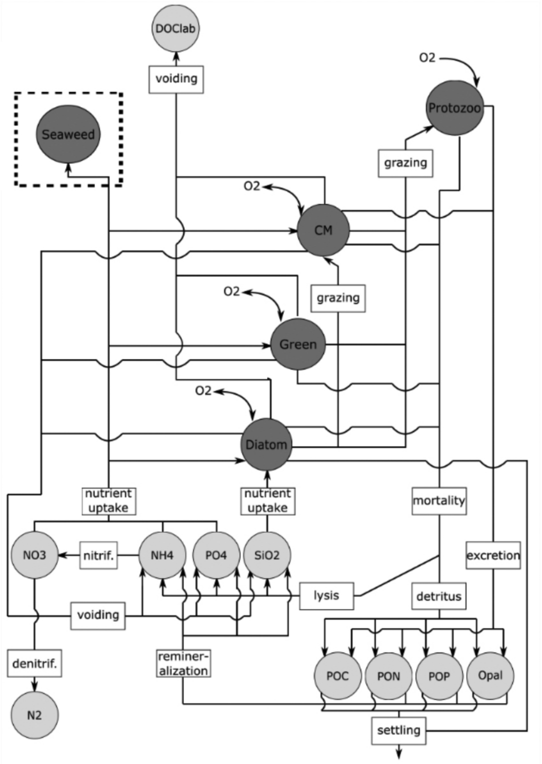

Figure 1 Conceptual ecological model. For the reference scenario, the dashed black box is deactivated. The light grey circles illustrate the abiotic components of the aquatic ecosystem model such as the dissolved inorganic nutrients and the particulate nutrients. The dark grey circles illustrate the biotic compartments of the aquatic ecosystem model such as seaweed, phytoplankton (diatom and green), protozooplankton (protozoo) and mixoplankton (CM).

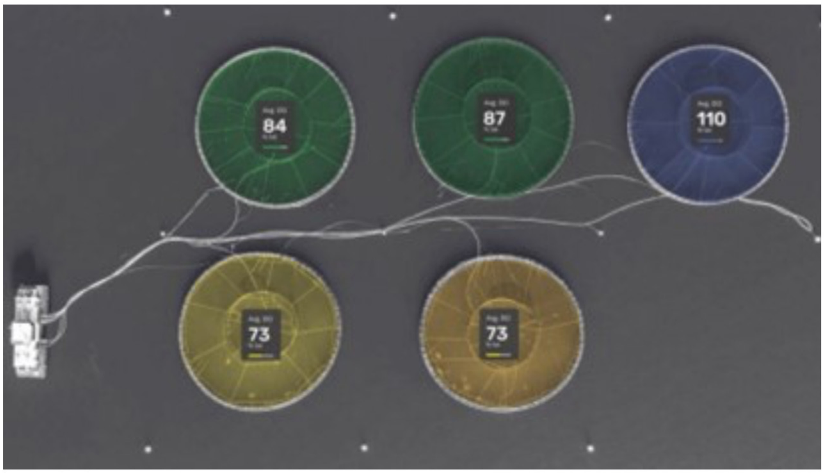
CREATING DEEPER VALUE FROM LIVE DATA: OXYGEN, TEMPERATURE AND ALGAL BLOOMS

Tyler Sclodnick, Jennie Korus, and Tim Stone

Innovasea
20 Angus Morton Drive
Bedford, Nova Scotia B4B 0L9
tsclodnick@innovasea.com

Tools to produce real-time data on aquaculture farms have become increasingly available and cost effective. These sensors enable farmers to make better decisions regarding feeding, aeration, and other operations. As more data becomes available, and systems to utilize those data streams become more sophisticated, farmers are able to create even more value from them.

Two examples will be explored detailing how access to live data creates value for farms. The first will examine in-pen oxygen sensors and how live data can be used to automate control of air diffusers to maintain a healthy environment for fish while minimizing compressor use and reducing fuel consumption. The second example will explore the potential for live data to be analyzed by machine learning algorithms to create forecasts of temperature extremes and algal blooms. These events are stressful for fish and can lead to reduced feed consumption, disease and parasite outbreaks, and mortality. Forecasts can be used to adjust feed schedules and use of air curtains or up-wellers.



EFFECTS OF DIETARY NUCLEOTIDES SUPPLEMENTATION ON PERFORMANCE, PROFITABILITY AND DISEASE RESISTANCE OF *Litopenaeus Vannamei* UNDER INTENSIVE OUTDOOR POND CONDITIONS

Sergi Segarra[1]*, Romi Novriadi[2], and Oriol Roigé[1]

1R&D Bioiberica S.A.U., Esplugues de Llobregat, Spain.
2Jakarta Technical University of Fisheries, Politeknik Ahli Usaha Perikanan

Email: ssegarra@bioiberica.com

Introduction:

The use of soybean meal (SBM) as replacement for fish meal (FM) in diets for Pacific white shrimp (PWS) has a negative impact on the health of PWS due to its high content in anti-nutritional factors. Dietary nucleotides (N) modulate the immune response and might be able to counteract this effect by enhancing PWS immunity and improving their performance and resistance to diseases. This study was aimed to evaluate the effects of dietary nucleotides supplementation in PWS, *Litopenaeus vannamei*, receiving diets in which fish meal (FM) has been partially replaced by vegetable protein sources.

Methods:

A total of 22,500 shrimp were classified into five study groups and received different diets for 110 days, according to the FM inclusion level and to whether N were added or not: 10FM (Control group; 10% FM), 6FM (6% FM), 10FMN (10% FM; 0.1% N), 8FMN (8% FM; 0.1% N) and 6FMN (6% FM; 0.1% N). Growth performance, body composition, total hemocyte count (THC), lysozyme activity and histopathology of the hepatopancreas were assessed. Organoleptic evaluation and profitability assessment were also performed. In addition, resistance of shrimp to a challenge with *Vibrio harveyi* was studied in shrimps over 5 days after having received diets for 30 days.

Results:

Reducing FM had a negative impact on growth performance (lower body weight and higher FCR) and led to hepatopancreas hemocyte infiltration and enlarged nucleus. Adding N allowed better performance (Table 1), a healthier histomorphological appearance of the hepatopancreas and significantly higher survival rate upon challenge with *Vibrio harveyi* (Figure 1). Moreover, supplementation with nucleotides did not negatively affect the organoleptic parameters and led to a higher profitability.

Conclusions:

Given the observed functional and nutritional benefits of 0.1% N, their nutritional supplementation could be considered to improve performance, profitability, and disease resistance in PSW cultured under intensive outdoor pond conditions.

IMPROVED PERFORMANCE, PROFITABILITY AND IMMUNE FUNCTION IN PACIFIC WHITE SHRIMP FOLLOWING DIETARY NUCLEOTIDE SUPPLEMENTATION UNDER CONTROLLED CONDITIONS IN VIETNAM

Sergi Segarra[1]*, Thanh Chau[2], Phuc Hoang[2] and Loc Tran[2]

R&D Bioiberica S.A.U., Esplugues de Llobregat, Spain
ShrimpVet Laboratory, Nong Lam University, Ho Chi Minh City, Vietnam.

Email: ssegarra@bioiberica.com

Introduction:

In Vietnam, vegetable protein sources are increasingly being used as replacement for fish meal (FM) in diets for Pacific white shrimp (PWS). This has a negative impact on the health of PWS due to their high content in anti-nutritional factors. Nucleotides (N) modulate the immune response and could counteract this effect by enhancing PWS immunity. This might improve PWS performance and, eventually, optimize profitability. The objective of this feeding trial was to evaluate the effects of dietary N supplementation in PWS, *Litopenaeus vannamei*, under a recirculating aquaculture system (RAS), and receiving diets in which FM has been partially replaced by vegetable protein sources.

Methods:

A total of 1,000 PWS were classified into five study groups and received different diets for 56 days, according to the FM inclusion level and to whether N were added or not: 260FM (Control group; 26% FM), 260FMN (26% FM; 0.1% N), 234FMN (23.4% FM; 0.1% N), 221FMN (22.1% FM; 0.1% N) and 208FMN (20.8% FM; 0.1% N). FM was replaced by vegetable protein sources. Total hemocyte count (THC), lysozyme activity, growth performance, and profitability (return on investment; ROI) were evaluated.

Results:

THC was significantly higher with 260FMN *vs* any other group, and THC in the 234FMN and 221FMN groups (with a 10% and 15% FM reduction, respectively) were also significantly improved compared to the control (regular 26% FM inclusion level) group (Figure 1). N supplementation led to improved performance, achieving better final mean body weight, final biomass, mean weight gain, average daily gain, and feed consumption *vs* 260FM. Several performance parameters were significantly better in the 260FMN group *vs* 234FMN, 221FMN and 208FMN, while this difference was not observed when the 260FM group was compared to the N-supplemented groups with FM reduction (Table 1). ROI improved in all N-supplemented groups (79.5% - 113.3% increase *vs* 260FM).

Conclusions:

Supplementation with 0.1% N for 56 days in PWS under RAS conditions in Vietnam leads to improved performance, immune function, and ROI, allowing FM replacement by vegetable protein sources without having a negative impact on performance.

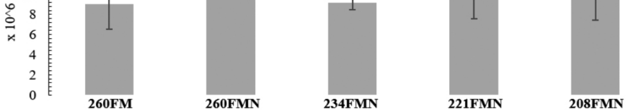

Figure 1. THC in shrimp from the different study groups after 56-day feeding trial. Different letters indicate significantly different values (P<0.05).

THE EFFECT OF WATER TEMPERATURE AND SUBSTRATE ON THE WARTY SEA CUCUMBER *Neostichopus grammatus* (CLARK) IN A FARMING ENVIRONMENT

Heleen E. Senekal*, P.J. Britz, C.L.W. Jones and M.J. Slater

Department of Ichthyology and Fisheries Science, Rhodes University. P.O Box 94, 6140 Makhanda (South Africa)
g20s9771@campus.ru.ac.za

Introduction

The warty sea cucumber, *N. grammatus* (Clark), is a potential aquaculture candidate for use in shore based integrated multi-trophic aquaculture (IMTA) with abalone *Haliotis midae* and several seaweed species at Wild Coast Abalone in the Eastern Cape of South Africa. Theoretically, *N. grammatus*, in co-culture with abalone, could reduce solid waste output from abalone tanks, improve effluent water quality, save farm resources in terms of labour and electricity costs, and produce another high value exportable crop (Qi *et al.,* 2013). The dried sea cucumber product, known as Beche-de-mer or Trepang, is considered a delicacy in several Asian countries and is highly sought after (Purcell *et al.,* 2012). In order to test the viability of co-culturing sea cucumbers with abalone, environmental needs and influencing factors have to be determined for inland breeding purposes.

Materials and Methods

Two environmental parameters (water temperature and substrate) were examined over a two-month period in a farming environment to determine the effects on growth and gonadal development. A Multivariate test of significance and a Repeated Measures Analysis ($p=<0.05$) was performed on the initial (WT 0) and final (WT 1) weights of the sea cucumbers to examine the effect of temperature and substrate on body growth over time. A Univariate test of significance ($p=<0.05$) was performed on the Gonadosomatic Index values to highlight the differences caused by the substrate and temperature on the maturation of the gonads.

Results

Preliminary results are shown in Figures one and two below.

The presence of sand in the sea cucumber tanks had a significant effect on the growth of the sea cucumbers over the two-month trial period. Animals kept at ambient temperature with sand as an additional substrate grew the most over the trial period. Sea cucumbers kept at ambient summer temperature (approx. 19ºC) grew slightly more than animals kept at colder (16ºC) temperatures. The animals that were not provided sand as additional substrate, at any temperature tested, lost body mass.

Captive sea cucumbers kept in tanks with sand had significantly higher GI values than animals kept without sand. Water temperature had a similar effect on gonadal development, although not as significantly.

Discussion

The addition of sand to sea cucumber tanks in farming environments is not common and not always practical. However, the results show that the addition of sand may be necessary when breeding *N. grammatus* sea cucumbers. Addition of sand to the tanks had a significant effect on growth and gonadal development. Animals kept in tanks without sand showed negative growth in terms of body mass and resulted in slower growing gonads. Sand is not only a substrate for the sea cucumbers to stick to, but is also a crucial part of their diet as detritivores (Purcell *et al.,* 2016).

Cold water temperature had a negative effect on body mass compared to ambient water temperature. Animals kept at a colder temperature showed less gonadal development compared to animals kept in ambient temperature water in the presence of sand. The sea cucumbers kept without sand had smaller gonads, with animals kept at ambient temperature showing the least gonadal growth. Animals kept at ambient temperature without sand had higher body masses than animals kept at colder temperatures, however the gonadal development does not produce the same results. This result is anomalous and may be inaccurate due to the short study period. Further research is necessary to conclusively prove what effect these variables may have on growth and gonadal development.

Conclusion

Ingestion of sand as a part of the normal sea cucumber diet is crucial for the inland production of *Neostichopus grammatus* sea cucumbers. Providing sand as a substrate in tanks is somewhat challenging and impractical in a farming environment, but adding sand to formulated sea cucumber feed might prove a possible solution. Furthermore, from a production and export view, *N. grammatus* grows significantly faster in ambient summer water temperatures than in colder water temperatures.

Introduction

European pikeperch (*Sander lucioperca*) is highly sensitive to environmental and handling stressors in aquaculture (Dalsgaard et al. 2013, Baekelandt et al. 2018)building, and operating intensive land-based RAS for different species. This study compiles and assesses published literature along with un-published hands-on experiences with rearing different species in RAS in the Nordic countries, including Atlantic salmon (Salmo salar, limiting the intensification of its farming in recirculating aquaculture. To increase the production of this species sustainably these cultivation modes are of interest (Steinberg et al. 2018) especially to the growing number of small-scale (10 – 20 tons) operations. Plant bioactive compounds can be effective feed ingredients that reduce stress and improve fish growth and immunity. Furthermore, plants also release exudates into the medium surrounding their roots. The influence of such plant metabolites on pikeperch or the performance of an aquaponic system has not been studied to date but could provide an option to improve its cultivation.

The European INTERREG Research project PERCIPONIE aims to develop perciculture in aquaponic systems through improvements on efficiency and fish welfare. One avenue of research is the identification of bioactive compounds emitted by plants cultivated in aquaponics and to test their effects on the growth and immunity of pikeperch. Based on an international consortium of partners, the project brings together stakeholders from research and industry to ensure scientific excellence and applicability of results.

Materials and Methods

The results of the final project stage will be presented. In a hydroponic cultivation experiment, metabolites of plant origin released into the system by different species of vegetables and aromatic plants were identified through untargeted metabolomics analysis. Supported by literature on their chemical properties (size, biological reactivity, solubility etc.) a number of polyphenols were identified. Ongoing experiments test the effect of these molecules on juvenile pikeperch i) in aquaponics systems comparing plant mono-cropping to plant diversity and unplanted control systems and ii) through direct addition of biomolecules to the cultivation water in recirculation systems. Their impact on zootechnical parameters such as growth, stress response and immunity will be evaluated. The results will provide insights into how agro-ecological approaches can be applied to further pikeperch aquaculture.

Introduction

In recent years, fish farms are gradually moving from sheltered coastal areas, estuaries and fjords towards offshore locations. Floating fish farm concepts for such exposed environments face a number of design challenges. For instance, extreme storm conditions can challenge the fish welfare as well as the structural integrity of the farm. At the same time, the farm should enable sufficient water refreshment, even in mild conditions, in order to maintain viable oxygen levels and to remove fish waste and bacteria.

A fish farm concept called the Viewpoint Spidercage was recently developed for offshore conditions. The design consists of a fish cage net that is suspended inside a semisubmersible ring that provides support and shelter against wave action (Fig. 1). The design was evaluated in terms of motions, (extreme) wave loads and sloshing behaviour through a combination of wave basin tests and numerical simulations (see van der Plas *et al.*, 2022). The present study follows up on these observations by addressing two additional objectives:

1. To quantify the wave shielding properties inside the fish farm for varying wave periods.
2. To quantify the water refreshment rates inside the fish farm in benign conditions.

Methodology

The shielding and refreshment properties are quantified through 3D computational fluid dynamics (CFD) simulations. The simulations are performed using ComFLOW, which solves the fluid continuity and momentum equations on a staggered grid with a Volume-of-Fluid approach and a piecewise linear interface construction of the free surface (e.g., Veldman et al., 2019). As such, ComFLOW allows the numerical reproduction of highly nonlinear wave interaction with fixed or moving floating structures.

The wave shielding properties were assessed by reproducing an earlier wave basin test in a so-called white noise wave condition, which consists of energy uniformly distributed at periods ranging from 5 to 25 s. Both the incident wave field and the floater's motions in waves were matched and synchronised with the experiments. In the simulations the wave field inside the fish farm was logged and used to calculate the response amplitude operator (RAO_η), which represents the ratio between the wave height inside the farm relative to the undisturbed wave height (i.e., the wave outside the farm). RAO_η is considered a good predictor for the wave transmission into the fish farm because the motion response and wave transmission are expected to be primarily linear for the vast majority of occurring (operational) sea states.

The refreshment properties were studied by keeping the fish farm at fixed position whilst generating different combinations of benign environmental conditions (current speeds up to $V_c = 0.2$ m/s, irregular waves up to significant wave height $H_s = 0.5$ m) at an upstream location. Refreshment rates were quantified by releasing a large number of passive tracer particles inside the fish farm and by Lagrangian-tracking their net removal from the farm due to water exchange at the open bottom of the structure (as illustrated in Fig. 2).

Results

The shielding properties are presented in Fig. 3. The left-hand panel shows the spatially averaged normalized wave height inside the fish farm. For long-period waves (wave period $T > 10.5$ s) RAO_η is close to or exceeds 1 m/m. In this regime the fish farm moves horizontally and vertically with the wave orbital motion and it provides limited shelter. Values over 1 m/m indicate a small amplification of the waves inside the fish farm due to reflections and sloshing. For increasingly shorter waves, which are more predominant in the North Sea, the RAO_η progressively decreases to about 0.4 m/m (i.e., a 60% wave height reduction) for wave periods of about 6 s.

(Continued on next page)

The right-hand panel in Fig. 3 presents the spatial contour for T = 6.0 s. This period corres-ponds to a standing wave (mode 3) of the wave field inside the moving fish farm. This explains the relatively high RAO_η at x = +/- 15 m from centre (location of anti-nodes) in combination with the low RAO_η at x = 0 m and +/- 30 m. Note that results are presented for regular waves; for more realistic irregular wave conditions less pronounced patterns are expected.

Fig. 4 presents flow field visualizations of the fluid refreshment simulations. The refreshment rates were analysed by studying the number of tracer particles present inside the fish farm over time. The particle counts followed an exponential decay which was used to establish half-life times of the water (i.e., the time required to refresh 50% of the water inside the farm). The following half-life times t_{50} were found:

- Case A. Current only (V_c = 0.1 m/s): t_{50} = 672 s
- Case B. Waves only (H_s = 0.5 m, T_p = 4 s): t_{50} = 1700 s
- Case C. Waves (H_s = 0.5 m, T_p = 4 s) + current (V_c = 0.1 m/s): t_{50} = 1367 s

It follows that the lowest water exchange rates occur for the simulations with only wave forcing (case B). The current contributes importantly to water exchange due to flow separation at the bottom of the ring, leading to a mixing region below the farm (Fig. 4A). In presence of waves, this separation zone becomes more diffuse (Fig. 4C) and the water exchange rates decrease, hence explaining the longer half-life times for case C relative to case A.

It is noted that in field conditions, the incident current will naturally be more turbulent. In addition, motions of the moored fish farm would contribute to fluid mixing and to relative currents between the structure and the water column. As these aspects were not considered, the refreshment rates in the present simulations are expected to be conservative.

Conclusions

CFD simulations were performed to quantify the wave height reduction inside a fish farm and the water refreshment rates due to flow exchange at the open bottom. The results illustrate the potential of high-fidelity numerical methods for design support of floating offshore aquaculture structures.

GENOTYPE BY ENVIRONMENT INTERACTION FOR PRODUCTIVITY TRAITS OF A HYBRID TILAPIA IN FRESH AND BRACKISH WATER PONDS

Priadi Setyawan[1,2*], Muhammad H. Fariduddin Aththar[1,3], Imron Imron[2], Bambang Gunadi[2], Joni Haryadi[2], John W.M. Bastiaansen[1], Mark Camara[1] and Hans Komen[1]

Introduction

Shrimp production is the most important aquaculture industry in Indonesia with the highest contribution to the national income (MMAF, 2018). However, recurrent farming failures and increasing production losses caused by disease outbreaks have hampered the growth of shrimp production, and driven Indonesian shrimp farmers to add tilapia as a second species. The Research Institute for Fish Breeding (RIFB) is developing a fast-growing salinity tolerant tilapia strain. A fresh water nucleus-based program is the simplest strategy to implement but requires knowledge on the extent of genotype by environment (GxE) interaction between fresh and brackish water environments to ensure that genetic improvement in the nucleus transfers to production systems in brackish water. The objectives of this study were: 1) to investigate the presence of GxE between fresh and brackish water ponds, and 2) to estimate genetic parameters for fresh and brackish water environments.

Materials and methods

We produced 91 fish families, and randomly choose 2 groups of 20 fingerlings that we PIT tagged and communally grown in brackish and freshwater ponds (120-147 days). We recorded stocking weight(SW), harvest weight (HW) and standard length (L) at harvest and calculated daily growth coefficient (DGC,(Trọng et al., 2013)) and growth rate in length (GR(L)) from these data. We estimated descriptive statistics using R, and estimated genetic parameters by fitting a series of bivariate animal models in ASReml (Gilmour et al., 2015).

Results

All observed trait of HW, L, DGC and GR (L) at harvest were higher in brackish water and significantly different ($P<0.05$) compared to freshwater (Table 1). The estimates of additive genetic variance (), heritability (h^2) and GCV within freshwater and brackish water for HW, L, DGC and GR (L) are shown in Table 2. Genetic variances and heritability estimates for all traits in freshwater were lower compared to the brackish water, except L. The h^2 estimates for HW, L, DGC, and GR (L) were moderate (0.35 – 0.43). In the freshwater pond, h^2 estimates of HW and L were higher compared to the brackish water while for DGC and GR (L), h^2 estimates were higher in the brackish water compared to the freshwater. The genetic correlation () for all observed trait between freshwater and brackish water were moderate, ranging from 0.65 – 0.74.

Discussion

RIFB has been developing this strain based on selection for own performance (mass selection) for growth and survival in brackish water ponds for 4 generations. However, this breeding scheme has several drawbacks including high mortality of selection candidates during the grow out period in unpredictable salinity condition; security issues; and mortality during transport and adaptation of candidates to the nucleus site in freshwater. Evaluating selection candidates in freshwater ponds and select on sib performance in brackish water could mitigate some of these complications and challenges. However, if G×E interactions are strong, this approach could result in reduced genetic gain due to inaccurate selection of breeding candidates in freshwater (Mulder & Bijma, 2005). In this study, our estimates genetic correlations between fresh and brackish water for HW, SL, DGC and GR(L) were 0.65-0.74 which suggests substantial re-ranking of genotypes between the two environments, suggesting that it is essential to incorporate information from full-sibs in brackish water into the genetic evaluation. Our results also show that HW, L, DGC and GR (L) in brackish water are greater than in freshwater, indicating that the Sukamandi strain has a high salinity tolerance. This is most likely because this strain is a unique composite of Nile tilapia with introgressed salinity tolerance genes from blue tilapia (Yu et al., 2021). The moderate heritabilities for all production-related traits (0.35-0.50) indicate the presence of sufficient additive genetic variance for future selection.

Conclusions

There is GxE interaction between brackish water and freshwater and a breeding program with the brood stock selection process in freshwater should incorporate the sib information of growth performance in brackish water.

Introduction

The obtention of high quality eggs, i.e. eggs that can be successfully fertilized and subsequently develop into a normal embryo, is required for closed-cycle aquaculture (Bobe and Labbé, 2010). While meeting dietary requirements is targeted, egg quality can be influenced by application of assisted reproduction techniques, i.e. the hormonal treatments that are used to stimulate vitellogenesis and oocyte maturation, and/or to induce ovulation (Bobe and Labbé, 2010). These are applied in some fish species that otherwise would not reproduce in captivity, such as European eels (*Anguilla anguilla*), for which vitellogenesis is commonly induced in captivity by chronic administration of salmon (SPE) or carp (CPE) pituitary extracts (Tomkiewicz et al., 2019). In the present contribution, we evaluated different egg quality indicators in batches with high and low larval survival, and the impact of two PE treatment schemes on egg quality parameters in both quality groups using farmed-raised broodstock on an enhanced diet.

Materials and methods

One group of farm-raised females (n = 13) received a weekly intermuscular injection of SPE in a constant dose of 20 mg/kg initial body weight (ibw), during ~15 weeks. A second group (n = 13) received weekly injections of CPE at a biweekly stepwise increasing dose starting at 5 mg/kg ibw and reaching 20 mg/kg ibw from week 10. Samples of unfertilized eggs were collected after stripping for biochemical determinations. Following a standardized gamete production and fertilization protocol, embryos were incubated at optimal temperature and salinity (Tomkiewicz et al., 2019). A sample of 4 hours post fertilization (hpf) embryos was photographed to assess the percentage of irregular cleavages. Samples of unfertilized eggs and embryos at 4 and 24 hpf were taken for molecular analyses. The expression levels of 5 target genes related to cell adhesion (*epcam*, *dcbld1*), stability and structural support (*plec*), and cell division (*cenpk*, *cenpf*) is currently being analysed. Fertilization and hatch success were estimated. Newly hatched larvae were reared in tanks connected to a RAS system. Batches with larvae reaching the first-feeding stage were considered to contain eggs of good quality. Following this criteria, they were categorized in two groups: high quality (n = 12) and low quality (n = 14).

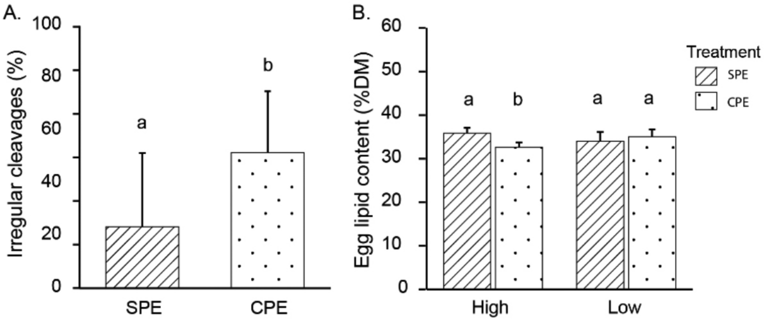

Figure1. Percentage of irregular cleavages of 4 hpf embryos (A) and unfertilized egg lipid content (B) from European eel females subjected to two hormonal treatments.

(Continued on next page)

Results

Fertilization success was similar for all quality groups and hormonal treatments. Hatch success was also not influenced by the hormonal treatment, but it was 2.4 times higher for the high quality batches. Egg diameter was not influenced by the hormonal treatment and was similar for both egg quality groups. The percentage of irregular cleavages at 4 hpf, on the other hand, was 2 times higher for the CPE than for the SPE treatment, with similar values for both quality groups (Fig. 1A). Total protein content in unfertilized eggs was similar for both hormonal treatments and for both quality groups. Lipid content was significantly influenced by hormonal treatment only in the high quality group, being 1.1 times higher for the batches from SPE treated females (Fig. 1B). The sum of SFA, individual n-3 and n-6 PUFA levels, as well as the sum of PUFA, and the EPA/ARA and DHA/EPA ratios were not influenced by treatment or quality group. However, the levels of C15:0, C16:0, 18:1n9 and sum of MUFA were higher for the CPE treatment than the SPE treatment within the high quality group but similar within the low quality group.

Discussion

Embryos from SPE treated females showed a lower frequency of irregular cleavages, in all quality groups. These results are in agreement with previous studies using constant SPE and CPE doses (Kottmann et al., 2020). Egg quality can be affected by the amount of lipids accumulated in the egg during its formation (Bobe and Labbé, 2010). High quality unfertilized eggs from SPE females contained a higher amount of total lipids, however this difference was not observed in the low quality group. Interestingly, fertilized embryos from females treated with a constant dose of CPE had a higher amount of lipids than SPE ones (Benini et al., 2022). This suggests that not only the hormone source but also the administration scheme can affect the amount of nutrients that are deposited in the oocytes during vitellogenesis. The levels of some saturated and monounsaturated fatty acids differed between hormonal treatments within the high egg quality group. Previous studies found no influence of SPE vs CPE on SFA and MUFA in European eel embryos and larvae, while MUFA levels were shown to decrease during embryonic and larval development (Benini et al., 2022). In this regard, the initial differences found in this contribution between treatments might not persist in later stages.

GLOBAL WARMING CHALLENGES FOR AQUACULTURE: THE CASE OF INDIAN MAJOR CARP ROHU, *Labeo rohita*

Md Shahjahan

Laboratory of Fish Ecophysiology, Department of Fisheries Management, Bangladesh Agricultural University
Mymensingh 2202, Bangladesh
Email: mdshahjahan@bau.edu.bd

Introduction

Among the environmental factors, temperature plays an important role in the molecular, biochemical and physiological properties of animals (Pankhurst and King 2010; Strussmann et al. 2010). The survival, distribution, metabolism and reproduction of fish are all contingent on water temperature (Shahjahan et al. 2013; Shahjahan et al. 2017; Rahman et al. 2019). Increase of water temperature as a consequence of global warming is anticipated to affect the physiological activities of fish, especially in tropical regions. To understand the effect of high temperature on embryogenesis and growth, the commercially important rohu carp (*Labeo rohita*) was selected for the present study.

Materials and Methods

In the first trial, embryos and larvae were reared at four different temperatures (30, 32, 34 and 36°C), and indices of their hatching, development, and mortality were observed throughout early development. In the second trial, growth performance of fingerlings was evaluated after rearing in the three temperature conditions (30, 33 and 36°C) for 60 days.

Results

Embryos exposed to 30 and 32°C showed normal development with highest rates of hatching success. Embryos at 34°C displayed evidence of damaged zygotes, cellular deformities, damaged yolk sac coupled with shortest incubation time and the lowest rates of hatching success. No hatching was observed at 36°C. Larvae of rohu exposed to 34 and 36°C showed developmental deformities (fusion in the eye, axial curvature, yolk sac ulceration, blood coagulation, tail shortening and ulceration) and minimal survival. The growth parameters - final weight gain, percent weight gain and specific growth rate were the highest at 33°C and the lowest at 36°C. Lowest FCR value was found at 33°C. The effects of high temperature on hemato-biochemical parameters and erythrocytes cellular and nuclear structures in rohu were studied. Exposure to high temperature decreased Hb and RBCs and increased the WBC and blood glucose levels of the fish. Frequencies of ECA and ENA were found to be increased at high temperature. High temperature significantly increased the number of neutrophils whilst decreased the number of lymphocytes.

Conclusion

Overall, this study confirmed that exposure to high temperature is stressful to Indian major carp rohu.

Introduction

One third of the global salmon production is currently contributing by Norway. To improve the focus on the environmental performance of fish farms in Norwegian aquaculture, new businesses and innovative technologies are frequently introduced and tested across the whole country [1, 2]. One of the innovative production systems is Semi Closed-Containment Systems (S-CCS), where the fish are separated from the outside natural environment with a physical barrier. With a proper enhanced control on tank hydrodynamics and self-cleaning, production cycle, disease transmission and environmental impact which makes S-CCS a favorable replacement to open-cage production systems [1, 3]. The overall hydrodynamic performance of the system is influenced by inflow characteristics, i.e. turbulence produced by inlet orientations but experimentally it is not feasible to study velocity, uniformity, vorticity and swirl number, respectively [5,6]. Therefore, computational fluid dynamics modeling (CFD) is considered as a most appropriate tool to investigate the hydrodynamics of such a large system.

The aim of current CFD investigation was to monitor the effect of inlet column nozzles orientation angle and water dividers placements on the hydrodynamics of S-CCS with rigid walls and establish the optimal inlet column nozzles orientation set-up for use during Atlantic salmon production in this system.

Materials and Methods

Circular shaped floating tank with rigid walls and a total volume of 3500 m^3 received water from two inlet column with nozzles (possible to operate 6 inlets columns simultaneously). The water is discharged through central outlets located at a depth from top **(between -1.5m to -5.5m)** (sieved region of 4m around the central outlet pipe). In order to design and find the most optimal inlet nozzles and water divider (V-shaped closed structure placed behind each column to split water stream) orientation angle for optimal water distribution, a set-up of four cases were developed in CFD (Table 1). The hydrodynamics of the system was evaluated using different flow field indicators, such as flow velocity, distribution of vortices, turbulence in the system and vorticity.

Naiver Stokes equation for incompressible fluids was solved with SIMPLE algorithm, which is Semi Implicit Method for Pressure Linked Equations._Where initially pressure and velocity values are estimated by algorithm and later pressure-correction equation $\nabla^2 p\nabla=1/\Delta t\ (\nabla\cdot V)$, is solved to obtain a corrected value of pressure and velocity field and at the solution convergence is checked. A k-omega SST turbulence model with first order accuracy in space and time is used to solve Turbulence Kinetic Energy (k) and Specific Dissipation Rate (ω) [4]. In present study, one assumption in selection of boundary conditions is that no external force factors are included in the system (sea waves effect).

Results

In all 4 CFD simulations cases are compared at different depths (-1, -3, -6, -9), respectively. Velocity and mixing pattern show hydrodynamic difference in flow field across the tank. Out of 4 analyzed cases, the best hydrodynamics in the system (Figure 1a and 1b) was achieved by case 1 set-up (Table I), while the large variation in hydrodynamics was observed between cases. Observed differences in velocities between CFD models and empirical measurements were further investigated.

Discussion and conclusion

To investigate the hydrodynamics of large systems, we compared different design and Computational models, respectively. The understanding of two inlets flow patterns plus extra water dividers installments behind all 6 pipe columns could be performed more efficiently and relatively cheaper with the help of CFD modeling and simulations. In order to achieve a good qualitive and more reliable results, it is very important to develop a Solid CFD bench model. In this study, initially we developed a reliable CFD bench model and then examined the complete flow patterns for 4 cases with different inlet nozzles and water dividers orientation angles (Table I). Large differences between the flow patterns are observed among various cases, based on their inlet orientation angle change. This factor has large impact on mixing and velocity factor across the system, which in turn effect water quality for optimal fish growth/welfare, health performance and particle removal. This study shows that further optimization of the system set-up is achievable with the help of CFD modeling.

DISSOLVED NUTRIENT EXCRETION IN NILE TILAPIA (*Oreochromis niloticus*) AND AFRICAN CATFISH (*Clarias gariepinus*): INVESTIGATING PROTEIN SOURCES IN FEEDS FOR CIRCULAR MULTITROPHIC FOOD PRODUCTION SYSTEMS

Introduction

With the goal of transcending recirculating aquaculture systems (RAS) and aquaponics, the CUBES Circle project [1] investigates the possibilities of combining the production of fish, plants and insect larvae to create a fully integrated land-based multitrophic food production system with the objective of increasingly closing internal nutrient cycles and thereby minimizing waste. This means to use internally produced solid and dissolved nutrients as effectively as possible by continuously recycling them through the three trophic levels, i.e. dissolved nutrients from fish production support plant growth, solid wastes from fish and plant production build the base for insect larvae nutrition and insect larvae as well as slaughter waste from fish production reenter the production cycle as ingredients of the fish diet. Fish diets for such a system need to not only ensure optimal fish performance and health but also have to be optimized for the provision of nutrients downstream to plants and insect larvae. Therefore, the first basic question posed was how different protein sources of the circular bioeconomy as alternative to fish meal (black soldier fly larvae meal, poultry by-product meal, poultry blood meal) affect growth as well as dissolved nutrient excretion (N, P, K) of the CUBES Circle candidate species Nile tilapia (*Oreochromis niloticus*) [2] and African catfish (*Clarias gariepinus*) reared in RAS (i). Based on these results, the following question was then how specific diets could be formulated for different plausible production scenarios to most effectively close internal nutrient cycles. Accordingly, internally available protein sources (insect larvae meal, slaughter by-product meal) were combined with additionally required external protein sources to formulate specific experimental diets that were compared to an industrial standard diet to judge their suitability to ensure adequate fish production while improving dissolved nutrient profiles for plant production (ii).

Material & methods

i) Four isolipidic and isonitrogenous (40 % crude protein, 12 % crude fat) single protein source diets were formulated with fish meal (FM), black soldier fly larvae meal (BSFM), poultry by-product meal (PM) and poultry blood meal (PBM) as the main protein ingredient, respectively, and fed to Nile tilapia and African catfish (initial weight 10 g) reared in RAS in two separate 7-week trials (n=4).

ii) Three isolipidic and isonitrogenous experimental diets were formulated on the basis of an industrial standard feed for African catfish (46 % crude protein, 19 % crude fat). All of the experimental diets included 13.3 % catfish by-product meal (CM) and 10 % PBM as protein sources supplemented by 1) PM, 2) BSFM and c) a 50:50 combination of PM and BSFM. Experimental diets and the industrial diet were fed to African catfish reared in RAS in a 10-week trial (n=4).

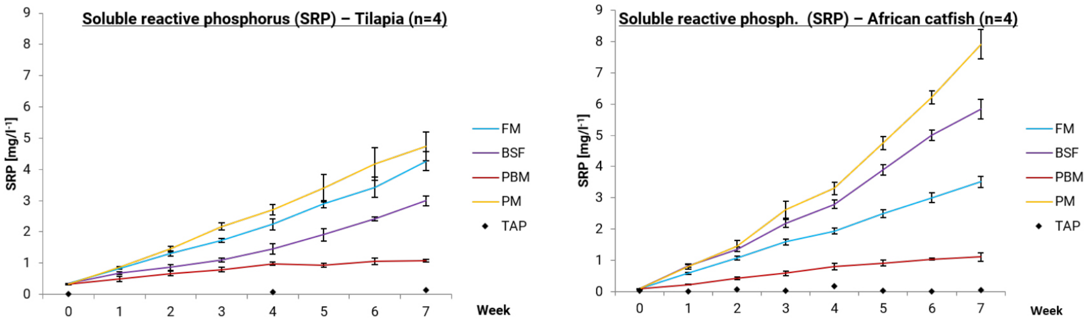

Figure 1. Accumulation of SRP in the RAS water over the period of the respective trials involving Nile tilapia (left) and African catfish (right).

(Continued on next page)

For all of the experiments above, dissolved nutrients in the process water were analyzed weekly (continuous flow analysis (CFA), inductively coupled plasma optical emission spectrometry (ICP-OES)) and growth performance was recorded at the end of the trial.

Results

Results of the first trials (i) showed that especially PM as the main protein source in diets for Nile tilapia and African catfish can match (in case of the tilapia) or at least come close to (in case of the catfish) a diet entirely based on fish meal in terms of growth performance and feed conversion. However, fish fed the BSF and PBM diet performed significantly worse regarding these measures. With respect to soluble reactive phosphorus (SRP) in the RAS process water, the PM feed resulted in the highest accumulation over the period of the trials for both fish species, with the differences being significant for African catfish. The accumulation of K was substantially and significantly higher for the BSF diet for both species.

Results for the follow-up trial (ii) are currently being generated and will be added to the oral presentation.

Discussion

The results support the general consensus that PM is a suitable protein source in Nile tilapia and African catfish nutrition and diets with PM can, even at high inclusion levels as the sole main protein source, rival the growth and feed conversion performance of an entirely fish meal-based diet. In addition, the PM diet produced higher dissolved SRP accumulation in the process water for both species which makes it an appropriate candidate for aquaponic diets which aim to increase phosphorus availability to plants. The BSFM, even though not enabling the same growth performance as PM and FM for both species, appears to be a rich source of dissolved K, also often insufficiently available in aquaponic waters. If combined with complementary protein sources to improve fish performance and still incorporated at sufficiently high levels, BSF meal could present an important ingredient in diets for aquaponics and multitrophic systems. As alluded to, the strategic supplementation of important protein sources which are internally generated in circular multitrophic food production systems (CM, BSFM) with externally obtained protein sources (PM, PBM) will subsequently yield further valuable insights into the opportunities of beneficially manipulating dissolved nutrient profiles.

Introduction

Smoltification is a complex developmental process that leads to changes in the fish physiology, morphology and behaviour including remodelling of the gill from an ion-absorbing epithelium to an ion-secreting epithelium [1-3]. Optimal smoltification is, therefore, crucial for normal development, growth, and health of farmed Atlantic salmon in seawater phase [4]. The aim of this study was to explore whether miRNAs are involved in regulation of gene expression during this important developmental transition by characterizing miRNAs differentially expressed during smoltification and the following seawater adaptation (SWA) in gill of Atlantic salmon.

Material and methods

Total RNA from Atlantic salmon gill collected before smoltification (T1), halfway through smoltification (T2), three quarters into smoltification (T3), one day prior to seawater transfer (SWT) (T4), one week after SWT (T5) and one month after SWT (T6) were used to study expression changes of miRNAs and mRNAs. Small-RNA sequencing and microarray analysis were applied to identify miRNAs and mRNAs that showed significant differences in expression when groups from the different time points were compared. In silico prediction of miRNA-target-genes were carried out applying the MicroSalmon GitHub repository (http://github.com/AndreassenLab/MicroSalmon/) [5] with differentially expressed miRNAs (DE-miRNAs) and differentially expressed mRNAs (DE-mRNAs) as input. Finally, gene ontology and pathway enrichment analysis of predicted DE-miRNA targets were conducted using PANTHER Overrepresentation Test (http://www.pantherdb.org/) to reveal significantly enriched biological processes and gene pathways associated with smoltification and SWA.

Results

In total, 32 mature miRNAs were differentially expressed, and 18 of these mature miRNAs were characterized as the biologically important guide miRNAs (gDE-miRNAs) by examining the relative abundance of the 5p and 3p miRNAs originating from same precursors [6]. Hierarchical clustering analysis of gDE-miRNAs showed two major clusters, one with a decreasing and one with an increasing expression during smoltification and seawater adaptation. The gDE-miRNAs were predicted to target 747 of the genes that showed significant differences in their expression in the microarray analysis. Enrichment analysis of these predicted target genes revealed that they were enriched in several biological processes including processes associated with immune system (e.g., regulation of macrophage derived foam cell differentiation, regulation of dendritic cell antigen processing and presentation, viral entry into host cell and T cell activation), regulation of cell growth and lipid metabolic process (e.g., tissue regeneration and steroid biosynthetic process), reactive oxygen species metabolic process and response to stress. Additional pathway enrichment also showed that pathways associated with immune system (e.g., cytokine signaling in Immune system, neutrophil degranulation and adaptive immune system), extracellular matrix organization, signal transduction and metabolism of lipids, vitamins and cofactors as enriched.

(Continued on next page)

Discussion and conclusion

The finding that some enriched biological processes and pathways were associated with immune system, were as expected as gills are the main mucosal surfaces and immune barriers where several immune related cells including the coordinated expression of cytokines are presented [7]. The gill mucus cell population has also been reported to increase in number in response to increased salinity [8]. Regulation of cell growth and steroid synthesis may play a role in smoltification-associated osmoregulatory changes as growth hormone and cortisol have been suggested to stimulate salinity tolerance and NKA activity by promoting the formation of the seawater mitochondria-rich cells or chloride cells [9,10]. Gene ontology group response to stress was also enriched, which is in agreement with previous study that reported that stress response genes were upregulated in the gill of Atlantic salmon in response to smoltification and SWA [11]. The findings that all transcripts enriched in these biological processes were predicted targets of the gDE-miRNAs, indicate that miRNAs are involved in post-transcriptional regulation of gene expression changes that are crucial for remodelling of the gill during this developmental transition. Furthermore, this study points out pairs of gDE-miRNAs and their predicted targets that may be validated and further studied by functional assays to explore their particular role in the smoltification process.

Introduction

The total food fish consumption has increased globally over the past decades. Over the same period, aquaculture has become the main aquatic food producer as capture fishery production is decreasing due to overfishing and water pollution. Aquaculture provides food for a growing population and is a major source of essential nutrients. Despite these advantages, traditional intensive outdoor aquaculture systems can have serious negative environmental effects as for example eutrophication, the spread of disease or the release of chemicals. Therefore, new aquaculture production technologies are needed. Land-based recirculating aquaculture (RAS) fish and seafood production is a possible alternative. Potential advantages of RAS fish production are, for example, controlled breeding conditions, optimized water quality and disease control or lower environmental impact. RAS as new technology has several limitations and disadvantages which require further research and development. These challenges include high capital and production costs, high energy consumption, the necessity for continuous performance monitoring, difficulties in treating diseases, or a need for a high level of technological and biological know-how due to the complexity of the system and its interactions. One major challenge in RAS production is the accumulation of off-flavour (taste and odour causing compounds) in fish filets. The main objective of the study was to reduce geosmin concentrations in RAS rearing water for Atlantic salmon *(Salmo salar)* production and, by this, also reduce the accumulation of geosmin into the fish fillet.

Methods

A commercial scale freshwater RAS for Atlantic salmon production was monitored over several months in high resolution with GC-MS for geosmin in water before and after the installation of a protein skimmer (with ozone) in combination with a UVC system. Water parameters of the RAS and flow through purge system were monitored over the whole measurement period.

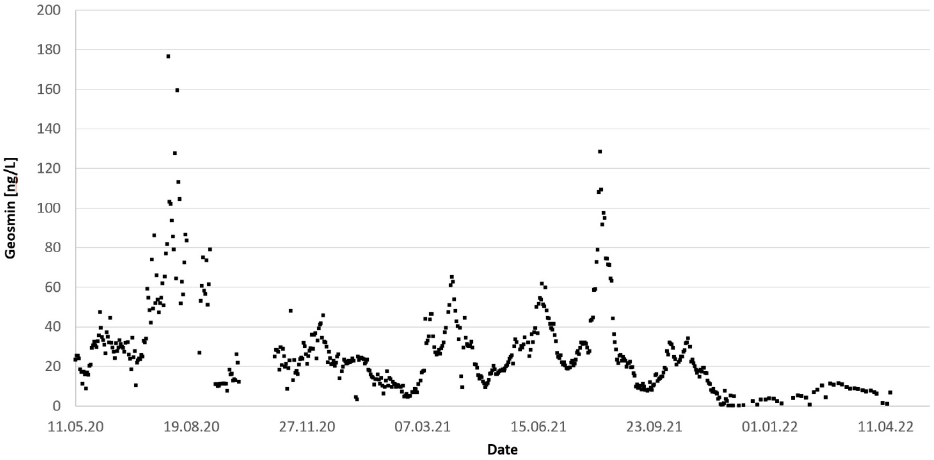

Figure 1: Geosmin concentration in Atlantic salmon freshwater RAS grow out process water over a measurement series of 23 months.

(Continued on next page)

Results

Before the use of ozone treatment, together with protein skimming and UVC, geosmin concentrations fluctuated in a daily resolution between around 5 ng/l and 180 ng/l. A by-monthly fluctuation is visible, which correlates with biomass transfers within the farm. After the start-up of the additional treatment loop and a last peak of geosmin, the average geosmin concentration dropped but still fluctuated and stabilized at a low level between <1 ng/l and 11 ng/l (see Figure 1). These low levels of geosmin in process water results in a low depot of geosmin for fish to be purged, reducing the needed purge time, weight loss and water consumption.

Conclusion

Technical approaches to control the growth of geosmin-producing microorganisms and improve the removal of geosmin can reduce geosmin concentration in grow-out freshwater RAS with a high effect.

RED KING CRAB (*Paralithodes camtchaticus*) IN AQUACULTURE: OPPORTUNITY AND CHALLENGES

S.I. Siikavuopio., F. Lian and G. Lorentzen

Nofima AS, Norwegian Institute of Food, Fisheries and Aquaculture Research
Muninbakken 9-13, Breivika, P.O. Box 6122, NO-9291, Tromsø, Norway
E-mail: sten.siikavuopio@nofima.no

Introduction

Red king crab (RKC, *Paralithodes camtschaticus*) has become important for the shellfish industries located in the northern parts of Norway. In fact, in 2021, 2261 metric tons of RKC was exported from Norway, amounting to 999 million (NOK), respectively. About 60% of the exported volume was traded live whereas the remaining share was exported as processed. Catches of king crabs have declined globally due to overfishing, which led to an increased focus on RCK farming in Norway. When you start with new species in aquaculture, it is important to determine the optimum environmental conditions such as temperature, water requirement and stocking density. Furthermore, it is important to develop new feed and technological solutions for live holding of RCKs for economic and animal welfare reasons.

The present study was undertaken to study how different enviromental conditions effect the growth and survival of the animal.

Material and methods

After capture in northern Norway, the RKC was transported to the Research Station in Tromsø, landed, and kept in tanks. To screen potential effect of different environmental conditions, parameters like water requirement, temperature, stocking density, feed, duration, and the time of the year, varied. During the period for aquaculture, the RKC was sampled and evaluated. The evaluation included growth, survival, water quality, metabolism study and evaluation of behavior of the animal.

Conclusion

In general, RCK have low water requirements, low feed intake, tolerate high individual densities and shows low negative social behavior compared to lobsters that must be kept individually. In case of farming RKC, we have demonstrated that increasing temperature and stocking densities increases the risk of cannibalism, mortality, and injuries. Furthermore, it is important to develop new technological solutions for live holding of RCKs on and improve the dry feed (texture and nutrition) for improving FCR and the animal welfare reasons.

MICROPLASTICS CONTAMINATION IN A VARIETY OF CANNED SEAFOOD WITH APPLICATION OF AN OPTIMIZED METHODOLOGY

The global production of plastics has continually increased from 1.5 million tons in 1950 to approximately 370 million tons in 2020, and a worldwide interest is growing on microplastics (MPs: plastic particles smaller than 5 mm) occurrence and impacts in marine environments. Seafood has a crucial importance for human consumers because it is an important source of high-quality proteins (including all the essential amino-acids), unsaturated fatty-acids (including Omega-3), fat-soluble vitamins and minerals, with numerous nutritional and health benefits. Thus, understanding the potential contamination of seafood with MPs is critical for food security and human health. Seafood is also highly perishable, and several preservation methods (like salting, freezing, or canning) are traditionally used to ensure the quality of the products. Canned seafood corresponds to approximately 10% of the total 178 million tons of the world fishery production, with the existence of a wide variety of canned organisms (*e.g.,* fish, molluscs, crustaceans), immersed in different edible liquids (*e.g.*, sunflower oil, olive oil, tomato sauce), each one with specific ingredients and nutritional facts (*e.g.*, fat, carbohydrates, proteins). Since consumers eat these products without any additional cleaning process, from a health perspective it is crucial to have a better understanding on possible MPs contamination both in the food tissues, as well as in the respective immersive liquids. The occurrence of MPs has been widely studied for several seafood species but, regarding canned seafood, there is still limited information. Thus, in the present work, a variety of canned organisms (n= 60) immersed in different types of oils and sauces were studied: tuna in olive oil, sardine in sunflower oil, sardine in tomato sauce, chub mackerel in sunflower oil, octopus in tomato sauce, and mussels in escabeche sauce. Samples were digested with 30% H_2O_2, followed by vacuum-filtration, and subsequent observation under a stereomicroscope. Recovered MPs were photographed and stored for posterior polymers analysis in FTIR (Fourier-transform infrared spectroscopy). The results showed that 45% of the samples had at least one microplastic, with all the studied organisms presenting MPs contamination. A total of 40 MPs items were found (Fibers= 30, Fragments= 7, Film= 3), with an average of 0.04 MPs/g of seafood tissue (n= 26), and an average of 0.01 MPs/g of seafood liquid (n= 14). The most contaminated seafood was the canned tuna, with an average of 0.11 ± 0.10 MPs/g, while canned sardine in sunflower oil was the less contaminated, with an average of 0.02 ± 0.04 MPs/g. FTIR analysis is still undergoing, and polymer cancerization of MPs observed will be used to try to identify contamination sources. Our results demonstrate that canned seafood is contaminated with MPs and constitutes a potential contamination pathway for humans, highlighting the importance of quantifying and regulating MPs in canned seafood, to increase food safety and human health.

Introduction

Microorganisms are omnipresent and crucial players in all aquatic systems. They can have a large impact especially in recirculating aquaculture systems (RAS), where water is reused continuously. In these systems, tight control on water quality is essential for successful and safe fish production. Microorganisms affect fish health in a multitude of ways and control of a RAS is inextricably linked to microbial concentrations, be it in the fish tanks where pathogen growth must be avoided, or in the biofilter, where microbial populations must be maintained abundantly for nitrification.

Online sensors are standard in the industry for multiple physicochemical parameters, however microbial concentrations are difficult to get by for fish farmers. Tracking of microbial dynamics requires sampling and analysis at very short intervals and ideally in real-time allowing for immediate interpretation/reaction. For decades this was impossible with conventional microbial cultivation-based methods but also with advanced molecular methods, which are still too labour-intensive, time-consuming, and costly for such applications.

One promising approach is the use of flow cytometry, which allows fast, accurate and reproducible quantification and differentiation of total and intact cells. This detection method has specific advantages including: rapidness, sensitivity, reproducibility, accuracy in quantification, and differentiation of total and intact cells.

Material and methods

In a first step, grab samples across the RAS were analysed by our flow cytometry protocol for total and intact bacteria. A perch and a carp cultivation were compared in terms of microbial concentration. In a second step, we used a fully automated online flow cytometry system that overcomes the tedious and restricting practice of grab-sampling and subsequent cultivation on agar plates Besmer et al. (2014). This system was used to monitor a perch RAS cultivation system. In short, water samples were drawn directly from several points in the system, mixed with a fluorescent stain, incubated, and then measured by flow cytometry. Rinsing and extended cleaning were performed regularly and periodically respectively. The resulting large sets of flow cytometry data were batch processed with custom software.

Results

Flow cytometry could successfully be used for the measurements of the grab samples. Background could be separated well, and the measurements were technically highly reproducible. The measurements showed significant concentrations of total and intact bacteria across each of the RAS, on the order of 10^5 to 10^6 cells/ml. Strikingly, while clear differences were detected between the carp and the perch cultivation systems, the concentrations across different locations within each of these systems were very similar.

The RAS is being monitored for an extended period, initiating one week prior to the fish entering the tanks, and continuing during the fish cultivation period. Changes in concentration of total and intact bacteria are being followed and compared with important process parameters like feeding and cleaning procedures.

Discussion and conclusion

Our results show the potential of advanced monitoring of microbial dynamics, which is critical for a better understanding of underlying causes of fluctuations as well as the ecological and operational consequences thereof.

We expect that these findings will massively enhance process monitoring, water treatment design and improvement (e.g., disinfection in RAS). In addition, we expect a potential for optimisation of feed and other production processes, including conceptual approaches to smarter sampling schemes, but also new applied and fundamental research directions.

FISH LOGISTICS; THE KEY TO SUCCESFULL CLOSED CYCLE TUNA AQUACULTURE

Paul-Daniel Sindilariu*, Jan Giebichenstein[1]

Introduction

Next Tuna GmbH is planning, the first of its kind, production facility for Atlantic Bluefin Tuna (*Thunnus thynnus*) (ABT) at the shore of the Mediterranean Sea. (see as well https://www.nexttuna.com/)

Tuna in general and specially ABT is very sensitive to handling. In the early live stages, the small fish are nearly impossible to touch, and at later stages, the fish are simply too big to be handled in a meaningful way.

Thus, internal fish logistics in the Next Tuna juvenile production concept becomes the main challenge to successfully produce ABT juveniles to a size of 2-10kg where they can be supplied into the existing Tuna fattening industry (see Fig.1).

In this contribution we want to present and discuss two novel approaches to internal fish logistics for tuna:

1. Internal transport in the hatchery by moving the entire tank around with a portal crane.
2. The use of floating RAS to facilitate transfer of the fish to transport net-pens, departing to Next Tuna customers.

Solution

<u>Hatchery internal transport by crane:</u>

For its hatchery operation, Next Tuna decided for movable tanks. The weaning and pre-growing tanks of Next tuna are planned in a way, that the whole tanks can be moved using a 40-tone overhead crane (Fig. 2). The bottom of the tank is equipped with an over-dimensioned bottom outlet to slowly release the fish. This avoids physical handling of the fish and adds a lot of flexibility in regards to fish density control. Another benefit of multiple movable units is a modular approach that will make it easy to refurbish and improve the systems for the specific needs of this species.

Floating RAS offer the advantage of land-based systems as long as they are connected to land, and in addition they offer the flexibility that they can be moved to the hatchery when loaded with juveniles, or joined with transport cages when fish are delivered to customers.

For fish delivery, the floating RAS is connected to the transport cages, comparable to the technology applied for fish transfer from one net-pen to another. Like this, the fish transfer from inside the RAS to the transport net-pen can be facilitate through a gate in the floating RAS side wall.

Discussion

Next Tuna wants to present these novel approaches to fish logistics to the audience and discuss the chosen solutions and their implications with the experts present at the conference.

[4]Riasearch, Lda., Murtosa, Portugal

Mercury (Hg) is a pollutant that requires particular attention due to its high degree of toxicity, persistence and bioaccumulative properties. Although its anthropogenic emissions have been largely reduced in Portugal, historical contamination leads to considerable burdens of Hg in the sediments of Ria de Aveiro and Ria de Olhão. Bivalves molluscs, in particular, are widely used as biomonitors of environmental metal concentrations, due to their feeding behaviour, filtrating Hg from the water column, suspended and particulate organic matter. Besides, these organisms may act as vectors for the spread of Hg to higher trophic levels. Furthermore, bivalves' molluscs are traditionally used in gastronomy, and their harvesting represents an important activity in coastal communities. Therefore, monitoring Hg's presence along the Portuguese coast is extremely relevant to both environmental and food safety questions. The aim of this study was to assess Hg concentrations in bivalve molluscs collected monthly in aquaculture areas of three coastal lagoons (Ria de Olhão, Ria de Aveiro and Lagoa de Óbidos, April 2019 – January 2020). In this sense, samples of two species of clams (*Ruditapes decussat*us and/or *Ruditapes philippinarum*) were collected and, the Hg quantification was carried out through the DMA-80 Evo Direct Mercury Analysis System. Clams proved to be good bioindicators of Hg presence. As expected, clams from Olhão and Aveiro lagoons presented the higher levels of Hg than Óbidos lagoon throughout the year. However, values obtained for these clams are below the maximum levels stablished by European legislation of 0.5 mg/kg. Fluctuations on Hg accumulation due to seasonality will also be presented and discussed.

PREDICTING EPA AND DHA DEPOSITION IN TURBOT (*Scophthalmus maximus*) FILLET WITH A NUTRIENT-BASED AND FATTY ACID DILUTION MODEL

Introduction

Concerns about sustainability have driven the evaluation and use of alternative lipid sources to replace fish oil (FO) in marine fish diets. However, total replacement of FO by other alternatives, such as vegetable oils (VO), is still hampered by the relatively low levels of long chain polyunsaturated fatty acids (LC-PUFAs; e.g., DHA and EPA) available in VOs. In addition to the fact that LC-PUFAs are required at considerably high levels by marine fish species to sustain adequate growth, they also make fish an attractive product for consumers, as it is considered a high-quality source of these essential fatty acids. In this sense, from the fish farmer point of view, delivering fish rich in LC-PUFAs, namely EPA and DHA, is a relevant concern, which may also contribute to the differentiation of their products in the market.

Mathematical models that support the definition of more efficient finishing feeding strategies, by predicting the deposition of EPA and DHA in fish flesh, may be useful tools for fish farmers, since the fatty acid (FA) composition of fish depends on several factors that may vary substantially during fish farming production.

This work aims to present the development and validation of a mathematical model, within the scope of the OmegaPeixe project, which was designed to support the evaluation of different feeding scenarios of turbot (*Scophthalmus maximus*) by measuring the impact on the EPA and DHA composition of the fish fillet.

Methodological approach

The mathematical model was developed based on a "energy-protein flux" approach (EP model; Nobre et al., 2019). Being a dynamic model (ordinary differential equations, ODEs), the whole-body content of protein, lipid and FA of fish are modeled as state variables. The FA deposition is modeled based on simple dilution model (Robin et al., 2003), assuming that the dietary FA incorporation occurs in tissues without the mobilization or turnover of pre-existing ones, i.e., in the same proportion as they are in the diet (Benedito-Palos et al., 2009). In order to convert the EPA and DHA composition from the whole-body to the fillet, the following equation was used:

$$FA_{fillet} = (lipids_{wholebody} \times a) \times (FA_{wholebody} \times b)/100$$

where:

FA_{fillet}	is the EPA or DHA composition of the fillet, in g/100g
$lipids_{wholebody}$	is the whole-body lipid content, in % of total weight
$FA_{wholebody}$	is the whole-body EPA or DHA content, in % of total lipids
a	is conversion factor of lipids (from whole-body to fillet)
b	is a conversion factor of EPA or DHA (from whole-body to fillet)

The model was calibrated for turbot using data from a wide range of growing conditions (experimental data collected from scientific publications and experimental/production data shared by FLATLANTIC). In addition, the model was validated with independent datasets, including one relative to a trial carried out in the context of the OmegaPeixe project (results available below).

(Continued on next page)

Model validation

The model validation results are shown in Figure 1. These results are related to an *in vivo* trial carried out with fish weighing initially 141.9 ± 6.5 g, which were fed over 75 days with 6 experimental diets formulated with different lipid sources.

Overall, the model predicts with very good accuracy both the growth and the EPA+DHA composition of the fish fillet over a 75-day period, presenting a mean absolute percentage error (MAPE) of 5.0% and 12.3%, respectively.

Final remarks

This work illustrates the development and validation of a nutritional mathematical model that can be used to support the definition of finishing feeding strategies, aiming the production of fish rich in EPA and DHA. The results obtained in a first validation step are promising, however further validation is required in order to gain more confidence in the model. This is currently in the pipeline of the OmegaPeixe project.

SOLEMAT: A MODELLING TOOL TO SUPPORT THE DEFINITION OF FEEDING STRATEGIES FOR SENEGALESE SOLE (*Solea senegalensis*) CULTIVATED IN RECIRCULATING SYSTEMS

Filipe Soares*[1], Tomé Silva[1], Ana Nobre[1], Luís Conceição[1]

[1]SPAROS Lda., Olhão (Portugal)
Email: filipesoares@sparos.pt

Introduction

Feeding operations have a substantial impact on the overall performance of recirculating aquaculture systems (RAS). The way fish are fed not only has direct consequences on the zootechnical and economic performance of fish production, but also has indirect consequences in terms of water quality. Under some conditions, these side effects, if neglected and not properly accounted for beforehand, can lead to undesirable negative consequences and, ultimately, pose a major threat to fish welfare and health.

Although most RAS are dimensioned to sustain a determined carrying capacity, it is important to bear in mind that the dimensioning is usually made by considering nutrient mass-balances that may not apply to all feeding strategies and farming conditions. For example, a fishmeal-free diet may lead to a 4-fold increase in phosphorus concentration, and to a 14% higher nitrate nitrogen concentration, compared to a fishmeal-based diet in a low water exchange RAS (Davidson et al., 2016). This illustrates the importance of evaluating the impact of new feeding strategies on the overall performance of the system, in order to ensure that there are no risks that could compromise production.

Decision-support tools based on mathematical models can be important assets in this regard. By predicting nutrient excretion over time and, hence, water quality parameters, based on a mass-balance approach, this kind of tools allow to gain more sensitivity and knowledge about the impact of different feeding scenarios on RAS performance.

The objective of this work is to present a prototype of a decision-support tool (SoleMAT), developed in the context of the FeedMi project (www.feedmi.ciimar.up.pt), which was designed to support the evaluation of different farming and feeding scenarios of Senegalese sole (*Solea senegalensis*) cultivated in RAS.

Methodological approach

The SoleMAT tool (Figure 1) was built on the top of a nutritional fish growth model, which is based on a "energy-protein flux" concept (EP model; Nobre et al., 2019), and which was calibrated for Senegalese sole using published data from several growth trials.

The EP model, scaled for the population/tank level, simulates what happens inside a tank, including the growth of fish, biomass evolution and total ammonia nitrogen (TAN) excretion, based on input data defined by the user about the feeding scenario to apply (i.e., feeds to provide over time, feed composition and feeding table) and expected farming conditions (e.g., temperature). For each tank defined by the user, the model is replicated and run in parallel. All EP model replicates are coupled to another model that simulates the removal/conversion of TAN into nitrites (NO_2) and nitrates (NO_3) by the water treatment system, thus allowing to predict the concentration of nitrogen compounds over time based on mass-balance approach that also takes into account the water renewal rate.

Tool overview

SoleMAT is implemented as a prototype tool through the integration of R scripts (compiled as executable files) and Microsoft Excel. It presents a user-friendly interface and requires a minimum set of input data (e.g., diet composition, feeding table, number of fish, initial fish weight, and temperature profile), thereby improving user-experience.

In terms of outputs, the tool provides not only time-dependent estimates of growth, biomass, FCR and nutrient excretion at the tank level, but also estimates on the water quality of the whole system, in terms of concentration of nitrogen compounds. Furthermore, this prototype tool allows the user to define critical concentration values of NH_3, NO_2 and NO_3, to facilitate the interpretation of results.

Introduction

Precision fish farming tools have a great potential to support the transition to more efficient fish farming production, particularly in the case of intensive systems. This kind of tools can be used to support different phases of the operational process, such as the observation phase, the interpretation phase, the decision phase, and the acting phase (Føre et al., 2018). Mathematical models can be inserted within the range of tools used to support the interpretation of data, allowing to act based on more informed decisions, thus contributing to improved performance in zootechnical and economic terms.

To contribute to an even more efficient fish farming industry, we have set up the NoviFEED project (www.sparos.pt/projects/novifeed), which aims to bring to market improved versions of the FEEDNETICS™ and FiT feeding tables™ tools for Atlantic salmon and meagre. Both tools are based on mathematical models that consider the effects of feed composition and temperature on feed intake, growth, nutrient retention and body composition of fish. With these tools users can evaluate the impact of different aquafeeds on their specific farming conditions and obtain the feed requirements for their targeted growth curve, allowing them to improve their feeding operations. Within the scope of NoviFEED, we will study the effects of dissolved oxygen on the voluntary feed intake of both species, aiming to include them on both tools through mathematical modelling.

This work aims to:

- Present the calibration and validation of the models behind FEEDNETICS™ and FiT feeding tables™ tools for Atlantic salmon (*Salmo salar*);
- Present other expected outcomes to be obtained in NoviFEED.

Model calibration and validation

The calibration of the models (ordinary differential equations, ODEs) behind FEEDNETICS™ and FiT feeding tables™ tools for Atlantic salmon was done by considering data from a wide range of growing conditions (experimental data collected from scientific publications, see Table 1) and by applying optimization algorithms that were used to define the values of some species-specific parameters based on an error-oriented approach (i.e., minimizing the error between observed and predicted data).

The validation of the models was performed by running them for independent datasets (i.e., out-of-sample data, not used in the calibration process) and comparing the results against observed data. This allowed a fair evaluation of model accuracy, avoiding some undesirable bias related to in-sample validation procedures. Figure 1 shows the validation results of FEEDNETIS™ (body weight comparison) and FiT feeding tables™ (feeding rate comparison) for Atlantic salmon.

Both tools provide reasonable estimates, presenting mean deviations of about 11.7% (FEEDNETIS™) and 14.0% (FiT feeding tables™) against the validation datasets tested. Despite these good results, through the project an additional set of *in vivo* nutritional trials will be carried out in order to generate detailed datasets, with the aim of refining the accuracy of both tools.

Expected outcomes of the project

The results presented in the previous section are the first outcomes of this project. Further work includes calibrating both tools for meagre (*Argyrosomus regius*) and studying the effects of dissolved oxygen on the feed intake of Atlantic salmon and meagre, through an extensive battery of short-term feeding trials (where feed intake will be recorded under different oxygen levels). If we are able to successfully observe clear effects of dissolved oxygen concentration on the feed intake, the next steps are to develop mathematical models to be included in new versions of both tools and demonstrate their use in operational environment to reach a complete and qualified system.

(Continued on next page)

Table 1 – Summary of calibration data used to calibrate the models for Atlantic salmon.

Number of rearing units and diets		BW and temperature range		Dietary composition range	
Number of rearing units	398	Body weight	1 – 6645 g	Crude Protein	29 – 54 %
Number of diets	350	Temperature	4 – 20 °C	Crude Fat	10 – 47 %

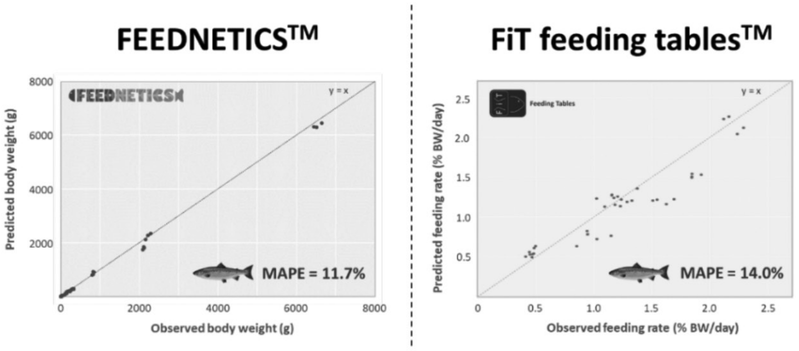

Figure 1 – Validation results of FEEDNETICS^{TM} and FiT feeding tables^{TM} for Atlantic salmon. MAPE = mean absolute percentage error

Final remarks

Nutrient-based mathematical models have great potential to contribute to precision fish farming, by providing, for instance, theoretical estimates of feeding rates and by allowing to compare different feeding regimes before field implementation. In order to extend the predictive capacity of this kind of tools, it is important to keep the development pipeline open to the inclusion of factors other than those related only to the nutrient content of feeds. Dissolved oxygen is a factor with a great impact on fish farming productivity. Therefore, tools that are able to quantify its impact on fish performance will allow to support the definition of more efficient feeding practices.

Introduction

Offshore aquaculture is a promising economic activity in waters of the Basque Country (SE Bay of Biscay) as a complement of the declining fishing activity in the area. Since 2011 efforts have been focused on the feasibility of mussel (*Mytilus galloprovincialis*) aquaculture in open waters, but there is also interest in diversifying the production by cultivating new species. In this respect, oysters are particularly attractive since they present a high market demand. However, the oyster precise species inhabiting the Basque coast as well as the pathogen prevalence is unknown, which is of vital importance for oyster farming profitability. In fact, the prevention and control of diseases is one of the challenges that has to face bivalve mollusc production. Thus, the aims of this study are (i) to identify the species of wild oysters inhabiting the Basque coast and (ii) to determine the prevalence of oyster diseases.

Material and methods

The study was carried out in 2020 in six locations distributed along the Basque. At each location 30 wild oysters were collected to characterise the oyster species and other 30 individuals were collected to determine the prevalence of pathogens, except in Mendexa, located in the Mollusc Production Area, where pathogens were detected on 30 commercial flat oysters. Characterisation of oyster species was performed by PCR-sequencing of a specific DNA fragment, belonging to the mitochondrial cytochrome oxidase I (COI) gene using the primers LCO1490/HCO2198 (Folmer et al., 1994). Sequences were aligned using the Basic Local Alignment Search Tool (https://blast.ncbi.nlm.nih.gov/Blast.cgi) with a >98% at reference species level. Pathogens were determined by qPCR (Herpesvirus-OsHV-1 μVar- and *Vibrio aestuarianus*) and PCR (*Mikrocytos mackini*) in the National Reference Laboratory for Diseases of Bivalve Molluscs, CSIC (Vigo, Spain), according to the methodology standardised by the European Reference Laboratory and/or by the Office International des Epizooties (OIE), renamed as World Organisation for Animal Health , and Bonamiosis and Marteiliosis diseases were determined in histological sections of commercial flat oysters.

Results

All wild oysters were identified as belonging to the genus *Magallana*. However, after sequencing the amplified fragments, one sample from the port of Mutriku was identified as *Magallana angulata*, while the rest of the samples turned out to be *M. gigas* (Figure 1). The European flat oyster (*Ostrea edulis*), the native species of European waters, was not found, except in the commercial batch reared in Mendexa.

Prevalence of herpesvirus ranged from 0% in oysters from Muskiz to 20% in oysters from Hondarribia. Accordingly, the highest prevalence values of *Vibrio aestuarianus* were recorded in oysters from Hondarribia (20%). *Mikrocytos mackini* was not found in any Pacific oyster from the Basque coast. On the other hand, a prevalence value of Bonamiosis of 3.3% was detected in commercial flat oysters from Mendexa but no Marteiliosis was registered (Table 1).

Discussion and conclusion

The vast majority of oysters from the Basque coast (99.3%) were identified as Pacific oyster (*M. gigas*), while no wild European flat oysters were found in the sampling locations. Oysters sampled on the Basque coast were infected to varying degrees by pathogens. However, it should be noted that the prevalence of the pathogens did not exceed 20% of cases, so for the moment they do not pose a major threat, but it must be taken into account that there is hardly any oyster farming activity in the Mollusc Production Area and that the density of farmed animals is low. If production increases in the future and more companies are set up, the risk may increase. It is therefore essential to develop a health surveillance plan to better prevent and control marine bivalve diseases and to promote a sustainable aquaculture.

Introduction

Offshore aquaculture has been recognized as a potential solution to the increasing demand for local seafood, while maintaining marine ecosystems. In recent years, due to the decline of fishing activities in the Basque Country (SE Bay of Biscay), a study was conducted to validate the feasibility of farming mussels (*Mytilus galloprovincialis*) in the Cantabrian open waters. Although this study concluded on the viability of this activity, the operational production phase started in 2019 by the first mussel production company installed, is encountering some difficulties that compromises the economic profit of the activity. These difficulties are related to an increase occurrence of different harmful algae blooms and to the deficient follow up of the mussels' reproductive cycle. The present study addresses these issues in detail, to provide better knowledge and management support on the periods of highest mussel meat quality and seed provisioning, as well as identifying toxic events that may impede mussel marketing.

Material and methods

This study was conducted from January to December 2021, on the offshore long-line installations located at two miles off the Basque coast, presently exploited by a mussel production company. Samplings were carried out monthly for the determination of mussel growth and reproductive cycle based on histological assessment, together with the measurement of environmental variables. Additionally, the analysis of mussel flesh for the presence of the regulated biotoxins (Diarrheic, Paralytic and Amnesic Shellfish Poisoning toxins, together with yessotoxins and azaspiracids) and the analysis of water samples for the presence of toxin-producing phytoplankton throughout the water column was carried out at least fortnightly.

Results

Gametogenesis took place in early winter, using reserves stored during the previous months. Mussels remained mature during winter and spring and mass spawning occurred in late summer. Subsequently a post spawning period was observed from late summer to autumn. However, it is worth noting that a continuous spawning was observed throughout the year. In some mussels, gonad restoration occurred in autumn to reabsorb their gonads concurrently with development of storage tissue. The onset of a new gametogenic cycle was expected by late summer (Figure 1).

Okadaic acid, a "Diarrheic Shellfish Poisoning" (DSP) toxin was produced by *Dinophysi*s *acuminata* and exceeded the legal limit in spring, from the beginning of March to the end of June as observed in other areas (Ruiz-Villareal et al., 2016) (Figure 2). On the other hand, lipophilic toxins of the yessotoxin group exceeded the legal limit during several days in June and October. The rest of the regulated lipophilic toxins (dinophysistoxins, pectenotoxins or azaspiracids) were not detected. The amnesic toxin (ASP) and paralytic toxins (PSP) did not exceed the legal limit for domoic acid and saxitoxin, respectively.

Discussion and conclusion

Although the main spawning peak occurred in late summer, a noticeable proportion of gamete releasing mussels was still detected throughout the year, which could lead to a decrease in meat quality. Therefore, to increase profitability of the production, the summer months should be avoided for the sale of the product. Instead, producers should be encouraged to place ropes on the longline for seed collection. However, previous studies have indicated that spring and autumn are the seasons with the highest risk of biotoxin events (DSP and PSP, respectively), and, consequently, closure of the mollusk production area. As there are no accredited laboratories for biotoxin analysis in the Basque Country, more efforts are needed to consolidate the value chain of aquaculture products. In addition, the use of screening tests for early detection of biotoxins could help to identify product sales windows and improve the management of the emerging shellfish sector in the Basque Country.

AQUACULTURE TECHNOLOGY AND GOVERNANCE – GOING DOWN RABBIT HOLES?

Introduction

Norwegian aquaculture has seen immense development. In less than half a century, it has developed from a fumbling, experimental activity; to a technologically refined, and highly efficient industry. In the shadows of its success, however, lie environmental impacts such as pollution, escapes, and sea lice. In addition, increased production has led to a scarcity of good production areas (Gullestad, 2011). To address these challenges, in 2015, a temporary licensing regime, *the development license regime,* was introduced. The intention was to stimulate technological innovations. As a result, several new production systems have been developed (Føre et al., 2022; MIF, 2004). Although promising, emerging technologies are characterized by *complexity, diversity, and uncertainty*, which challenge governing systems and create a pacing problem (Marchant, 2011; Marchant, 2020; Marchant et al., 2011). In Norwegian aquaculture, the pacing problem is driven, at least partially, by the development license regime, as regulations are not able to keep up with the technological development (Jensen, 2019). Using the development license regime as an example, we explore how government-initiated innovations drive technological innovation to the extent that regulatory regimes are not able to keep up, causing a pacing problem.

Materials and methods

The article uses an inductive, multimethod approach. A case study approach offers an in-depth understanding of the pacing problem in its real-life context (Yin, 2012). Grounded theory, using semi-structured interviews, provides a starting point for exploring the pacing problem (Glaser & Strauss, 1967), which is supplemented by document data and -analysis (Asdal & Reintertsen, 2020). Our approach is also abductive, as a continuous interaction between existing theories and empirical evidence generates hypotheses about the pacing problem (Timmermans & Tavory, 2012).

This study is a part of the DEVELOP project, financed by the Research Council of Norway (grant no. 301486).

Results

We study the development license projects in terms of their complexity, diversity, and uncertainty and how these characteristics challenge the governing system(s). First, development projects were required to be significant innovations and have therefore become complex assemblages of various technologies, e.g., oil platform technology combined with traditional aquaculture technology (Føre et al., 2022). As technological complexity increases, the complexity of regulatory processes increase, and become increasingly slow (Gaudet & Marchant, 2011). Second, to facilitate the development of a range of different technological solutions, development projects were required to differ significantly from each other. Without established guidelines, the resulting diversity proved to be a challenge for the bureaucracy in terms of processing and evaluating the development projects. Finally, complexity and diversity led to uncertainty, not only in terms of investment risk but also concerning the future trajectory of the technological solutions (Herkert, 2011), and the management thereof.

Conclusion

This article shows how government-initiated technological innovations lead to a pacing problem in Norwegian aquaculture governance. In particular, it shows how complexity, diversity, and uncertainty of the development projects, cause the governing system(s) to lag industry innovation. The question is whether initiatives, such as the development license projects, will be a solution to the perceived problems, or whether we are going down rabbit holes, in which the pursuit of one solution simply further exacerbates the pacing problem?

Introduction

The majority of successful aquaculture has come from a relatively small number of species; however, still many economical important species remain underdeveloped. In particular, egg hatching and survival of larvae have proven to be bottlenecks to the complete and sustainable aquaculture of many species. The European eel is one such yet underdeveloped species, both as human food source and as object needing conservations measures after a dramatic decline in glass-eels (juveniles) over the last 40 years (Dekker, 2008). During their early life stages in the wild, they are exposed to oceanic environments low in microbial activity (Sjöstedt et al., 2014) while in aquaculture, they are vulnerable to bacterial infections (Sørensen et al., 2014) due to an immature adaptive immune system (Suzuki et al., 2000; Swain et al., 2009) well known especially for marine fish larvae (Hansen & Olafsen 1999). A stable and healthy microbial community within these aquaculture systems is therefore a prerequisite for a suitable European eel production environment. Eel therefore provide an excellent model for investigating the effects of microbial communities on fish egg hatching and larval survival. Aquaculture microbial community is significantly stabilized utilizing RAS technology (Recirculating Aquaculture Systems) (Attramadal et al. 2013). RAS enable stable microbial systems over time, by the constant feedback of nutrients released from organisms providing a selection and stabilization force of the microbial community (Attramadal et al. 2013). Although a well-balanced community is known to be of pivotal importance for the system, little is known regarding the forces that drive stability and how to reach a healthy state (Blancheton et al., 2013). By using microbiological and chemical analysis techniques, we compare pelagic eel embryonic and larval bacterial communities in response to water cleaning treatments such as ultra-filtration (500kd), UV and ozonation as well as biological maturation to create different types of aquatic environments. The aim is to understand the dynamics of aquatic microbial communities and the forces that drive them. This knowledge is of pivotal importance to enhance offspring survival during the early life stages of sensitive marine fish species. Using the European eel as a model species, we utilize state-of-the-art chemical and microbiological techniques, to endeavour scientific adaptability of complex aquatic microbial communities and aim ultimately to improve sustainability of aquaculture.

Material and methods

Harvested eggs of captive bred European eel were fertilized using prediluted milt and activated using artificial sea water based on reverse osmosis water and reef salt (Sørensen et al., 2016). Buoyant eggs were distributed into three 60L conical incubators connected to three types of sea water applied as flow-through with water inlet at the bottom of the tank. Incubators were held at 18ºC, at low light and constant supply of 0.2 μm filtered air. Three water masses used for incubation were treated as follows: i) preconditioned microbial matured seawater in RAS; ii) afore mentioned water type passing through cross flow Ultrafilter ~500KD, removing bacteria and vira; iii) first mentioned water mass passed through UV-C and Ozon. Each incubator was sampled daily to estimate egg density, bacterial load, fertilization, survival, hatch success, and subsequently larval survival to day 12. Egg associated bacteria we quantified at 0, 2, 4, 24, and 48 h post fertilization using enzymatic metabolic processes of bacteria (Bactiqant, Mycometer, Hørsholm, Denmark). Along with egg-associated bacteria, we quantified bacteria in the incubation water both regarding in- and out-flowing water to assess impact of eggs and their bacteria on water quality. Water characteristics of in- and out-let water were additionally analyzed by spectrophotometry characterizing the fluorescent dissolved organic matter (FDOM) known to nourish heterotrophic bacteria in the rearing medium. Hatch success was assessed by sampling ~100 buoyant embryos at 50 HPF from each water type, inserted into triplicate antibiotic flask containing 200 ml of the respective water but with the addition of 50 ppm rifampicin and 50 ppm ampicillin (Sørensen et al., 2014), and incubated in a temperature controlled environment (18ºC) until 60 HPF, when the ratio of hatched and unhatched larvae was determined. Larval survival was estimated by random selection of 3 × 20 larvae from each water type and inserted upon hatch into 200 ml flasks of antibiotic similar to above. Flasks with larvae were cultured in a temperature controlled environment and survival was quantified daily throughout the yolk sac period until day 12 DPH (Sørensen et al., 2016). Larval microbial community was assessed from larvae reared in kreisel tanks after hatch until day 10.

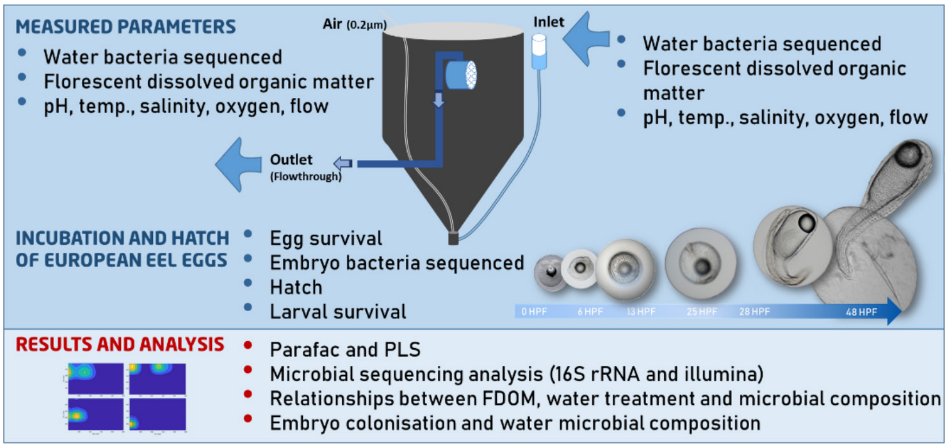

Fig. 1: Bacteria activity on incubated eggs and in the rearing water of European eel eggs reared using Matured, Ultra filtered (500kd crossflow membrane), and UV + ozon treated seawater.

Results and Discussion

The study outline links between microbial processes in a hatchery setup and how cultured organisms influence this at different means of water cleaning. Figure 1 outlines the measured parameters and how results and analysis are approached. We show how potential water cleaning techniques e.g. ozon and UV improves some rearing scenarios, while the associated instability that may follow negatively impacts other. The links between water biochemistry and emerging microbial community in water and colonizing embryos is discussed in light of survival.

Results show a steady and constant build-up of bacteria numbers on embryos but due to community differences resulting in different survival of embryos and larvae. Bacterial colonization happens rapidly and various filtration techniques can improve survival, but tend to induce instability and increase variability forming a “virgin” water mass ready for colonization by opportunistic pathogens (Vestrum et al., 2018). By analyzing water content and characteristics regarding fluorescent dissolved organic matter, we could differentiate between the carbon footprint of ‘good’ and less ‘good’ aquatic environments and their effect on colonization level/speed on incubated eggs.

Introduction

European eel, *Anguilla anguilla*, is critically endangered and hatchery technology for commercial production of glass eels is fundamental to sustainable eel aquaculture, as wild-caught glass eels is still basis of eels cultured to marketable sizes. During the past 15 years, DTU researchers have engaged in the development of captive breeding technology for European eel aiming at a closed life cycle in culture (Tomkiewicz et al., 2019). As reproduction and early life history in nature is uncharted, experimental research is pre-requisite to fill gaps in knowledge. Thus, on the one hand research has targeted broodstock nutrition and reproduction, while on the other the establishment of larval culture systems, rearing conditions and diets. Encouraging for this research is the progress of hatchery technology for Japanese eel (*A. japonica*), now approaching commercialization. To date, European eel research has successively improved assisted reproduction methodologies leading to enhanced broodstock responsiveness, quantity, and quality of gametes as well as viability of offspring, now entering the first feeding stages. Broodstock involve captive-raised and wild-caught females using the latter as benchmark, while targeting a closed-cycle production, also aiming at benefits regarding lower disease risks and better performance in culture systems (low stress). Here, we present progress made during the innovation project ITS-EEL (2018-2021) focussed on up-scaling viable egg production and establishing the technology for feeding larval culture. This involved tailoring broodstock feeds and refining hormonal treatments, while progressing larval survival through custom-designed culture systems and novel diets for feeding larval culture.

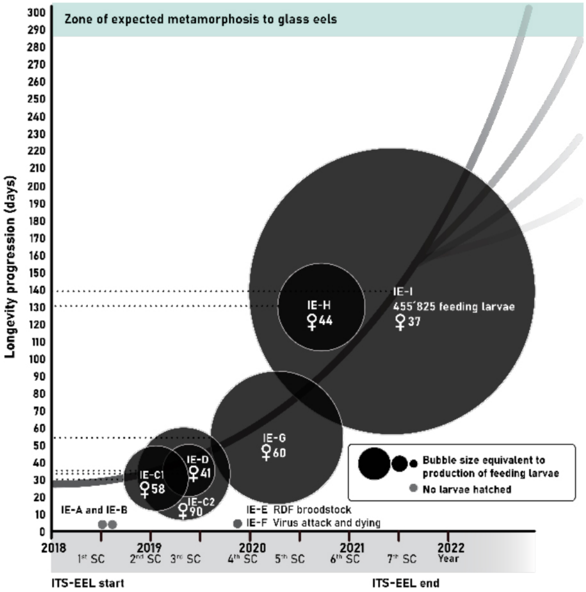
Material and methods

The experimental research was conducted at the prototype eel hatchery, EEL-HATCH, Hirtshals, Denmark. Farmed broodstock were raised from the glass eel stage either at commercial farms or at the EEL-HATCH facility on customized feeds (SPAROS) for periods between 1 (Royal Danish Fish) and 3-4 years (EEL-HATCH). Wild-caught broodstock was obtained from a Danish nature reserve, Saltbaek Vig, through September and October new moon periods and transported to the EEL-HATCH facility. Here, broodstocks were acclimatized to 36 psu and 20°C at low intensity light:dark 12:12h photoperiod (Tomkiewicz et al., 2019), maintained in RAS setup. System maintenance involved water exchange of 5% per week, adjusted salinity to 36 PSU using Aquaforest Sea Salt (Brzesko, Poland). Different female broodstock treatments were tested including administration of estradiol for captive-raised females to synchronize ovarian development, pituitary extracts, CPE or SPE (Argent Chemical Laboratories, USA) at various levels (18.75, 20 and 25 mg/kg body weight), and different doses of 17α,20ß-dihydroxy-4-pregnen-3-one (Sigma-Aldrich, USA) to induce final maturation and ovulation, preceding strip spawning (Tomkiewicz et al., 2019). *In vitro* fertilization has been applied using pre-diluted milt at a fixed ration to newly stripped eggs, while being activated under standardized conditions (Butts et al., 2014). Buoyant eggs were incubated in 60L black incubators supplied filtered 36 PSU seawater and 0.2µm filtered air at 18°C in darkness. Following hatch, larvae were moved to custom made 70L semi-Kreisel-type tanks, applying stabile rearing conditions at 20°C and darkness until first feeding, happening in 8L Kreisel tanks at 18 PSU and 20°C.

Results and Discussion

Seven full reproduction series leading to larval production was conducted of where two series applied captive-raised females and five tested wild-caught. Diets for captive-raised female, targeted enhanced essential fatty acid composition, resulted in reproductive responsiveness similar to wild-caught silver-eels. Wild-caught females produced larger quantities of eggs of superior survival however once hatched, the larval quality of captive-raised approached that of their wild-caught counterparts (length and body area) (Kottmann et al., 2020a). Dietary improvements also enhanced male reproductive

(Continued on next page)



performance (Butts et al., 2020). Reproductive experiments documented that egg quality and embryos of SPE-treated females was higher than for CPE-treated females, however, the appearance of larvae surviving until the feeding stage was similar (Kottmann et al., 2020b; Benini et al., 2022). Here, treatment of 20 mg SPE/kg female body weight adjusted by the metabolic rate was best. Moreover, generation of dedicated tanks and RAS adjustments in rearing conditions facilitated high survival of embryos and yolk sac increasing numbers entering feeding and dietary trials. In total, 276 female eels successfully reproduced, with an avg. production of 447,333 to 672,865 eggs per female and mean fertilization success of 32 to 48% among series. This resulted in 21,167 to 70,217 hatched larvae per female, of which 2,191 to 12,320 larvae per female reached first feeding. Overall, an yearly average of ~30 M buoyant eggs was obtained, leading to an yearly hatch of ~3.5 M larvae of where ~0.5 M reached the feeding stages (10 dph). The costs of production currently entail prices of ~0.17 € per hatched larvae and correspondingly, the price per larvae reaching the first feeding stage is ~1.8 € incl. Notably, an economical analysis conducted shows a cost reduction of ~50%, once the present high level of research is no longer needed (i.e. when glass eel production and technology are established). These results, will be presented and discussed in context of an emerging hatchery enterprise.

THE EFFECT OF SODIUM HYPOCHLORITE ON TOMONTS OF THE PARASITE *Amyloodinium ocellatum*

*Email: rui.sousa@s2aquacolab.pt

Introduction

The parasite *Amyloodinium ocellatum* is one of the most common and important dinoflagellates infesting fish. *A. ocellatum* causes serious morbidity and mortality in both brackish and marine warmwater fishes farmed in aquaculture facilities worldwide. *A. ocellatum* has a direct, but triphasic life cycle that can be completed in less than a week in favourable environmental conditions, consisting of a free-living flagellate, the dinospore, the parasitic stage, the trophont, and a cyst stage, the tomont. Current therapies target the free-living flagellate and trophonts, while tomonts are highly resistant to treatments. More studies are needed to evaluate the efficacy of new treatments on tomonts to reduce the impact of this parasite on aquaculture.

Material and Methods

Tomonts were obtained from European seabass *Dicentrarchus labrax* infected experimentally with *A. ocellatum* into an *in vivo* propagation system on EPPO-IPMA. Infected fish were immersed on freshwater and tomonts were collect, washed, counted and exposed to a solution of sodium hypochlorite (SH; 13% chlorine) at 10, 100, 250, 500, 750 and 1000 ppm of chlorine and incubated on 96 flat bottom well-plate at 23ºC for 96h. Additional tests were performed by exposing tomonts for 1 h to SH with the same concentrations and washed before incubation. All tests were performed in triplicate, with a negative control. Evaluation of tomont inactivation was done by daily monitorization of sporulation (tomites/tomont) till 72 h. Tomonts that did not perform any division in the first 72 h were considered inactive. Dinospore production per tomont was also evaluated at 96 h of incubation.

Results and discussion

Continuous exposure to SH for 72 h showed to be effective in reducing tomont division at concentrations as low as 10 ppm, and to completely arrest the division process at 250 ppm (Figure 1A). Exposure for 1 h to the same concentrations revealed a similar trend, with 10 ppm being effective at limiting tomont division and 250 ppm arresting completely the division process (Figure 1B). Tomont inactivation was significantly higher after a continuous exposure to concentrations higher than 100 ppm ($p\text{-value} < 0.00001$) (Figure 1C) Similar results were observed for an exposure to the same concentrations for 1 h

LESIONAL PATTERN OF TURBOT (*Scophthalmus maximus*) FURUNCULOSIS: NEW ADVANCES FOR INDUSTRIAL DIAGNOSIS

Introduction

Turbot (*Scophthalmus maximus*) is a flatfish of great importance in European aquaculture (APROMAR, 2021). One of the biggest threats of turbot culture is furunculosis, a disease caused by the bacterium *Aeromonas salmonicida* subsp. *salmonicida* (Coscelli et al., 2014). In turbot, furunculosis mostly appears as a chronic disorder, where single to multiple swelling nodules emerge through the skin of the animal. These nodules are firm, grey to reddish, usually delineated by a rim of pale tissue and vary in size (2-6 mm in diameter) (Coscelli et al, 2014). However, the distribution pattern of nodules has not been thoroughly described and remains as a knowledge gap to the understanding and handling of the disease. Geographical Information Systems (GIS) are a software typically used in Earth sciences, but in the last few years, they have also appeared as a very useful tool for human and animal health sciences (Cromley, 2003), since they allow the treatment of different kind of data preserving their spatial component. Therefore, the objective of this work was to study the lesional pattern of turbot chronic furunculosis by means of GIS.

Materials and methods

For this study, 165 turbot coming from tanks naturally infected with *Aeromonas salmonicida* subsp. *salmonicida*, that showed skin lesions compatible with furunculosis, were selected. The number of lesions and their location (ocular or blind side) were recorded, and skin samples were taken for histological and immunohistochemical confirmation of the disease. Two photographs (one per side) of each animal were taken, besides recording of their age, weight, and time elapsed since diagnosis. Images were later digitalized, and lesions were transferred to a unique standardized template and processed with ArcGIS© software.

Results

The histological features of the skin samples where compatible to those described in the literature for turbot chronic furunculosis (Coscelli et al., 2014). Immunohistochemical studies confirmed the presence of *Aeromonas salmonicida* antigens in most of the samples taken.

The mean number of lesions per fish was 2.8 ± 0.3, with bilateral asymmetry with predominancy of the ocular side (2 ± 0.2 mean lesions), when compared to blind side (0.7 ± 0.2). Furthermore, as it can be noted in figure 1, most fish had lesions on ocular side, with only 3% of them showing lesions affecting the blind side alone.

With Kernel density estimation tool from ArcGIS© software, it was possible to project a heatmap with the most frequent occurrence sites for furunculosis lesions, such as the mouth and the area of the head rostral to the operculum, in both ocular and blind side (figure 2). In addition to these findings, variations were seen depending on the size of the fish, with lesion concentration in the rostral edge of the operculum on turbot with lower weights and in the mouth on fish with the higher ones.

Discussion

The evidence of a clear distribution pattern in turbot furunculosis lesions entail a new step in this disease management. Operators at turbot culture facilities can easily be trained to inspect the heat regions detected in this study, to quickly detect the disease once it appears on the farm, preventing big outbreaks. Moreover, since most affected fish show lesions in the ocular side, it is possible to detect many of them in the conveyor belt of the grading line, saving the time of turning them over and making viable the development of diagnostic techniques based on gross examination and automatized detection and discarding of affected animals.

Introduction

The use of zebrafish as a model organism has grown exponentially in recent years. This small organism creates a point of union between two great fields of research: aquaculture and biomedicine. Being able to apply the technologies and tools of one field to the other improves the knowledge of both disciplines. Several research uses embryos or larvae of just a few hours or few days of life, for example, for testing molecules with immunostimulatory effect for their application in diets. The study of these models in early stages of development provides interesting advantages for many laboratory techniques. However, the small size of these fish encourages them to be lost or spoiled during the process, as it happens with histological processing. Therefore, it is interesting to look for alternatives that allow the paraffin-wax embedding of samples of such a small size. The objective of this work has been to develop an inclusion protocol focused on zebrafish embryos and larvae.

Materials and methods

The experience in the processing of histological samples, with the knowledge of the behaviour of the agarose against different compounds, and the learning of new technologies such as 3D print were added to achieve the objective. The methodology followed is based on the design and printing of a rectangular countermold of acid polylactide (Fig 1). Its surface has protrusions with custom shape and dimension, according to the stage of development of the fish to be studied. From this one countermold, an agarose mold is obtained with wells corresponding to the protrusions of the printed countermold.

Results

The agarose mold allowed the embedding of up to 16 zebrafish embryos 48 hours post fertilization. In addition, the design of the mold and the wells includes two important aspects: maintain the traceability of the samples, since the wells are individually identifiable, and allow the control over the orientation of the embryo, which may be important for certain studies. Furthermore, this procedure allows the treatment of multiple specimens as if they were a single sample, enabling its histological processing by routinary means.

Conclusion

This solution is another example of how multidisciplinarity within the work teams is a strong ally for the improvement of the techniques applied to this model species and other small size samples. Being able to design and manufacture this type of molds in the laboratory opens the door to endless potential applications.

Introduction

Pikeperch (*Sander lucioperca*) farming has been studied extensively in last couple of decades, nevertheless, the progress is still slow. One of the main bottlenecks is still the variable outcome of juvenile production (Policar et al., 2019). According to Müller et al. (2017) hybridization with Volga pikeperch (*Sander volgensis*) may result in an upturn of favorable properties in production, such as straightforward weaning to the dry feed, and more efficient start of first exogenous feeding as well as the reduction of cannibalism which could improve the rearing in all types of production systems of pikeperch. Triploidization as a method to improve production has already found its application in aquaculture. It is now commonly used in salmonid fish species with the main aim to avoid sexual maturation of animals and thus improve meat quality and growth (Janhunen et al. 2019). Likewise, the existence of a third set of chromosomes increases the chance that recombination of genes will avoid population depression (Fraser et al. 2012). Triploidization might reduce the aggressiveness of the fish (Garner et al. 2008) what might be beneficial in pikeperch considering its cannibalistic behavior in young juvenile stage (Ljubobratović et al., 2015; Colchen et al., 2020) The aim of the present study was to evaluate the effects of hybridization and triploidization on pikeperch larviculture.

Material and Methods

The eggs used in the present trials were obtained via artificial reproduction of six female pikeperch in preseason according to protocol described by Ljubobratović et *al. (*2021). The eggs of three females were fertilized with the sperm of pikeperch and the rest with sperm of Volga pikeperch. Half of the eggs of each group was submitted to the triplodization induction via hydrostatic pressure shock as described by Káldy et al. *(2021*). Following hatching all larvae from each group were mixed. At 6 days post-hatch, larvae were stocked in a larviculture recirculation system. Thus, in total four duplicate groups were formed: diploid (D), triploid (T), hybrid diploid (HD), hybrid triploid (HT). The trial lasted 40 days, in a temperature range of 16 ± 0.5 ºC and a light regime of 14:10 L:D. Larvae were fed with freshly hatched and enriched *Artemia nauplii* and starter feeds, finally weaned at 32 DPH. Sample measurement of body weight and length were performed on a weekly basis while all larvae were counted at the end of the trial and evaluated for the presence of swim bladder inflation.

Results

Chromosome analysis showed that the triploids were free of the presence of mosaic structures in the sample. Condition factor was significantly affected by triploidization being lower in triploids. Juvenile yield in form of swim bladder inflated juveniles per volume of rearing unit was significantly affected by hibridization. Likewise, hybridization had a significant effect on the percentage of swim bladder inflated fish.

Discussion

Hybrid groups showed enhanced larviculture performance in terms of production of fish with inflated swim bladder. With respect that the larviculture survival is the main bottleneck for the upgrade of pikeperch farming, this improvement might be beneficial for the sector and thus further evaluated in future studies. Triploidization did not yield positive results in in this study, however should be evaluated in more appropriate nutritional regimes.

2. Forschungs- und Entwicklungszentrum Fachhochschule Kiel GmbH, Schwentinestraße 24, 24149 Kiel
*t.staufenberger@kieler-meeresfarm.de

Within the research project UNTIED (Multi-Use offshore platforms demoNstrators for boostIng cost-effecTive and Eco-friendly proDuction in sustainable marine activities), five different pilot sites in Germany, the Netherlands, Denmark, Belgium and Greece were chosen to investigate current bottlenecks relating to the large-scale installation of ocean multi-use activities, demonstrate business synergies and benefits of ocean multi-use and provide a roadmap for deployment in future multi-use sites and potential scaling barriers to be addressed through best practices and lessons learnt. Each Pilot investigates different aspects. Focus within this work is given to the findings and importance of the nearshore site of the German pilot in Kiel. The German pilot as a whole looks into possible synergies of the cultivation of blue mussels, seaweed and offshore wind energy. Main purpose of the nearshore site was testing of materials, antifouling strategies, sensor connections and data transmission, handling of equipment and training of staff in a small workin mussel and algae open water aquaculture. Testing of material revealed weaknesses in camera fixtures and lead to improved design and material usage.Testing of antifouling strategies for stationary objects with air diffusers, wipers, UV light, ultrasonic vibrations, novel mesh covering and biological friendly chemical antifouling coating showed best result for the wiper technique and the chemical coating. Testing of sensor connectivity and transmission in the nearshore site allowed for adjustment and fine-tuning without costly repetitive offshore trips. Training of the staff in deploying handling and adjusting equipment in a comparably low risk, easily assessable surrounding allowed for repetitions and adjustments in an easy way. As the nearshore site lies in the Baltic Sea, while the offshore site lies in the North Sea mussel and algae growth, recruitment and settling was not tested, as due to the different conditions a transferability and value of knowledge was deemed highly unlikely. However if materials, techniques and data-transmission and handling does fail in a low risk, low energy nearshore site, they will not work in the high energy high risk offshore locations. Yet findings of the nearshore site have to be critically checked.

UNITED is a research project co-financed by the European Union Horizon 2020 program

A BIOENERGETIC APPROACH TO MODELLING OXYGEN AVAILABILITY IN FISH CAGES. TOWARDS A TOOL FOR EARLY WARNING IN AQUACULTURE

O. Stavrakidis-Zachou[1,2]*, K. Lika[2] and N. Papandroulakis[1]

[1]Institute of Marine Biology, Biotechnology and Aquaculture, Hellenic Center for Marine Research, AquaLabs 71500, Gournes, Heraklion, Greece
[2]Department of Biology, University of Crete, 71003, Heraklion, Greece
E-mail: ostavrak@hcmr.gr

Introduction

Oxygen constitutes one of the most important environmental factors for fish farming since it affects fish growth and health. Given that the sustainable development of aquaculture necessitates the adoption of precise and automated methods, it is important to develop tools that enhance our predictive as well as monitoring capacity with respect to the oxygen conditions at the farming sites (Royer et al., 2021). In this study we propose a modelling approach that uses bionergetic models coupled with the water properties at the farming site to simulate the oxygen consumption of fish and the oxygen availability within a typical production unit (i.e. marine cage). The aim of constructing such models is to incorporate them to an early warning system that will be able to utilize remote sensing data and produce relevant alerts to the operators of aquaculture facilities in Greece.

Materials and methods

Models based on Dynamic Energy Budget (DEB) theory (Kooijman, 2010) previously developed for European sea bass (*Dicentrarchus labrax*), gilthead seabream (*Sparus aurata*), and meagre (*Argyrosomus regius*) (Stavrakidis-Zachou et al., 2019; 2021) were validated against production datasets with respect to their predictions of growth, feed consumption and oxygen uptake. These models simulate the bioenergetics of individual fish as a function of temperature and food availability following with an extrapolation to the population level. Therefore, the models can be used in simulations to predict and report the total oxygen demands of a fish cage under the prevailing environmental conditions. In addition, we developed an approach to assess the adequacy of oxygen availability by modelling the supply of oxygen to the cage for a given area as a function of water velocity and cage characteristics. The above approach was conceptually tested at HCMR's pilot scale farm (Souda Bay, Greece).

Results

Validation of the models showed that they performed well and could sufficiently capture changes in oxygen uptake under varying environmental conditions. Subsequent application of the models at the pilot scale farm under typical farming conditions revealed that the models could not only predict the anticipated oxygen availability patterns but also detect potentially alarming signals for the farm operation. Specifically, using the E. seabass as an example, it was observed that the most frequent for the region water velocities (2-6 cm s^{-1}) provide sufficient oxygenation at the cage level since the oxygen supply far outweighs the oxygen demands of the fish (Fig 1). However, particularly low water velocities, which have however been recorded in the area (0.2 cm s^{-1}), may lead to suboptimal or even dangerous oxygen conditions for the fish.

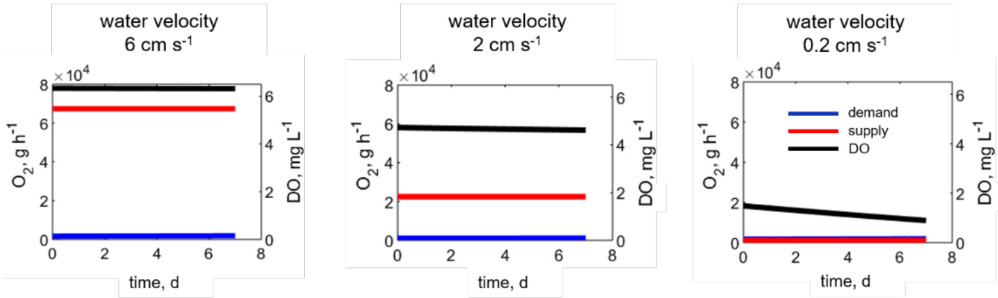

Fig. 1. Simulations of E. seabass juveniles (50g) reared at the pilot scale farm at Souda under three water velocities (6, 2, 0.1 cm s^{-1}). Red indicates the supplied oxygen in the cage, blue the oxygen demand by the fish, and black the dissolved oxygen in the cage. Temperature: 27°C, stocking density: 10 kg m^{-3}.

(Continued on next page)

Conclusion

In this study we used mechanistic models for three fish species, which based on bioenergetics, simulate the oxygen consumption of a fish population at the marine cage level. This output is integrated with the estimation of oxygen supply in the area in order to assess the oxygen available to the fish within the production unit. At a subsequent stage, the simulated output will be fed to an early warning system to provide alerts to aquaculture farm operators in cases of low oxygen availability. Initial testing of this approach has validated its capacity in predicting anticipated patterns and highlighted its potential as a tool for detecting alarming scenarios.

NORTHERN EUROPE'S SUITABILITY FOR FLAT OYSTER (*Ostrea edulis*) REEF RESTORATION AND OFFSHORE AQUACULTURE

Brecht Stechele[1]*, Anna Hughes[2], Steven Degraer[3], Peter Bossier[1], Nancy Nevejan[1]

Introduction

After centuries of overexploitation, flat oyster (*Ostrea edulis*) habitats are being protected and large-scale oyster reef restoration projects are about to be kickstarted in the North Sea, the English Channel and the north-eastern Atlantic. Oyster reefs are recognised biodiversity hotspots that provide many ecosystem services and bolstering of these habitats will provide ecosystem services that will support the marine ecosystems in northern Europe. At the same time, interest grows for offshore production of flat oysters, possibly combined with other marine uses such as offshore wind. Understanding the habitat requirements of flat oysters is key in the site selection process of restoration efforts and offshore aquaculture.

Material and methods

Establishing the theoretical niche for all life stages of the European flat oysters is done through a dynamic energy budget model forced with temperature, chlorophyll a and salinity in combination with sediment composition. The suitability of Northern Europe's marine environment for flat oyster is evaluated by applying the proposed niche model on a spatial scale and evaluating spatio-temporal variability in life history traits and metabolic characteristics such as fitness, reproductive output, settlement success, and growth.

Results

According to the results of this study, habitat suitability is limited by low maximum summer temperature and low food availability at higher latitude and in areas under strong influence of the Atlantic Ocean. Restoration efforts and aquaculture in Ireland and Scotland should be limited to protected and shallow coastal environments. Suitability in the southern North Sea is patchy and mainly depends on seabed substrate (for restoration and bottom culture). The coastlines enclosing the English Channel are highly suitable. The suitability of coastal areas is mainly limited by low salinity levels due to river runoff and unfavourable sediment.

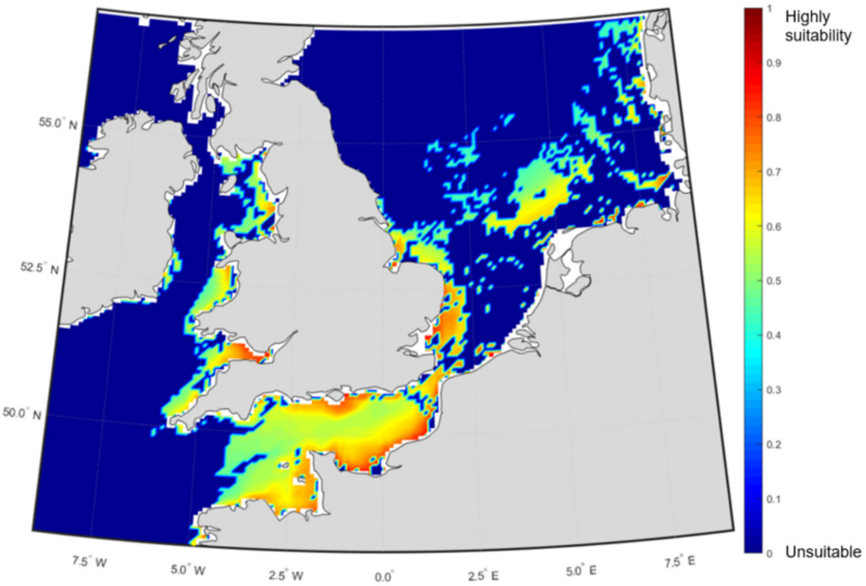

Figure: Site suitability for European flat oyster (*Ostrea edulis*), include locations that support high fitness, growth rate and reproductive output and enable life history events such as spawning and settlement (on suitable substrate).

COMPARING ASC CERTIFIED SHRIMP FARMS WITH CONVENTIONAL FARMS AND LITERATURE – SHORTCOMINGS AND OPPORTUNITIES

Kathrin Steinberg*

Aquaculture Stewardship Council (ASC), Daalseplein 101, 3511 SX Utrecht, The Netherlands
kathrin.steinberg@asc-aqua.org

Introduction

The Aquaculture Stewardship Council (ASC) is an independent not for profit organisation founded in 2010 by the World Wide Fund for Nature (WWF) and the Dutch Sustainable Trade Initiative (IDH). The ultimate goal of all ASC standards is to reduce the environmental and social impact of aquaculture worldwide. The standards are reviewed and revised every 3 – 5 years at a minimum in order to incorporate learning from stakeholders' feedback and, among other things, update the metrics within the standards according to the ASC Metrics Methodology.

The ASC Shrimp Standard was recently reviewed and data from certified and non-certified farms as well as from literature was compared and used to update the metric requirements. Three of the key performance metrics for shrimp production are farm survival rate, feed conversion ratio (FCR) and forage fish dependency ratio, which describes the quantity of wild fish used per quantity of cultured fish produced. These metrics not only provide measures of production efficiency, but are also important indicators of impact of aquaculture on wild fish stocks and the environment, reliance on limited resources, and fish welfare.

This data collection provides an interesting overview over shrimp production worldwide and shows what ASC can accomplish, but also where there are shortcomings especially in regards to data collection and comparability.

Methods

Within the revision of the ASC Shrimp Standard data from ASC certified and non-certified farms as well as literature data was taken into account. Survival rate, FCR and FFDR were selected for the purpose of this report to compare the performance of farms producing *P. vannamei* and *P. monodon*. Data on survival is differentiated by systems, based on the definitions used in the current ASC Shrimp Standard. The data was collected alongside additional metrics to inform the updating of the ASC Shrimp Standard. Data from ASC certified farms was extracted from a total of 233 audit reports (initial audits, surveillance audits and recertification audits) from 15 countries. Data from non-certified farms was provided to the ASC during the public consultation phase from a total of 257 shrimp farms, mainly covering Indonesia, Ecuador, and Thailand. Literature data was derived from a total of 24 scientific articles published until December 2019.

Comparisons between certified farms, non-certified farms, and literature values were made on the basis of averages and the standard deviation. Limited datasets and varying methods of data collection did not allow for statistical testing of the observed differences.

Table 1 Summary of data from literature and certified and non-certified farms, including quartiles

Requirement	Certified Farms	Non-certified Farms	Literature
Annual average farm survival			
Unfed and non-permanently aerated	33.4 ± 14.4	14.5 ± 8.8	no data
Fed but non-permanently aerated	62.9 ± 12.2	29.7 ± 19.6	60.3 ± 14.1
Fed and permanently aerated	78.3 ± 9.7	62.1 ± 15.5	81.8 ± 15.9
Forage Fish Dependency Ratio (FFDR)			
P. vannamei	0.9 ± 0.4	1.2 ± 0.6	1.4 ± 0.6
P. monodon	1.6 ± 0.4	1.6 ± 0.3	2.3 ± 1.3
eFCR			
P. vannamei	1.5 ± 0.4	1.4 ± 0.4	1.4 ± 0.3
P. monodon	1.7 ± 0.1	1.5 ± 0.3	1.5 ± 0.8

(Continued on next page)

Results and Discussion

Results for annual average farm survival, FCR and FFDR are shown in Table 1. The data shows that survival rate seems to be an issue for non-certified farms. This was also mentioned in the stakeholder feedback as a major concern for farmers. Literature data shows significantly higher survival rates. This does not only underline the differences between research data (often conducted in closed laboratories) but also the importance to collect real time data on the farms. The Forage Fish Dependency Ratio (FFDR) describes the quantity of wild fish used per quantity of cultured fish produced. Fishmeal derived from by products that meet the sustainability and traceability criteria defined by the ASC Shrimp Standard are not included in this calculation. Values for non-certified farms were estimated based on an average fishmeal content of 20%, as this was stated as average by the farmers. Most scientific literature provided detailed information on fishmeal content in the diet. If this was not available, the average FM content reported by the FAO of 25% was used. FFDR values for *P. vannamei* are lower on average for certified farms, whereas values for *P. monodon* are similar for farms and show high fluctuations in literature. This could be due to the fact that some certified farms deduct the sustainably sourced FM, whereas there was no information available for non-certified farms or literature. The general decreasing trend of reliance on whole fish from wild stocks in recently collected data (on farms) relative to older data from literature could also be an explanation. These differences and uncertainties underline the importance of field studies on non-certified farms in order to evaluate the difference between certified and non-certified farms in more detail.

Certified farms had a slightly higher FCR than non-certified farms for both species considered. This could be a result of differences in data reporting methodology, or could reflect a potential trade-off between feed efficiency and changing feed composition to include lower rates of fish meal and fish oil.

This short data overview shows the variability between research and farming, underlining the importance to collect data in field studies. However, most of the data was reported to the ASC and not collected specifically for this purpose. Different methods can have a tremendous effect on the quality of the data. In the future, the ASC will need to conduct more field verification studies and thus work closer with both academia and farmers all around the globe.

APPLICATION OF EPIDEMIOLOGICAL MODELLING *OF Sparicotyle chrysophrii* TRANSMISSION IN *Sparus aurata* FARMS

Introduction

Mediterranean aquaculture production is known to have impacts on the environmental and marine habitat, impairing water and bottom sediment quality. Furthermore, rapid development of cage fish farming has been associated with propagation of infectious diseases, pathogens and parasites.

Sparicotyle chrysophrii is a common parasite of cultured Gilthead sea bream (*Sparus aurata),* an important species for Mediterranean aquaculture production. The parasite attaches on fish gills and can cause lethal epizootics in sea cages. Infections depend on environmental factors, in particular on water temperature (Antonelli et al., 2010).
Epidemiological modeling represents a valid tool to help fish farmers understand parasite transmission and evaluate possible control measures. To this purpose, in the following we analyze a novel epidemiological model of *S. chrysophrii* transmission.

Methods

We developed a novel stratified compartmental model where each compartment X_{ja} represents the abundance of fish infected with j juvenile parasites and a adults. The model further accounts for environmental abundance of eggs and miracidia, where the latter determines the force of infection, i.e. the rate at which parasite larvae attach to fish. The dynamics further accounts for egg production and hatching, parasite development, baseline mortality for parasites and fish, and parasite-induced fish mortality. Critical parameters controlling the progression of the disease are assumed to be temperature dependent.

We applied the model to data collected in six cages of a sea bream farm managed by Cromaris (Bisage, Croatia). A controlled experiment was run between February and November 2021 in which 30 fish were collected each month and, for each fish, all eight arc gills were examined to count the number of attached parasites.

We estimated model parameters in a Bayesyan framework, sampling the posterior distribution with a Markov Chain Monte Carlo algorithm. Specifically, the model estimates the temporal dynamics of the probability that a sampled fish hosts a certain number of adult parasites. The likelihood of a monthly sample is calculated assuming a multinomial distribution, where the event probabilities are estimated through the deterministic model simulation given a certain parameter set. We further included the total number of fish alive at any time in the determination of the likelihood.

Results

Results show that the model is able to reproduce the distribution of the number of parasites hosted by the sampled fish (Figure 1), as well as the temporal progression of the prevalence of infection (i.e., the number of fish hosting at least one parasite). Data shows that prevalence has a peak in August, after the period with the warmest water temperature, and then decreases.

Discussion and conclusions

We applied a novel epidemiological model to a dataset of *S. chrysophrii* infections collected in a sea bream farm. The model succeeds in simulating the effects of environmental factors (e.g., water temperature) on the infection dynamics. Posterior distribution of parameters shed insights on crucial process rates that control disease transmission. Future developments could involve coupling the epidemiological model with a fish growth model to simulate the effect of parasite burden on fish metabolism. The knowledge gained through this combined experimental and modeling exercise could be used in the future for designing and implementing strategies to control the spreading of the infection and, accordingly, to improve both fish health and aquaculture production.

AIR BASED CO2 MEASUREMENTS FOR INDUSTRIAL CARBON DIOXIDE DEGASSING UNIT AUTOMATION

K. Stiller*, J. Kolarevic, A. Meriac

Nofima AS, Sjølseng, 6600 Sunndalsøra, Norway
Kevin.Stiller@nofima.no

Introduction

The development of energy- efficient recirculating aquaculture systems (RAS) for Atlantic salmon is one of the main future goals of aquacultural engineering. RAS facilities are on its way to have more and more automated technologies. However, CO_2 degassing units normally are not regulated or automatised. They just running on full power even if they have strip out very little CO_2 from the production water. Energy prices increased a lot over the last years and an automation of CO_2 Degassing units could help to significantly reduce energy costs in fish production. Degassing performance can be measured through sensors and displayed on the operating computer of the control panel of the RAS unit. This could be used to regulate the fan, pump, and blower performance to transport the high CO_2 air more economically (save energy) out of the production facility. Dissolved CO_2 sensors have their limitations (low accuracy, pression and response time). However, it is possible to measure CO_2 directly in the outflowing air of the degassing unit. The air-based measurements can be a proxy for degassing performance. Air based non-dispersive infrared gas analysers are much faster, precise, and reliable and perhaps a good online control option for aquaculture CO_2 degassing units.

Material and methods

CO_2 removal in brackish and seawater RAS is theoretically less efficient compared to freshwater. We compared the degassing performance in fresh (0 ppK) and brackish water (12 ppK) at the Nofima Centre for Recirculation in Aquaculture (NCRA), Sunndalsøra on the main experimental degassing units (AquaOptima AS, Norway). A $CO_{2/}$Air water vapor compensated CO_2 meter (Li-850; LI-COR Biosciences, United States) was verified at the in- and out-flow of the degassing tower with high precision automated titration water-based carbonate data (TL7000; VWR International AS, Germany) and dissolved CO_2 measurements (OxyGuard International, Denmark). Dissolved CO_2 measurements (Oxyguard & TL7000) were done before the biofilter, after the biofilter and after the degassing tower. The LI-COR system (up to 2 measurements per sec) could provide fast, precise, and robust measurements in the air leaving the degassing units. Degasser design is system-specific and can vary in hydraulic loading rate, packing height and Gas:Liquid ratio. Therefore, degassed air CO_2 concentrations "needs to be calibrated" to the dissolved CO_2 levels in the water as a proxy for degassing performance (system-specific).

Results

As expected, removal of dissolved CO_2 from water and CO_2 increases in air leaving the degasser were proportional and no differences between salinities could be observed. In our system, "removing (delta- in and out- flow)" 1 mg L^{-1} dissolved CO_2 in water, increased air CO_2 "removal (delta out- and in- flow)" by about 52 µatm. Also as expected, CO_2 removal increased with an "absolute" increasing dissolved water CO_2 levels into the degasser from the fish tanks. In our system, an increase of 1 mg L^{-1} dissolved CO_2 out of the fish tanks into the degasser increased the "removal" CO_2 concentrations" in air by about 29 µatm. The air "removal (delta out- and in- flow)" values can be used to predict the incoming concentration of dissolved CO_2 into the degassing unit.

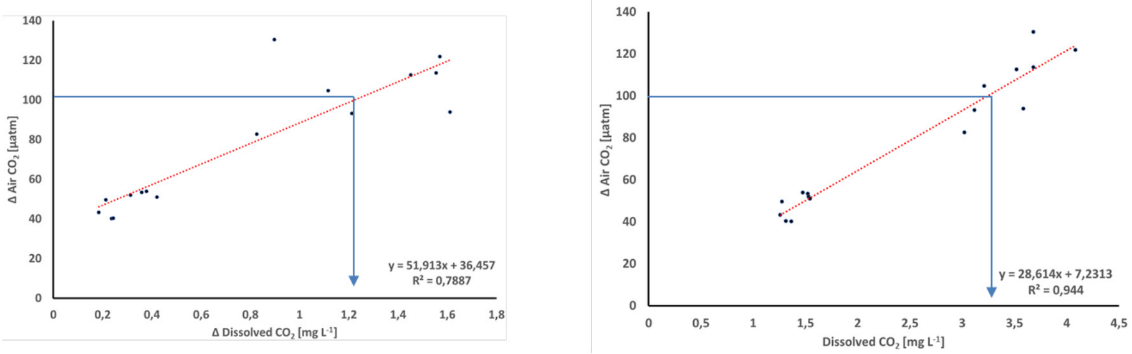

Figure 1: (A) Proportionality of CO_2 removal in water to air and (B) dissolved CO_2 concentration dependency of air CO_2 removal.

(Continued on next page)

Example

Under constant operating conditions, we observe an increase of 100 µatm in our off-gas. Using Figure 1 A, this corresponds to a CO_2 removal of about 1.2 mg L^{-1} in water. Using Figure 1 B, we estimate that our CO_2 concentration in water entering the degasser is about 3.2 mg L^{-1}. The calculated CO_2 removal rate is about 36% which fit perfectly with the manual measured data.

Discussion

Air based measurements showed a good correlation with dissolved CO_2 removal from water and allowed estimating dissolved CO_2 concentrations entering the degasser. Having online measurements in milliseconds of CO_2 concentrations in air could make the online LICORE unit reliable, and fast enough (which is a huge benefit compared to submerged dissolved CO_2 sensors) for controlling the degassing unit (blowers and pumps). In future automated CO_2 degassing unit controlled by online CO_2 measurements can likely contribute to energy savings in RAS production.

ALLOCATION OF ZONES FOR AQUACULTURE IN TUSCANY REGION: THE CASE STUDY OF FOLLONICA GULF

P. Stipa

Agroittica Toscana Soc. Agr srl, Italy
Email: p.stipa@agroitticatoscana.it

Introduction

A key bottleneck of marine aquaculture in Italy has been due to the lack of allocated space. This is recognized to be one of the most relevant constraints to limit the expansion of the mariculture industry (COM 2021/236 final). The process through which space is allocated to marine farms, Maritime Spatial Planning, has been defined by ISPRA and the Ministry of Agriculture through a technical manual (Marino et al 2020). Such process, although not yet mandatory, is applied by competent authorities to help identify Allocated Zones for Aquaculture (AZA), consequently allowing for the culture of specified fish and bivalve species, and the monitoring of environmental impacts within such zones.

The first fish farms cluster in Italy was established by the Municipality of Piombino within the gulf of Follonica, allocating an extensive area to multiple mariculture activities.

The area, as we know it today, has been established through the administrative decision Delibera Giunta comunale di Piombino n. 104 del 17/3/2013, a practice lacking a true scientific-based zoning process. Due to an extensive expansion of aquaculture within this zone from 2009 to 2018, this has created a hotspot of fish and bivalve culture, all one next to the other.

Materials and methods

The whole licensed AZA within the gulf is more than 16 mil m^2 wide; allocating 5.8 mil m^2 to fish culture and 3.7 mil m^2 to bivalve culture. The remaining 7.1 mil m^2 were identified by the municipality as safety and transition zones.

The boundaries of the zone run due north-south and east-west. $\Delta\omega$ 2', ie 3.7km, $\Delta\lambda$ 3.2', ie 4.5km.

Isobaths run along the coastline (West to South-East), with depths ranging 20 to 35 m. On the Northern part of the AZA the seabed consists of dead mattes of *P. oceanica* (approx. 20m), whilst more intermediate depths are characterized by a mud and silt composition. The deeper ranges of the seabed are composed of sand and mud.

Hydrodynamic forces guarantee optimal water circulation in the bay; currents are seldom less than 10cm/sec, and with wind driven swell occurring within the 1st, 2nd, and more predominantly 4th quadrant (Fig. 1).

Data on aquaculture facilities, such as number of farms, size, production data etc. were collected having direct field survey with fish and mussel farmers operating in the AZA (Table 1).

Results and discussion

The present study identifies the administrative process and technical decisions which have led to the current allocation and use of marine space within the bay.

Each concession license within the AZA has been classified and analyzed in terms of: distance from ports, bathymetry, interference with fishing and tourism related activities, as well as production potential.

A comparison between actual and potential or desired production scenarios has been carried out to estimate and forecast the potential environmental impact and carrying capacity of the AZA.

Dependent on the production output and site-specific parameters (depth, sediment composition, and hydrodynamic forces) for each farm, an environmental monitoring scheme has been developed in correspondence to the ISPRA, ARPAT, and ASC Guidelines.

Introduction and research question

Biosecurity is crucial for sustainable and safe aquaculture. Biosecurity entails a set of management measures to reduce the risk of transmission, development and spread of infectious diseases, between populations, production zones, means of transport, sites, and enterprises (Lillehaug et al. 2015). Deviations in biosecurity can be caused by limited knowledge, cost considerations, technology design, and increased professional and operational complexity (Larsen et al. 2020).

In Norwegian salmon farming, the smolt is essential. Actors within research, industry and government have urged for more knowledge about biosecurity, particularly for the smolt. A recent Norwegian study shows a great potential for infection control in the hatchery and wellboat operations, due to uncertainty associated with water quality, technical design and quality control (Larsen et al. 2020).

To improve biosecurity for the smolt, this research project will suggest measures for predictable and efficient water treatment and disinfection in RAS facilities (“recirculating aquaculture systems”) and smolt transport. The main study topics are microflora, technology, and operational routines. To find adequate measures, several methods will be employed, and the current presentation will report the results of the first step, namely a document analysis.

Method

This is an analysis of documents from the quality management systems of three Norwegian fishfarm and wellboat companies. Documents relevant for biosecurity have been selected, such as risk considerations, technical parameter settings, operational procedures, deviation reports, internal audits, shift schedules, etc. This document analysis is a supplement to the project’s main methods of microorganism sampling, analysis of technology design, and interviews and operations of operational routines. The presentation may give hints to tentative results from the other approaches too.

Background and earlier research

The transfer of microorganisms and infectious agents between fish populations and between systems has been a challenge for the aquaculture industry since its commercialization in the 1960s. Disease spread has been reduced through technological, organizational and biological advances such as vaccines, disinfection systems, hygiene routines, and combat zones for PD and ISA. A basis for increased biosecurity is to identify risk factors that can introduce infectious agents to a fish population and use the risk assessments to make – and follow – biosecurity plans (Lillehaug et al. 2015).

Transport of live animals is one of the most prominent risk factors for the spread of infectious diseases (Sommerset et al. 2021), and in aquaculture, wellboats are a significant route of infection (e.g. Murray et al., 2002). Nevertheless, there is still limited knowledge about infection in and from wellboats. Studies of the external hull and internal seawater systems have found multiple places problematic for access and cleaning (Cahill &Floerl 2019). Biosecurity on wellboats shall be safeguarded through e.g. technical standards, cleaning practices, and hygienic treatment of intake and discharge water from the vessels, but this is not done sufficiently today (Larsen et al 2020). It has previously been described that wellboats operate with small margins which can lead to shortcuts (Fenstad et al. 2008).

There has been a significant development with the use of recirculating aquaculture systems (RAS), which require new practices and knowledge about biosecurity and disinfection routines at hatcheries (Lazado &Good, 2021). Different facilities have different practices for production and disinfection, resulting in different microbiota composition at plants (Dahle et al., 2020; Dahle et al., 2021; Lazado &Good, 2021). In addition, there are major differences in mortality between hatchery facilities, which suggests an opportunity for improvement, e.g. through routines and technology (Tørud et al., 2019). Interview studies at RAS facilities, among others, have shown that employees consider some operational routines to be unwavering due to the plant’s design, but that many hatcheries still can improve their biosecurity routines (Tørud and Størkersen 2021). Larsen et al. (2020) urge for more knowledge so it can be possible to establish a best practice for RAS facilities.

(Continued on next page)

Results and conclusion

The aquaculture industry needs control of infectious agents and biosecurity. This document study shows how three Norwegian fishfarm and wellboat companies plan and control their procedures related to microflora, technology design and operational routines. The oral presentation will compare the companies' parameters and routines regarding for example filters, UV, washing and disinfection eliminate bacteria and viruses in RAS and wellboats.

DECISION MECHANISMS IN NORWEGIAN AQUACULTURE: COMPARISON BETWEEN CONVENTIONAL AND NEW PRODUCTION SYSTEMS

M. Thakur*, A. V. Strand

SINTEF Ocean, Postboks 4762 Torgarden, NO-7465 Trondheim, Norway
E-mail: maitri.thakur@sintef.no

Introduction

The Norwegian salmon supply chain represents a global food system with a complex logistics network taking feed inputs from one part of the world and distributing products to different parts of the world after processing them in various locations. Salmon aquaculture is also heavily influenced by political decisions in terms of regulation of where farm sites and slaughter plants are located and legislation regarding feeds and medication use (Ziegler, et al. 2012). Although, production volumes have been increasing over the past decades, further growth is expected to diminish due to biological boundaries with only a 3% annual growth rate from 2019 to 2023 (Hoel and Howell 2021). Production using the conventional open-nets pens is limited under the current licensing regime and this is where new production systems can offer various advantages.

Sustainable growth of the aquaculture sector also needs to consider synergies between competing interests, the development of entire value chain and the corresponding infrastructure requirements. The current regulatory framework applies mainly to the conventional production systems, there is an urgent need to develop regulations that are aligned with the development of technical innovations in the aquaculture industry. A comprehensive understanding of the impact of regulations on decision making in the aquaculture supply chain is still lacking. COMPAREIT project is funded by the Research Council of Norway and addresses how new production systems should be regulated, administered, and where they could be best located, which are highly relevant questions for a sustainable development of the industry that safeguards other societal interests. This study focusses on mapping the key decisions in aquaculture production and the regulations that affect them.

Methods

The farming stage in the Norwegian aquaculture supply chain is particularly affected by regulations, volume constraints and is in need of technical development to increase production volumes in a sustainable manner (Ernst & Young 2021). This study investigates key decisions in the farming stage of the Norwegian aquaculture supply chain. The work focusses on all decision phases including strategic, tactical and operational planning for conventional and new production systems. Most key decisions are affected by regulations which are identified and compared for the conventional and new production systems. The work is based on a review of existing literature supplemented by interviews with aquaculture experts including researchers at SINTEF Ocean and industry partners in COMPAREIT project.

Results & Discussion

The Directorate of Fisheries, the County Authority, the County Governor, the Norwegian Coastal administration and the Norwegian Food Safety Authority are the key decision makers that govern the aquaculture sector by granting production licenses and regulating production locations and production volumes. The County Authority grants the aquaculture licenses and takes advice from Directorate of Fisheries, municipalities based on the area plan, the Norwegian Food Safety Authority based on the Animal Welfare Act and the Food Act, the County Governor based on the Pollution Act and Norwegian Water Resources and Energy Directorate based on the Water Resources Act if there are outtake of freshwater in case of land-based systems. Compared to conventional sea-based production systems, the regulations for new production systems are lacking.

To achieve its growth targets in a responsible manner, the Norwegian aquaculture sector must consider the multiple dimensions of sustainability in its regulations and decision-making processes by individual companies and not merely a branding exercise to gain consumer confidence. For instance, land-based production systems can potentially eliminate the negative impacts on wild salmon and reduce the overall impact of the salmon supply chain as production can take place close to major consumer markets in turn reducing emissions linked to transport to global markets, a significant portion of which takes place by air-freight (Thakur, Johansen, et al. 2020). On the other hand, land-based farming could have a negative impact on fish welfare because fish in land-based tanks is more densely packed compared to the 25.0 kg/m³ rule that applies for sea-based farming. The trade-offs between various dimensions of sustainability are, therefore, an important consideration in decision making and design of future regulatory frameworks.

Further work in COMPAREIT will focus on analysing the infrastructure requirements to achieve sustainable future production growth through implementation of new production systems using the input-output modelling approach. Future scenarios will be developed taking into consideration the current and future anticipated regulatory framework.

START-UP AND PERFORMANCE OF A DENITRIFICATION BIOREACTOR IN A COMMERCIAL SMOLT PRODUCTION FACILITY (RECIRCULATING AQUACULTURE, AKVA-GROUP) IN MID NORWAY

S. M. Strauch*, I. Henry, K. Kjøk, H. K. Tangen, S. Tømmerås, W. Koppe

AKVA group ASA, Plogfabrikkvegen 11, 4353 Kleppe, Norway
E-mail: sstrauch@akvagroup.com

Introduction

To provide capacity for the increasing production volumes of Atlantic salmon smolt and post-smolt in Norway, land-based recirculating aquaculture systems undergo rapid technological development and upscaling. To meet economic and environmental expectations, fresh-water usage and emissions of NO_3-N and PO_4-P must be minimized. The zero-water concept (ZWC, AKVA Group, Norway) allows the removal of P by precipitation, and the removal of N by heterotrophic microbial denitrification. While the precipitation of P is an instant and easy to control chemical reaction, the stable control of the anoxic microbiological denitrification is more complex. To achieve a full performance of the facility at an early stage, protocols for rapid start-up and operational management for the denitrification must be followed. While literature describes start-up and operation of lab-based reactors, protocols for the start-up at commercial scale and (low) temperatures around ~13°C are lacking (Oboody, 2017). To assist RAS operators with these challenges, we provide a protocol that allows for the stable denitrification within 10 weeks in maturation.

The protocol was applied at a commercial smolt production facility in Mid Norway. This study reports the performance of the denitrification bioreactor during start-up under controlled conditions, as defined by AKVA group's standard operating procedure (SOP). Solutions for minimizing the risk for H_2S formation are given.

Materials and Methods

The RAS bioreactor is part of a smolt production facility in Mid-Norway. The system is characterized by the following key performance indicators: Max feed rate = 3.2t/d, operating temperature = 13-16°C, max salinity = 6ppt. The removal of solids is achieved by mechanical drum filters, the nitrification by fixed bed bioreactors with semi-automated cleaning technology (SAC, bio-media is circulated by water injectors), ozone is used to decrease turbidity, and degassing of ozone and CO_2 is achieved in a degassing tank.

The denitrification fixed-bed-bioreactor has the following measures: $l \times w \times h = 12.7 \times 2.2 \times 4.3\text{m} = 120\ \text{m}^3$ total volume. The relative volume of the fixed-bed bio-media account for 50 %, providing 60 m^3 of total bio-media volume. Multiplied with the specific surface area of the bio-media (800 m^2/m^3), a total surface area of 48,000 m^2 is available. The maximum flow rate is 100 m^3/h, accounting for a hydraulic retention time (HRT) of ~45 min and the treatment of ~35 % RAS-volume/d. Intake water for the denitrification bioreactor originates mainly from the fish tanks, and to smaller extend from rinsing water from the drum filters. The fixed-bed bio-media are connected to a semi automated cleaning system, consisting of 6 water injector pumps which facilitate continuous circulation of the bio-media. The start-up of the denitrification bioreactor was on 14th of Jan 2022. To create low oxygen concentrations, the HRT was was increased from 45 min to ~3h. To provide for chemical oxygen demand (COD), methanol was injected via an peristaltic pump to achieve a target ratio of NO_3-N:COD = 1:4.5 (stoichiometric optimum for complete denitrification with methanol). Given a background COD of ~100 mg/l, and a NO_3-N concentration of ~70 mg/l, 200 mg/l COD was supplemented. Water samples at the inflow and outflow of the reactor were analysed for dissolved oxygen, NH_4-N, NO_2-N, NO_3-N and COD twice daily. The first sampling took place during the first 10 days after start-up (14-20 Jan 2022), at high stocking densities (~180t total biomass) and feed input (~2.6 t/d), so elevated levels of nitrate are to be expected. A second sampling was taken approx. 1-month after start-up (08-11 Feb 2022). This sampling followed a vaccination event, with high water exchange and low nitrate levels to be expected. A 3rd sampling was taken 68 days after start-up (23 Mar 2022). This event followed a cleaning of the reactor 4 days earlier.

(Continued on next page)

Results

On day 1 after start-up, oxygen values in the outflow of the reactor remained well < 1mg/l. The average level of NO_3-N entering the reactor was ~67 mg/l. On day 1, about 10% of the NO_3-N entering the reactor was removed. The removal increased to 26% relative to the input on day 10 after start-up (Figure 1).

A 2nd sampling was carried out on day 27 after start-up. NO_3-N levels entering the reactor were ~32 mg/l and decreased to ~10 mg/l in the outflow, so by ~69% relative to the inflow values. A 3rd sampling was carried out on day 68 after start-up, NO_3-N levels entering the reactor were ~65 mg/l and decreased to ~10 mg/l, so by ~85% relative to the inflow values.
We expect that under decreased HRT (45 min/h), nitrate-N levels will be maintained below 75 mg/l, with substantially less water reuse.

Discussion and Conclusions

We found, that when HRT and COD are adjusted according to our recommended values, the denitrification increases rapidly after just a few days. According to project partners (R. Netzer, 2022), denitrifying microorganisms are detectable also inside the nitrification bioreactor. Therefore, facilitating optimum conditions for these bacteria inside the denitrification bioreactor will result in rapid colonization and reactor performance, hence conversion of NO_3 to N_2 gas. This was obvious in the increase of nitrate removal over the first 10 days of sampling.

The second sampling at low nitrate levels (day 27) revealed that this process is also strong at low levels of nitrate (~30 mg/l NO_3-N).

Almost complete denitrification was detected at day 68 post-start (3rd sampling). We therefore expect that at the 4th sampling in May 2022, when stocking densities, feed input and nitrate levels are high, and HRT at normal operational levels (45min/h), the performance of the reactor will allow maintaining nitrate levels below the maximum tolerable level of 75 mg/l NO_3-N.

The installation of an ORP-monitoring system (connected to SCADA) allows the precise adjustment of COD to achieve good denitrification, but also to decrease the risk of H_2S formation.

MULTI-USE SYSTEMS – A SOLUTION TO COMPETING INTERESTS IN OFFSHORE SPACE? FIRST LESSONS LEARNED FROM THE GERMAN NORTH SEA PILOT

E. Strothotte*, T. Staufenberger, J. Pforth

*R&D Centre Kiel University of Applied Sciences GmbH, Schwentinestr. 24, D-24149 Kiel
Email: eva.strothotte@fh-kiel-gmbh.de

Introduction

The competition for marine space is a well-recognized challenge. The climate change commitments set by governments - triggering the development of renewable energy production-, the request for food and resource security - driving research for marine biomass production-, and a growing tourist sector next to societal challenges, increase the transformation of the marine realm. Multi-use offshore projects are experiencing a wide variety of challenges due to their different requirements for licensing, different needs in logistics and operational intensity. Particularly when extreme exceptional situations become a permanent factor excellent communication and intensive cooperation between the users and all those involved is essential. Experts are urgently required in all relevant areas, such as for the organisation of specified logistics, for specialized installation procedures, for complex legal contexts and pre-testing of materials and technologies for a successful functioning of the multi-use system.

Thus, the UNITED (Multi-**U**se offshore platforms demo**N**strators for boost**I**ng cost-effec**T**ive and **E**co-friendly pro**D**uction in sustainable marine activities) project investigates the technical, regulatory, economic, social and environmental viability of multi-use systems, which imply a combination of offshore wind farms with complimentary marine activities. Until today, there are only few successfully implemented multi-use systems, in spite of the encouragement of politicians and scientists. Hence, the project aim is to raise the technological, commercial readiness and innovation capacity of selected multi-use solutions, while reducing associated risks through the development of demonstration pilots in real life environment. This way, additional benefits to multiple sectors could be generated, infrastructural synergies could be created and the competitiveness of maritime businesses and economic opportunities could be increased within limited marine areas. In pursuing a more efficient use of ocean space and resources, synergetic effects shall be exploited, while reducing the overall environmental impact of a given use by combining it with another profitable activity.

This paper takes a special look at lessons learned from the German pilot. Experienced challenges and potential ways of solving unforeseen problems arising from the still largely unexplored multi-ise concept are presented.

Materials and Methods

In order to assess the benefits of offshore multi-use activities, five demonstration pilots, are set up in the North-, the Baltic- and the Mediterranean Sea, of which four pilots address the combination of offshore wind farms with aquaculture or tourism. The German pilot combines offshore wind energy research and aquaculture at a very exposed location (45 nautical miles from the shore), and thus reflects a situation where remote operational logistics are essential.

Major challenges had to be overcome due to the underdeveloped or missing framework conditions and unforeseen crises like COVID19 or a war in Europe. Problems arose because of restrictions affecting the supply and service industries. The pressure grew to focus on automation, alternative logistics, additional training and capacity building of personnel as well as health and safety issues.

The operational offshore phase of the project builds upon these developed strategies, which have only partly been tested so far. This phase of the project is ongoing and provids most valuable information on possible solutions in a still low developed area, as there are no practical examples from which experience can be gained. Limited experience of successful MUCLs under these new conditions requires research inputs to find new solutions to arising questions in support of the development:

- What reorientation of which industry sectors is necessary to implement the idea of offshore multi-use in practice?
- What innovative approaches are needed to integrate an additional user to an already established offshore project?
- What information must be available to potential partners for the successful implementation of new multi-use initiatives?

(Continued on next page)

Results

The planning of this project was done at least a year before the unexpected outbreak of COVID19. Within weeks after project approval these plans and some objectives were at risk and became redundant due to the outbreak. Underdeveloped or unavailable but existentially needed service for various areas from infrastructure to technical safety standards to legal and environmental expertise led to the development of diverse alternatives at the onset of the project. Several properly planned activities ready for timely implementation, had to be interrupted /postponed and subsequently to be cut short due to the need of implementing new structures. Alternatives had to be found to serve the original plans for data acquisition, particularly for monitoring instrument and their capabilities. Fortunately, the existence of a broad stakeholder register turned out to be most valuable to foster consensus building and gain improvement-oriented inputs. Thus, new adapted pilot solutions in one place mandatorily required a close communication not only within the pilot, but also between affected parties and this for the remainder of the project.

The pandemic demanded a new way of training and capacity building of personnel, creating teams with broad skills rather than single specialists. The operational phase teaches a lot of lessons learned to determine the future-oriented needs for a successful multi-use offshore operation. These results so far were not only used to educate internal personnel but also to facilitate a trans-disciplinary knowledge exchange of best practices from different fields, and to combine skills in order to be prepare the way for future operations.

Conclusion/Outlook

Risks and challenges of multi-use systems strongly vary between activities and sites, requiring adjusted planning and consideration of individual environmental, socio demographic and geographic conditions. However, when UNITED proves the success of multi-use activities that are ecologically, legally, socially and economically feasible in offshore wind farms, the way for future implementation of multi-use and co-location systems on a broader scale is paved. The need for time to exchange all available information and to cope with reservations and concerns should be considered in planning of future projects. The pandemic situation demanded an even broader and more flexible approach than ever anticipated. Documenting these lessons is strongly recommended as additional benefits to multiple sectors will be generated and diverse synergies are already created. If these will be implemented wisely, multi-use may support the EU Blue Growth strategy in mitigating the competition for marine space and promoting innovative economic uses and sustainable ecological processes.

This Project has received funding from the European Union's Horizon 2020 Research and Innovation Programme under Grant Agreement no 862915.

NEONICOTINOIDS AND MARBLED CRAYFISH (*Procambarus virginalis*): CHRONIC AND ACUTE TOXICITY OF INSECTICIDE AND ITS ACTIVE SUBSTANCE

Introduction

Neonicotinoids have gained a strong position in the insecticide market over the past thirty years. Their importance lies mainly in their effectiveness on various invertebrate organisms. In both insects and mammals, neonicotinoids act as agonists of nicotinic acetylcholine receptors (nAChRs). Due to the different structures of nAChRs, they show higher selectivity toward invertebrate receptors than vertebrates (Morrissey et al., 2015; Tomizawa and Casida, 2005). Due to the low toxicity of neonicotinoids to standard test species, they were not expected to significantly impact the aquatic ecosystem until later studies showed that aquatic invertebrates, especially insects, are much more sensitive to neonicotinoids (Morrissey et al., 2015; Sánchez-Bayo et al., 2016).

A suitable indicator species for toxicity tests is the marbled crayfish (*Procambarus virginalis*). Its breeding is undemanding; it has a fast life cycle, and, thanks to parthenogenic reproduction, it produces genetically identical offspring. Crayfish are suitable for laboratory experiments, given that they meet the 3R concept (Replacement, Reduction, Refinement). In crayfish, it is possible to observe changes in the organism at the molecular level due to the action of pollutants.

Material and methods

The pure insecticide acetamiprid (99 %) and the insecticide Mospilan 20SP, which contains 20.2 % of the active ingredients acetamiprid, were chosen to assess the effect of neonicotinoids on marbled crayfish. Adult marbled crayfish were used for acute and chronic toxicity tests.

The acute toxicity test on crayfish was performed according to OECD methodology no. 203 (OECD, 2013) with modifications for crayfish by Velíšek et al. (2013). Seven concentrations were used to test pure acetamiprid and eight to Mospilan 20SP. Each concentration was performed in duplicate. For acute toxicity tests, 180 individuals were used in total. Acute lethal toxicity of acetamiprid and Mospilan 20SP was assessed by the number of crayfish dying at individual test concentrations over a time period of 24 h, 48 h, 72 h, and 96 h median lethal concentrations (LC0, LC50, LC100). Lethal concentrations were determined by linear regression and probit analysis with a confidence interval of 95 % using the EKO-TOX program (v. 5.2, INGEO Liberec).

Based on the results of the acute toxicity tests, a chronic toxicity test was performed on crayfish. The crayfish were exposed to the effect of two different concentrations of the test substances (acetamiprid and Mospilan 20SP) dissolved in water for 20 days; after the exposure, the crayfish were left in pure water for another 10 days. All experimental groups were performed in two repetitions. A total of 160 crayfish were used. Tested concentrations were determined based on acute tests as 0.1 % and 1 % detected 96hLC50. Tissue samples for further analysis were taken for 10 and 20 days of exposure to the test substances and after 10 days of depuration. From each tested group, six individuals were always selected, from which a sample of haemolymph and tissues - hepatopancreas, muscle and gills - were taken after killing.

Biochemical analysis of proteins, lipid peroxidation (LPO), glutathione S-transferase (GST), reduced glutathione (GSH), catalase (CAT) and superoxide dismutase (SOD) was performed on the tissue samples.

(Continued on next page)

Results

Acute toxicity (96hLC50) of acetamiprid was 0.8 mg.l^{-1} and of Mospilan 20SP 2.71 mg.l^{-1}. Based on acute toxicity tests was found the theoretical acute toxicity of Mospilan (96hLC50 = 4.0 mg.l^{-1}). According to the theoretical toxicity of Mospilan, especially at the beginning of exposure (48hLC50 = 34.7 mg.l^{-1}; 48hLC50 Mospilan = 10.73 mg.l^{-1}; 48hLC50 acetamiprid = 6.94 mg.l^{-1}), can be consider that additives contribute more significantly to the toxicity of Mospilan than the active substance acetamiprid alone.

Acetamiprid and also Mospilan affect levels and concentrations of oxidative stress and antioxidant biomarkers. Significant changes (p<0.1 and p<0.5) in tissues of marbled crayfish from acute toxicity tests were observed at concentrations of tested substances 0.5 mg.l^{-1}. In tissues from chronic exposure, significant changes were observed at concentrations corresponding to 0.1 % (acetamiprid) and 1 % (Mospilan) of 96hLC50.

Conclusion

The toxicity of neonicotinoids varies for different species. High differences are shown, especially between invertebrate and vertebrate organisms. The fact that standard test organisms are relatively resistant to their effects also contributed to their worldwide spread.

The marbled crayfish, as a representative of invertebrates, appears to be a suitable organism for toxicity testing. It is a relatively sensitive species. When using it in toxicity tests, evaluating several parameters, such as changes in behaviour and mortality, is possible. From tissue samples is possible to evaluate changes in the levels and concentrations of antioxidant biomarkers and oxidative stress biomarkers. It is also possible to evaluate biomarkers contained in haemolymph and histological changes in tissue samples such as muscles, gills or hepatopancreas.

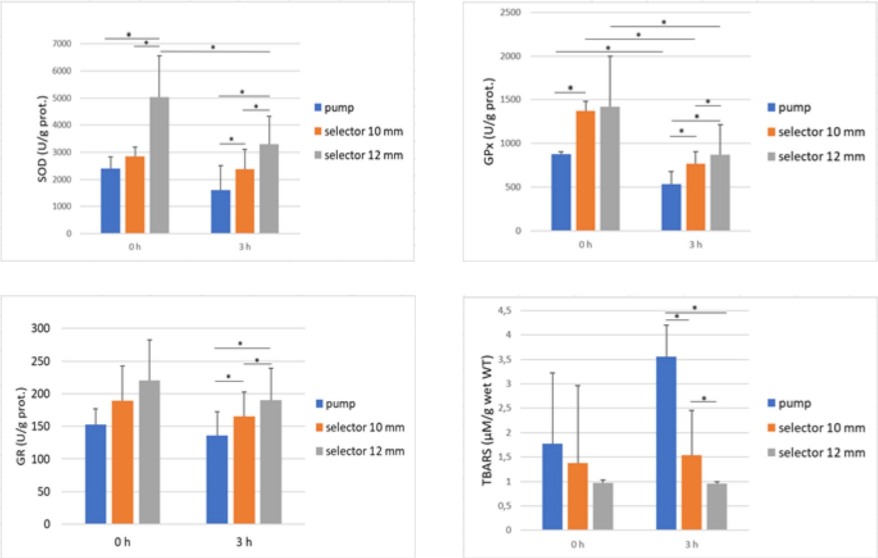
Introduction

In recent decades, the population of small pelagic fish such as sardine (*Sardina pilchardus*) has declined in the Mediterranean. In order to conserve fish stocks, various fishing techniques are being developed. One of them is the return of live, unwanted fish to the sea. However, the crowding in the purse seine, catching and handling onboard can expose fish to stress that affects their welfare, health and ability to survive after release (Marçalo et al., 2008; Waley et. al., 2021). Stress response of fish to commercial fisheries are poorly studied. Therefore, the objective of this study was to evaluate antioxidative defense and lipid peroxidation in sardine gills to detect early stress response during fisheries that use onboard pumping techniques in combination with fish selection to separate and return of unwanted fish to the sea.

Materials and Methods

A total of 160 live sardine (mean total length 138.20 ± 7.81 mm, mean weight 18.41 ± 3.43 g) were sampled during a commercial fishing by purse seine in the central Adriatic Sea. Fish was brought on board using the fish pump (Faivre, France) instead of handling them manually. Hauling time was around 90 to 115 min while the transfer period (by pump) lasted 10 to 30 min. After pumping fish were selected through a selector (selection grid 10 mm and 12 mm) and placed into 400 L tanks (70 fish/tank). Fish for analysis were collected immediately and 3 h after pumping and selection procedures. Gill samples of each fish were homogenized in phosphate buffer (pH 7.4, PBS, Sigma), and centrifuged at 9,000x *g*/4^{o}C/10 min. The antioxidant enzyme activities and lipid peroxidation were measured from supernatants. The activity of superoxide dismutase (SOD), glutathione reductase (GR) and glutathione peroxidase (GPx) was determined by Randox commercial kit (Ireland) and analyzed on the biochemical analyzer ARCHITECT c4000 (Abbott, USA). Lipid peroxidation, expressed as thiobarbituric acid reactive substance (TBARS) was measured in accordance with Babić et al. (2016) using the plate reader (Infinite M200, Tecan). Statistical analyses were performed using SigmaStat and SigmaPlot Statistical software version 11.0 (Jandel Corp., San Rafael, USA). A $p < 0.05$ was regarded as statistically significant.

Figure 1. Antioxidant enzyme activities and lipid peroxidation levels in sardine gill tissue immediately (0 h) and 3 h after pumping on board and pumping combined with selection through grid 10 mm and 12 mm. Values are means ± S.D. The asterisk denotes a significant difference between groups ($p < 0.05$).



(Continued on next page)

Result and Discussion

The effects of fishing operations on antioxidant enzyme activities and lipid peroxidation are presented in Figure 1.

Significantly higher SOD and GPx activities were recorded in fish sampled immediately after pumping combined with selection through the grid of 12 mm than in other groups. Higher but not significant GR value was also recorded in the same group. Three hours after fishing, decreasing SOD level was significant only in fish pumped and selected through 12 mm grid while GPx activity significantly dropped in all groups. GR activity was also decreased but not significantly. Opposite to antioxidant enzyme, TBARS levels were lower immediately after capture than 3 hours later in all groups. However, significant increase was noted only in fish subjected to pumping procedure only. The obtained results demonstrate that fish transferred from purse-seine onboard and returned to the sea by pump induce less damage to the fish as they carry a mixture of fish and seawater that protects the fish from shocks. Additional selection through selector with different grid size could help to release unwanted sardine to the sea but induces higher level of stress. However, decrease in enzymatic activity three hours after capture indicates that the fish gills could recover after returning to the sea.

Conclusion

Fish welfare is affected by commercial fishing. Improvements in commercial fishing practices could increase chances of survival of fish that are returned to sea.

THE MICROBIOTA KNOWS: HANDLING-STRESS AND DIET TRANSFORM THE MICROBIAL LANDSCAPE IN THE GUT CONTENT OF RAINBOW TROUT IN RAS

Marvin Suhr[*], Finn-Thorbjörn Fichtner-Grabowski, Henrike Seibel, Corinna Bang, Andre Franke, Carsten Schulz, Stéphanie C Hornburg

[*] Institute of Animal Nutrition and Physiology, Christian-Albrechts-University Kiel
Hermann-Rodewald-Straße 9, 24118 Kiel, Germany
Email: suhr@aninut.uni-kiel.de

Background
The aim of the present study was to characterize the effects of handling stress on the microbiome in the intestinal gut contents of rainbow trout (*Oncorhynchus mykiss*) from two different breeding lines fed with a plant-based diet. Two experimental diets were provided for 59 days to all female trout and half of the fish were shooed with a fishing net twice per day to induce handling-stress (groups 0 and 1) in a fully recirculating aquaculture system (RAS). Experimental diets were formulated according to commercial trout diets differing in fish meal (35 % diet F, 7 % diet V) and plant-based proteins (47% diet F, 73% diet V).

Results
No differences in performance parameters were found between treatment groups. By using 16S rRNA amplicon sequencing of the hypervariable region V3/V4 we examined the microbial community in the total gut content of fish at the end of the trial. We discovered no significant differences in alpha diversity induced by one of the two factors within both trout lines. However, the microbial composition is significantly driven by an interaction of stress and diet in gut contents of trout line A. Otherwise, in trout line B the main factor affected the microbial composition was stress. The communities of both breeding lines were predominantly colonized with bacteria from the phyla *Fusobacteriota, Firmicutes*, *Proteobacteria*, *Actinobacteriota* and *Bacteroidota*. The most varying and most abundant taxa have been found to be *Firmicutes* and *Fusobacteriota*, where at the genus level *Cetobacterium* and *Mycoplasma* are key components in terms of adaptation.

Conclusion
We conclude, that microbial gut composition is highly influenced by stress which is presupposed by diet formulation and trout origin but constant microbial diversity and performance parameter.

APPETITE FOR PRODUCTION – FEEDING AND DIGESTION STUDIES IN THE EMERGING SEA CUCUMBER SPECIES *Parastichopus tremulus*

Jan Sunde* and Gyda Christophersen

Møreforsking AS, Ålesund, Norway
Post Box 5075, N-6021 Ålesund, Norway
jan.sunde@moreforsking.no

Introduction

The red sea cucumber, *Parastichopus tremulus*, is an emerging aquaculture candidate species which in recent years has drawn attention from fishers, farmers, and traders (Landes et al. 2019; Christophersen et al. 2021, 2022; Schagerström et al. 2022). The species may be suited for cultivation all along the Norwegian coast, as its geographical distribution in the north-east Atlantic is from the Barents Sea in the north to the Canary Islands in the south. Deposit feeding species such as *P. tremulus* are able to ingest and utilise nutrients from particulate organic matter and have therefore been suggested for inclusion in integrated multi-trophic aquaculture (IMTA) systems. It has been suggested that particular waste (sludge) from fish farms could be suited as feed or a feed ingredient for sea cucumber aquaculture. The Norwegian salmon aquaculture production annually results in an estimated 500 000 tonnes of sludge (Aas 2021). This nutrient-rich side stream consists of uneaten feed and faeces, of which only a minor fraction currently is collected and used for low-value applications. There is an increased interest in valorising this waste stream. Performance of *P. tremulus* in aquaculture is unknown and species specific biological knowledge gaps need to be filled for a potential industry to succeed. In particular, little information exists on its nutritional requirements and efficiency in extracting organic matter from different feed sources (Hauksson 1979). The aim of this study was to assess the feasibility of formulating sea cucumber feeds from salmon aquaculture sludge.

Methods

This study was part of the research project "Emerging species for sea cucumber aquaculture", investigating the aquaculture potential of several tropical and temperate species from Norway and South Africa. The individuals used in the experiments were obtained from the fjord system around **Ålesund** in Møre and Romsdal county in the north-western part of Norway (62°N-6°E). Before the trials, the animals were acclimated in flow-through tanks supplied with unfiltered seawater from 40 m depth. For the feeding trial, nine sea cucumbers (mean weight 98.7 ± 76 g) were held individually in flow-through aquaria (25 L) supplied with filtrated seawater (1 **µ**m). Three different experimental feed mixes were given in a rotating experimental design. Sea cucumbers in three aquaria (n=3) where given the same feed for one week, and at the end all individuals had been presented with all feeds. The experimental feeds were composed of sand (0-1 mm) mixed with different ratios of either dried *Sargassum thunbergii* powder, a common ingredient in feed for Asian sea cucumber species, or dried aquaculture sludge acquired from a land-based Atlantic salmon smolt facility. Two experimental feeds were composed with sludge (50 and 75 % (v:v)) and dried *S. thunbergii* (50% v:v) was used as control. The sludge raw material contained 27.9 % protein, 4.4% lipids, 33.2% carbohydrates and 22.2 % ash with an energy content of 953 kJ/kg. The *S.thunbergii* powder was lower in energy (551 kJ/kg), protein (10.2%) and lipids (0.4%) but higher in carbohydrates (39.7%) and ash (41.8%). Both sludge feeds were added 1% guar gum as a binder to prevent leaching of nutrients to the water. All feeds were supplied in excess (30% dry weight/wet weight animal/week) and faeces collected daily. After 7 days of collecting faeces, remaining feed was removed from the tank and animals starved for 72 h before the entire sequence was repeated with a new feed. Feed and faeces samples were analysed for total organic matter (TOM) by drying and ash weight determination. These data were used to calculate daily ingestion rates (DM day^{-1}) and organic matter extraction efficiency (TOM %).

Results

The TOM content of the feeds were 13.4 ± 0.5 % (control), 24.6 ± **0.3** % (50% sludge) and 44.1 ± 0.5 % (75% sludge). Feed intake (% DM feed × WW animal $^{-1}$ day^{-1}) was significantly higher for the control feed (0.85 ± 0.62 %) than for either of the experimental feeds (0.02 ± **0.01 % and** 0.04 ± **0.04** %, respectively). On average, digestibility was estimated to 32.5 % (control feed), 29.6 % (50% sludge) and 57.8 % (75% sludge), and large individual and day-to-day variation was seen.

(Continued on next page)

Discussion/Conclusion

In a circular economy perspective, the utilisation of aquaculture sludge as feed for sea cucumbers is an attractive concept. Our results indicate that digestibility of sludge in *P. tremulus* is high, suggesting that it could have a potential application as an ingredient in feeds for sea cucumber aquaculture. However, additional research is needed on its long-term effects on growth and health parameters in *P.tremulus*.

Unfortunately, since regulatory restrictions currently prohibit the use of aquaculture sludge as feed for animals intended for human consumption, legislation needs to change to make this concept feasible in the future. Caution should also be taken regarding potential accumulation of toxic and undesirable substances in the sludge. A step-by-step approach to understand the requirements of the *P. tremulus* in captivity is ongoing, but much more knowledge is needed to establish reliable procedures for aquaculture production. Biological and technological constraints still hinder the development of large-scale aquaculture production of *P. tremulus*, and substantial research is needed on the areas of reproduction, nutritional requirements, and water quality.

TOWARDS HUMANE SLAUGHTERING OF SNOW CRAB (*Chionoecetes opilio*)

R.A. Svalheim*, E. Grimsbø and B. Roth

Nofima AS, Muninbakken 9-13, Breivika, 9291 Tromsø
E-mail: ragnhild.svalheim@nofima.no

Introduction

The snow crab fishery takes place in the Barents Sea far from land and therefore majority of the crabs are slaughtered on board the fishing vessels. A common slaughter method is the use of a splitting machine. This machine works by fixating the crab's walking legs and claws and flipping off the carapace before splitting the crab in two using either a knife blade or a water jet. Despite the widespread use of this method, there is little evidence as to whether this renders the crab unconscious, or if there could be alternative methods that may be more humane. In our study we aimed to investigate three different slaughter techniques (chemical, mechanical and electrical) and assess the welfare using behavioural and neurological (EEG of thoracic ganglion) measurements to examine response and loss of consciousness and death.

Materials and methods

Three slaughtering techniques were tested; chemical, mechanical and electric. The chemical method was injecting saturated potassium chloride (KCl) directly into the heart using a syringe. Welfare was evaluated by scoring responsiveness of eyes, antenna, mandibula, chelae, walking legs, claw and tail along with EEG. The mechanical method was splitting the crab in two using a large kitchen knife. Welfare was evaluated as above. The electric stunning was carried out using a dry stunner 50 Hz, 220 V AC. The crab was placed on a metal plate and the electrodes were placed either on the carapace or fixated on the legs to simulate the splitting machine onboard fishing vessels.

Results

Of the three methods, correct splitting gave what appeared to be a quick epileptic seizure followed isoelectric line indicating a cessation of nerve signa i.e. death. However, if the splitting was only slightly off the middle, signal would continue, even when the crab was non responsive during the behaviour tests. KCl had varying results from fast cessation of signal to continuing signal until euthanasia. Eyes, antenna, mandibula, chelae, walking legs, claw and tail were all negative on the responsiveness test, but EEG could still sometimes show signals during the test. Electrical stunning also gave epileptic seizure, but some individuals appeared to regain a "normal signal" after 3-4 minutes which coincided with increased response to stimulation, whereas other did not regain either normal signals or responsiveness. With electric stunning there was in general good correlation between behavioural response during stimulation and increased amplitude and frequencies of signal measured by EEG.

Conclusion

The preliminary data indicates that here is not always a good correlation between behavioural responses and neural activity (indication of potential consciousness) during slaughter of snow crab when using splitting or injection of KCl. Of the three methods, splitting and electrical stunning appears to be the most promising. We propose a combination of the two, - a stun splitter, to be a potential new and humane method for slaughtering snow crabs.

INVESTIGATION OF LIFE-HISTORY TRAITS FOR *Ophryotrocha craigsmithi*: IMPLICATIONS FOR ITS ROLE IN INTEGRATED MULTITROPHIC AQUCUALTURE SYSTEMS

S. G.B. Svensson, *H. Jansen, *T. Strohmeier, *H. Sveier

University in Bergen, Institute of Marine Research, Bergen, Norway
Email: signe.svensson@leroy.no

Introduction

High Densities of the deep-sea polychaetes belonging to the genus Ophryotrocha sp. have repeatedly been observed to colonize and feed on aquaculture waste accumulating under salmonoid fish cages in both Norway (Hansen et al., 2011, Eikje, 2013, Brennan, 2018) and Canada (Salvo et al., 2015, Armstrong et al., 2020).

There is an increasing interest in integrating these polychaetes in circular production systems for the mitigation of organic fish-waste and for the future production of a new aquaculture feed ingredient (Nederlof et al., 2019, 2020). Information regarding life-history traits are essential for the successful integration of these polychaetes and has until now been undescribed for one of the main candidate species in Norwegian waters, *Ophryotrocha craigsmithi*. Information about growth, fecundity and larval development provide elements necessary for more refined estimates of bioremediation potentials performed by populations of polychaetes colonising benthos under fish farms. In addition would knowledge about population turnover for *O. craigsmithi* be important for future harvesting strategies. Here we present life history traits for the polychaete species *O. craigsmithi*.

Materials and methods

Collection

Polychaetes were collected under an aquaculture farm at approximately 200 meters depth outside the west coast of Bergen, Norway. For this equipment developed to both attract and facilitate the establishment of epibenthic polychaetes where used. *O. craigsmithi* was then successfully reared in the laboratory facility for approximately five months.

Growth

Polychaetes were held in flow-through tanks with temperature and salinity (~ 8-9 °C and 34-35 ppm) similar to their natural habitat. Holding tanks were sampled for individuals used in a growth experiment with the aim to determine growth throughout the life cycle of *O. craigsmithi*. For this 3x3 groups of cohorts representing small, medium and large sized individuals were divided in to separate 8,5 L flumes and fed ad libitum with fish pellets. Feed was provided in excess to resemble fish farm conditions, where food is not assumed to be a limiting factor. Chambers were photographed on a weekly basis and images were later analysed in order to extract survival and length data of polychaetes. Photographing chambers allowed gentle handling of polychaetes and reduced stress to a minimum.

Fecundity

The total fecundity of *O. craigsmithi* was measured through the process of induced spawning by increasing water temperature in known volumes of water. Individuals of different sizes were collected from the laboratory holding tanks and eggs were later counted and measured with the help of a PAMAS field laser counter.

In this study the total fecundity was defined as the amount of eggs counted for one individual of a given size, including both mature and immature eggs. The size of mature eggs were defined in a separate experiment were groups of *O. craigsmithi* were allowed to spontaneously spawn and eggs were collected, investigated under a microscope and later measured with a PAMAS laser counter.

Histology

Individuals ranging in size from ~ 4-14 mm were selected for histological sectioning in order to investigate the presence of male/female gametes and for the indication of size for the onset of Oocyte production in females. Polychaetes were relaxed in isotonic magnesium chloride, measured under a dissecting microscope and later fixed in Davidson`s fix before casted in to paraffin and longitudinally sectioned in 3 μm thick sections and analysed.

(Continued on next page)

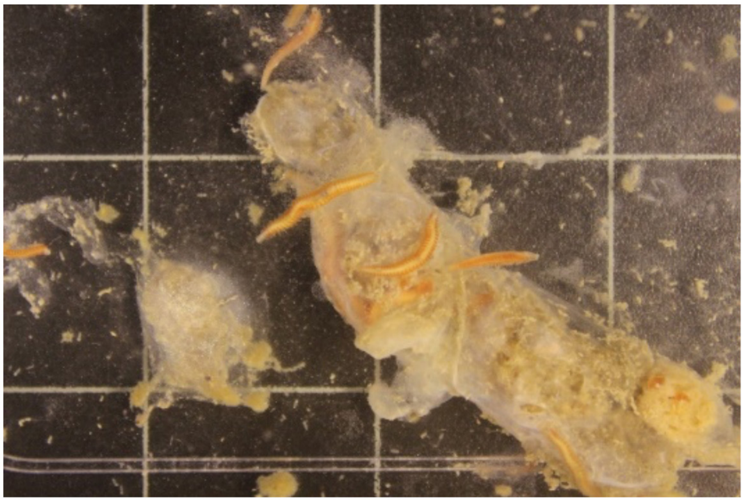

Figure 1) Individuals of O. craigsmithi occupying growth flumes. O. craigsmithi crawling inside and around a mucus construction containing organic material and bacteria. White squares 30x30 mm.

Results

Preliminary results show that it takes approximately two weeks for the small group of *O. craigsmithi* (3-5 mm long) to double in size. The maximum size of adult individuals was reached around 20 mm. Fecundity measurements indicate that mature adult females can contain around 1000 eggs within the size range 90 to 190 μm. A mix between mature an immature eggs was almost exclusively observed in al spawning size-groups of *O. craigsmithi*, this was also supported by histological sections. Fecundity and histological measurements together indicate that females can start egg production with few, but mature eggs from about 6 mm in length. Histological sections has not yet revealed any individuals producing both male and female gametes, pointing at separate sexes for this species. Additional observations made for *O. craigsmithi* in the laboratory study was that they possess a free swimming larvae stage with the first segment appearing after a few days. *O. craigsmithi* was also observed to efficiently collect food and bacteria in 3D mucus complexes (Figure 1). Results from this study increases the understanding and biological requirements for a successful incorporation of *O. craigsmithi* in systems like integrated multitrophic aquaculture.

Introduction

Recent substitution of fish meal with alternative ingredients has led to the inclusion of more carbohydrates in fish feeds (Sinha et al., 2011). Several studies have addressed the effect of novel raw materials on growth and overall fish performance (Francis et al., 2001) but little is yet known about the impact of those fibrous ingredients on aquaculture system performance. Nonetheless, waste production and managament becomes more and more relevant as recirculating aquaculture keeps growing. In view of this, fish farming in closed systems poses more challenges when faecal volume gets higher due to lower diet digestibility, and faecal waste is prone to disintegration due to poor quality (Kokou & Fountoulaki, 2018). Therefore, the present study examined the impact of different carbohydrate sources on nutrient digestibity and subsequent faecal excretion, with the aim to identify dietary ingredients which improve waste removal efficiency.

Materials and methods

A trial was conducted in which juvenile European seabass (*Dicentrarchus labrax*) was fed restrictively (1.7% of body weight) with eight experimental diets in triplicate; seven diets included a different carbohydrate source in the form of non-starch polysaccharides, chitin and keratin, while one served as control (basal diet). The test diets consisted of 85% basal mixture, diluted with 15% of each test ingredient. The ingredients examined in the current setup were: 1) wheat dried distillers grain with solubles; DDGS, 2) shrimp-shell meal; SSM, 3) type I hydrolyzed feather meal; FM-I, 4) type II hydrolyzed feather meal; FM-II, 5) insect meal; IM, 6) single-cell protein; SCP, and 7) seaweed protein; SWP. To evaluate the impact of diet on nutrient digestibility and waste production, each tank was equipped with an individual swirl separator for faeces collection. Nutrient digestibility, calculated as apparent digestibility coefficient (ADC), was measured after 3 weeks of acclimatization to the respective diet, based on yttrium oxide (0.2 g/kg feed) as an inert marker. Additionally, faecal waste production was estimated via organic matter (OM) digestibility values, whilst faecal recovery was determined by quantification of the OM collected via swirl separators over a 48-hour period.

Results & Discussion

The present study demonstrated that European seabass is able to digest carbohydrate-rich diets, at least up to 15% inclusion levels, despite being a typical carnivorous species. However, the ADC of all nutrients but fat differed among dietary ingredients, with the lowest values for ADC crude protein and carbohydrate being reported for SWP and DDGS, respectively. Similarly, OM digestibility was higher for the ingredients of animal origin compared to the plant-based ones, which can be likely attributed to the high presence of indigestible non-starch polysaccharides (e.g. lignin, cellulose, pectins) in the latter, as previously suggested for European seabass (Fountoulaki et al., 2022). This consequently denotes that faeces production is lower for the animal-based diets and thus a smaller volume of faecal waste needs to be treated in a recirculating aquaculture system (RAS) under these conditions. In addition, SSM resulted in the highest faecal recovery, followed by IM (Table 1). This suggests that chitin is possibly a polysaccharide with binder capacity which improves faecal stability and facilitates faecal removal via basic mechanical filtration methods. This is in line with results previously reported for other insoluble fibres (Amirkolaie et al., 2005). As such, chitinous feeds are exprected to accommodate RAS performance since they may reduce the accumulation of small particles in the recirculation loop. Overall, the obtained results show that the type of dietary carbohydrate determines faecal quantity and quality with potential implications on system performance and hence therof inclusion should be considered during formulation of RAS aquafeeds.

Introduction

Aquaculture is the fastest growing food production sector and currently accounts for the majority of human fish consumption (FAO 2020). In Scotland, the salmon aquaculture industry consists primarily of sea cages within fjordic sea lochs which provide an environment that is relatively sheltered from wave exposure. However, the restricted water exchange may create several problems, including reduced temperature and dissolved oxygen gradients, increased mortality from harmful algal blooms, and increased risk of ectoparasites and disease transmission. Recently, interest has increased in the possibility of moving salmon aquaculture 'offshore' into more exposed environments with higher energy currents and waves (Morro et al. 2021). While the more dispersive environment may reduce effects of waste and decrease exposure to parasites such as sea lice, expectations for the effect on fish health and wellbeing are largely speculative, and the interactions of the multiple stressors faced by fish in offshore farms may result in both synergistic and antagonistic effects (Matzelle et al. 2015; Orr et al. 2020). Here, we use health and welfare data from sea cage farms in western Scotland representing a gradient of wave exposure as an offshore proxy to assess the effects and interactions of environmental variables and management treatments on fish health and mortality using hierarchical Bayesian models.

Materials and methods

Eight sea cage farms in western Scotland were selected based on the similar characteristics of the Atlantic salmon (*Salmo salar*) smolts used for stocking and their contrasting locations and physical conditions (Fig. 1). Data were collected at each farm from July 2018 – March 2020 by a collaborating fish farming company, which included mortalities, number of sea lice per fish (*Caligus sp*., *Lepeophtheirus salmonis*), Amoebic Gill Disease (AGD) score (1-4), and administration of anti-lice (Thermolicer, Hydrolicer, SLICE, Salmosan, Alphamax) and anti-AGD treatments (Freshwater, H_2O_2).

Wave exposure at each site was characterised using the 50-year significant wave height as predicted by the West Scotland Wave Model (Hardwick 2020). Environmental variables were extracted from the WeStCOMS hydrodynamic model, which predicts hourly conditions at 10 depths based on observed environmental forcings (Aleynik et al. 2016, Dale et al. 2020). The daily 90th quantile at each farm was calculated for temperature and water velocity at 6 m depth, as well as wind velocity.

The joint effects of environmental and health variables on daily mortality rate were estimated using a hierarchical Bayesian model. The full model used logit-transformed mortality rate as the response, predicted by effects of wave height, temperature, wind velocity, water velocity, fish abundance, number of adult lice, average AGD score, days since mechanical or chemical lice treatments, and days since anti-AGD treatments. We included interactions between wave height and each variable, explored lagged impacts, and incorporated effects of fish cages nested within each site. We used regularlised horseshoe prior distributions for each slope.

Analyses were performed in R 4.1.3 with the package *brms* v. 2.16.3 (Bürkner 2017), which fits hierarchical Bayesian models using Markov Chain Monte Carlo with the statistical platform Stan (Stan Dev. Team, 2022). For each model, we ran four chains of 3,000 iterations each, with the first 1,500 as warmup. Suitability for interpretation was assessed with posterior predictive checks, ensuring that all < 1.1, and confirmation that no divergences occurred during the sampling.

Results

The model development is currently in progress and the abstract will be updated to include the results.

Preliminary analyses show suggestive correlations ($|r| > 0.2$) between mortality rate and temperature, lice density, and time since chemical lice treatments (Fig. 2). Further, when sites are classified as 'inshore' or 'offshore', fish at offshore sites tend to be smaller and thinner ($P < 0.05$), while inshore fish show higher levels of cortisol and reduced density of adult sea lice in the summer ($P < 0.05$).

Introduction

Aquaculture is a globally expanding industry that contributes to feeding an increasing global population. Shellfish cultivation is one of the largest sectors of aquaculture and one of the few food productions that have the potential capacity of acting as carbon sink. In fact, more than 90% of bivalve shells are calcium carbonate ($CaCO_3$), synthetized during biocalcification process, which incorporates a molecule of CO_2. Manila clam (*Venerupis philippinarum,* Adams&Reeves, 1850) and Mediterranean mussel (*Mytilus galloprovincialis*, Lamarck, 1819) are two of the major groups of cultivated shellfish. Our aim was to assess the potential role of those two bivalve species in the overall marine carbon balance using an ecosystem approach, and to evaluate if they can be definitely regarded as carbon sink.

Materials and Methods

The contribution to CO_2 emissions (as CO_2 eq./kg of fresh products) due to mollusk farming has been also calculated as carbon-source term by means of Life Cycle Assessment (LCA). LCA is nowadays the most shared and accepted tool for evaluating the environmental impacts of aquaculture productions. The carbon sequestration capacity during biocalcification process has been also calculated. As a case study, the Sacca di Goro coastal lagoon (Northern Adriatic Sea, Italy) has been considered, because it is the premier site in Europe for clam farming, and one of the most important for mussels.

Results

Our study has shown that for each kilogram of harvested and packaged clams and mussels, shell formation throughout the mollusk growth allows to permanently capture 254 and 146 g of CO_2, in the face of 22 and 55 g CO_2 eq. emitted for farming, respectively. As a result, clams and mussel aquaculture could be considered as a carbon sink, with a net carbon capture capacity of 233 and 91 g CO_2/kg of fresh product, respectively. In a wider context, bivalve aquaculture could be included in the carbon trading system and played a role towards the carbon-neutral economy.

GROWTH PERFORMANCE, AMINO ACID AND FATTY ACID COMPOSITION OF GILTHEAD SEABREAM (*Sparus aurata*) FED ALGAE MEAL DIETS

Introduction

Aquaculture sector is thriving as a response to the rapidly increased demand for seafood products. The sector is using, 18 million tons of wild fish that are targeted for fishmeals and fish oils in aquafeeds (FAO 2020), thus affecting the sustainability of marine ecosystem. This has led the research to focus on environmentally sustainable sources of proteins and lipids as replacements of fishmeal and fish oil. Microalgae biomasses seem to be potential feed ingredients containing sustainable amounts of essential amino acids, essential fatty acids, vitamins, and pigments, that could be produced with a low environmental footprint (Nagappan et al. 2021). This study aims to investigate the effect of dietary inclusion of algae meal on the growth performance, amino acid composition and fatty acid composition of the white muscle of gilthead sea bream (*Sparus aurata*).

Material and methods

The experimental trial was conducted at the Department of Ichthyology and Aquatic Environment, University of Thessaly, in Volos, Greece. Briefly, 360 individuals *S. aurata* (initial mean weight 6.43±0.04g) were distributed randomly to six 250l tanks. Two experimental diets were formulated to be isonitrogenous, isolipidic, and isoenergetic with diet 1 (PA) consisted of 8% *Phaeodactylum tricornutum*, and diet 2 (HA) consisted of 8.23% *Schizochytrium limacinum*. Each diet was assigned to triplicate groups of 60 fish per group. The trial lasted 45 days, after 15 days of acclimatization. The fish were fed three times per day *ad libidum*. Fish were weighted individually at the beginning and end of the experimental trial under anaesthesia. Feed consumption was recorded daily in order to evaluate accurately values for feed utilization.

Results

The results showed that weight gain, feed consumption, specific growth rate and survival did not have statistically significant differences ($p>0.05$) between fish fed the diet consisted of *Phaeodactylum tricornutum* (PA) and the diet of *Schizochytrium limacinum* (HA). Fish fed with PA had statistically significant ($p<0.05$) lower feed conversion ratio and higher protein efficiency ratio (Table 1).

Amino acid composition revealed a strong positive correlation, highly significant ($p<0.05$) between diets and the white muscle of fish in each treatment. Moreover, fatty acids analysis showed a significant decrease ($p<0.05$) of eicosapentaenoic acid (EPA) and an increase ($p<0.05$) of docosahexaenoic acid (DHA) in white muscle of seabream fed the HA diet, compared to the PA treatment. Arachidonic acid (ARA) of white muscle was unaffected ($p>0.05$) between the dietary treatments.

Table 1: Growth performance parameters of gilthead seabream fed the experimental diets.

	PA	HA
Final Weight (g)	26.54 ± 0.34^a	26.62 ± 0.35^a
Weight gain (g)	20.07 ± 0.34^a	20.22 ± 0.35^a
Feed consumption (g/fish)	15.48 ± 0.53^a	17.89 ± 0.78^a
Specific growth rate (SGR, %/day)	3.10 ± 0.02^a	3.13 ± 0.02^a
Feed conversion ratio (FCR)	0.81 ± 0.01^a	0.93 ± 0.01^b
Protein efficiency ratio (PER)	2.92 ± 0.04^b	2.52 ± 0.04^a
Survival (%)	98.88 ± 0.55^a	99.44 ± 0.55^a

Values are presented as means±standard error. Means sharing the same superscript are not significantly different from each other ($P<0.05$).

(Continued on next page)

Discussion

The results of this study showed that the inclusion of algae meal in *S. aurata* diets did not affect growth performance and amino acid deposition. The lower FCR and higher PER exhibited in fish fed the PA diet denotes a better protein utilization of *P. tricornutum* diet than *S. limacinum* by *S. aurata*. In terms of aquaculture sustainability, the substitution of fish oil with heterotrophically produced microalgae in salmon feeds proved the nutritional feasibility of low trophic level organisms such as algae in aquaculture fish feed (Kousoulaki et al., 2017). In accordance with the results of this work, fishmeal replacement with the microalgae *P. tricornutum* in started diets of *S. aurata* showed that SGR was not affected (p>0.05) and there was an increase of saturated fatty acids in fish (Atalah et al. 2007). Moreover, the inclusion of 2.5% *P. tricornutum* in finishing diets of gilthead sea bream did not significantly change growth, feed utilization parameters and muscle fatty acid profile (p>0.05) (Ribeiro et al. 2017). Furthermore, the 2.5% inclusion of *Schizochytrium* sp. as lipid source and especially DHA source in microdiets of *S. aurata* had no negative effect on larvae (Ganuza et al. 2008). In contrast to the forementioned authors, Eryalçin & Yildiz (2015) reported that the replacement of fishoil with dried *Schizochytrium* sp. meal had a negative effect on growth of seabream although the DHA was increased.

The differences found in the fatty acid profiles on the muscle tissue of fish are characteristic to the fatty acid's profiles of each algae species as *S. limacinum* is known for being richer in DHA and poorer in EPA compared to the *P. tricornutum* and *S. limacinum* has been used successfully in the diets of seabream and other species, mainly for fishoil replacement. According to Santigosa et al. (2021), the growth performance of seabream fed 3.5% *Schizochytrium* sp. oil as replacement of fishoil was unaffected and fillet fatty acid composition was in accordance with the diet fatty acid composition, suggesting that dietary microalgae could lead to an environmentally friendly final product rich in n-3, n-6 fatty acids. The dietary inclusion of algae meal (*Phaeodactylum tricornutum* and *Schizochytrium limacinum*) does not influence growth performance but there is an effect on FCR, PER, amino acid deposition and fatty acid composition of the white muscle of seabream (*Sparus aurata*) follows the fatty acid and amino acid composition of the two algae suggesting they can be used and produce a final product rich in n-3 and n-6 fatty acids. Algae meal biomass is promising ingredient to move the formulation of sea bream feed to a more sustainable future.

Introduction

Soy is one of the most common plant-based protein ingredients in aquafeeds because of its consistent nutrient density, favorable amino acid profile, good palatability and high availability. However, the main factor limiting the extended use of conventional solvent extracted soybean meal (SBM) in salmon diets is the presence of anti-nutritional factors like oligosaccharides, raffinose, saponins, etc., which have been shown to reduce digestibility, growth, and induce enteritis in the distal intestine of Atlantic salmon. To overcome this issue, new varieties of SBM called ultra-high protein (HP, 60.9% crude protein) and ultra-high protein low-oligosaccharides (HPLO, 60.5% crude protein) have been developed. The objectives of this study were to 1) determine nutrient digestibility of HP and HPLO, 2) evaluate the effects of dietary inclusion of HP and HPLO on growth performance, nutrient utilization, feed efficiency, intestinal histology, and blood parameters.

Materials and methods

A digestibility trial using striping method was conducted with triplicate groups of 22 fish/tank (599.7 ± 12.9 g). Fish were fed with one reference diet and two test diets utilizing a 70:30 mixture of reference diet and test ingredients (HP or HPLO) to determine apparent digestibility coefficients (ADC) of nutrients.

In the growth trial, post-smolt Atlantic salmon (243.4 ± 6.0 g) were randomly allocated into 24 400-L tanks as groups of 35 in triplicate and fed with isonitrogenous (42% crude protein) and isolipidic (25% crude lipid) experimental diets (A-H). Soy protein concentrate (SPC) and conventional SBM were used as the primary protein sources in diets A and B, respectively. The other six diets were formulated with increasing graded levels (10, 20 and 30%) of HP (diets C through E) and HPLO (diets F through H) to progressively replace SPC. Fish were reared in a flow-through system where salinity, temperature and oxygen were maintained at optimal levels for growth and health of salmon. Fish were hand-fed experimental diets to apparent satiation three times per day. At termination (day 84), body weight was recorded, and whole-body (10 fish/tank), blood samples (5 fish/tank), livers (5 fish/tank) and distal intestines (5 fish/tank) were collected.

Results

HP and HPLO were highly digestible ingredients, with ≥92% ADCs of protein and essential amino acids. In the growth trial, final body weight ranged between 504.6-594.6 g, with HP and HPLO-fed groups (diets C–H) performing similarly to fish fed SPC (diet A). Likewise, HP and HPLO-fed groups had good feed conversation ratios (FCR < 0.9), showing a comparable or numerically better FCR compared to SPC- and SBM-fed groups. Fish fed diet B exhibited typical SBM-induced enteritis signs such as lack of normal vacuolization, increased necrosis, apparent inflammation of lamina propria and submucosa, whereas these conditions were improved in fish fed diets containing HP, HPLO and SPC. There were no statistically significant differences in final whole-body proximate composition (e.g., protein, lipid, ash and essential amino acids), hepatosomatic index as well as blood parameters (e.g., ions, glucose, total protein, hematocrit, etc). Based on these findings, HP and HPLO are considered highly digestible, nutritious, and safe protein alternatives that could be included up to 30% in salmon diet.

GUT MICROBIOTA IN ATLANTIC SALMON AFTER NUTRITIONAL PROGRAMMING WITH A VEGETABLE-BASED DIET

Introduction

In an effort to promote sustainable aquaculture, the formulation of Atlantic salmon (*Salmo salar*) feeds has changed in the past decade, with a focus on replacing marine-based ingredients with the plant-based alternatives. The concept of nutritional programming involves initially feeding fish a specific diet type to promote successful metabolism when faced with the same or similar diet in later life. However, little is known about how these plant-based diets may impact the gut microbiota at first feeding. There is increasing evidence that initial gut microbial colonisation is essential for regulating the development of the digestive system and that these communities also aid digestion, nutrient metabolism and immune function within the gut. This study investigated the nutritional programming concept in terms of whether the initial microbiome can be permanently influenced by the first feeding diet. In our work, vegetable and marine-based diets were compared. The mechanisms by which nutritional programming occurs is not clear but there may be a contribution by microbial communities, making this study important to current understanding of the dynamic crosstalk between intestine and diet.

Materials and Methods

We investigated differences in intestine microbial communities in Atlantic salmon fed a marine rich diet (M) compared to a vegetable-based diet (V) at first feeding (Figure 1A). Samples were initially taken after two weeks of feeding either M or V (stimulus phase; Stim). All fish were then fed exclusively on a M diet and samples taken after 12 weeks (intermediate phase; Interm). Finally, fish were challenged with the V diet for six weeks and sampled (challenge phase; Chall). Whole (at Stim) and distal (at Interm & Chall) intestines were taken from 18 fish per group (six randomly sampled fish from triplicate tanks at each phase, n = 108 total). Water and feed samples were also collected at each phase. Microbial communities were assessed by 16S rRNA V3-V4 amplicon sequencing using Illumina MiSeq platform. Sequences were analysed using DADA2 pipeline to identify the microbial community as Amplicon Sequence Variants (ASVs). Functionality of the microbial communities was inferred using PICRUST2.

Results

Alpha diversity refers to the diversity within a sample, examining the microbiota structure in regard to richness (number of taxonomic groups; Chao1 index), evenness (distribution of abundances of the groups; Pielou index), or a combination of the two (Shannon index). Microbial diversity and richness was highest in the intestine at Stim (Kruskal–Wallis $p<0.001$) with a distinct and significant reduction at the Interm phase and a further decrease ($p<0.05$) at Chall. The drop in diversity was the result of an increase in relative abundance of Pseudomonas at Interm ($p<0.0001$) and Chall ($p<0.05$) phases (Figure 1B). Beta diversity refers to microbial community differences between samples or groups. Beta diversity revealed more clustering between sample types (intestine, feed and water) at each phase rather than between different phases. PERMANOVA analysis revealed less microbial homogeneity between Interm and Chall in M ($p<0.001$) compared to V ($p=0.041$). Water samples were predominantly comprised of Proteobacteria and Bacteroidota whereas Firmicutes had the highest abundance in feed. At genus level, in both M and V, *Pseudomonas* in intestinal samples increased in abundance from the Stim to Interm (Mann–Whitney $p<0.0001$) and Chall ($p<0.05$). In contrast, *Lactobacillus* decreased in abundance from Stim into Interm ($p<0.01$) and Chall ($p<0.01$) (Figure 1C). In feed, *Lactobacillus* relative abundance constitutes more than 70% of total abundance. A core microbiota was detected at ≥ 0.1% in 80% of the fish. At Stim, 14 and 10 ASVs were identified in M and V respectively, with 10 ASVs overlapping between M and V. At Chall, an unclassified genus of family Ruminococcaceae (of Phylum; Firmicutes) was present in both M and V. *Pseudomonas* sp. was additionally detected in M. There was no difference at the functional level for the Chall M vs V.

(Continued on next page)

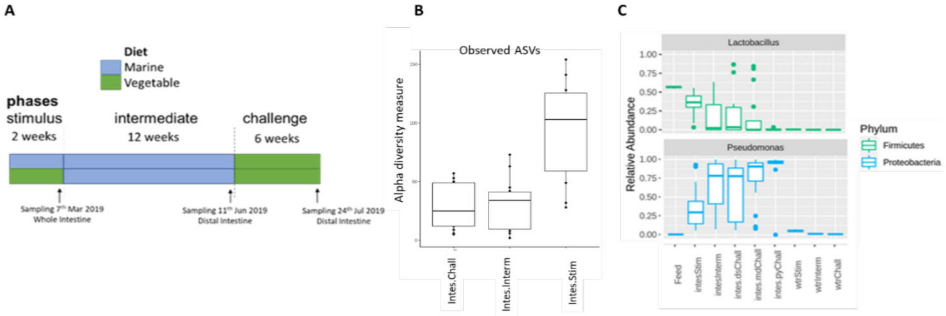

*Figure 1 **A**: Timeline of dietary manipulations with three sampling points for gut microbiota. **B**: Alpha diversity of intestinal samples across phases., **C**: Relative abundances of Pseudomonas (Firmicutes) and Lactobacillus (Proteobacteria) across sampling points and sample types.*

Discussion and conclusions

Although well-established in mammalian species, nutritional programming in fish has only relatively recently received attention. The microbial richness, evenness and diversity were highest at Stim although no difference between M and V was observed in the microbial homogeneity with the intestinal microbial community dominated by Firmicutes (mainly *Lactobacillus* sp.) and augmented by Proteobacteria. Comparison of intestine with feed and water suggested acquisition of microbiota from the environment (Firmicutes from feed and Proteobacteria from water). At Interm, richness and diversity were higher in M than V, while V was more homogenous, this may reflect the change of diet form vegetable to marine in V, while M was kept on marine during Stim and Interm. Across phases, M was microbially richer than V (mainly Firmicutes) that could imply the marine diet represents a rich medium for different microbes to be established. Interestingly, when fish were subsequently challenged with vegetable diet, there was similar microbial homogeneity between M and V. Additionally, there was comparable homogeneity and beta diversity in V at both Interm and Chall whereas for M treatment, microbiota was less diverse at Chall compared to Interm. This may suggest that fish fed V were nutritionally programmed at an earlier stage and adapted the response to V diet to be more similar in the microbial community composition to M. This was also supported by having the same core microbiota Ruminococcaceae that was observed in M and V. Moreover, there was a lower number of core microbiota in Chall compared to Stim with no statistical difference between top genera taxa in M vs V across phases (except for *Pseudomonas*). These results indicate that fish gut microbiota communities shift in a homogenous pattern with age regardless of diet and then select a more specific microbial community as the fish develops. It is worth noting that although the *Pseudomonas* sp. were not classified at Chall, we observed no negative impacts on health or functional inference suggesting that *Pseudomonas* sp. was not pathogenic.

TOTALLY TUBULAR: EXPERIENCES WITH A PROTOTYPE SUBMERSIBLE MUSSEL CULTIVATION SYSTEM

D. Taylor*, F. Bak, P. Nielsen

Section for Coastal Ecology, DTU Aqua, Øroddevej 80, 7900 Nykøbing Mors, Denmark
Email: dtay@aqua.dtu.dk

Adoption of tube-net systems by mussel farmers as an alternative technology to longline systems in northern Europe provides potential for increased biomass yields and decreased operational costs. These systems are typically designed as a 100m PE tube for support and buoyancy of a suspended net as substratum for mussel attachment. Fixed buoyancy and mechanization of harvest or thinning reduces labor requirements for farm maintenance. Controlled submersion of the system, similar to finfish cages, has gained substantial interest primarily for eliminating visibility of farm structures (social acceptance), reducing predation from molluscavorous waterfowl, and offshore production. Visibility of tube-net farms in Denmark, for example, has generated negative feedback from coastal residents and consequently a more protracted permitting process for new farms. Predation by eider ducks, related to farm visibility, has been documented to cause extreme losses of mussel biomass, if not total. Transitioning mussel production offshore, in higher energy conditions, demands more robust engineering of cultivation gear and positioning of farms in the water column below potential wave height.

In the EU Horizon 2020 Aquavitae project, we developed a prototype submersible tube and observed its behavior over two growing seasons. Mussel settlement and biomass accretion were monitored, while manipulation of the system's buoyancy was conducted to maintain a submerged position off of the sea floor. Different ballast techniques were tested in order to control the position of the system relative to biomass loads. In contrast with submersion of the conventional tube-net system, this modified tube requires substantially less ballast and has potential for some automation in buoyancy control. We present the tube design, experiences managing the system, and lessons learned.

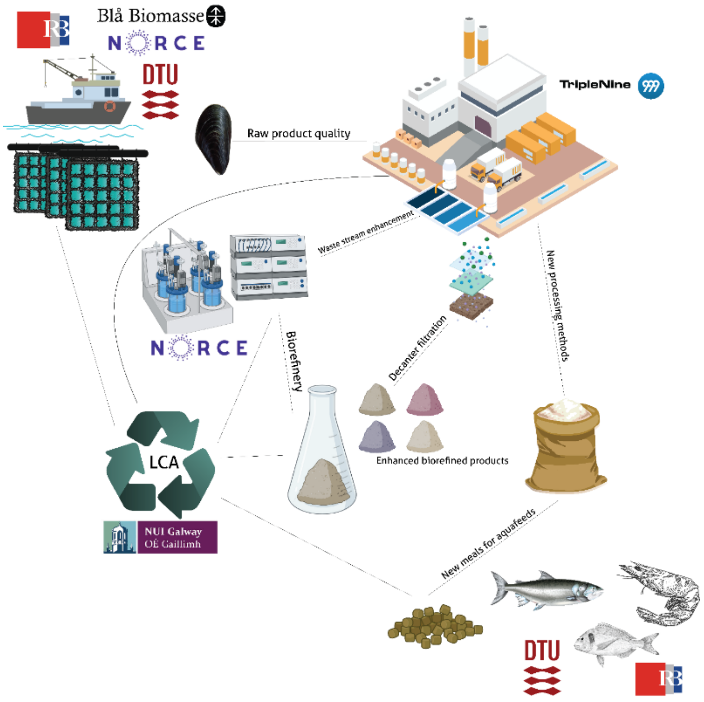
The MuMiFaST project gathers European expertise on the value chain related to undersized non-uniform mussel biomass compared to mussels produced for human consumption. As either a new industry utilizing undersized mussels, or as one focused on maximizing production of heterogeneous mussel biomass, this marine bioresource can be produced sustainably, and exhibits promise in use as a high-quality animal feed and in nutritious value-added food products. The primary needs for innovation in this industry are related to post-harvest preprocessing and processing of large volumes of heterogeneous mussels to a quality standard suitable for the aquaculture feeds industry. In this project the partners will develop advancements in the supply system of blue bioeconomy value chains of mitigation mussels between TRL3-6, providing proof of concept of new perspectives on waste reduction and utilization of the entire biomass towards production of highly quality ingredients for the aquaculture feed industry. Application of this undersized mussel model in a wider European context will be explored through the partner organizations and broad stakeholder engagement.

A brief introduction to the project and its work packages is presented.



THE EUROPEAN PERCID FISH CULTURE CORE GROUP AS A KNOWLEDGE SHARING GROUP

S. Teerlinck

Inagro, Practical Research Aquaculture Center, Ieperseweg 87, 8800 Rumbeke- Beitem (Belgium)

e-mail: stefan.teerlinck@inagro.be

In 2012 the European Percid Fish Culture (EPFC) was founded as a thematic group within the European Aquaculture Association (EAS). This EPFC was mend to bring researchers in contact with their target group, being the upcoming pikeperch (*Sander lucioperca*) and European perch (*Perca fluviatilis*) producers. From the founders' point of view, research needs to solve, clear-out, the bottlenecks in the industry and to push this new sector forward.

The fist EPFC workshop was held in 2012 during the EAS congress in Prague, Czech Republic. Year by year the network of researchers and fish producers expanded, and the contacts and exchange of knowledge and insights became more valuable. All with one common topic: percid fish culture. In 2017 the idea grew to evolve from an knowledge exchanging platform towards a knowledge sharing group.

Beginning 2019 the EPFC Core Group was founded as a knowledge sharing group within the EAS thematic group EPFC. All 26 members paid a membership fee and signed a cooperation agreement for 3 years. A Short overview of the first 3 years activities and future activities is given in the presentation.

THE SMALL DIFFERENCE - PRACTICAL IMPLICATIONS OF PH ON TARGET PLANT NUTRIENT CONCENTRATIONS DERIVED FROM HYDROPONICS IN AQUAPONICS

Anıl Axel Tellbüscher* and Jan Mráz

Introduction

In aquaponics, imbalances in concentrations of plant nutrients are commonly reported. Supplementation of nutrients is suggested to balance the nutrient profile of water in a way that it resembles nutrient solutions used in hydroponics. However, studies within this context found limitations in the manipulability of some nutrients (Shaw et al., 2022). A key difference between aquaponics and hydroponics is the maintained system pH, among other parameters. Considering the importance of the pH for the solubility of a broad range of salts (Sambo et al., 2019), the question must be raised whether nutrient concentrations targeted in hydroponics can be reached under aquaponic conditions. This work intends to provide a first insight into the implications arising from the pH as master variable, determining solubility of poorly soluble salts in different aquaponic systems.

Material and Methods

Nutrient concentrations reported for the Hoagland plant nutrient solution were used for further calculations (Resh, 2012). A pH of 6.0, 6.8 and 7.5 and a CO_2 partial pressure of 0.054 atm was assumed for hydroponic, coupled, and decoupled systems, respectively. Concentrations of CO_3^{2-} and PO_4^{3-} species were calculated using the target concentrations stated in the formulation of the nutrient solution as total concentrations. Resulting maximum solubility of the cationic plant nutrients forming poorly soluble salts was calculated and target concentrations of the cations were eventually divided by the theoretical maximum solubilities to obtain maximum solubility satiation levels.

Results and Discussion

According to the calculated theoretical solubility of calcium, $Ca_3(PO_4)_2$ is exceeding the maximum solubility in all three systems. This could be due to interactions between calcium and other ions that are not covered by the simplistic approach used. On the other hand, the low system pH reduces the carbonate concentration in hydroponic systems to a level where precipitation of calcium carbonate does not occur. The threshold concentration is exceeded at higher pH as present in coupled and decoupled aquaponics. This might explain why calcium deficiencies are reported in aquaponic systems (Goddek et al., 2019). Magnesium solubility ranges at levels where target concentrations for optimum plant growth are unaffected. Recommended concentrations for iron are higher than the solubility of poorly soluble iron salts such as iron phosphate. While exceeding the calculated threshold concentration in hydroponics is possible by addition of iron in complexed form (e.g., FeEDTA), the same effect can be achieved by interactions of iron cations with dissolved organic matter. A study has shown that the addition of fulvic acid has the potential to mobilise iron (da Silva Cerozi, 2020). However, studies showing the feasibility of adding increased amounts of fulvic acids in aquaponics have not been conducted until now.

The maximum solubility copper might be exceeded in decoupled aquaponics, with precipitation of copper phosphate taking place within the aquaculture unit if copper is excreted as part of feed metabolization or direct addition. This could lead to losses of copper if precipitation occurs at inaccessible places such as the inside of the pipes. Manganese and zinc, on the other hand, might not be affected by increasing pH.

Overall, the results clearly show that the pH could be a causative factor for nutrient imbalances in aquaponic systems, allowing higher nutrient concentrations in hydroponics. However, smart nutrient management could reduce nutrient losses and increase the efficiency of aquaponic food production.

Introduction

Gut health plays a key role in fish nutrition since it is closely associated with an effective nutrient uptake and with the modulation of fish immune system and antioxidant status. A disruption in the fish intestinal permeability and homeostasis may result in reduced growth and feed efficiency, lower resistance to stressors and diseases, and overall poorer health status.

Soy saponin (SAP) and dextran sodium sulphate (DSS) have been shown to provoke mild to severe intestinal inflammatory processes in fish and mice, respectively. This study aimed to assess these compounds as potential disruptors of intestinal permeability and homeostasis in gilthead seabream juveniles by evaluating the intestinal response to different doses of SAP and DSS at 24, 48 and 72 h. Moreover, the expression of genes coding for antioxidant response (catalase – *cat* and glutathione peroxidase – *gpx*), paracellular permeability (occluding – *ocl*, claudin 12 – *cldn12* and tight junction protein 2 – *tjp2*), and immune response (cyclooxygenase 2 – *cox2* and immunoglobulin M – *IgM*) was evaluated to identify molecular markers that highlight homeostatic disruptions in the gut.

The validation of an experimental model causing acute gut inflammation and dysbiosis will allow the evaluation of functional feeds and ingredients as potential promoters of gut health. Furthermore, the validation of such model would be a step forward to investigate the underlying physiological and molecular mechanisms involved in fish intestinal recovery and health.

Materials and Methods

Gilthead seabream juveniles with an average body weight of 152 ± 22 g were sedated with 2-phenoxyethanol (300 ppm) and fed gelatine capsules by the "assisted-feeding" technique. This method ensured that the capsules reached the fish stomach after being gently pushed through the mouth with a hollow tube. Fish were fed capsules containing SAP or DSS at different doses according to the experimental treatment: CTRL – fish fed empty gelatine capsules; SAP1, SAP2, SAP3 – fish fed gelatine capsules containing soy saponin at 125, 350 or 700 mg, respectively; DSS1, DSS2, DSS3 – fish fed gelatine capsules with 125, 350 or 700 mg of dextran sodium sulphate. All fish were fed one capsule, except fish fed the highest doses of SAP and DSS (SAP3 and DSS3), which were fed two capsules. After the assisted-feeding, individual fish were placed in clean and aerated seawater to eliminate any residual anaesthetic and monitored for eventual capsule regurgitation. Once recovered, eighteen fish per treatment were transferred to two 100 L cylindric-conical tanks (density: 13.7 Kg m^{-3}; temperature: 16 ºC; salinity: 32 psu). Details on the experimental design are presented in Figure 1.

At 24, 48 and 72 h after capsule ingestion, the anterior and posterior intestine were sampled from six fish per treatment for gene expression, histology, and microbiome analyses. The differential expression of the selected molecular markers was evaluated. Data was subjected to principal component analysis (PCA) using the prcomp R function in the auto-scaled matrices to find potential clusters of observations. Score plots were generated for the two first principal components using the ggbiplot and factoextra packages for the open-source software R version 4.2.1 (R Core team).

Results and Discussion

DSS3 fish had a mortality rate of 88.9 %, indicating that the ingestion of the highest dose of DSS (700 mg) led to irreversible injuries in fish intestine. Therefore, the ingestion of DSS at 700 mg would not be a suitable candidate to validate this novel technique. Conversely, no mortality was observed in the remaining treatments over the 72-hour trial.

(Continued on next page)

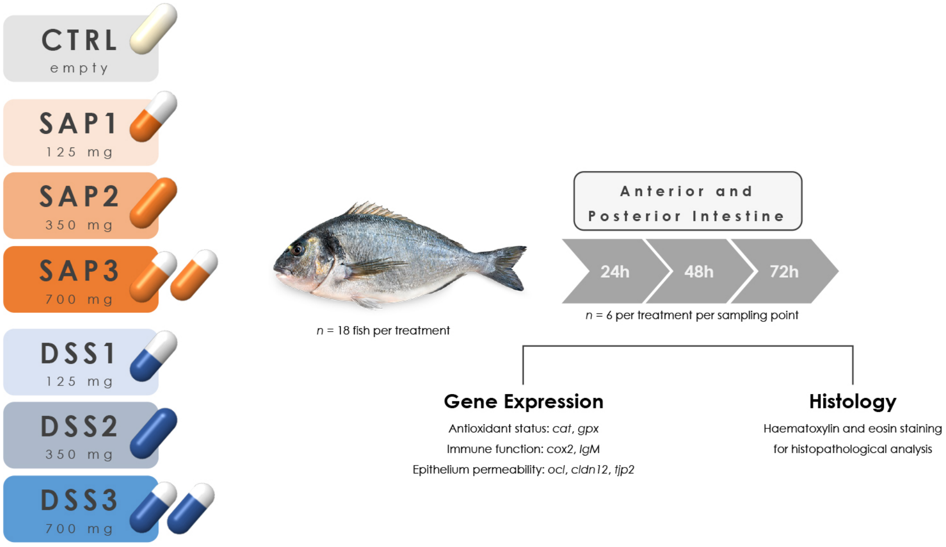

Figure 1. Experimental design.

Histology of anterior intestine sections of all sampling points, in addition to gene expression data from the 24-hour sampling, are currently being evaluated. Furthermore, posterior intestine sections will also be analysed and compared with the results obtained for the anterior intestine.

Gene expression data was generated for the anterior intestinal sections of fish at 48 and 72 h after ingestion of the gelatine capsules containing the different compounds at different doses. After 72 h, fish from the SAP3 treatment presented a differential response revealed by PCA, being the differential expression of *gpx*, *tjp2* and *cox2* the main loadings responsible for clustering SAP3 observations.

Preliminary results suggest that after 72 h, the oral administration of 700 mg of soy saponin may provoke disruption of intestinal homeostasis in gilthead seabream. This novel technique may be viable to evaluate the potential role of functional feeds as gut health promoters.

SAFE OPERATIONS IN AQUACULTURE

T. Thorvaldsen*, I.M. Holmen, K. Størkersen

SINTEF Ocean, Postboks 4762 Torgarden, NO-7465 Trondheim, Norway
E-mail: trine.thorvaldsen@sintef.no

Introduction

Risk in aquaculture operations has been described according to five dimensions: risks to material assets, personnel, fish welfare and health, environment, and food safety (Yang, Utne and Holmen, 2020)irregular and often high winds, sheer remoteness, and limited weather window amplify the hazards during aquaculture operations. This paper presents a methodology for identifying hazards in aquaculture operations that take into account risks to personnel, material assets, the environment, fish welfare and food safety. The methodology considers the marine fish farm, its support service systems, external agents impacts, potential environmental disturbance and the likelihood of hazard interactions, and fish in the cage. The methodology has been used to analyse a net-cleaning operation, and the results show that it provides a good overview of hazards in a specific operation. The operator can have a better understanding of the nature of the operation to be better prepared for what can go wrong. The paper concludes that the risk assessment framework for aquaculture operation needs to be holistic to take into account multiple dimensions of risk, and the proposed methodology serves a good basis to develop the framework further. The paper also brings up the necessity to investigate further the definition of major accident and major accident hazards in aquaculture, especially for exposed fish farms that are exposed to different hazards comparing to the coastal fish farms today.","container-title":"Safety Science","DOI":"https://doi.org/10.1016/j.ssci.2019.09.021","ISSN":"0925-7535","page":"430-450","title":"Methodology for hazard identification in aquaculture operations (MHIAO. Workers at sea-based fish farms must consider all these risk dimensions in their everyday work. The occupational injury and fatality rate in Norwegian fish farming is high compared to other industries. On average, there has been one fatal accident per year in the period 2012-2020. Common modes of injuries include falls, blow by objects, entanglement/crush as well as cuts. Manual tasks are part of the work, and a survey showed that strain injuries was a main reason for worry, and the primary cause for work-related sick leave among aquaculture workers.

To support safe operations in aquaculture, safety management is mandatory. This presentation provides knowledge about the status of safety management and suggests improvements for occupational health and safety.

Materials and methods

The findings presented here are based on interviews, workshops, surveys, and document studies conducted over a period of almost ten years. Key projects include SFI Exposed (grant no. 237790), and Safer operations and workplaces in fish farming (grant no. 254899) supported by the Research Council of Norway.

Results

The focus on safety management from the regulatory authorities has expanded in recent years. The change from detailed, specific safety rules to functional regulatory requirements has increased the number of company-internal procedures (Størkersen et al., 2020). Aquaculture managers and operative personnel experience improved systematic safety work, but also that safety management systems could be more integrated in daily work (Kongsvik et al., 2018). Findings show that internal procedures are seen as too complicated, and that operators are not involved in the analysis phase of risk assessments (Holmen, Utne and Haugen, 2018). Challenges also exist regarding the implementation of risk assessments in the organizations and the transfer from risk assessments to improved operational safety.

Safety management that aims to protect workers must also consider the other risk dimensions found in operations, as well as the regulatory framework of the industry. Conflicting objectives related to protection versus production are found in aquaculture operations (Størkersen *et al*., 2021), and a survey showed that some employees think that production is prioritized at the expense of safety (Kongsvik *et al*., 2018). This may be related to organizational factors such as long work shifts and heavy workloads during large operations, which in turn may be connected to regulatory requirements.

Reduction of salmon lice and prevention of escape remain the major risks that guide regulation and technology development Salmon lice is the only indicator for sustainability and guides growth through the traffic light system. Delousing operations thus become highly important to make sure lice numbers are below the limit, but these operations may increase the risk levels personnel, fish welfare and environment negatively. A survey showed that during delousing, personnel report that they may work up to 20 hours for several days in a row (Thorvaldsen et al., 2020). Delousing has also been identified as an operation where risk of escape, lower fish welfare and fish mortality increases (Føre and Thorvaldsen, 2021).

(Continued on next page)

Practitioners experience an abundance of internal rules and protocols due to mechanisms such as work auditability, managerial insecurity and liability and audit practices. It is therefore important to avoid implementing measures that increase the distance between how we think work is done, and how it is actually done. Safety management requires procedures, resources and involvement of personnel, and the practical value depends on the communication between those who develop the system and those who use it. Research confirms that safety measures that fit well with the everyday reality of workers are generally considered to have a higher practical relevance than others. For instance, the perceived practical relevance of measures such as planning (to avoid long working hours and alone work), involving personnel and a ensuring a skilled team, is considered to be higher than procedures (Thorvaldsen *et al.*, 2021).

Conclusion

To ensure adequate safety management it is important to consider how operations are conducted. Safety activities should be assessed through involvement of personnel at the fish farms who have detailed knowledge of work practices. This way all risk dimensions and how they affect occupational health and safety can be considered.

A CROSS REGIONAL STUDY OF DRIVERS FOR INNOVATION IN AQUACULTURE

T. Thorvaldsen*, MS. Olsen, HM. Føre, T. Osmundsen, A. Misund, K. Størkersen, S. Afewerki, R. Tveterås, S. Sønvisen, P. Lader, D. Kitazawa, C. Mather, M. Rust, JL. Anderson, MD. Smith, R. Shields, K. Heasman

SINTEF Ocean, Postboks 4762 Torgarden, NO-7465 Trondheim, Norway
E-mail: trine.thorvaldsen@sintef.no

Introduction

Norway is a leading producer and exporter of Atlantic Salmon (*Salmo salar*) globally. Open cages in the coastal zone remain the most common type of production system, but new production systems for open ocean aquaculture, and closed production cages in sea or land-based sites are also emerging. There are multiple reasons for the development in the Norwegian industry. Environmental challenges have resulted in regulatory changes over the past decade. The Norwegian government implemented several measures to make the aquaculture industry more sustainable, especially focused on environmental sustainability. Important initiatives include regulations that aim to spur innovation to reduce environmental impact and thus, enable industry growth. Key drivers for technology development in Norwegian aquaculture include prevention of fish escape, reduction of salmon lice levels in the fish farms and utilisation of new areas further from shore (open ocean aquaculture) or on land. To promote technological innovation, development licenses were introduced by the government in 2015 (Føre et al. 2022).

In the project DEVELOP, innovation in aquaculture resulting from development licenses was studied. This research was funded by the Research Council of Norway (grant number 301486). We also investigated drivers for innovation beyond the Norwegian regulatory context. To compliment the impacts to innovation of Norway's development licenses we investigated and compared similarities and differences in the observed/present drivers for innovation in aquaculture industry across nations and regulatory contexts.

Materials and methods

The international advisory board for the project DEVELOP conducted an online workshop to compare and discuss current technology status and drivers for innovation in different geographical regions. This comparison was based on the participants own experiences and as well as literature reviews.

Results

In Canada, drivers for innovation are geographically variable and are substantially different between the west and east coasts of the country. While all operators face challenges associated with climate change and warming waters, sea lice and disease, and mass die offs, the social drivers for innovation are more intense on the west coast where licences are being phased out and where there is strong pressure to shift to land-based systems of production. On the East Coast, producers enjoy the support of provincial governments and so social opposition plays a somewhat smaller role in driving innovation.

In Japan, environmental problems and more use of unused sea areas are key. Environmental problems are regulated by Sustainable Aquaculture Production Assurance Act. Most cages are in sheltered areas, but several offshore and submergible cages projects have been tried.

In USA aquaculture is regulated through environmental laws. Identifying suitable geographic areas called Aquaculture Opportunity Areas is ongoing. Identifying and mitigating environmental, economic, social, and cultural considerations as a part of an Environmental Impact analysis are a part of this process.

In the UK strategic plans for increasing growth exist. For salmon transparency in sea lice numbers and mortality is required. Innovation drivers include fish health and welfare, environmental sustainability, final product quality, diversity and inclusiveness, HSE and social license to operate.

In New Zealand, shellfish and seaweed structures for exposed sites are being developed. Innovation drivers include sustainability, efficiency, reduced negative impact on surroundings, animal welfare, utilization of exposed sites and development of equipment for exposed areas as well as social upliftment of low-income areas.

(Continued on next page)

Conclusion

When comparing the regions, there are several overlapping challenges driving the innovation in aquaculture. Still, the political ambition for the industry to grow is more prominent in Norway than the other regions. The regulatory scheme based on production licenses, which are limited and have considerable value, equip the Norwegian authorities with an effective policy tool (the possibility of allocating new licenses) to spur technological innovation by providing risk-relief and increased production capacity to actors that bring about technological innovations. Hence, a key attribute for policy to spur innovation is the licence value and the existing competition for increased allowed production capacity. Common drivers across nations are related to the need to reduce environmental impacts, the need for area (sheltered and less sheltered), need for economic development, and the need for social license. Many of these are related, however, the regulatory contexts varies and as a result, there are different implications for innovation and how these drivers for innovation will affect industry development and regulation.

Social license is pointed out to be an important driver for innovation as specific environmental challenges affect the social acceptability of the industry. Although not stated explicitly, this is an important underlying cause for governmental and industry actors when deciding on regulations and measures for innovation. Further investigation of social implications of innovation in aquaculture could be fruitful for understanding the possibilities of regulatory measures targeting technological innovation in aquaculture.

OVERCOMING THE INFERTILIY PARADOX TO PRODUCE INFERTILE GENOME-EDITED FISH

Alan E Tinch*

The Center for Aquaculture Technnologies, San Diego, USA.
Email: atinch@aquatechcenter.com

Genome Edited (GE) fish are already available in some markets and as permissive legislation becomes more common they will be available elsewhere. GE will be used by established breeders to bring sustainable benefits in health, welfare and efficiency. GE can improve traits that were previously difficult to handle such as infertility, sex, disease resistance, efficiency and yield. GE alterations are indistinguishable from natural mutation. Breeders will make edits that have large effects on traits that improve adaption to farm environments but may reduce fitness in the wild. Most fish farming happens in an open environment and escapees could interbreed with wild counterparts. Fish that have been genome edited for improved commercial performance should be made infertile to prevent introgression of new gene variants into the surrounding environment.

The infertility paradox where breeders need fertile broodstock and producers need infertile production fish makes it challenging to breed for infertility. This paradox can be overcome if desirable genotypes can be made infertile by GE and their germ cells transferred to surrogate broodstock for multiplication. Using this reproductive strategy, GE of functional traits in high merit fish can be combined with GE for infertility and surrogate broodstock used to produce large volumes of infertile juveniles for production. Infertility is integrated into the breeding programs to ensure ecological sustainability and prevent movement of GE alleles for improved farm performance into wild populations.

GENOME EDITING TO PRODUCE MONOSEX AND STERILE FISH FOR AQUACULTURE

Genome Editing to Produce Monosex and Sterile Fish for Aquaculture

John Buchanan, Xavier Lauth, Takeshi Umazume and Alan Tinch

WIPO (PCT) Patent Appln No. US2019/046088

Introduction

Aquaculture involves farming fish in increasingly large volumes to meet the needs and expectations of consumers for high quality protein. It is generally advantageous for farmed fish to be produced as sterile. This creates efficiency in production, reduces environmental impact by preventing problems of escapees interbreeding with wild counterparts, and provides a foundation for future GE applications.

Three lines for making monosex infertile fish

The sterile host: A line of agametic fish with intact somatic gonad capable of nursing donor derived germ cells. *Hemizygous mutant can be breed to produce 25% of surrogate for germ cell transfer.*

The infertile monosex donor: Edited genes to block male or female sex determination and sexual maturation. Inactivated genes only affect the somatic cells of the gonad.

The transplanted host gonadal chimera to mass produce monosex infertile fish

The germ cell free recipient line

Genetic control of sex determination

Genetic control of female infertility

Genetic control of male infertility

Phenotype of infertile females

Phenotype of infertile males

This project was partially supported by the Biotechnology Risk Assessment Program competitive grant number 12575705 from the USDA - National Institute of Food and Agriculture (09/01/2018-08/31/2021).

USDA United States Department of Agriculture National Institute of Food and Agriculture

Propagation via germ cell transplantation

Structure of the sterility technology

- Multiplier Broodstock crosses
- Gene Editing for Sterility and monosex if necessary
- Germ Cell Extraction

Growth benefit of all male sterile tilapia

+22% Males >Females

+12% Sterile > fertile males

Results and conclusion

We have identified and inactivated evolutionarily conserved genes whose functions are essential for both sex determination and gametogenesis. Double edited combination of those genes produced monosex infertile fish that can be propagated via germ cell transplantation. All infertile male tilapia grew 12% faster than their fertile siblings starting around the time of puberty. The concepts and technologies proposed in this project have been validated in tilapia, the third most important fish in aquaculture, but should prove broadly applicable across multiple fish species.

IMPACTOFPHOTOPERIODE,TEMPERATUREANDFEEDINGREGIMEMANIPULATION ON ATLANTIC SALMON, *Salmo salar,* FRESH WATER GROWTH PERFORMACE AND GENE EXPRESSION

M. J. Tollervey*, M. Bekaert, H. Migaud· J. Taylor, A. P. Gutierrez

Institute of Aquaculture, University of Stirling, Stirling FK9 4LA, Scotland, UK
Email: mjt4@stir.ac.uk

Introduction:

Atlantic salmons early and freshwater developed is regulated by both endogenous and exogenous environmental ques (Steffansson et al., 2008). Commercial production often manipulates the culture environment to both increase production and its flexibility (Bjornsson et al., 2000). Use of land-based systems, such as recirculating aquaculture systems (RASs), are now increasing in use in order to maintain productivity gains while mitigating negative effects to the wider environment (FAO, 2017). However, the environment provided in RASs can have heightened stability lacking variation know as important to salmon's development. The accumulated effect of the RASs specific environment is therefore hypothesised as contributing to the poorer performance of fish produced in these systems later in life. We therefore aim to investigate the potential negative impacts of common husbandry manipulation and lack of environmental entrainment of RASs. Specifically, the (possibly interacting) effect of photoperiod, temperature and feeding stability on *s.salar* and how this has differently impacted on gene expression and growth performance.

Materials and Methods:

The fish originated from a stock housed at Buckie burn facilities, University of Stirling. Approximately 2,500 were transferred to temperature aquarium at the University of Stirling at 15g and held under constant light, constant feed and 11.5 degreesC. Whole brain tissue samples were taken at baseline (n=6). Fish were pooled and split between six treatment groups for 800dd, each run in triplicate. Treatments were a combination of photoperiod, feeding, and temperature regimes (see table 1). At 800dd whole brains were sampled from 6 fish per treatment (n=36). Feed intake was assessed for the two weeks following final sampling. RNA was extracted from all samples and sequenced by Novogene on NovaSeq 6000 PE150 platform. Three libraries were removed from further analysis due to high duplication rate (52.6%, 63.3% and 64.7%). Libraries cleaned using fastp and aligned against *s.slara* genome (Ssal_v3.1, RefSeq GCF_905237065.1) with hisat2 and Stringtie. Using DESEq2 differently expression genes (DEG) were identified, with p<0.001 and –logfold2 change >2 thresholds. DEG genes were identified relative to control conditions, accounting for DEG through time (baseline compared to 800dd control).

Results and Discussion:

Temperature had the greatest impact on fish growth, with low temperature treatments on average gaining 49.54g (SEM: 2.26) over 800dd, 16.64g more than those held at 15.5degreesC. While fish exposed to continuous light and continuous feed showed greater weight gains, they were not significantly greater than other treatment groups. Interactions between environmental treatments reiterated these trends. Considering all treatments (table 1), significant differences in growth were only seen when comparing treatments at low temperatures, where the best performing group was under continuous light and feed (gaining 52.90g, SEM 1.61), in line with other findings. Principal component analysis also indicated temperature as an impactful factor, with low and high temperature treatments clustering separately along PC2. Photoperiod regime also appeared to have a secondary impact on samples along PC1, with only high temperature groups differentiating along PC1 (figure 1). DEG due to photoperiod, temperature and feeding regimes, relative to the control were identified. Results indicated that temperature maybe principally driving changes in gene expression, whereby relative to low temperature control, a higher number of DEG were seen in treatment groups held at 15.5degreesC, for example across the six treatment groups no DEG were identified in those held at low temperature relative to the control.

In summary, in terms of growth low temperature, continuous feed and continuous light produced the best performing fish. Out of these treatments, temperature appears as having the greatest impact on gene expression in Atlantic salmon brains, with secondary impact of photoperiod, acting particularly at high temperatures despite no difference seen in their growth. Continual analysis will identify the function of DGE as well as these samples methylation patterns to further understand the implications the RAS environment.

Introduction

Aquaculture provides two-thirds of the world's aquatic products. It represents a source of high-quality protein for humans and has become one of the fastest-growing industries in global food production. Along with the world population increase, global aquaculture production is expected to increase swiftly to meet the fish demand for human consumption in the forthcoming years [1]. Indeed, the rapid rise of the aquaculture production system has led to several issues, such as fish over-feeding, disease outbreaks, and water pollution. For this reason, the industry and academic community are requested to seek strategies to increase productivity and efficiency of the aquaculture systems, while controlling the negative impact [2]both for production systems and for breeding programs. Most of the current methods are based on manual measurements, which are laborious and stressful to the animals. Therefore, the development of fast, precise and indirect measurement methods for traits such as body weight (BW and improving the environmental, economic, and social sustainability. In this framework, automation and smart technologies are gradually gaining traction in the sector. Precision aquaculture applies control-engineering standards to fish production, to improve farmers' monitoring, control, and recording of biological processes in fish farms [3]. The management of land-based and offshore aquaculture facilities requires an accurate periodic estimation of fish length and weight to control the growth of fish, allowing for calibrating feed administration and evaluating animal welfare. Length and biomass estimation is usually conducted manually on a reduced subsample. Here we present a low-cost prototype system ("smart buoy") tested in a commercial mariculture cage. The buoy, equipped with stereoscopic cameras, can capture fish images, which are then automatically analyzed using the cognitive capabilities of AI and computer vision algorithms. This technology allowed achieving precise automatic length and weight estimation of cultured gilthead seabream (*Sparus aurata*, L.) during the on-growing period.

Materials and methods

The study was conducted at the "Maricoltura e Ricerca Soc. Coop." fish farm (Capraia Island, Italy), approximately 0.17 nautical miles from the coast. The underwater stereo camera was installed on a floating buoy anchored within a commercial-scale farming cage. The two-camera lenses were spaced 8 cm apart on the vertical axis and oriented towards the cage net at about 3 m. The buoy transmitted over a mobile network to a cloud-based site where images were stored. Images capturing and analysis were carried out during the last day of the commercial finishing phase, in a cage that hosted about 3500 gilthead seabreams. For fish body length estimation, a complex AI pipeline was designed; the pipeline has been split into smaller packages to break down the final task into its components and thus simplify and manage the analysis more efficiently. The raw stereo images were fed to an improved Convolutional Neural Network (CNN) called YOLOv4 [4]and theoretical justification of the result, is required. Some features operate on certain models exclusively and for certain problems exclusively, or only for small-scale datasets; while some features, such as batch-normalization and residual-connections, are applicable to the majority of models, tasks, and datasets. We assume that such universal features include Weighted-Residual-Connections (WRC, trained to locate the single fish in the image through the use of bounding boxes. In a second step, each bounding box was used to obtain the individual image of the fish and then entered into a CNN, RESNET-101 (RES101) [5], optimized for image recognition. From each image, the relevant individual fish were extracted and annotated with two reference points (landmarks), which allowed the system to measure the fish standard length in pixels by connecting the two marks. Finally, the length unit was transformed from pixels to centimeters, using the translation information derived from the calibration phase with the chessboard target.

(Continued on next page)

A total of 190 fish (from catches intended for sale) were also collected and photographed in controlled conditions (digital scale, tripod, and professional camera). The data obtained from this subsample were used to *i)* compare biometric results obtained from AI; *ii)* calculate a length-to-weight relationship (LWR) curve, and *iii)* deduce fish side view area (in cm^2). To improve the biomass calculation performance, not derived by the estimated standard length (SL), a new approach was also developed to infer the weight of the fish from its side view area. Here we present the preliminary methodological results based on Mask R-CNN, a framework for the segmentation of object instances that will be exploited for the automatic extrapolation of the area [6]. Moreover, to fit a model fitting between natural log-transformed body weight and side area (RANSAC algorithm [7]Random Sample Consensus (RANSAC), a total of 190 seabreams were weighed and photographed in controlled conditions: 110 from the same cage equipped with the smart buoy and 80 from a land-based experimental farm in Italy. The Mean Absolute Percentage Error (MAPE) was used to measure the accuracy of the prediction between the measured weight and the estimated weight from the side area of the fish.

Results and Discussion

The AI algorithm identified 272 fish from 76 shoal images taken within the cage. Of the total, 148 fish were discarded as the translation rate fell below a threshold of 140 pixels. The remaining 124 fish were automatically processed for standard length estimation (AI measurements). The mean standard length and weight (± SD) of fish obtained from sampling and those estimated by the AI were respectively 27.1 ± 1.6 cm and 26.3 ± 4.4 cm, and 606 ± 103 g and 585 ± 239 g, with mean differences for length and weight of 3.0 and 3.6%. Both distributions behaved as normal curves (Shapiro = 0.9, $P = 0.07$; Shapiro = 0.99, $P = 0.59$, for sampled and AI estimated, respectively), although variances were not homogeneous (Levene test $P < 0.0001$). However, the most representative classes (26, 27, and 28 cm bins) were found to be the same from both actual measurements and AI. The distribution estimated by the AI had greater dispersion than the sampled one, which was more clustered. On the other hand, the means were not significantly different ($F = 3.90$, $P = 0.05$).

Preliminary results concerning a novel automated approach to estimate the biomass of a single fish from its side view area have shown promising results: the RANSAC algorithm significantly fitted between seabream measured weight and estimated area (in cm^2) (calibration dataset n = 127; equation: $y = 1.58x - 2.05$; $r^2 = 0.945$, $P < 0.0001$). MAPE (±SD) between measured vs. estimated weight reached 1.26 ± 1.55 % (validation dataset: n = 63). As reported by previous studies [8], [9]500 weights and corresponding images of harvested Lates calcarifer (Asian seabass or barramundi, there is a strong positive relationship between weight and side view area in several fish species. We believe this evidence can be used to deduce the single fish biomass starting from data obtained by an AI approach independent of the estimated length. In this way, more accurate results would be found compared to those obtained through the traditional length-to-weight relationship, a method commonly used but strongly influenced by the rearing site and which involves important estimation errors.

Computer imaging together with artificial intelligence perfectly meets the needs of a modern European sustainable aquaculture by optimizing operational activities and decreasing operating costs. The buoy developed in this study, despite being a prototype, gave accurate results (3% of the fish standard length between AI and sampling measurements, along with a very similar size class distribution), proved to be viable in commercial mariculture, and has a moderate cost (about €3,000) compared to other solutions on the market. Further steps will cope with the improvement of the buoy system and the quality of the stereo photos. These upgrades will allow for better monitoring of farmed fish characteristics, in particular biomass estimation, and will allow the device to be applied to other types of farming, such as land-based aquaculture (raceways, ponds, and tanks), and different fish species.

Introduction

Pikeperch (*Sander lucioperca*) is characterized by rapid growth, high breeding performance, and its fillet is popular among consumers and therefore in great demand on the national and international markets. As a result, there is a high research interest in this good-tasting and highly traded percid species. The effects of different production systems on pikeperch growth and health are well studied (e. g. Zakes et al. 2012, Policar et al. 2016, Baekelandt et al. 2018). However, all of these studies do not address muscle tissue and its influence on fish meat quality.

Our previous studies revealed significant differences in physical meat quality and lipid composition, dependent on the animal origin and season (Komolka et al., 2020, Tönißen et al., 2022). Based on these findings, we further investigated the cellular and genetic differences of muscle tissue and the resulting meat quality in pikeperch. In the present study, we compared the biochemical, genetic, and histological characteristics of muscle tissue of wild and farmed marketable pikeperch.

Methods

Pikeperch from recirculating aquaculture system (RAS) were obtained from the Mecklenburg-Vorpommern Research Centre for Agriculture and Fisheries, Germany. The fish were fed a commercial diet (Coppens Supreme-10, 4.5 mm pellet size) with a feeding rate of 1.0% per body weight. Wild pikeperch aged two years were sampled from a fishery at Hohen Sprenz Lake in Mecklenburg-Vorpommern, Germany. They comprised the same age and sampling period as the RAS fish. White muscle tissue analysis included biochemical parameters (nucleic acid amount, protein content), enzyme activity of CK (EC 2.7.3.2), LDH (EC 1.1.1.27) and ICDH (EC 1.1.1.42), gene and protein expression (PAX3, MYF5, IGF1, IGF2 and MSTN). In addition, muscle fibre structure at the caudal penduncle (H&E and NADH diaphorase staining) and immunohistological staining of myogenic progenitor cells (Pax3+, Myf5+) was performed. Significant differences were determined with a two-tailed Student´s t-test ($q < 0.05$) and a general linear model using SAS software version 9.4 (Statistical Analysis institute Inc., USA).

Results

The white muscle of wild pikeperch had a significantly higher RNA and DNA content than the RAS pikeperch, but the protein content in RAS fish is 30% higher ($p < 0.01$). In contrast to the comparable enzymatic activity of ICDH, the CK was 1.4 times higher and the LDH was 1.8 times higher ($p < 0.0001$) in wild pikeperch. This allow us a first look at the metabolic cycle of the pikeperch.

Furthermore, we were able to gain insights into the muscle fibre structure of pikeperch. The muscle structure differed in the white, intermediate and red fibre, but was not influenced by the origin of the fish from wild or RAS facilities. The number of nuclei per fibre cross-section were higher in the white fibre area ($p = 0.027$), but the nucleic density is higher in red fibre ($p < 0.001$). RAS pikeperch indicated significantly higher values in the myonuclear domain (ratio nuclei/μm^2) of white and red fibre compared to the wild animals. Additionally, immunhistological staining of the myogenic precursors revealed that in wild pikeperch, the distribution of $Pax3^+$ and $Myf5^+$ nuclei was not significantly different between the fibre types. However, the RAS animals had a significant higher proportion on $Pax3^+$ nuclei (group*fibre; $p = 0.03$) and reduced number of $MYf5^+$ nuclei ($p = 0.02$) in the white fibres. Due to this shift, the proportion of $Myf5^+$ nuclei in the red fibre area was twice as high as in the white fibre area. These results were confirmed by protein expression analysis. In RAS pikeperch the protein expression of Pax3 and Myf5 was significantly higher ($p < 0.0001$ rsp. $p < 0.01$) than in wild fish. In contrast, the white muscle-specific gene expression was comparable in wild and RAS pikeperch.

(Continued on next page)

Discussion

Due to its positive growth characteristics and the excellent taste of its fillet, the pikeperch is a promising candidate for RAS. The present comparative study to wild pikeperch allows us to investigate the effects of RAS husbandry on muscle tissue. Knowledge of pikeperch muscle tissue is important for successful breeding, rearing and growth in aquaculture systems as well as for ensuring fish meat quality.

Many of the muscle parameters presented here have been studied for the first time in pikeperch. For example, the biochemical performance parameters have shown that the species-specific and relatively constant DNA content is influenced by the cultivation of the pikeperch. The use of biochemical markers to assess nutritional or health status has been studied in other fish species (e.g. Ferguson et al. 1986, Hussna et al. 2020), but not in pikeperch. Our enzymatic data presented show that biochemical markers could be used in pikeperch aquaculture. Together with the gene/protein expression data and muscle structure analysis, this leads to a better understanding of the muscle tissue of pikeperch.

In general, the influence of abiotic and biotic factors on muscle physiology in pikeperch has not yet been sufficiently investigated. Our data demonstrate that some of the parameters studied are influenced by environment or origin. Therefore, the multiple parameters of the pikeperch muscle and their patterns presented here provide a basis for further analysis. How these parameters can be maintained or improved for the desired fish meat quality in aquaculture will be subject of further research.

Introduction

Since conventional statistical techniques cannot analyze large numbers of interrelated variables, a statistical approach with the power to extract principal components from a multitude of data needs to be applied (Sun et al., 2011). Application of mathematical and statistical methods used in order to process large data sets in an optimal way is termed multivariate data analysis (Kurtanjek and Gajdoš Kljusurić, 2014). Multivariate tools (MVA) used for reduction of variables, for classification and grouping, are Factor Analysis (FA) and Principal Component Analysis (PCA). They can give an overview of complex multivariate data and reveal relations between observed samples, allowing detection of significant variables as well as outliers (Bro and Smilde, 2014). The aim of the study thus was to assess the value and applicability of MVA for hematological and plasma biochemical responses of fish over two seasons, using physicochemical water properties and heavy metals concentration of water as determinants of multiple fish stressors.

Materials and methods

Important parameters were extracted from physicochemical water properties, heavy metals from water, leukogram with PCV values, and plasma biochemistry from *Carassius gibelio* blood, all measured in previous studies (Topić Popović et al, 2015). For this work, four different MVA tools were used; three of them were Analysis of Data and one was a Modeling Data tool. Analysis of Data tools: Agglomerative Hierarchical Clustering (AHC), FA and PCA. Modeling Data tool: Partial Least Square Regression (PLSR). After extracting primary parameters, PLSR was used to investigate the possibility for direct and rapid prediction of expected hematological and plasma biochemistry responses based on the water quality. Water and fish were sampled during the operation of a municipal wastewater treatment plant (WWTP) in NE Croatia. Representative seasons: spring (S) and fall (F). Representative sampling sites: 1. polluted canal receiving the outflow of treated wastewater (TW), and 2. unpolluted natural creek (NC) in vicinity of the WWTP.

Results and discussion

According to AHC, concentration of heavy metals had the same grouping pattern as plasma biochemistry (Figure). Clustering allowed grouping of observed data sets based on similarity of the observed cases, i.e. based on the season and the site of sampling. Clustering regarding fish plasma biochemistry showed an increase of linkage distance (> 45) for fish caught in spring in TW vs. NC. The same trend, but with larger linkage distance (> 200) was noted when the observed variables in the clustering process were heavy metals. Cluster analysis grouped the data based on the similarity of cases while FA, as an explorative analysis, grouped similar variables into dimensions, but FA does not distinguish between independent and dependent variables. It reduced the information by reducing dimensions of observations thus eliminating variables which were not significant enough (COD, ammonium, nitrite and nitrate, Hg and Pb, monocytes and PCV, and ALP). PCA analysis was conducted to determine similarities and differences in the observed sets of data depending on sampling sites and seasons, on the reduced data, and confirmed the AHC results. It also demonstrated which parameters were dominant in which season and on which sampling site. Unlike in the AHC method, there were quantitative differences for the observed parameters. PLSR was used to investigate a possibility for direct and rapid prediction of expected hematological and plasma biochemistry responses to water quality. It was an additional confirmation for the soundness of conducted methods of multivariate analyses, as well as the applicability of the model for prediction of expected parameters in the blood of *Carassius gibelio* based on water pollution in different seasons. The MVA tools provided valuable information on fish physiological status and stress impact on blood biochemistry.

Introduction

A proper development of the aquaculture sector implies: (a) an effective replacement of marine raw ingredients (fish meal, FM; fish oil, FO) by emergent raw materials and (b) a successful breeding program addressed to improve growth, feed utilization and fish health. However, there is still some hesitancy towards the potential side effects of novel ingredients on critical aspects such as fish disease resistance, mucosal health or alterations on the fish gut microbiota homeostasis. Thus, to study if selected fish genotypes can benefit from the use of functional additives in aquafeeds to guarantee a future scenario covering the limitations on the availability of FM/FO, in terms of enhancing fish growth performance, mucosal health and disease resistance, is the aim of the present study.

Materials and methods

Two batches of European sea bass juveniles, high growth selected (HG; selected sires x selected dams) and wildtype (WT; wild sires x selected females) populations produced at MARBEC-IFREMER, were grown at the facilities of the Parque Científico-Tecnológico Marino (PCTM) at University of Las Palmas de Gran Canaria (Telde, Canary Islands, Spain). Fish were fed a "future diet", replacing totally FO by a combination of PO and DHA oil and reducing by a 50% FM content by PM inclusion (Skretting ARC, Norway), until achieving the initial experimental size of 16 g. After that, fish were randomly distributed in 24 tanks of 500 L (34 fish/tank; 12 tanks by genotype; 19.0 ± 0.4 g) and supplemented with 3 different experimental functional additives (INVE, Belgium) top-coated on future diet as follows: (i) 2 weeks at high dose followed by (ii) 10 weeks at low dose. The functional additives used were a probiotic mixture (PROB), organic acids mixture (ORG) and a phytogenic (PHYTO). Growth performance and feed utilization parameters were calculated for both feeding periods. Fish were sampled for gut integrity, functional microbiome and gut gene expression at the end of the total feeding trial. After each dosage feeding period, a pathogen challenge test (*Vibrio anguillarum*) plus stress condition (overcrowding) was applied to study the potential of additives to ameliorate the combined effect of both pathogen and stress condition. Fish were fed their respective diets along the challenge test and fish survival was recorded daily.

Results

No effects on weight gain were detected after 2 weeks of feeding in relation to fish genotype origin and functional diet supplemented. The results of the challenge test after two weeks are shown in Fig.1A (HG) and 1B (WT). A significant effect was detected for diet ($F=3.469$, $p=0.0411$), presenting fish fed the high dose of PROB a lower ($p<0.05$) survival than fish fed control diet, regardless of the fish genotype origin.

After 10 weeks of low dose experimental functional additives supplementation, HG fish presented a higher weight ($F=193.988$, $p<0.0001$) and SGR ($F=53.389$, $p<0.0001$) than WT fish, presenting fish the control diet higher ($p<0.05$) final weight than fish fed the PROB diet within the HG genotype group. WT fish presented lower total feed intake than HG fish at the end of the total feeding trial ($p<0.05$), regardless of the diet fed. After the final challenge test, diet fed influenced ($p<0.05$) the fish survival probability, presenting fish fed the ORG diet the lowest ($p<0.05$), irrespective of the fish genotype, whereas fish fed the future and PHYTO diets presented the lowest mortality in HG and WT groups, respectively (Fig.1C

(Continued on next page)

and 1D).In terms of GALT-related gene expression, HG fish presented lower ($p<0.05$) cyclooxygenase-2 (*cox-2*) gene expression that WT fish in both distal and proximal gut regions, regardless of the diet fed. The same effect was observed for cluster of differentiation 4 (*cd4*) gene expression in the proximal intestine. Neither the fish genotype nor diet affected the gene expression of *il-1b* gene, however fish fed PROB diet presented an upregulation ($p<0.05$) of *il-1b* gene expression compared to fish fed control diet within the HG genotype. Similarly, semiquantitative gut morphological analyses did not show evident changes in the incidence and patterns of distribution of intraepithelial lymphocytes, granulocytes, goblet cells, vacuoles and mucosal branching in both intestinal regions associated neither to diet nor fish genotype. Slight variations on the distribution pattern were detected for rodlet cells in fish fed functional diets compared to fish fed the future diet, regardless of the fish genotype origin. In terms of gut microbiota, discriminant analysis did not show a clear separation among fish fed the future diet and fish fed the experimental additives regardless of the genetic background, however variations on specific taxa relative abundance were detected. For example, fish fed ORG diet presented higher relative abundance of *Streptococcus* in both genotypes, whereas for fish fed PHYTO this effect was observed for Lactobacillales order and in fish fed PROB presented lower abundance of *Pseudomonas* and *Acinetobacter* genera.

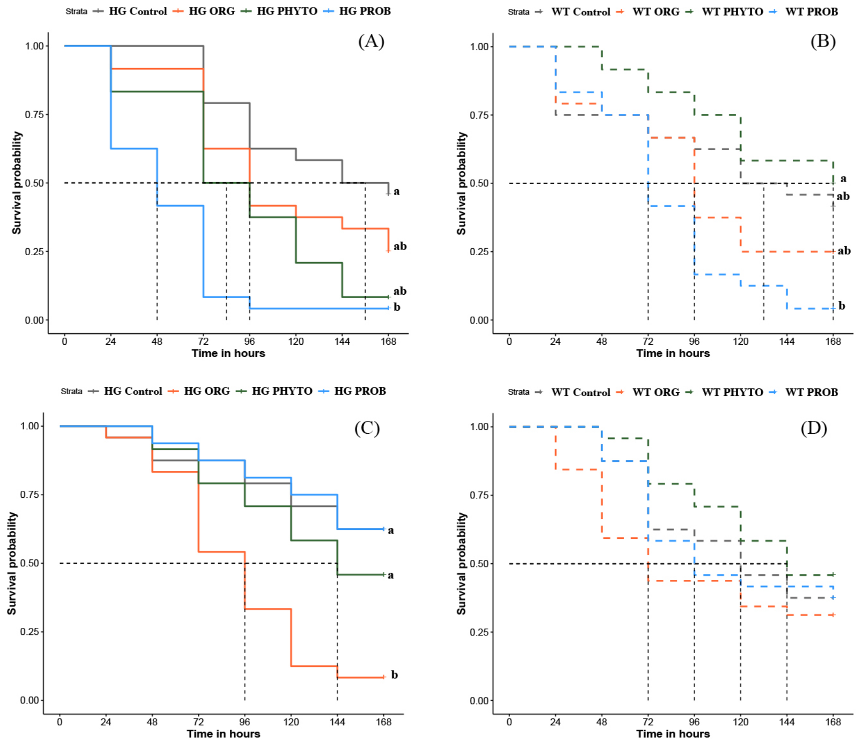

Fig. 1. Cumulative survival (%) of European sea bass (*Dicentrarchus labrax*) along the challenge test against *V. anguillarum* combined with stress by confinement after 2 weeks of high dose for HG (A) and for WT (B) genotypes and 12 weeks of feeding (2 weeks high dose + 10 weeks low dose) for HG (C) and for WT (D) genotypes. Different letters denote statistical differences ($p<0.05$; Kaplan-Meier survival). HG, genetically selected genotype; WT, wild type European sea bass genotype. Diets: probiotic mixture (PROB), organic acids mixture (ORG), phytogenic (PHYTO).

THE POTENTIAL FOR USE OF CAVIPLASMA DEVICE FOR ELIMINATION PATHOGENS IN WATER

Ivona Toulová*, Ivana Papežíková, Věra Nováková, Miroslava Palíková

University of Veterinary Sciences Brno, Palackého 1946/1, 612 42 Brno, Czech Republic
E-mail: H21277@vfu.cz

Currently, water contamination is of high importance and researchers are looking for new methods to purify water. Researchers from Brno (Czech Republic) developed a new technology for water purification using low-temperature plasma and cavitation. This device is called CaviPlasma which is now protected by a Czech patent (Rudolf et al., 2019). CaviPlasma can remove chemical residues such as oestrogens from contraceptive products and kill pathogenic microorganisms. First experiments with CaviPlasma demonstrated its exceptionally high efficacy in purifying water contaminated with cyanobacteria (*Microcystis aeruginosa*) (Maršálek et al., 2019). Another study demonstrated the ability of CaviPlasma-treated water to inactivate algae and cyanobacteria (Čech et al., 2020). We are considering the possibility of using this device to eliminate fish pathogens in water. We tested efficiency of CaviPlasma on the survival of bacteria (*Aeromonas salmonicida*, *Aeromonas hydrophila* and *Flavobacterium psychrophilum*). Thirty ml of bacterial suspension was inoculated into three l of tap water in sterile bottles and mixed well. 500 ml was used as positive control without treatment and 2,5 l was used for CaviPlasma treatment. Water with added bacteria underwent five passages through CaviPlasma device After each passage, samples of treated water were taken for futher analysis. During the first set of experiments the water flow rate was set to 1 m^3/h (ca. 17 slpm) and the separation of electrodes was approx. 16 cm. The backpressure was lowered to set the cavitation cloud spanning from the nozzle electrode to half the electrode distance. The discharge was energized using a HV generator set to approx. 65 kHz frequency at an input power of 600 W. The total treatment time of loaded batch of contaminated water was set to 65 seconds and 105 seconds. During the second set of experiments the separation of electrodes was set to 12 cm and the cavitation cloud spanned the entire inter-electrode space. At these conditions the input power was increased to 1 kW keeping the treatment times the same as previous. Samples of treated water were cultured at 17 °C and concentration of bacteria was regularly measured during the whole cultivation using plate count method. After cultivation, grown colonies were counted as colony forming units (CFU) per ml. In the first set of experiments, *Aeromonas* spp. survived in the treated water. The second set of experiments affected the survival of *Aeromonas* ssp. The bacteria were present in low quantities and gradually their quantities were decreasing. *Flavobacterium psychrophilum* was killed after only one passage of water in both sets.

We are testing the potential of CaviPlasma to eliminate a parasitic ciliate *Ichthyophthirius multifiliis* (the causative agent of the white spot disease). Water with developmental stages of *Ichthyophthirius multifiliis* was treated with CaviPlasma. This water underwent one or 5 passages through CaviPlasma device. Positive and negative control groups were included. The experiments on the effect of CaviPlasma on *Ichthyophthirius multifiliis* are in progress, the results will be presented as a poster at the conference.

This study was funded by the Internal Grant Agency of the University of Veterinary Sciences Brno (project no. 220/2022/FVHE) and by the Ministry of Agriculture of the Czech Republic (project no. QK21010030).

Introduction

Eurasian perch (*Perca fluviatilis*) is a fresh water carnivore that is relatively new in aquaculture and gaining increasing attention in recirculation aquaculture system in Europe. Eurasian perch culture is an expanding area of commercial fish farming in Europe. This species requires high protein diet formulated with marine fishmeal for balanced nutritional composition to optimize digestibility because of their very low feed consumption rate compared to other carnivore fishes. Several factors such as temperature, pH, diet, and age affect enzyme activity in the gastrointestinal tract of fish and thus can influence the biological availability of the feed. An alteration of the environmental temperature can affect food intake and gastrointestinal transit time, digestive enzyme activity, absorption of nutrients and how they store energy. There is a strong influence of temperature of fish due to their ectothermic nature. Knowing the activity of the digestive is important in designing feeding and rearing protocols which is suitable to the digestive physiology of respective fish species. The most important digestive enzyme in carnivore fishes are the protease enzymes (pepsin, trypsin, chymotrypsin and alkaline phosphatase activity) and lipase, although there is presence of amylase activity it is has less importance. The correlate of trypsin, chymotrypsin and alkaline phosphatase activity with fish growth has been established. The time it takes for food to pass through the gastrointestinal tract is influenced by numerous factors like fish species, size/age, food quality and quantity (ration and feeding frequency), and temperature. The aim of this study is to examine the digestive enzyme of Eurasian perch and determine which temperature is optimal for digestion.

Materials and Methods

For this study *Perca fluviatilis* (perch) fish (1-year-old, 50-60 g, 10 cm) were maintained at 16°C, 18°C, 20°C and 22°C, in 150 liters' aquarium and acclimatized for 48 hours and emptying of the digestive tract before feeding. The fish were fed commercial feed containing 48% protein and 13% fat content at first feeding 0,75% of their body mass and second time after 6 hours another 0,75% of their body mass. Fish were then euthanized 6.5 hours after the first feeding, then were dissected to gain their continuous digestive system (stomach, intestine) for further analyses. 25-25 specimens per treatment specimen were stored at -20°C until processing them into analytical samples. Enzyme activity measurements were carried out in three replicates per treatment by three aliquots. Pepsin activity was made according to Anson (1938) from gastric enzyme extract. Intestinal enzyme extract was used to measure trypsin activity, amylase activity, lipase activity, total alkaline protease activity according to Hummel (1959), Bernfeld (1955), Carriére et al. (1993), and Peña et al. (2015); García-Ortega et al. (2000) Walter (1984) respectively. The protein content of the enzyme extracts was used to correct the enzyme activities hence the results were given in Units/mg protein.

Result

The pepsin activity and trypsin activity at 18°C and 20°C is significantly higher than 16°C and 22°C. pepsin and trypsin activity follow the same trend, increasing from 16°C, peaking at 20°C and drastically reducing at 22°C There was significant difference in total alkaline proteolytic activity between 16°C and 22 °C but it was not significantly different at 18°C and 20°C. The lipase activity at 18°C was significantly higher than at 16°C, 20°C and 22°C. Although the lipase activity at 20°C and 22°C was lower than at 18°C, it was still significantly higher than at 16°C. The perch kept at 20°C and at 22°C had significantly higher α-amylase activity than those that were cultured at 16°C and at 18°C. Our result indicates that 18°C and 20°C seemed to be the most appropriate for maximal protease (pepsin, total alkaline proteolytic, trypsin) activity.

(Continued on next page)

Conclusion

Eurasian perch is carnivorous in feeding habit hence we recommend a temperature between 18°C -20°C for optimal protein and fat digestion, however it is important to consider other factors other than enzyme activity to find a balance when selecting an optimal rearing temperature. There have been recommendations of higher growth rate at 23°C, higher SGR at 26.5°C and easier control of infection at 20°C. Finding a balance between all this factor is the key to a successful production cycle.

EFFECTS OF HIGH STOCKING DENSITY AND MILD HYPOXIA ON GILTHEAD SEA BREAM INTESTINAL TRANSCRIPTOME AND MICROBIOME

S. Toxqui-Rodríguez[1,2*], F. Naya-Català[1], P.G. Holhorea[1], J.A. Calduch-Giner[1], M.C. Piazzon[2], A. Sitjà-Bobadilla[2], J. Pérez-Sánchez[1]

[1]Nutrigenomics and Fish Growth Endocrinology Group, Institute of Aquaculture Torre de la Sal (IATS, CSIC) Spain
[2]Fish Pathology Group, Institute of Aquaculture Torre de la Sal (IATS, CSIC), Spain
E-mail: Socorro.toxqui@csic.es

Introduction

Studies in gilthead sea bream evidenced that high stocking densities exacerbate the negative impact of reduced oxygen availability, showing transcriptional analyses a different contribution of analyzed tissues (liver ≥ heart > muscle > blood) to the hypoxic- and crowding stress-mediated responses to cope with a changing environment (Martos-Sitcha et al., 2019). Moreover, blood metabolic and muscle transcriptomic landmarks indicate that mild hypoxia induces a hypometabolic state, increasing the contribution of lipid metabolism to the whole energy supply to preserve the aerobic energy production during exercise (Naya-Català et al., 2021a). The intestinal microbiota also has key effects on host health and welfare, and these complex populations tightly interact with the host affecting local and systemic physiological functions (Naya-Català et al., 2021b). Thus, the aim of the current study was to assess how mild hypoxia and high stocking rearing conditions affect the intestinal health of gilthead sea bream by applying a hologenomic approach to determine the host-microbiota interactions.

Methods

Two-year-old gilthead sea bream (450-500 g) were tagged and distributed in 3,000 L tanks to achieve three different initial rearing densities (low, LD: 6 kg/m^3; medium, MD: 12 kg/m^3; high, HD: 22 kg/m^3). Fish were fed close to satiety with a commercial diet from May to June (8 weeks) under natural photoperiod and temperature conditions at our latitude (40°5’N;0°10’E), varying the concentration of dissolved oxygen from 6-5 ppm in LD fish to 5-4 ppm in MD fish, and 4-3 ppm in HD fish. At the end of the trial, the growth rate of HD fish was 40% lower than that of MD/LD fish, and randomly selected fish from each group were taken to obtain tissue and mucus samples from the anterior intestine. RNA extracted from the anterior intestine from 10 fish/group was sequenced using NovaSeq PE150 (50 M reads/sample), and reads were assembled and mapped against the gilthead sea bream genome. DESeq2 was used to extract genes with $P < 0.05$ in all comparisons, that were used to perform discriminant and cluster analysis to determine the number of differentially expressed genes among conditions. K-means, GO and KEGG enrichment analyses were subsequently performed. The V3-V4 regions of the 16S rRNA of the mucus DNA samples from the same animals were amplified and sequenced by Illumina MiSeq. After quality filtering, taxonomic assignment was performed with a custom-made pipeline using the RDP database. Alpha diversity was calculated using Phyloseq and beta diversity using PERMANOVA and PLS-DA models. Correlations between differentially expressed genes and discriminant bacteria were studied using the corrplot R package.

Results

RNAseq and discriminant analyses revealed that a total of 2,813 differentially expressed genes significantly separated the three groups (Fig. 1A). K-means analysis divided these genes into four different clusters according to their expression patterns in each group, separating one cluster of 800 genes with higher expression in LD, a second cluster of 1,103 genes with higher expression in MD, a third cluster of 688 genes with higher expression in HD, and a fourth cluster of 222 genes that gradually increased expression with the stocking density (LD<MD<HD). GO and KEGG enrichment analyses showed that genes with higher expression in LD were related to immune responses, including Th1 cell and tolerance-related pathways, inhibition of apoptosis and biogenesis. Genes with higher expression in HD were related to Th17 responses, hormone synthesis and circadian rhythms. The rearing density also affected gut microbiota composition. Although no changes in richness were detected, beta diversity index was clearly different among groups, being the HD group the most divergent. Thus, HD fish showed a significantly higher abundance of Actinobacteria, exemplified by the genus *Prauserella*. Conversely, MD and LD groups presented a higher abundance of Proteobacteria with

Conclusions

Crowding and mild hypoxia had a significant impact on gut health, evidenced by significant changes in host intestinal transcriptome and associated microbial population. These results offer the possibility of developing new tools and approaches for a more precise evaluation of welfare in farmed fish. The ultimate goal is to mitigate the negative impact of stressors related to intensive rearing and climate change on aquaculture production, promoting a more ethical and sustainable production.

2. Institute of Marine Research, Bergen, Norway
3. Institute of Marine Sciences, CSIC, Barcelona, Spain
Email: partha.s.tripathy@nord.no

The mitochondrion is a cellular organelle that plays a central role in the regulation of respiration and metabolic processes in the cell, which are essential for muscle function and growth. Mitochondrial efficiency is directly linked with growth rate and varies among individuals, but the molecular basis of these differences is currently unknown. The aim of this study was to investigate a potential link between mtDNA methylation and growth rates in Nile tilapia (*Oreochromis niloticus*) muscle, since we have reported that the liver mitogenome is 20 % methylated (25 % CpGs) in this species. (Nedoluzhko et al., 2021). Fast muscle was sampled from slow and fast-growing Nile tilapia males and females, and used for genomic DNA isolation and construction of PCR-free libraries. In a representative library, the Nanopore MinION Mk1C sequencing workflow generated 673 Fast5 files, which were used for basecalling and methylation analysis with Megalodon v2.4.2 and Remora v0.1.2. The mean sequencing read length was 3275 bp and the coverage obtained for Nile tilapia mtDNA was 1082X. Methylation data generated from Nanopore long-read sequencing constitute a valuable resource for future research on the mitoepigenome related to muscle growth, metabolism and oxidation status of farmed fishes.

Introduction

Rising seawater temperature as a result of climate change can have detrimental effects on aquaculture production, which is exposed to interactions with environmental factors. Seafood is the main source of animal protein for a billion people worldwide and has a key role in global food security, while such changes in production can have very negative socioeconomic impacts for local communities and national economies. Therefore, understanding the possible impacts of climate change on salmon production and exploring possibilities for mitigation, is crucial.

Previous studies in salmonids suggest that changes in seawater temperature can have negative impacts on fish health and welfare by causing stress (Anttila et al. 2013); for example, there has been observed between-family variation in thermal tolerance (Anttila et al. 2013), environment effects on sexual maturation (Wild et al. 1994), and temperature-related immune response changes associated with amoebic gill disease (Benedicenti et al. 2019). Research in salmon genetics has allowed to identify genomic variants that impact resistance to important infectious diseases (e.g. Houston et al. 2010) and growth (e.g. Tsai et al. 2015), and to optimise the use of genomic data for selective breeding in a cost-effective manner (Tsairidou et al. 2019). However, robustness to climate change effects has not been routinely included in breeding goals as yet, in part because this requires identifying suitable target traits. The aims of this pilot project were to (a) record and assess changes in major growth, survival, maturation and health traits in Atlantic salmon post-smolts, challenged with moderate and with more extreme heat-wave conditions on the west coast of Scotland; and, (b) investigate the existence of temperature-dependant genotype-by-environment interactions and the potential of selective breeding to improve temperature resilience as mitigation strategy.

Materials and Methods

This study focused on a Scottish Atlantic salmon breeding programme population of 518 salmon post-smolts, of age 13-14 months, from 54 families, which were challenged for 4 weeks in 3 tanks at (i) ambient temperature, (ii) ambient +4°C, and, (iii) ambient +8°C. Data were recorded pre- and after-treatment. Oxygen and water temperature were recorded daily reaching a maximum of 24.39°C, approximating heat-wave conditions for the west coast of Scotland. Fish were genotyped with the Hendrix Genetics multispecies SNP array (8,978 SNP genotypes for 492 fish after quality control).

Results and Discussion

There was a significant relationship between treatment and survival (p-value <5%), while ANCOVA analyses for growth traits including body weight, Fulton's performance index and average daily gain calculated for the duration of the trial, showed statistically significant differences between-tanks after treatment, indicating that a moderate increase of water temperature (+4°C) is beneficial for growth compared to ambient temperature, but further exceeding salmon's optimal zone (+8°C) has a negative impact on growth, possibly due to the additional energy requirements to cope with more severe heat-stress. Using ultrasound scanning, palpation and colour observation, it was observed that higher temperature treatments induced early maturation (grilsing), and an increase of AGD scores. QPCR essay for a range of pathogens and using 10 gill swab samples selected randomly (based on AGD scores) from each tank, revealed quantifiable Ct values for *Aeromonas hydrophila* and total bacterial load. *Aeromonas hydrophila* was detected on all swabs in higher temperatures, and is an opportunistic pathogen that can lead to outbreaks associated with increased water temperatures, mainly found in areas with warm climates. Structure analysis revealed the presence of three distinct clusters, hence principal components were fitted as covariates in all genetic models. Firstly, genomic heritability estimates were obtained across the entire population; growth traits provided moderate heritabilities, i.e. body weight and length before and after the trial (~0.39), and average daily gain (0.26). Binary survival estimated with both a linear and a generalised linear model, and day-of-death provided boundary small estimates (<0.05). Maturation (grilsing) provided a ~0.2 heritability, while for AGD score

(Continued on next page)

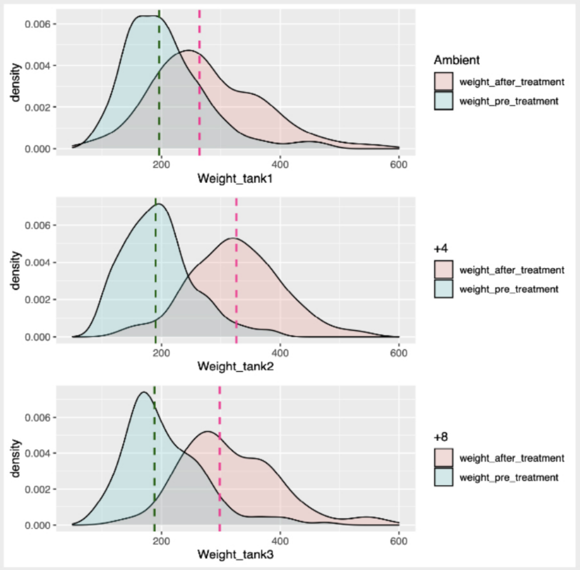

Figure 1. Distributions of body weight before and after treatment for each environment; dashed lines represent the median before (green) and after (pink) treatment.

it was not possible to detect genetic variance as the prevalence was extremely small. Within-tanks heritability estimates, showed small differences between-tanks, however, for growth traits heritabilities remained within the range observed in the overall population. For maturation the genetic variance that could be captured within each tank was very small with large standard error, while for survival traits it was possible to capture genetic variance only in the high temperature tank. This was reflected in the bivariate analyses to estimate covariances between environments; genetic correlations between-tanks for growth traits were very close to 1, indicating no significant re-ranking between environments, and for maturation the genetic correlations were very close to 1 but with large standard errors. Although in this data there was no indication for genotype-by-environment interactions, these results should be further validated in larger populations containing larger genetic variance in the traits of interest.

Introduction

Within the globally growing aquaculture industry recirculating systems are getting more important. While these land-based systems have high-tech infrastructures, their potential for on-farm data management and analysis is far from being fully utilized. This hinders their operation on environmentally and economically optimal levels and lowers operational security and with it fish welfare.

Urban Blue offers land-based aquaculture farms a software solution which enables them to monitor key farm aspects and manage, analyse, and visualize this data to enable a better system operation. The Urban Blue system is a combination of a computer-based platform, hardware sensors and a mobile phone app allowing to assess the system (pumps, tanks, valves) and manage the operational workflow (task, routines, lists).

Together with the Zurich University of Applied Science Urban Blue has launched the Innosuissse innovation project AWACS (Animal Welfare Assessment and Control System for fish farms). The project aims at developing the automated assessment of fish-based parameters and adding them to the Urban Blue system in order to provide the aquaculture industry with a truly comprehensive solution, which allows fish-farms to constantly monitor, automatically assess and visually analyse fish health and welfare.

Safeguarding fish welfare by thinking worker-centred

Currently operational personnel on fish farms often reacts to imminent situations threatening the system's operation and the fish's welfare. Expanding data collection augments surveillance and available information about the system and fish. Improving data management enables personnel by moving from an experience-based to a knowledge-based farm operation. And enhancing data analysis facilitates early detection of problematic situations allowing workers to move away from reacting and towards acting. The key is to translate the farm's data into actionable insights and present them to the farm team in a useful way. To do this the AWACS team developed an innovative notification software based on flagged situations. This Urban Blue software assists data collection, management and analysis and with it empowers farm teams, secures system operation and safeguards fish health and welfare (Fig. 1).

Securing fish welfare by automating assessments

Conclusion

Aquaculture can benefit greatly from the development of modern technologies such as data science and artificial intelligence. However, these methods will only be applicable in the industry if the focus is on the interface between farm workers and computer software.

Introduction

Aquaculture fish and shellfish production is continuously expanding due to increased demand and the simultaneous stagnation of capture fishery production. Due to the negative environmental impact of traditional intensive aquaculture, land-based fish and seafood production through recirculating aquaculture system (RAS) is considered as a great alternative. But despite the advantages of RAS (e.g. optimized water quality, reduced or no use of antibiotics, etc.) off-flavour substances (geosmin and methylisoborneol) can cause musty-earthy flavour in filets of fish which can lead to significant economic problems for RAS companies. Since off-flavour is not a critical factor for smolt production, which has a high technical level in freshwater RAS engineering, limited data is available about the formation and reduction of off-flavour substances in freshwater grow-out system. Therefore, many projects rely on purging processes.

Methods

Despite the common approach to improve the purge process, this study focuses on a reduction of geosmin in the rearing water, thus reducing the accumulation into the fish fillet. Understanding the origin and dynamics of geosmin production, accumulation and removal mechanisms in RAS is an important part of off-flavour management. By using a stable analysis procedure with GC-MS and high-resolution sampling, a commercial-sized RAS for Atlantic Salmon (*Salmo salar*) farming was monitored over 23 months. Dissolved and bound geosmin fractions were analysed in system water, sludge, biofilm on surfaces, biofilm on biochips and geosmin concentration in fish fillet.

Results

The results show a correlation between rearing water geosmin concentration and fish fillet. Concentrations in fillets are 50 to 100 times higher than in the rearing water. Rearing water geosmin concentrations can therefore be used to predict geosmin concentration in the fish fillets. Further on, mass balance equations considering input and output flows of the RAS show that the main removal mechanism for geosmin control was the solids removal unit. This leads to the conclusion that geosmin concentrations in RAS can be improved by solids control and do not mainly depend on the water exchange of the RAS.

Contrary to the widespread opinion that the RAS biofilter is the main/only source of off-flavour substances in RAS grow-out, we demonstrate that biofilm or deposits formed on various open sites within the RAS plant are a major contributor to off-flavour production and release. Thus, controlling the growth, disturbance and detachment of these unwanted biofilms plays a vital role in off-flavour management.

Conclusion

Understanding the dynamics of geosmin and other off-flavour substances in freshwater RAS is important for research, engineering, and operation. For research and operation, correct sampling strategies over long periods of time are important to understand geosmin dynamics. Regarding engineering and operation, preventing the growth and improving the removal of off-flavour producing microorganisms and the geosmin they produce profits from a deeper understanding of geosmin dynamics.

EFFECT OF DIETARY MANGANESE ON GROWTH AND SKELETAL DEVELOPMENT IN GILTHEAD SEABREAM (*Sparus aurata*) LARVAE

Introduction

Manganese (Mn) is an essential micromineral involved in several biological processes such as protein metabolism, bone mineralization, immuno-modulator, and energy metabolism (Aschner and Aschner, 2005). Moreover, Mn plays an important role in antioxidant defence system, a Mn-dependent superoxide dismutase (manganese superoxide dismutase, Mn-SOD) which functions against oxidative damage in mitochondria. The deficiency of dietary Mn in juvenile fish caused poor mineralization, increased skeletal abnormalities, growth reduction, low Mn content in body tissue, and reduced liver Mn-SOD activity (Yamamoto et al., 1983, Antony Jesu Prabhu et al., 2016). In fact, the reduction of MnSOD caused by deficiency of Mn may alter the mitochondrial function resulting in mitochondrial dysfunction, ultimately increasing the production of Reactive Oxygen Species (ROS) and leading to oxidative stress (Li and Yang, 2018). The excessive ROS production may disrupt the balance between MSC (Mesenchymal stem cells)-mediated bone formation and HSC (Hematopoietic stem cells)-mediated bone resorption and thus leads to bone disease (Li et al., 2021). However, high Mn supplementation in diet (1000 mg/kg) reduce feed efficiency and body Fe, Ca, P concentration in grouper (Ye et al., 2009). Therefore, it is needed to define the optimum dietary Mn level to fulfil the Mn requirement level for fish.

Mn requirement studies have been carried out in several of juvenile fish (Antony Jesu Prabhu et al., 2016, Dominguez et al., 2020), the requirement levels vary from 2.4 – 24.9 mg/kg bases on the growth performance, vertebrae Mn and Liver Mn-SOD level. However, the effects of dietary Mn on growth, skeletal development and antioxidant activity have been scarcely studied in marine fish larvae. Copepods are part of the natural food for marine fish larvae, Mn content in copepods range between 8-25 mg/kg (Hamre et al., 2008)using copepods as feed. The present study compares the micronutrient concentrations in rotifers with those of copepods, with the aim of identifying nutrients that may be limiting for normal growth and development of cod larvae. An additional criterion used is the nutrient requirements given for fish in general, by NRC (1993. Hence, this study aimed to investigate the effect of dietary Mn level below 8 and beyond 25 mg/kg in growth, skeletal development, and antioxidant activity in gilthead seabream larvae. As, gilthead seabream larvae are prone to present skeletal anomalies during the early developmental stage (Boglione and Costa, 2011), this study would help in bridging the knowledge gap on Mn and its effect on skeletal development in gilthead seabream larvae.

Materials and methods

Diets. Six experimental microdiets based on squid meal and casein and containing different levels of Mn at the levels of 6.3, 39, 75, 87, 200 and 270 mg/kg were tested. Manganese sulfate monohydrate ($MnSO_4.H_2O$) was used as the Mn source. Larvae (dry weight: 0.29 ± 0.06 mg, total length 7.02 ± 0.71 mm, 23 dph) were randomly distributed into eighteen tanks (1800 individuals/ 200 L tank) and hand fed every 45 minutes from 8:00 am to 8:00 pm until 48 dph. Larvae dry weight and length were measured at different points: initial (23 dph), intermediates (29, 38, 43 dph) and final (48 dph). At the final sampling, larvae were collected for whole mount stain and gene expression, and the remaining larvae for mineral analysis. Daily mortality was calculated for survival rate. All data were tested for normality and homogeneity of variances and means compared by Tukey's test and p values were estimated using regression ($P < 0.05$). Quadratic and linear regressions were used to establish a relation between dietary Mn level and their effect on the different variables.

Results and Discussions

After 26 days of feeding, fish larvae fed increasing dietary Mn levels showed an increase in body weight and total length, followed by the linear regression (Fig.1 Left) and significantly ($P<0.05$) increased the Mn levels in larvae whole body content from 2.03 to 7.67 mg/kg (Fig.1Right). Noteworthy, in the previous study, Mn content at 7.5 mg/kg in the red seabream (*Pagrus major)* larvae fed with enriched artemia significantly increased the growth (Satoh et al., 2008). This suggesting the 7.67 mg Mn/kg in larvae whole body consumed from the diets may be one of the reasons causing an increase in the larval growth in the present study. This reflects the importance of Mn supplementation in the diet to maintain the normal growth in fish. Larvae survivals were not significantly affected by dietary Mn levels, average survival rate was 37%. The *mnsod* expression of larvae (48 dph) showed a significant ($P<0.05$) up regulation with increasing dietary Mn levels

(Continued on next page)

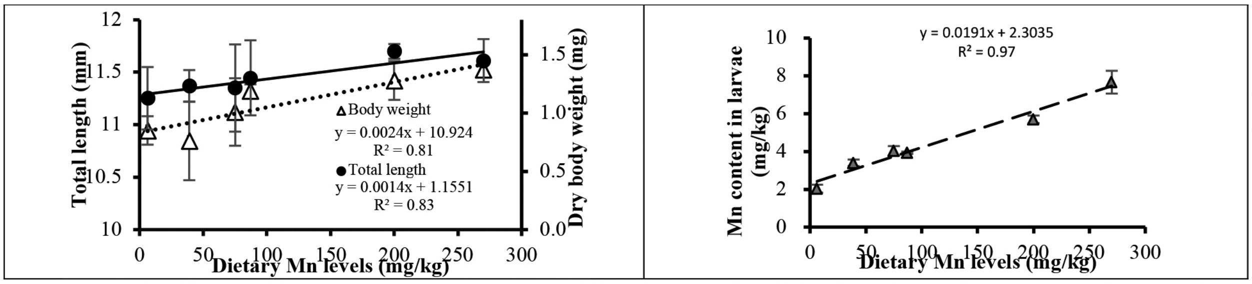

Figure 1: *Left.* Effect of dietary Mn on total length and body weight in gilthead seabream larvae (48 dph) following a linear regression ($p<0.05$). *Right.* Mn levels (mg/kg) in gilthead seabream larvae (48 dph) fed different diets after 26 days ($p<0.05$)

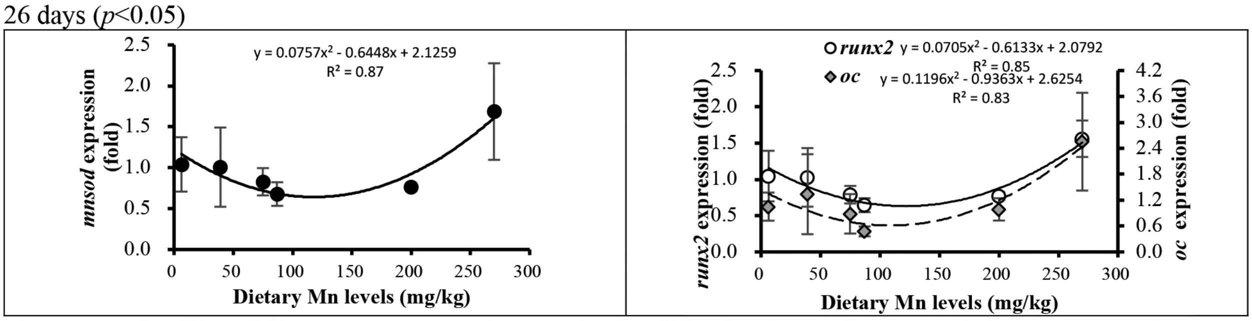

Figure 2: *Left.* Effect of dietary Mn on *mnsod* expression in gilthead seabream larvae (48 dph) ($p<0.05$) *Right.* Effect of dietary Mn on *runx2* and *oc* gene expression in gilthead seabream larvae (48 dph) fed different diets after 26 days ($p<0.05$).

(Fig.2 Left). A similar trend was found in the expression of *runx2* (Fig.2 Right), whereas *oc* genes showed the significantly ($P<0.05$) highest expression in larvae containing 7.67 mg Mn/kg fed the 270 mg Mn/kg diet thus resulted in a higher mineralization.

Conclusions

In summary, larvae fed the non-supplemented diet (6.3 mg Mn/kg) showed symptoms of Mn deficiency, including low growth, *oc* expression, Mn content in larvae and reduced bone mineralization. Whereas larvae fed with highest amount of dietary Mn level at 270 mg/kg didn't show signs of toxicity in gilthead seabream larvae at 48 dph.

Introduction

Meagre (*Argyrosomus regius*) is a sciaenid species with a progressively growing scientific interest due to its great potential for aquaculture enhancement (Duncan *et al.* 2013). Towards this direction, in the present study, we attempt to assign offspring from a mass spawning event to their putative parents using a multiplex of 12 microsatellites and later combine the acquired pedigree information with phenotypic data of body weight and length at different timepoints, in order to estimate the genetic parameters of these economically important traits.

Material and Methods

Offspring coming from a hormone-induced spawning event of thirteen broodstock (of which 12 were injected with GnRHa) were reared together until grading at 297 Days Post Hatching (DPH), when big and small-sized fish were graded and transferred to different cages. At 394 DPH, 600 fish from each cage were randomly selected, individually tagged with a Passive Integrated Transporter (PIT-tag), fin-clipped and transferred into a rectangular cage. Weight was measured on all the surviving offspring at 394 DPH (BW1), 770 DPH (BW2) and 978 DPH (BW3). Additionally, length was measured on all surviving offspring at 770 and 978 DPH (Len2, Len3, respectively).

Fin clips sampled from all broodstock and offspring fish were used for DNA extractions. Genotypes were acquired using a multiplex of 12 microsatellite loci from Nousias *et al.* (2020, 2021) and later used for parentage analysis with the exclusion-based computational method, allowing for 2 mismatches. Heritability estimates as well as genetic and phenotypic correlations for the aforementioned traits (BW1, BW2, BW3, Len2, Len3) were obtained using a Restricted Maximum Likelihood method (REML), with a bivariate animal model in AIREMLF90 (Misztal *et al.* 2018) for all pairs of the studied phenotypes with the cage, in which fish were placed after grading, as a fixed effect.

Results

Parentage assignment and later genetic analysis included 1,179 offspring individuals, since 21 samples were excluded due to low DNA quality. The assignment rate of the parentage analysis was 71.8%, *i.e.*, 847 out of 1,179 offspring were successfully assigned to their putative parents with 0 to 2 mismatches. The 847 offspring were distributed in 24 out of the 42 expected families (6 males by 7 females), forming 3 large families (>15%) and 3 smaller families (5-9%). The rest of the formed families represented a very small percentage (< 2% each). All broodstock were identified as possible parents, except for one female. Unequal parental contribution was observed at both sexes.

Heritability for body weight and length ranged from 0.32 to 0.80 and 0.58 to 0.72, respectively, and tended to increase with age. Estimates were high for all the studied traits, except for body weight at 394 DPH which is within a medium range (0.20 – 0.40). Genetic correlation between body weight and length were high (>0.90) at both 770 and 978 DPH. Genetic correlation between body weight at different ages were lower (0.46-0.56). Finally, standard errors were quite high both for heritability and genetic correlation estimates. Most of the heritability and phenotypic correlation estimates exhibit statistical significance, while genetic correlation estimates were not significant.

(Continued on next page)

Discussion/Conclusion

Higher assignment rates (>90%) have already been reported in meagre in previous studies (Nousias *et al.* 2020; Vallecillos *et al.* 2021). The average assignment power of the multiplex used in this study can probably be attributed to high kinship within the broodstock as well as elevated inbreeding indices and low number of observed alleles (<6/locus) in the multiplex employed. The unbalanced family distribution and the consequent unequal parentage contribution has previously been reported in meagre (Nousias *et al.* 2020; Vallecillos *et al.* 2021) and other fish species (Liu *et al.* 2013).

The estimated heritability for body weight and length was relatively high and fell within the range reported by Nousias *et al.* (2020) but higher than those from Vallecillos *et al.* (2021), suggesting a possible highly profitable selection for these traits. The observed increase in the estimates of heritability with increasing age has been previously reported by Soula (2012) in meagre. The estimated values for genetic and phenotypic correaltions were very high between body weight and length at all studied ages, indicating the potential of using only one of these traits in selective breeding programs while also suggesting a possible pleiotropy and/or linkage among the genes affecting these traits. The respective genetic correlation estimates for body weight between different ages were lower. Last, the progressively smaller sample size due to high mortality in the studied offspring set could be the reason for the very high standard errors of the aforementioned estimates.

Acknowledgments

The study has received funding from the Greek Republic through the “MeagreGen” project under the call “Special Actions – AQUACULTURE” in the Operational Program “Competitiveness Entrepreneurship and Innovation 2014-2020”.

DIEL OSCILLATIONS IN MICROBIAL PLANKTON COMMUNITIES IN AQUACULTURE ENVIRONMENT

[3]Institute of Marine Biology, Biotechnology and Aquaculture, HCMR,71003 Heraklion Crete Greece

Introduction

Microbial plankton modulates oceanic function[1], is highly dynamic and oscillate over diurnal, seasonal and annual cycles. Diel oscillations are mainly driven by changes in light but also in nutrient and chlorophyll concentration, temperature and the presence of other organisms. The diel vertical migration of zooplankton has been studied in depth[2]. Prokaryotic community diversity, metabolism and abundance are frequently higher during the night[3,45,6], photosynthetic pigment production and cell division higher at night[7,8] while a consistent peak for heterotrophic protist and bacterial abundance is detected during the second half of the day[9]. The aim of this work is to describe diel oscillations in all microbial groups for the first time in aquaculture environment with metabarcoding analysis. We studied prokaryotic and eukaryotic diversity at 3 time points within the day and 3 sites having high, low and no impact from fish farming, and correlated diversity shifts with nutrients. The significance of nutrient pulses in shaping the dynamics of the basal members of all marine food webs is under investigation here, since it is possibly large enough to alter or “hijack” the microbial diel rhythms.

Material and Methods

Sampling took place within TAPAS (http://tapas-h2020.eu/) and LIFE+ AquaPEF projects (https://lifeaquapef.eu/) in areas where intensive aquaculture production of European seabass and gilthead seabream is occurring. Samples were collected from a site next to one fish cage (One Farm: OF) and another next to multiple fish cages (Multiple Farms: MF), and from a non-impacted site (Control: C), at 3 time points within the day [06:00 am (morning), 14:00 pm (noon), 22:00 pm (evening)]. Water was filtered for the collection of microbial plankton. Meso-plankton was collected via a vertical haul. DNA extraction was done following a CTAB protocol and PCR amplifications with a 2-step protocol[10]. The 16S rRNA gene was amplified for prokaryotes, the 18S for eukaryotes and the region ITS1-ITS2 for fungi. Sequencing was accomplished in the HCMR Illumina MiSeq platform. Sequence processing was done through PEMA v.2.1.4.[11] that operates in HCMR with high-performance computing cluster Zorbas. Reads of >150 nucleotides were organized into Operational Taxonomic Units (98% similarity) using Silva_132, PRS2 and MIDORI v2 databases. Differences in community composition were tested by applying multivariate analysis of variance using the factors “aquaculture” (Farm, Control), “type of aquaculture” (C, OF, MF) and “time of the day” (morning, noon, evening) using PRIMER v6 (Plymouth Marine Laboratory, UK). Distance-based redundancy analysis (dbRDA) was used to summarize the variation in the biological data that was explained by the abiotic data.

Results and Concluding remarks

Free and particle-attached prokaryotic communities were significantly different between C and Farm sites ($p<0.05$), while particle-attached prokaryotes differed also between morning, noon and evening. At both fractions, Gammaproteobacteria and Verrucomicrobia contributed more in Farm, while Cyanobacteria contributed more in C but showed substantially lower diversity. Interestingly, Chitinophagales, Cytophagales and *Rhodobacteraceae* increased from C to OF and further to MF, opposite to the SAR11 clade that decreased markedly from C to OF and further to MF. Meso-zooplankton community was significantly different between C, OF and MF ($p<0.05$), with the dominant phyla Arthropoda, Mollusca and Brachiopoda contributing more in Farm than C. Only some zooplankton phyla showed diurnal pattern. Diurnal effect was also detected for Dinoflagellata (decreased from morning to noon and further to evening), while Bacillariophyta and Radiolaria contributed less at Farm sites. Fungal community was significantly different between C and Farm and between C, OF and MF ($p<0.05$), although 65-85% of reads remained unassigned. All microbial communities were related to the concentrations of dissolved inorganic nitrogen forms and particulate organic carbon and nitrogen (dbRDA, $p<0.05$). Knowing the synthesis of a microbial plankton community may help us understand the function and performance of a given environment. This is

(Continued on next page)

particularly important in aquaculture areas that have major sustainability issues nowadays due to the substantial amounts of nutrients that are released on a daily basis. Our study showed that prokaryotic community was significantly affected by fish farming. Higher diversity, with taxa known for their opportunistic behavior (i.e. *Rhodobacteraceae*) prevailed near fish cages, while oligotrophic taxa increased in contribution away from cages. The eukaryotic community, including fungi, also differed with respect to farming, with diatoms contributing less near fish cages. The time of the day seemed to affect only some zooplankton phyla (but not the whole community) and particle-attached prokaryotes that are largely affected by organic matter produced by phytoplankton, exuded by zooplankton and released due to the farming operation. Altogether, aquaculture seemed to have a great effect in community synthesis which was supported by the consistent association with nitrogen forms, while the diel oscillations were milder and observed in specific taxa. Diel rhythms may be hijacked by continuous nutrient supplies within the aquaculture environment, altering ecosystem function, and thus, requiring further investigation for the consequences.

Introduction

Gilthead seabream (*Sparus aurata*) and European seabass (*Dicentrarchus labrax*) are emblematic species of Mediterranean aquaculture, the second most important aquaculture industry after the Atlantic salmon in the European Union (Llorente et al. 2020). Hatchery stages are critical to the whole production cycle, as they determine the plasticity of body morphology and shape, growth potential and robustness (Kourkouta et al. 2021a, 2021b). Currently, larval quality is assessed through a series of Key Performance Indicators at different stages of development based on the desired traits of fast-growth, robustness of juveniles and adults free of morpho-anatomical defects (Kourkouta et al. 2021b). The aim of the present study was to screen for a set of molecular markers that could be used as quality indices for gilthead seabream and European sea bass larvae, and to develop a time- and cost-efficient tool for real-time batch quality evaluation in the hatchery.

Materials and methods

Gilthead sea bream (SBG) and European seabass (BSS) larvae of four stages [first feeding (FF), flexion (FL), end of larva rearing (ELR) and mid metamorphosis (MM)] were sampled from four and three commercial European hatcheries, respectively. Samples were used for RNA extraction followed by quantitative PCR (qPCR) and whole mount bone staining. For skeletal quality assessment alcian blue /alizarin red whole mount-stained larvae were analysed to establish the incidence of malformations. For both species quality was scored, based on the existence and the severity of deformities (Kourkouta et al. 2021a, 2021b). In the case of BSS, an additional quality score based on axial growth rate was used. Only, the best (BEST) and worst (POOR) performing production batches were used for further analysis. Following total RNA extraction and cDNA synthesis, the expression levels of 22 and 24 genes were measured by qPCR in SBG and BSS, respectively. A Wilcoxon signed-rank test was used to examine significant differences per gene and stage between the two quality extremes scored, BEST and POOR. The multi-collinearity of the variables in the data set, was assessed with a Pearson correlation coefficient. A multivariate approach and permutational analysis of variance (PERMANOVA) evaluated differences in gene expression and the size of the variability explained by the quality score. Random forest was trained as the classification algorithm using the gene profile obtained for the samples of known quality i.e. BEST and POOR. A quality prediction model was built and then used to classify samples for which the quality was masked before analysis.

Table 1. Accuracy, sensitivity and specificity of random forest algorithm for the examined stages and quality scorings for both SBG and BSS

Species	Stage	Accuracy	Sensitivity	Specificity	Quality scoring based on….
SBG	MM	**0.86**	0.90	0.83	Deformities
BSS	ELR	**0.86**	0.77	1.00	Deformities
BSS	MM	**0.84**	0.80	0.88	Deformities
BSS	ELR	**0.80**	0.93	0.60	Growth
BSS	MM	**0.88**	0.92	0.83	Growth

(Continued on next page)

Results and Discussion

The general strategy applied for both species was as follows: the first step was to screen for candidate genes that presented significant differences between the two quality scores (BEST vs POOR). The genes with no significant differences were excluded from the rest of the analysis. In the second step, correlation analysis was used to identify highly correlated genes (correlation coefficient of > 0.7) in each of the four stages. From each group of highly correlated genes, only the gene with the highest p-value in the Wilcoxon signed-rank test, between samples from the two extremes of quality were used in the next step of the analysis. Based on the criteria outlined above, sets of quality-related genes were selected for each stage. Subsequently, the PERMANOVA results were used to identify the stage/stages in which the differences between the two quality scores (BEST-POOR) were explained by the gene variables. Based on the results, genes were selected that were highly associated with quality at a given stage/stages for SBG and BSS and used for the random forest algorithm. The accuracy along with specificity and sensitivity of the applied random forest model for each stage and each species is presented in Table 1. Finally, the top five genes were identified that, when combined, contributed to generate a model predicting quality with high accuracy. A unique gene set was identified per species, stage, and quality criteria.

The study evaluated a set of genes that participate in key biological functions for their predictive power to estimate quality of commercial batches of SBG and BSS. This addresses a need for tools for real-time monitoring of batch quality during production cycles and may also reflect on the actual juvenile quality. The molecular index generated that consists of the top 5 most informative genes represents a novel, relatively fast and cost-effective tool for global larval quality screening. Finally, the accuracy of the model was ≥ 0.8 in all the cases. The algorithm could be further trained and refined for specific quality characteristics with the input of more data and by further validation with datasets for which quality has been masked.

Introduction

In a constantly changing aquatic environment due to the climate change, the influence of temperature on fish physiology is becoming crucial for the future of fisheries and aquaculture. An increase in temperature leads to an increase in metabolic rates in most fish species, accompanied by increased respiration rates, and changes in survival rates, behavior, development and growth. Oxidative phosphorylation (OXPHOS) is a metabolic pathway that uses five multiprotein complexes localized inside the mitochondria to produce almost 90% of the cellular ATP needs in higher eukaryotes. In this study we investigated the impact of different early rearing temperatures on OXPHOS NADH: ubiquinone oxidoreductase (complex I) at distinct developmental stages in the gilthead seabream ontogeny.

Materials and methods

Gilthead seabream (*Sparus aurata*, SBG) eggs from a spontaneous spawn of captive breeders were subjected to 17, 20 and 23°C, from the onset of the epiboly to the end of yolk-sac larval stage and the beginning of exogenous feeding; subsequently all groups were kept under identical rearing conditions and constant rearing temperature (20°C) up to the end of the trial (18–19 mm TL). Larvae at three developmental stages, namely first feeding (FF), notochord flexion (FL) and mid metamorphosis (MM), were sampled and stored in methanol at -20 °C until RNA extraction. RNA was isolated from eight individual samples for each condition and were pooled. A typical pipeline for RNA sequencing was conducted on the pooled samples and the results were analyzed using the R package edgeR (Robinson MD et al., 2021). Most information about OXPHOS has derived from studies in human and other mammals. SBG genome was investigated for paralogs of CI genes in respect to the teleost specific genome duplication (TSGD), using the human peptide sequences as “bait” and following a reciprocal BLAST approach. All genes identified that code for complex I (CI) were included in the analysis.

Table 1 Influence of temperature to the number of differentially expressed genes per developmental stage

	17 - 20	**20 - 23**	**17 - 23**
FF	0	4	1
FL	3	0	0
MM	4	**10**	**29**

	FF - FL	**FL - MM**	FF - MM
17°C	5	4	3
20°C	12	**28**	4
23°C	5	**33**	29

(Continued on next page)

Results and Discussion

Complex I is the largest of the five complexes of OXPHOS in terms of number of subunits, with 44 subunits in Human. From these subunits seven are coded from the mitochondrial genome and the rest from the nuclear genome. Fourteen genes code for the core subunits (7 mitochondrial coded and 7 nuclear coded) and they are responsible for the electron transfer through the enzyme and the proton pumping to the intermembrane space, while the rest, referred as supernumerary, contribute to the structure of the enzyme. From our analysis in the SBG genome we identified three CI nuclear-coded genes (*ndufv1*, *ndufs1* and *ndufs8*) that have retained paralogs compared to Human, and redefine the total number of CI genes in SBG to 47. RNA-seq analysis revealed a number of differentially expressed genes (DEG's) between developmental stages and rearing temperatures, with log fold changes ranging from 0.6 to 1.9 for numerus genes. It appears that the impact of early rearing temperature is low at FF and FL stages, whereas there is an increase to the number of DEGs at the MM stage for the larvae that had been exposed to 23°C (Table 1). Examining the changes to the number of DEGs at the transition between the developmental stages (Table 2), one can see that CI gene expression levels are stable between the developmental stages in larvae reared at 17°C with only a few exceptions, whereas a high number of DEGs were observed at the transition from FL to MM in larvae reared at 20°C and 23°C. Moreover, all the DEGs between FL and MM at 20°C and 23°C were up regulated at MM. Interestingly, one paralog from each of the three core gene families identified was highly expressed compared with the other in a consistent manner across all stages and temperatures of the study.

Oxidative phosphorylation is a crucial process for the cell and therefore, for the organism, and intense changes to the process or its regulation could result in low fitness or even death. On the other hand, the fine tuning of OXPHOS regulation provides plasticity that is important to cover efficiently the organismal energy needs under different circumstances. In this study, we provided evidence that different rearing temperatures, applied in a short time window at the beginning of development, can trigger changes in the regulation of OXPHOS CI later in development at the stage of MM, when the original thermal stimulus has been lifted, indicative of the epigenetic effects of early temperature. In conclusion, OXPHOS demonstrates, at least to some extent, thermal plasticity at the ontogeny of SBG. Further investigation is needed to fully understand the biological and physiological impact of the thermal plasticity of OXPHOS, in a way that can be manipulated for increasing SBG larvae and juvenile quality.

Introduction

European seabass (*Dicentrarchus labrax*) is one of the most significant species farmed in the Mediterranean; yet a very perishable product. Its quality deteriorates rapidly as a result of three mechanisms: microbial activity, chemical oxidation, and enzymatic degradation. Microbial spoilage is the mechanism that contributes most to the quality deterioration of fresh and non-processed fish (Thomas et al., 2021)gills and intestines bacterial microbiome. Whole gilthead seabream was packed aerobically or under modified atmospheres (60% CO_2, 30% N_2, 10% O_2. The composition of initial microbiota is strongly dependent on many factors. The skin microbiome of unstressed fish is dominated by taxa recognized for their probiotic and antibacterial activities, whereas the skin microbiome of stressed fish is dominated by potential pathogens. And although mucosal surfaces, such as skin, gills, and the gut, operate as primary barriers to infections, they may be impacted by several pathogens. Stress can derive from anthropogenic stressors and farming conditions such as overcrowding and low oxygen concentrations and can cause variations in microbial composition, causing a shift in microbiome abundance (i.e., dysbiosis), leading to substantial losses. In addition, pathogenic bacteria that are generally prevalent in aquatic environments may also be present in fish microbiomes (Rosado et al., 2019)which is known to facilitate pathogen infections. The skin and gills are the primary defense organs against pathogens, thus, characterizing their microbiome composition in farmed fish is pivotal for detecting potential alterations that may lead to disease susceptibility. Here, we assessed the skin and gill microbiomes of two of the most important adult fish species farmed in southern Europe, the seabass and the seabream, during winter months. We coupled next-generation sequencing (MiSeq. Given the importance of the skin microbiome in fish innate immunity and the economic burden of fish losses in fish farming, characterization of the trajectory of the seabass skin microbiome is vital. To this end, our study aims to identify the composition and trajectory at storage of the European seabass skin microbiome from two distant aquaculture installations.

Materials and methods

Sampling of commercial size European sea bass (300-500g) took place at harvest days in two commercial fish farms in Western and Central Greece, at sea water temperature 20ºC and 21ºC, respectively. Fish were harvested using different methods; direct immersion in ice water or slurry ice; application of electrostunning prior to immersion in ice water. Samples were collected on day0 (harvest day) and day7 or day8 post-harvest using a sterile scalpel blade to swab several times along the right upper lateral part of the fish skin from head to tail in a sterile Eppendorf tube. Samples were kept at -80ºC until processing. DNA extraction was performed using the PureLink™ Genomic DNA Mini kit with modifications. DNA quality and quantity were assessed and then samples were pooled, properly diluted, and sent to BGI Genomics for 16S rDNA sequencing using the HiSeq 2500 Illumina platform. The selected area for sequencing was the hypervariable V3-V4 region of the 16S (small ribosomal subunit) gene. FASTQ files were analyzed with the DADA2 pipeline and clean sequences were aligned against the SILVA (138 release) reference database. All analyses were performed in R studio.

Results and Discussion

The analysis, after filtering for archaea, chloroplast, and mitochondria, showed that the 2571 amplicon sequence variants (ASVs) corresponded to 647 different genera. These genera belonged to 289 families. The genus present across all the comparisons was the genus *Psychrobacter.* Microbial composition revealed Proteobacteria and Bacteroidetes as the most abundant phyla, in accordance with the current knowledge on the skin microbiome of European seabass (Rosado et al., 2019)which is known to facilitate pathogen infections. The skin and gills are the primary defense organs against pathogens, thus, characterizing their microbiome composition in farmed fish is pivotal for detecting potential alterations that may lead to disease susceptibility. Here, we assessed the skin and gill microbiomes of two of the most important adult fish species farmed in southern Europe, the seabass and the seabream, during winter months. We coupled next-generation sequencing (MiSeq. When comparing the two fish farms only 135 ASVs, on harvest day, were shared with the farm in Western Greece revealing 680 unique ASVs of lower abundance (Figure 1a). The dominant genera in the latter farm were *Pseudomonas* and

(Continued on next page)

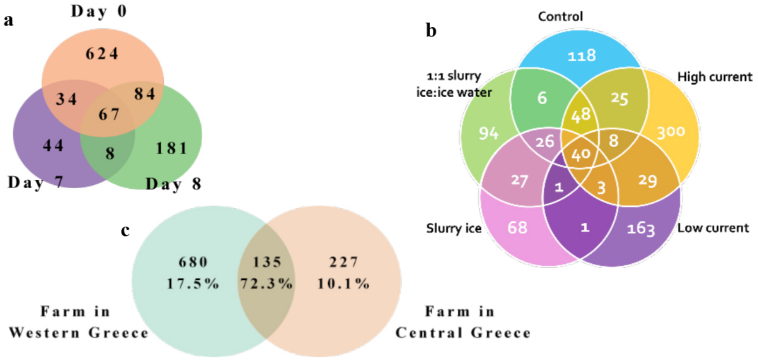

Figure 1a-c. Venn diagram showing the shared ASVs amongst the comparisons. The percentage shows the percentage of the sequences represented in the ASVs.

Pseudoalteromonas, whereas in the farm in Central Greece *Shewanella* and *Psychrobacter* genera were overrepresented (Figure1b). When comparing the different harvest methods used, only 40 ASVs were universally represented. The dominant genera for each harvest method were different, revealing the effect of the harvest method on the skin microbiome. Finally, when comparing the trajectories of the samples stored at 4ºC, only 67 ASVs were found to be shared by all samples (Figure 1c). By day7 or day8, the most prevalent genera were *Shewanella, Pseudomonas, Pseudoalteromonas,* and *Psychrobacter.* The relative abundance of each genus was strongly dependent on the harvest method. All these genera contain species such as *Shewanella putrefaciens, Pseudomonas aeruginosa, Pseudoalteromonas spp., and Psychrobacter sp.* that can be implicated in the deterioration and loss of the final product.

Conclusion

Differences in the microbiome composition of European seabass samples were observed, with an evident influence of the environment and harvesting procedures on the skin microbiome trajectory following storage at 4°C.

Introduction

Climate change is expected to impact all facets of primary production by driving developmental and physiological adaptations of farmed organisms to new trajectories. This is particularly important for poikilotherm organisms like fish that cannot regulate body temperature, with unforeseen ramifications for fisheries and aquaculture. Early developmental stages exhibit high thermal plasticity that can be decisive for robustness and growth performance at later stages. The purpose of this study is to explore how early thermal regime impacts in mechanisms associated with the perception of photoperiod in the gilthead seabream, *Sparus aurata L.*, an important species for the European aquaculture. Photoperception, is the ability of fish to perceive light, allows them to adapt their circadian rhythm, obtain an overview of their immediate environment in real time, detect their food, recognize predators, and seek potential partners for mating (2). Photoperception is mediated by optical cells, which are distinguished in rod and cone cells. Their outer parts contain photosensitive substances (pigments) that are different in rods and cones. All pigments contain an aldehyde of vitamin A and a protein called opsin. Opsin genes belong to G protein-coupled receptors (GPCRs) superfamily and form the core of vision. Their expression profile may be influenced by environmental factors such as water depth, water quality and tension, and they differentiated according to the wavelengths they can absorb. In this study we determined the ontogenetic profile of the opsins as it was shaped by different early thermal regimes as a means of information about fish photoreception (3).

Materials and methods

Gilthead seabream (SBG) eggs from a spontaneous spawn of captive breeders were subjected to 17, 20 and 23°C, from the onset of the epiboly to the end of yolk-sac larval stage and the beginning of exogenous feeding; subsequently all groups were kept under identical rearing conditions and constant rearing temperature (20°C) up to the end of the trial (18–19 mm TL). Larvae at three developmental stages, namely first feeding (FF), notochord flexion (FL) and mid metamorphosis (MM), were sampled and stored in methanol at -20 °C until RNA extraction. RNA was isolated from eight individual samples for each condition and were pooled. A typical pipeline for RNA sequencing was conducted on the pooled samples and the results were analyzed using the R package edgeR. SBG genome was investigated for paralogs of opsin genes in respect to the teleost specific genome duplication (TSGD), using the human peptide sequences as "bait" and following a reciprocal BLAST approach.

Results

In total, 37 opsin genes were identified in the SBG genome, 20 of which exhibited differential expression (p-adjust <0.05, absolute value of log fold change> 1) in pairwise comparisons between different stages, controlling for temperature. Of these, 5 belong to visual and the rest to non -visual opsins. Gene ontology enrichment analysis confirmed their involvement in photoperception mechanisms, absorption of visible light, cellular response to light stimulus and G protein-coupled receptor signalling pathway.

The expression of the paralog visual opsin genes followed reverse patterns; short wavelength sensitive opsin 1 (*sws1*), long wavelength sensitive opsin 1 (*lws1*) and the green wavelength sensitive opsin *(gws1)* were highly expressed at FF stage and their expression decreased thereafter. Conversely, an increased expression of *sw2* was recorded at mid metamorphosis, whereas its expression was low in the early stages. In addition, rhodopsin expression exhibited a gradual increase as development progressed. On the other hand, non-visual opsins expression gradually decreased as stages transitioned.

(Continued on next page)

Discussion and conclusion

To our knowledge this is the first study evaluating the expression patterns of opsins at different developmental stages in SBG. The biggest differences in expression were recorded between the FF and the FL stage. Increased expression of *sws1* and *lws1* genes at first feeding and gradual decrease at the other stages is viewed as directly related to the environment and depth of water, given juvenile fish inhabit euphotic water zones. The increase in *sws2* following metamorphosis coincides with their migration to deeper environments where the light spectrum is limited. Concerning rhodopsin, expression patterns appear to follow the morphological changes of fish during development, as the fish increases in size, so does gene expression (4). As for the non-visual opsins, they appear to be overexpressed at FF stage and their expression is reduced at later stages. These genes are involved in several basic mechanisms, such as induction and regulation of the circadian rhythm, and overexpression in early developmental stages is likely related to the adaptation to external stimuli and abrupt changes (5). The clarification of the effect of other factors, such as temperature, in the expression of circadian genes will provide us with useful information on the adaptive potential of fish and to address environmental challenges, such as climate change.

RETHINKING PLASTIC PACKAGING FOR FISH AND SEAFOOD: NOVEL MATERIALS AND PROCESSES FOR A ZERO-WASTE FUTURE

Introduction

According to FAO, significant amounts of fish and seafood are wasted worldwide due to spoilage and degradation during icing, packaging, storage, and transportation (ranging from 30-50%). . Developing novel and efficient packaging solutions to improve food quality and shelf life and reduce food waste while not raising the amount of packaging waste is a significant challenge for improving the sustainability of food supply chains. During the last decade, joint efforts by the packaging and the food industries have aimed to reduce the amount of petroleum-based polymers and food packaging waste (Tsironi and Taoukis, 2018). Biopolymers have been considered promising materials for this purpose. However, they generally present poor mechanical properties since the fragility and brittleness may limit their potential for industrial application. The properties of the developed materials depend on formulation and processing parameters. Edible packaging systems may be used as thin layers of materials to coat or wrap food products, aiming to extend their shelf life and reduce the required polymers for food preservation. In active packaging, the traditional role of packaging is accompanied by the conservation role of antimicrobials, antioxidants, and other components (Oreopoulou and Tsironi, 2021).

Polymeric surfaces are mainly hydrophobic, attributed to their characteristic low surface energy, and this implies that these do not possess the specific surface properties demanded in various applications. Moreover, the production of multi-layer structured food packaging polymers is economically demanding. To obtain polymers with the desired properties, in most instances various surface treatments are employed. Cold Atmospheric Plasma (CAP) induces several chemical and physical processes on the plasma-polymer interface, which modify the surface properties. These phenomena are at limited level exploited, to impart selective and tuneable surface energies to the packaging polymers for promoting adhesion or improved printability, sealability, imparting antimist properties and improving the polymer's resistance to mechanical failure (Hetemi and Pinson, 2017; Pankaj et al., 2014).

The objective of the study was to develop sustainable packaging materials by (a) the application of CAP for the surface modification of polymers, and (b) the partial replacement of plastics in packaging by the application of edible materials with high preservative effects for fish and seafood, including also the incorporation of active compounds with antimicrobial and/or antioxidant activity.

Materials and methods

CAP was applied directly on one side of a HDPE film and a LDPE film (20 μm and 40 μm thickness, respectively) using an atmospheric pressure cold plasma jet (kINPen® IND, neoplas GmbH, Germany) supplied with argon at a flow rate of 4 L/min and a conical probe of 16 cm diameter for uniform plasma application onto the film surface. Gas (O_2) permeability and water vapor transmission rate (WVTR) were evaluated using standardized methods (ASTM F2622, ASTM E96/E96M). Wettability of the packaging materials was characterized based on the determination of the contact angle (Theta Flow Optical Tensiometer, Biolin Scientific). Two alternative edible packaging systems were designed (a) an edible coating based on chitosan and acetic acid, and (b) an edible film based on carboxymethyl cellulose (CMC), sodium alginate (SA) and glycerol. The effectiveness and preservative effect of the developed packaging materials were evaluated on actual food environments (fish and seafood) through case studies and systematic shelf life testing.

Results

CAP increased OTR and decreased WVTR of PE films with the increase of treatment time. Wettability of PE films increased up to 48% after 30 min of CAP treatment, indicating a significant effect on the surface properties of both HDPE and LDPE.

The developed CMC-SA edible films had OTR and WVTR as 88218 cm^3*m^2/h and 14,514 g/m^2/h, respectively, indicating a high hydrophilicity in the developed edible system. A chitosan-acetic acid edible coating extended the shelf life of gilthead seabream fillets up to 5 days at 2°C, based on growth microbial spoilage (total viable count and *Pseudomonas* spp.)

(Continued on next page)

Discussion and conclusion

The results of the study show the potential of CAP treatment to modify the barrier properties of food packaging films. The developed methodology may be applied to a wide range of food contact surfaces, such as polypropylene and polyethylene-terephthalate, which alongside with PE account for more than 80% of food packaging polymers. The modification of packaging materials and the application of appropriate edible packaging will reduce petroleum-based plastics in a cost-effective manner with sustainable systems offering improved quality and extended shelf life of fish and seafood.

Introduction

Packaging of fish and seafood provides protection against chemical, biological, and physical modifications during storage. Recent research has been initiated to address three major trends in the food packaging sector, namely the health trend, the green movement, and the food safety trend (Tsironi and Taoukis, 2018). The recent trends towards the adoption of circular economy and the EU Directive 2019/904 regarding the reduction of the impact of plastic products on the environment has raised significant concerns about the sustainability and future of conventional polymers as food packaging materials. Polyvinyl alcohol (PVA) is a popular synthetic biodegradable polymer along with chitosan, a natural biopolymer obtained from crustaceans (Haghighi et al., 2019). Polylactic acid (PLA) is a biopolymer obtained from renewable resources, with similar properties to several conventional synthetic polymers (Ma and Wang, 2018; Armentano et al, 2015). Polyhydroxybutyrate (PHB) is an aliphatic polyester, synthesized by microorganisms, with high biodegradability and biocompatibility (Armentano et al, 2015). PLA/PHB blends have gained significant interest lately, since their combination can create new biomaterials with interesting physical, thermal, and mechanical properties (Ma and Wang, 2018; D'Anna et al., 2019). Biopolymers such as polysaccharides, proteins, and lipids may also replace petroleum-based plastics as alternative, green food packaging systems. Food-grade components can be used for the development of edible packaging materials. Pectin, gelatin and hydroxypropyl methylcellulose (HPMC) have been reported as effective raw materials for food packaging due to their non-toxic, biocompatible, and biodegradable properties. Pectin is a structural polysaccharide that comes from the cell walls of plants (Mellinas et al., 2020). Natural compounds with antimicrobial and/or antioxidant activity can be incorporated into active food packaging materials and delay spoilage of perishable foods, extending shelf life and reducing food waste (Oreopoulou and Tsironi, 2021). For example, eugenol is the basic compound of clove essential oil, "generally recognized as safe" (GRAS) and known for its antimicrobial and antioxidant activity (Li et al., 2021).

The objective of the study was to evaluate the shelf life of chilled gilthead seabream fillets and Pacific white shrimp, packed using alternative, environmentally friendly food packaging materials.

Materials and methods

Several alternative packaging films were developed by using a blend of PLA and PHB in a ratio 80/20 and glycerol monolaurate (GML) as a plasticizer (10% w/w of polymers), using the solvent casting method. Eugenol was added as an active compound in different concentrations (0, 0.1, 0.25, 0.5 and 1.0%v/v). PVA/chitosan films were also developed using GML as plasticizer. In order to synthesize edible films, pectin, gelatin and HPMC were used at a percentage of 2%, by solvent casting method. The solutions were mixed in proportions of 1:1, and three additional types of films were produced: pectin-gelatin, HPMC-pectin and HPMC-gelatin. The *in vitro* antimicrobial activity of active packaging materials was determined with a disk diffusion assay against *Pseudomonas fluorescens* (ATCC 13525) and *Escherichia coli* (UNIMORE 40522), while the *in vivo* antimicrobial activity was determined with the application of the developed films on fresh gilthead seabream (*Sparus aurata*) fillets or Pacific white shrimp (*Litopenaeus vannamei*) stored at refrigerated conditions (2°C). Shelf life evaluation was based on microbial spoilage (total viable count, *Pseudomonas* spp.), pH and sensory evaluation (appearance, odour).

(Continued on next page)

Results

The results showed that the edible materials developed by pectin-gelatin, HPMC-pectin and HPMC-gelatin may adequately replace petroleum-based polymers, such as polyvinyl chloride, and maintain a high quality of fish fillets without affecting shelf life. The antimicrobial activity of the PLA/PHB films against *P. fluorescens* was enhanced by increasing the concentration of eugenol, while eugenol was not effective against *E. coli*. At the end of the storage period of gilthead seabream fillets (i.e., 16 days at 2°C) the microbial load in the 0% eugenol films was 1 log cfu/g higher than the respective values for fish fillets packed in the 0.5% and 1% eugenol films.

Discussion and conclusion

The results of the study show the potential of PVA, PLA and PHB for the development of innovative, environmentally friendly packaging films for the preservation of fresh fish and crustaceans. Pectin, gelatin and HPMC edible films can be effectively applied as fish and seafood packaging systems for maintaining food quality and reducing the impact of packaging waste.

COMPARISON STUDY OF USING TWO FEEDING REGIMES IN GILTHEAD SEA BREAM (*Sparus aurata*) UNDER DIFFERENT DISSOLVED OXYGEN SATURATION LEVELS

P. Tsoukali[1*], L. Katsika[1], A. Samaras[1], m. Mastoraki[1], m. vasilakis[1], I. Papadakis[1]

[1]Institute of Marine Biology, Biotechnology and Aquaculture, Hellenic Centre for Marine Research, Greece

Introduction

It is a fact that the way of feeding can affect the total amount of consumed feed, the fish growth and fish behaviour (Kentouri *et al.*,1994). Fish can control the feeding level according to their energy, nutritional requirements, and feeding time. An urgent need to develop a feeder to support aquaculture in cost effects and water pollution caused the thought of using a self-feeder system. The aim of this study was to compare the self-feeder feeding with hand-feeding in Seabream (*Sparus aurata)* under different oxygen saturation, investigating fish behaviour, growth performance and the quality of the final product.

Materials and Methods

Two different feeding regimes; automatic self-feeder system and feeding by hand, were implemented in Sea bream under two different ranges of dissolved oxygen (DO) saturation, 40-60% and 60-80%. The experiment was conducted in Aqualabs facilities of the Institute of Marine Biology, Biotechnology and Aquaculture (IMBBC) of the Hellenic Centre for Marine Research (Heraklion, Greece. Each diet was fed to three replicate groups (initial mean weight; 97.0±0.98 g, n=25) either by hand to apparent satiation twice per day or by automatic self-feeders (the fish ingested the food during the day) for 83 days. The trial was carried out in 3 closed recirculation systems (RAS) each consisting of 500L capacity tanks under fully controlled oxygen, light and water flow conditions. The rearing water temperature was 26.5°C and the photoperiod 12L:12D. The DO levels were selected based on results of previous trials and oxygen levels were fully audited and supported by an automatic oxygen system. The self-feeders used were connected to a special recorder where the frequency of activation during the 24 hours will be recorded. A camera system over each tank was placed to observe and record the fish's behaviour and activity. Software designed for this purpose informs their feeding frequency, consumption, and preference time.

Table 1. Growth / somatometric indices for Sea bream under two different feeding regimes and oxygen saturation levels.

Feeding regime	**Hand**	**Self-feeder**	**Hand**	**Self-feeder**
Dissolved oxygen %	**60-80**	**60-80**	**40-60**	**40-60**
Initial weight (g)	95.60 ± 0.44	97.00 ± 0.75	97.47 ± 0.40	97.77 ± 0.45
Final weight (g)	298.73 ± 0.94 ^{a}	300.42 ± 12.05 ^{a}	269.55 ± 10.21 ^{b}	266.58 ± 12.21 ^{b}
Daily growth rate - G (%)	2.56 ± 0.02 ^{a}	2.53 ± 0.17 ^{a}	2.13 ± 0.13 ^{b}	2.08 ± 0.14 ^{b}
Specific growth rate (SGR %)	1.37 ± 0.01 ^{a}	1.36 ± 0.06 ^{a}	1.23 ± 0.05 ^{b}	1.21 ± 0.05 ^{b}
Feed conversion ratio (FCR)	1.28 ± 0.02	1.34 ± 0.01	1.31 ± 0.12	1.21 ± 0.05
Daily feed consumption (DFC)	1.60 ± 0.03 ^{a}	1.65 ± 0.11 ^{a}	1.44 ± 0.09 ^{b}	1.32 ± 0.05 ^{b}
VSI	5.94 ± 1.08	6.82 ± 1.36	6.62 ± 0.85	5.98 ± 1.01
Perivisceral fat	1.86 ± 0.99	2.94 ± 1.05	2.50 ± 1.00	2.36 ± 0.63
HSI	1.02 ± 0.21	1.21 ± 0.19	1.07 ± 0.18	1.07 ± 0.25

(Continued on next page)

Results and Discussion

Growth indices for sea bream under two different feeding regimes and DO levels are shown in **Table 1**. Feeding regimes did not significantly affect final body weight, growth rates, FCR and daily feed consumption (P>0.05). However, the DO levels appeared to affect growth indices for sea bream, with better growth values presented by the groups of higher DO levels (60-80%, P<0.05). FCR was invariant between different feeding regimes and oxygen levels (P>0.05). In addition, neither the feeding regime nor the oxygen levels had any statistically significant effect on the somatometric indices for sea bream (P>0.05). The results of this study indicate that sea bream can achieve similar growth rates both by hand feeding and by using an automatic feeder by adjusting the amount of feed consumed per day. Feeding by hand proved to attain growth and feed consumption comparable to those fed by automatic self-feeders. In each case, the highest growth rates are achieved at the optimal oxygen levels for the species. The results of the present work regarding feeding regimes seem to coincide with those of Yamamoto et al. (2002) for juvenile rainbow trout (*Oncorhynchus mykiss*), where no differences in growth between hand and self-feeder feeding regimes occurred. Voluntary feed consumption and specific growth rates, as well as the hand-feeding amount, were significantly decreased when oxygen levels were low. Boujard and Médale (1994) observed that rainbow trout could regulate with great precision the amount of feed is consumed, regardless of the feeding technique. Hence, no differences in growth between hand and self-feeder feeding appeared. It has also been mentioned that continuous feeding (self-feeders) reduced the swimming activity and increased the aggressive fish encounters compared with the hand-feeding regime (Almazán-Rueda *et al*., 2004).

CARP FARMING IN PONDS IN POLAND AS AN EXAMPLE OF AN ECOSYSTEM APPROACH IN AQUACULTURE

K. Turkowski

Institute of Management and Quality Sciences, University of Warmia and Mazury in Olsztyn
10-957 Olsztyn (Poland)
E-mail: kontur@uwm.edu.pl

Introduction

Aquaculture now provides half of the world's fish supply and is one of the fastest growing food production sectors in the world. Unfortunately, this growth is often accompanied by a number of negative phenomena, such as the occupation of large areas for aquaculture facilities, increased pollution, and the spread of disease. The integration of aquaculture into a broader system that takes into account the sustainable nature of socio-ecological interconnections is expected to prevent the above negative phenomena. Soto et al. (2008) found that three main principles underlie the development of environmentally and socially sustainable aquaculture: first, aquaculture must take into account the full range of ecosystem functions and services that should be provided to society in a non-threatening and sustainable manner; second, aquaculture should contribute to the well-being and equality of people representing all stakeholders; and third, aquaculture should be developed taking into account other sectors, policies and their objectives. Success in achieving the above goals requires, on the one hand, appropriate management of aquaculture development at the institutional level, and on the other hand, social acceptance of the measures taken. Pond carp farming is a type of aquaculture that is able to meet all of the above criteria.

Pond carp aquaculture in Poland

Poland has the largest area of carp ponds in the European Union, estimated at about 70,000 hectares. It is estimated that an additional 12,000-15,000 hectares is the total size of small rural ponds that are not distinguished in land records. Annual domestic carp production varies between 16,000 and 20,000 tons (Eurostat, 2022). Poland is the main European market for fresh carp, with a stable consumption of more than 21,000 mt. The carp aquaculture preserves its traditional character with low intensification of production (usually 450 – 500 kg/ha/year), and a large share of natural food (growing in the pond) in fish diet. Rearing common carp usually employs mixed species stock (polycultures). The share of other fish species, mainly grass carp, silver carp, crucian carp, tench, pikeperch, sturgeon, pike and trout, is around 13%. Low-intensive production, large areas of ponds and their open nature mean that the ponds, over decades and hundreds of years of use, have become an integral part of the local environment. They resemble vast, shallow lakes, providing a range of ecosystem services. The non-productive qualities of the ponds have helped expand the traditional carp economy to include tourism, recreation, catering, hospitality and other services (Békefi & Váradi, 2007). Pond farms that use traditional methods of fish production that are compatible with the needs of the environment and its protection can expect to be compensated for the additional costs incurred or income lost as a result. A multifunctional farm model that draws on tradition and culture has been identified as one of the primary strategic objectives for the development of domestic aquaculture (Figure 1).

Ecosystem services of carp ponds

The non-productive values of carp fish ponds have long been recognized by ecologists (Dobrowolski et al., 1994), fishing industry experts (Leopold, 1983) and fishermen (Turkowski, 2021). Studies conducted in France (Mathé & Rey-Valette, 2015) and Poland (Turkowski & Dubrowski, 2022) have shown that people not professionally involved in fishing are also fully aware of the importance of the environmental and social functions of carp ponds. This is the premise of public acceptance of the European fisheries policy, which aims to develop aquaculture without environmental deterioration, creating a balanced relationship between producers and the broader consumers of productive and non-productive aquaculture products.

OFFSHORE SALMON AQUACULTURE FINANCIAL RISKS AND INVESTMENT ANALYSIS: IMPLICATIONS FOR GOVERNMENT REGULATIONS AND TAX REGIME

Ragnar Tveterås*, Tord Ludvigsen, Bård Misund

University of Stavanger Business School, 4036 Stavanger, Norway
Email: ragnar.tveteras@uis.no

Introduction

Marine aquaculture is today dominated by open cage inshore farming. Open cages can be very productive as they benefit from continuous inflow of huge volumes of water and discharge of effluents. But with increasing production and farm density open cage production may become less sustainable due to higher disease pressure and negative environmental effects in inshore waters. If it is not possible to increase inshore production using open cages in a sustainable manner, then society and industry can benefit from innovation in closed production systems or offshore farms that have smaller negative biological and disease externalities. Today we observe innovations and investments in these technological alternatives in Norwegian salmon aquaculture. However, the new offshore aquaculture sector faces significant biological, technical and financial risks. For government this may have significant implications for the design of regulations and tax regime.

The research questions we ask are as follows: (1) How do different investment costs and operating costs in offshore salmon aquaculture affect financial returns compared to conventional inshore salmon aquaculture? (2) How does the structure of biological, technological and financial risk differ between offshore and conventional inshore farming? (3) What are the implications for government offshore aquaculture regulations and tax regime to provide sufficient economic incentives for investment?

Empirical analysis

We provide a comparative empirical analysis of conventional salmon aquaculture and offshore aquaculture in Norway, which includes (1) an investment analysis of net financial returns (NPV) under different scenarios and employing sensitivity analysis, and (2) analysis decision trees which include decision points (e.g. investment decisions, government license allocation), uncertainties and risks for aquaculture investment projects. In the analysis we use firm-level economic data from the Norwegian Directorate of Fisheries, and data from companies on new offshore farm concepts.

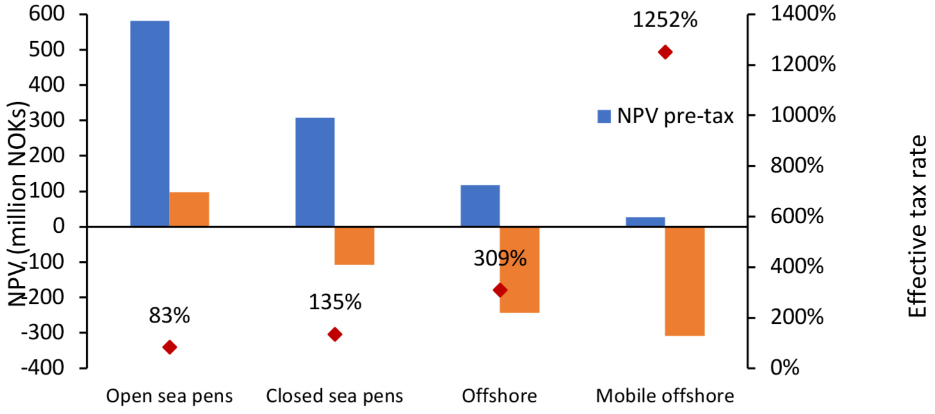

Figure 1. Net present value (NPV) before and after resource tax

(Continued on next page)

Offshore farms will have a much larger scale than conventional inshore farms: Typical production at inshore salmon farms is 2000-5000 metric tonnes (MT), while offshore farms may have a production volume of 10,000-25,000 MT. Investment in farm capital equipment (cages, feed barge, etc.) is typically 10-20 million Euro for a conventional inshore farm, while for an offshore farm investment costs may be 100-200 million Euro. Lead times from investment decisions to production start will also be considerably longer offshore, and with much higher negative cash flow before harvesting can begin. Offshore farming also represents a new production environment with generally stronger winds, higher waves, longer periods with weather that prohibits farm operations, and periods with extreme weather conditions. This implies higher biological and technical risk, and ultimately higher financial risks. It is reasonable to expect that increased risk compared to inshore farming should also lead to higher capital rate of return requirements for investors.

We calculate net present value (NPV) of aquaculture investment projects using different inshore and offshore cases and sensitivity analyses. The after-tax free cash flow at time *t* ($FCF_t^{before\ tax}$) is calculated as:

$$\mathrm{FCF}_t^{after\ tax} = (P_t \cdot Q_t - OPEX_t - DEP_t) \cdot (1 - \tau) - CAP_t - \Delta WC_t - IMM_t + DEP_t \tag{2}$$

where P_t is the salmon price (net of transportation and processing costs) at time *t*, Q_t is production volume, $OPEX_t$ is operation costs, DEP_t is depreciation, CAP_t is capital expenditures, ΔWC_t is change in working capital, IMM_t is investments in licenses (license fee to government), and τ is the tax rate on taxable income (in this case earnings before interest and taxes, i.e. EBIT). We also evaluate other tax structures.

We calculate the net present value (NPV) for different offshore and inshore projects, with different investment costs, operating costs, sales prices, rate of return requirements (discount rate), and taxes. As an example of the analyses we undertake, figure 1 shows the net present value before and after a resource tax, including effective tax rates.

Conclusions

Our analysis shows that offshore salmon farm concepts have much higher upfront investment costs and cumulative negative cash flows before the first harvesting, together with longer lead times until harvesting and significant new biological and technical risks. This should imply that investors' financial rate of return requirements will be higher in offshore aquaculture. Economies of scale and less negative biological externalities from inshore farms are potential benefits from offshore farming. We find that the NPV of offshore farm concepts are more sensitive to price and cost shocks than conventional inshore farms.

Our analysis also implies that the Norwegian government should not adopt all elements of the regulatory and tax regime currently present in inshore salmon aquaculture, but needs to consider innovations in regulations and taxation. This includes production license fees, tax rates, and timing of payments to government, which we analyze here. It also includes options to co-locate offshore farms in the same area to exploit economies of scale in farm production cycles, sea vessel logistics and energy infrastructure. With an appropriately designed regulatory and tax regime, government can provide incentives for investment in offshore farm projects that reduce biological and environmental externalities, and provide acceptable returns to society and industry.

EFFECT OF PARTIAL REPLACEMENT OF FISH MEAL WITH VARIEGATED GRASSHOPPER (*Zonocerus variegatus*) MEAL ON GROWTH, BODY COMPOSITION OF HYBRID AFRICAN CATFISH (*Clarias gariepinus X Heterobranchus bidorsalis*)

Introduction

According to the FAO, Global fish production is estimated to have reached about 179 million tonnes in 2018, with a total estimated value of 250 billion dollars, of which 82 million tonnes valued at 250 billion dollars came from aquaculture production (FAO, 2020). Increasing aquaculture production has implications for the demand and price of aquaculture feed ingredients. There is an over-dependence by fish farmers on conventional feed ingredients such as Fish oil (FO), Fish meal (FM), soybean meal (SBM) as a source of protein, for which there is already an increase in demand because of the intensification of farming methods relying on complete fish feed (Tacon & Metian, 2008). FM, for example, is valued for its balanced amino acid and vitamin, which are essential nutrients in most fish feeds (Tacon, 2002). However, FM is the most expensive feed ingredient used in aquaculture feed formulation; due to increasing competition indirect human consumption. Edible grasshopper meal (GM) has been reported to have crude protein content between 29 to 61.50% (Alegbeleye et al., 2012; Okoye & Nnaji, 2005). Therefore, the study sought to evaluate the effect of partial replacement of FM with Variegated Grasshopper (*Zonocerus variegatus*) meal on growth, body composition of hybrid African catfish (*Clarias gariepinus x Heterobranchus bidorsalis*) which is one of the most cultured catfish species in Nigeria.

Methodology

90 days feeding trial was conducted to evaluate the effect of grasshopper (*Zonocerus variegatus*) meal (GM) inclusion in practical diets of hybrid African catfish (*Clarias gariepinus x Heterobranchus bidorsalis*). Five diets were formulated to include GM in hybrid African catfish diet at inclusion levels of 0, 10, 20, 30 and 40%; so as to partially replace 0% (control), 18.53%, 37.12%, 55.78% and 74.5% of respectively. The experimental diets were designated GM_0 (0% inclusion),GM_{10} (10% inclusion), GM_{20} (20% inclusion), GM_{30} (30% inclusion) and GM_{40} (40% inclusion). Hybrid African catfish fingerlings (n = 225) with a mean weight of 2.24±0.02 g were randomly distributed into 15 hapas with dimensions of 0.4m x 0.4m x 0.6m suspended in three concrete ponds and fed experimental diets in triplicate for 90 days.

Table 1: Growth performance and feed utilization of Hybrid catfish (*Clarias gariepinus x Heterobranchus bidorsalis*) fed increasing levels of GM in replacement of FM

	Control	**Treatments**			
	GM_0	**GM_{10}**	**GM_{20}**	**GM_{30}**	**GM_{40}**
Initial weight (g)	2.22 ± 0.00	2.22 ± 0.01	2.26 ± 0.02	2.24 ± 0.01	2.24 ± 0.01
Final weight (g)	31.45 ± 0.46^c	31.88 ± 0.16^c	33.33 ± 0.09^b	36.41 ± 0.14^a	31.53 ± 0.11^c
WG (%)	1304.70 ± 20.7^d	1336.04 ± 7.03^c	1374.81 ± 4.04^b	1525.54 ± 6.45^a	1296.21 ± 5.02^d
Survival (%)	100.0 ± 0.0	100.0 ± 0.0	92.0 ± 0.01	92.0 ± 0.0	92.0 ± 0.0
SGR (% day^{-1})	2.95 ± 0.02	2.96 ± 0.01	2.99 ± 0.01	3.10 ± 0.01	2.94 ± 0.55
FI (g)	36.72 ± 0.67^c	37.31 ± 0.42^b	37.93 ± 0.11^b	41.57 ± 0.34^a	36.86 ± 0.14^c
FE $^{1)}$	0.80 ± 0.01^b	0.80 ± 0.01^b	0.82 ± 0.01^a	0.82 ± 0.01^a	0.79 ±0.01^b
PER (g g^{-1})	2.14 ± 0.01^b	2.13 ± 0.01^b	2.19 ± 0.01^a	2.20 ± 0.01^a	2.13 ± 0.01^b
PR (%)	39.11 ± 0.08^b	38.98 ± 0.27^b	39.99 ± 0.16^a	40.05 ± 0.12^a	38.64 ± 0.22^b

Values are means ± standard deviation of triplicate samples. Means of different superscript within the same row are significantly different (P < .05). Abbreviations: WG: per cent weight gain; SGR: specific growth rate; FI: Feed intake; FE: feed efficiency; PER: Protein efficiency ratio; PR: Protein retention

(Continued on next page)

Results

At the end of the trial, no statistical differences between dietary treatments were observed for all haematological parameters and specific growth rate (SGR). However, statistical differences were observed for percentage weight gain (%WG), feed intake (FI), feed efficiency (FE), the protein efficiency ratio (PER), and protein retention (PR). Treatments fed GM_0 (control), and GM_{40} had significantly lower WG (%) and FI (g) than in GM_{10}, GM_{20}, and GM_{30}.

In comparison, treatment fed GM30 had significantly higher WG (%) and FI (g) than other treatments. In terms of FE, PER, and PR, treatments fed GM_{30} and GM_{20} had significantly higher values than other treatments. Treatments fed GM_{20} and GM_{30} had significantly higher VSI = Viscerosomatic index (VSI) value while those fed GM_{10} had the lowest VSI but did not significantly differ from those fed GM_0 and GM_{40}. Hepatosomatic index (HSI) was significantly lower in treatment fed GM_{10}, but no differences were detected in treatments fed the other inclusion levels. Whole-body composition showed no statistical differences among treatments for crude protein and ash content, but showed a difference for lipid and moisture content; lipid was significantly higher in the body of treatment fed GM_{40} while lipid was lowest in the body of treatment fed GM10 but did differ significantly from the treatment fed GM_0. Treatment fed GM_{40} had significantly lower moisture content in their body than treatments fed other dietary treatments. Protein ADC was significantly higher in treatments fed GM_{20}, and GM_{30}.

Discussion and Conclusion

Data from this study indicated that GM inclusion in dietary treatment significantly influenced growth, feed utilization parameter, hepatosomatic index, visceral somatic index, apparent digestibility coefficient, and whole-body composition of hybrid African catfish (*C. gariepinus x H. bidorsalis*); however, the hematological parameters of the fish were not influenced by GM inclusion. This study suggest that up to 55.82% of FM could be replaced by variegated grasshopper (*Z. variegatus*) without compromising the growth performance, survival, feed utilization, and health of hybrid African catfish (*C. gariepinus x H. bidorsalis*).

Introduction

Skeletal development in hatchery reared gilthead seabream larvae (*Sparus aurata*) is a crucial process, where fish often present several anomalies such as lordosis, kyphosis, cranial malformations, and other vertebral anomalies (Izquierdo et al, 2019). This onset of skeletal anomalies lowers the survival rate by affecting the larval growth, swimming behaviour, and other physiological functions (Boglione and Costa, 2011). To overcome this issue, studies have tried to improve the larval production by altering the biotic and abiotic factors affecting larval skeletal development (Izquierdo et al., 2016). In accordance with that, nutrition is one of the major factors involved in skeletal development during early larval stages (Izquierdo et al. 2000). Hence, a series of trials focused on studying the effects of essential fat-soluble micronutrient vitamins D and K on gilthead seabream skeletal development during larval and juvenile stages were conducted. In addition, fish vertebra-derived cell lines were also used to understand the action of these vitamins on bone cell mineralization.

Vitamin D and K are essential micronutrients as they can't be synthesised *de novo* in fish (Lock et al., 2010, Krossoy 2011). They are involved in bone formation by regulating calcium metabolism and bone biomarkers in fish (Graff et al., 2016). They work synergistically to synthesise bone regulators such as osteocalcin (*oc*) and matrix Gla protein (*mgp*), which function in bone formation, mineralization, and soft tissue calcification, respectively (Graff et al., 2016). Deficiency of these vitamins in diet causes skeletal anomalies, growth reduction and increase mortality in fish (Udagawa 2000, Dominguez et al.,2021,2022). Thus, the aim of the study was to determine the dietary requirement of vitamin D and K and its physiological role on growth and skeletal development of gilthead seabream larvae, juvenile and skeletal derived-bone cells.

Experimental Design	Vitamin D	Vitamin K	Vitamin D & K Interaction
Larvae	✓	✓	✓
Juvenile	Dominguez et al., 2021	Dominguez et al., 2022	✓
Skeletal derived bone cells	✓	✓	✓

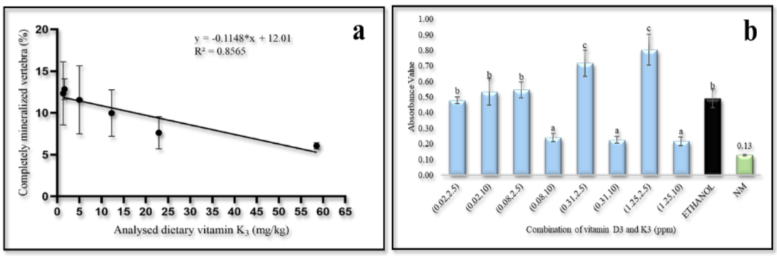

Figure 1: Effect of dietary (a) vitamin D_3 on percentage of completely mineralized vertebra in gilthead seabream larvae following a linear regression, $R^2 = 0.857$, $p = 0.008$ and (b) combination of vitamin D_3 and K_3 on extracellular matrix mineralization percentage in Vsa13 bone cells determined by one-way ANOVA ($p = 0.001$).

(Continued on next page)

Materials and methods

Four different *in vivo* experiments were conducted with dietary vitamin D and vitamin K, in which two were focused solely on vitamin D or K, while other two were aimed at understanding the interactions between both vitamins. Additionally, a similar model was designed for an *in vitro* cell culture study (Table 1).
Table 1. Experimental design and number of experiments conducted.

Gilthead seabream larvae and juvenile were obtained from Aquaculture research group (GIA), ECOAQUA Institute, University of las Palmas de Gran Canaria, Spain. For larval study, they were initially fed with enriched (ORIGREEN, Skretting, Norway) rotifer (*Brachinous plicatilis*) and randomly distributed into experimental tanks at a similar density. For the juvenile study, fish were screened for abnormal body shape, which were considered to present skeletal anomalies, were removed and the fish with normal body shape and a similar body weight were homogenously distributed in experimental tanks. At the end of the experimental period, fish were sampled for growth performance, skeletal anomalies, gene expression and other biochemical analysis. For the cell culture study, VSa13 bone derived cell lines from CCMAR (Centro de Ciências do Mar, Faro, Portugal) were used. The cells were regularly observed under the microscope and growth media (contains different dilution of vitamin) was changed at regular time intervals to understand the effect of vitamins in cells. Cultured cells were analysed for extracellular mineralisation (ECM), cell toxicity and gene expression.

Results and Discussion

Larvae fed increasing dietary vitamin D_3 showed an increase in complete vertebral mineralization with increase in severe skeletal anomalies and a reduced survival rate. The *bmp2* and *alp* gene expression were affected with the highest dietary group. Meanwhile larvae fed increasing dietary vitamin K_3 showed a reduction in complete vertebral mineralization (Figure 1a) with increasing abdominal kyphosis and reduced survival rate. Heatmap showed a reduced expression of osteocalcin (*oc*) gene expression with increase in dietary vitamin K_3. On the other hand, when larvae were fed with different combination of vitamin D and K there were no significant differences with skeletal anomalies among the groups and there was a tendency to reduce the larval survival at the group fed with the highest dietary vitamin D and K combination. The vitamin K-dependent proteins such as *oc* and *mgp* were highly expressed during day 7 and tended to reduce at day 21. The other bone biomarker gene such as *bmp2* were also affected on day 21 along with calcium regulators on both day 7 and day 21. However, when a different combination of dietary vitamin D and K were fed to gilthead seabream juvenile, no significant differences were observed among growth parameters and skeletal anomalies between the groups. Despite that, the combination of vitamin D and K upregulated the *bmp2* and *alp* gene expression and calcium regulators in gilthead seabream juveniles. In the case of*, in vitro* cell culture, the cells treated separately with vitamin D and vitamin K showed no significant difference in extra cellular mineralization (ECM). However, the combined effect of vitamin D and K showed significant reduction in ECM when treated with higher dilution of vitamin K with different vitamin D level (Figure 1 b).

Conclusion

- Analysed dietary level for gilthead seabream larvae between 25 - 30 μg/ kg of vitamin D_3, and 4.98 – 12.26 mg/ kg of vitamin K_3 would improve vertebral mineralization and reduce skeletal anomalies
- In gilthead seabream juveniles, the dietary combination of 0.04 mg/kg vitamin D_3 and 12 mg/kg vitamin K_3 diet would be recommended for optimum growth and reduced skeletal anomalies.
- The VSa13 *in vitro* cell culture suggested that an increase in the concentration of vitamin D_3 (0 – 2.5 ppm) and K_3 (0 – 20 ppm) and their interaction at (0.08-1.25 ppm VD and 10 ppm VK) caused cell toxicity and reduced extracellular matrix mineralization in bone cells.

Introduction

Water quality si an important attribute in many fields, including aquaculture production, biosystems protection and preservation. The water clarity could be affected by anorganic or organic contamination. The organic is represented mainly by the algae and cyanobacteria species, causing water blooms and increasing optical density. The anorganics are mainly minerals, soils, sand, mug, and clay particles. In case of fish welfare, biomonitoring, and bioimaging tasks depend on visible patterns of the fish body and behavior parameters. Therefore, it is crucial to achieve the adequate visual information, usually by digital camera and further processing and analysis of the obtained images or video. The turbidity affects the optical path differently for each wavelength of the light spectrum. The visible light suffers strongly with higher turbidity. In UV range, only the UVA is penetrating. The similar limitation is also valid for the imaging systems, namely CCD, CMOS, and Foveon detectors. The IRA part of the NIR spectrum is detectable by the visual cameras without the covering IR fiter.

Recently, the grow of the IoT and microcomputers allowed to to use pinhole cameras even as spectrophotometers. Therefore, optical properties of the water or water cloud could be also analyzed by the image processing and analysis. In this work we deals with the UVA and IRA imaging systems and investigate the possibility of such systems to overpass the turbidity effect, limitation, and dependency of absorbance caused by water cloud.

Materials and Methods

We achieved the measurement of visibility in part spectrum in artificial conditions in aquarium with different light sources (IRA, VIS, UVA). The digital image measurement itself was done in transmittance mode, the cameras were mounted on the opposite sides of the given light source, and therefore measuring the light shined through the water.

For the measurement we used the plastic chessboard like the Secchi disc, however instead of white there was blank, to be able to measure in transmittance mode. As a water cloud inducing substance was used the mineral clay. The additional measurement of the water samples was performed by portable spectrometer with standard plastic pathlend square cuvettes.

Results and Discusion

The absorbance mesurements were analysed using Vernier Spectral Analysis. The images were processed and evaluated by the MathWorks Matlab environment. the original RGB images were converted into grayscale intensity images, channels weighted respectively to each other. The optical visibility was evaluated via the root mean square contrast to compare the same water transparency properties for different imaging systems (IRA, VIS, UVA). The water turbidity could be from transparency point of view considered as a optical dence environment such as fog, where the IRA shows the best testing contrast ratio for direct beams. In practical use, the IRA imaging and capturing systém is used for evaluation in real conditions, like the monitoring of fish ladders in the rivers.

Introduction

Fish farming in Serbia is mostly carried out in cyprinid and salmonid (trout) fish farms (over 95% of the total fish produced). Based on the official data from Statistical Office of the Republic of Serbia (2021) the total production of all fish species in cyprinid fish farms for human consumption in Serbia in 2020 was 4.761 t. The total number of cyprinid farms is 65. In Serbia, marketable carp (*Cyprinus carpio*) is often grown with other cyprinids (grass carp *Ctenopharyngodon idella*, silver carp *Hypophthalmichthys molitrix* and bighead carp *Aristichthys nobilis*) but carp fry is mostly grown in monoculture, often feed with the addition of supplemental diets. Water quality is the most important limiting factor in rearing of fish and directly affects feed efficiency, growth rate, fish health, and survival (Svobodova, 1993). It is therefore important to monitor water quality parameters to ensure they remain within the optimum range for farmed fish. As Serbia has become a candidate country for European Union membership, it is obliged to harmonize regulations in regard to water quality control in fish ponds, especially with Directive 2006/44/EC about the quality of fresh waters needing protection or improvement in order to support fish life (Directive, 2006).

To the best of the authors knowledge, in the past decades there no monitoring of water quality was carried out in cyprinid farms in Serbia The objective of this study was to screen the main physicochemical parameters of water in cyprinid ponds in different geographical areas of Serbia and compare them with recommended and mandatory values in the Directive 2006/44/EC.

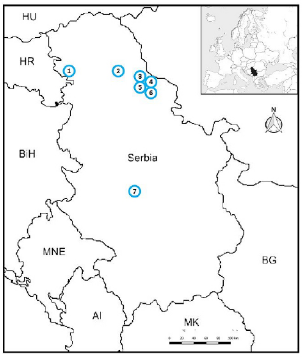
Materials and Methods

Water quality was assessed in 12 ponds in total of 7 fish farms of cyprinid fish species. The geographical locations of investigated ponds in our study are shown on the map (Fig. 1). All samples were taken in October 2021. The total water surface area of the sampled ponds is calculated to be 2162

.

According to the rearing method, they belong to intensive (farms No. 1 and 7) and semi-intensive production (all other farms). Basic water quality parameters were measured on site: air and water temperature (thermometer, Testo, Germany), concentration of dissolved oxygen (DO), % of DO saturation and conductivity (oximeter and conductometer, Eutech Instruments, Netherlands), pH (pH meter, Testo, Germany), while portable photometer (Lovibond, Germany) was used to determine total ammonia (NH4+), unionized ammonium (NH3), carbonates (CaCO3), zinc (Zn) and free copper (Cu). Total suspended solids were determined by photometric method (photometer, Lovibond, Germany).

Figure 1. The map of fish farms in realized research survey



(Continued on next page)

Results and discussion

Water temperature at the time of sampling was within the recommended limit and ranged from 9°C to 13°C. Of the 12 ponds water samples tested, 4 (all in intensive system) and all 6 exceeded the recommended limits of ≤1mg/L and ≤0,025 mg/L of total ammonium and non-ionized ammonia, respectively. Of the 12 fishponds tested, 5 exceeded the recommended limits of 0.4 mg/L of total phosphorus. The levels of dissolved oxygen in accordance with percent of saturation were below desirable limits in 9 of the tested ponds: 50 % ≥ 8; 100 % ≥ 5. All of the tested ponds had higher concentration of dissolved copper than the recommended limits of ≤0,04 mg/L, while zinc was below detection limit. In this study, >70% of the ponds were found to be unfit for fish rearing based on their chemical parameters. The pH was in the range of 7,06 – 8,53, which belong to recommended values (6-9).

The findings of this study strongly suggest that there is big space for improvement of relatively poor water quality in selected fish ponds (e.g., high levels of copper). These results should help in the development and implementation of consistent national laws and regulations related to aquaculture production, based on the existing EU legislation and best practice currently implemented in EU Member States.

PRELIMINARY RESULTS OF WATER QUALITY IN RAINBOW TROUT FARMS IN SERBIA - ARE WE CLOSER OR FURTHER FROM THE DIRECTIVE 2006/44/EC?

Miroslav Urosevic*[1], Jasna Grabic[1], Nora Navarro-Gonzalez[2], Segolene Calvez[2]

[1]Faculty of agriculture, University of Novi Sad, Trg Dositeja Obradovica 8; 21000 Novi Sad, Serbia Novi Sad Serbia

Introduction

Fish farming in Serbia is mostly carried out in cyprinid and rainbow trout fish farms (over 95% of the total fish produced). Based on the official data from Statistical Office of the Republic of Serbia (Anonymous, 2021) the total production of rainbow trout fish farms for human consumption in Serbia in 2020 was 1.247 t. Whereas the total water surface used for rainbow trout (*Oncorhynchus mykiss*) breeding is known from official statistics (68,092 m^2), this is not the case with a number of rainbow trout farms. Because of difficulties to find an official source of this data, the total number of rainbow trout farms can only be estimated to be at least 100. In Serbia, marketable rainbow trout is only reared in open raceway systems with flow-through water circulation, especially in south - west regions of the country (located in highland regions). Traditional flow-through systems generally involve a multi-use (or multi-pass) of water, with different ponds supplied with flowing water. No water treatment is performed before being discharged to the receiving water, although some reuse might involve a supplementary oxygenation step. It is therefore important to monitor water quality parameters to ensure they remain within the optimum range for farmed fish. As Serbia has become a candidate country for European Union membership, it is obliged to harmonize regulations in regard to water quality control in fish ponds, especially with Directive 2006/44/EC about the quality of fresh waters needing protection or improvement in order to support fish life (Directive, 2006). The objective of this study was to screen the main physicochemical parameters of water in rainbow trout farms in different geographical areas of Serbia and to compare them with recommended and mandatory values in the Directive 2006/44/EC.

Materials and Methods

Water quality was assessed in 13 ponds in total of 4 rainbow trout fish farms of. The elevation of farms No. 1 and 2. was 477 m.a.s.l. and other two farms (3, 4) at 254 m.a.s.l. All samples were taken in March 2022. The number of investigated ponds per fish farm was 3 with exception of farm No. 4 (4 ponds). For each farm the measures were taken on three location: source of water (SW), ponds for juvenile stage (JS) and ponds of fish for consumption (FC). Basic water quality parameters were measured on site: air and water temperature (thermometer, Testo, Germany), concentration of dissolved oxygen (DO), % of DO saturation and conductivity (oximeter and conductometer, Eutech Instruments, Netherlands), pH (pH meter, Testo, Germany), while portable photometer (Lovibond, Germany) was used to determine total ammonia (NH4+), unionized ammonium (NH3), carbonates (CaCO3), zinc (Zn) and free copper (Cu). Total suspended solids were determined by photometric method (photometer, Lovibond, Germany).

Results and discussion

The results of our survey compared with recommended and mandatory values of Directive 2006/44/EC are shown in Table 1.

Water temperature at the time of sampling was within the recommended limits and ranged from 7,81 °C to 9,51 °C. Out of the 13 ponds water samples tested, the JS and FC of farm No. 1 and all three ponds of farm No. 2 exceeded the recommended limits of dissolved oxygen in accordance with percent of saturation (50 % $\geq$ 9 and 100 % $\geq$ 7). This has been a main problem in the past two decades because of a decrease in the water amount from the mountain rivers which supply these two farms. Concerning pH, it was in range of 7.43 – 8.40, which falls within recommended values (6-9), as well as zinc. Total ammonium and non-ionised ammonia were within mandatory range, $\leq$ 1mg/l NH_4^+ and $\leq$ 0.025 NH_3 respectively, but nitrites were slightly elevated, as well as total phosphorus and dissolved copper concentrations. The findings of this study suggest that there is a certain space for improvement of some parameters of water quality in selected fish ponds (e.g., high levels of copper). These results should help in the development and implementation of consistent national laws and regulations related to aquaculture production, based on the existing EU legislation and best practice currently implemented in EU Member States.

This research was funded by the French Ministry of European and Foreign Affairs in the frame of project “FAN-AQUA” granted in “ES BALK” - FSPI program (Fonds de Solidarité pour les Projets Innovants) and by the Ministry of Education, Science and Technological development of Serbia on the basis of the contract No. 451-03-68/2022-14/200117.

CYPRINID FISH FARMS IN THE HUNTING GROUNDS AND RAMSAR CONVENTION: EXAMPLE FROM NORTHERN SERBIA

Miroslav Urosevic*[1], Igor Ponjiger[2], Zoran Ristic[2], Jasna Grabic[1]

[1]Faculty of agriculture, University of Novi Sad, Trg Dositeja Obradovica 8; 21000 Novi Sad, Serbia Novi Sad Serbia
[2]Faculty of sciences, University of Novi Sad, Trg Dositeja Obradovica 3; 21000 Novi Sad; Serbia Novi Sad Serbia
E-mail: miroslav.urosevic@stocarstvo.edu.rs

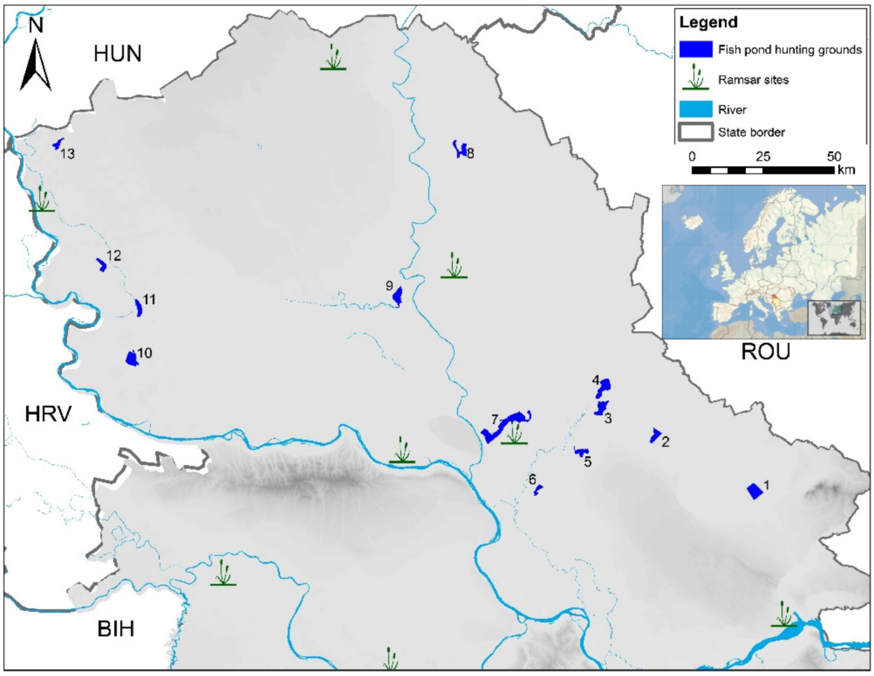
According to the Law on hunting (Official Gazette of RS, 18/2010) in Serbia hunting grounds are established as open or fenced. The open hunting ground cannot be less than 2,000 ha, except for special-purpose hunting grounds and hunting grounds on the surface of a registered fish pond. The hunting grounds on the surface of the registered fish ponds cannot be smaller than 200 ha. In the Autonomous Province Vojvodina (north part of Serbia) there are 13 hunting grounds of this type with a total area of 9501.89 ha. The hunting grounds on the map of the territory of northern Serbia (Province Vojvodina) are shown in Figure 1.

The main purpose of establishing these hunting grounds is primary for managing the population of great cormorants (*Phalacrocorax carbo*) and other species that present predatory for fish rearing in ponds. The great cormorant is a protected species according to the Serbian legislation (Ordinance, 2016), however, culling is permitted in the hunting grounds established around fisheries. According to the Proclamation on hunting seasons (Official Gazette of RS, 75/2016) great cormorants can be hunted during the entire year (1.1. - 31.12.). Hunting ground users may hunt exclusively to prevent damage in the fish ponds, following the annual hunting ground management plan. Besides preventing damages management plans also define cull quotas for the abundant species of waterfowls (ducks and geese) and other feathered game. These are important hunted species in the hunting tourism offer in the Vojvodina Region.

The Ramsar Convention (The Convention on Wetlands) refers to the conservation of wetlands of international importance, especially as waterfowl habitats. The Institute for Nature Conservation of Serbia has established a preliminary list of 68 potential Ramsar areas in Serbia.

Another important aspect of these hunting grounds is the fact that most of them are close to Ramsar sites, and present important habitats for endangered species. In Vojvodina, there are 8 Ramsar sites, which are shown on the map of the territory of northern Serbia (Figure 1). These 8 Ramsar sites cover a total area of 57.255 ha.

Figure 1. Map of northern Serbia showing the location of the surveyed fish farms



(Continued on next page)

While fish production is the main goal of registered fish ponds they also have great potential as generators of hunting tourism. Also, since wetlands are threatened these areas are valuable as habitats for birds. So, sustainable use of these resources could generate more funds that could be used for environmental protection.

All of these farms belong to the cyprinid farms, and rear firstly marketable carp (*Cyprinus carpio*) often together with other species grass carp (*Ctenopharyngodon idella*), silver carp (*Hypophthalmichthys molitrix*) and bighead carp (*Aristichthys nobilis*) in the polyculture system.

The total water surface area of the showed farms is calculated to be 8.913 ha, which is 75 % of all cyprinid farms in Province Vojvodina, 6.681 ha in total. The water surface of the fish farms in hunting grounds ranged from 260 to 1.100 ha, in average 607 ha (Fig. 1). Most of them belong to semi-intensive system of fish production.

We can conclude that hunting tourism in most of a.m. areas is relatively developed but in some of them is still in its early phase according to the achieved turnover and tourism infrastructure. Contrary big potential exists in connection with other types of tourism (i.e. fishing) with connected offer of a.m. fish ponds in hunting areas and Ramsar sites in their neighborhood. Primarily because tourism activities are similar in character and potential. Directing economic development towards tourism could divert local communities from the activities which are traditionally present in the area but may significantly degrade it.

This research was funded by the Ministry of Education, Science and Technological development of Serbia on the basis of the contracts for the realization and financing of scientific research work in 2022 (The Contract No. 451-03-68/2022-14/200117.).

Introduction

Aquaculture contributes for nearly half of the global food fish consumption, being a major source of eicosapentaenoic acid (EPA) and docosahexaenoic acid (DHA) for the burgeoning human population. However, as most marine fish species have limited ability to convert 18C fatty acids (FA) into long chain polyunsaturated fatty acids (LC-PUFA), fish farming is itself dependent on the dietary supply of those LC-PUFA, traditionally obtained from fish oil (FO) and fish meal (FM) (Tocher et al., 2019). In order to decrease the use of FM and FO in the aquafeed industry, it is necessary to find new sources of EPA and DHA in order to ensure adequate, sustainable and secure supply to the sector (Naylor et al., 2021).

The potential of marine alternative lipid sources (salmon oil, algae oil and a blend of micro and macroalgae) currently available in the market was compared to the traditional sardine oil used in aquafeeds. Sensible combinations were formulated to provide diets able to meet EPA and DHA dietary requirements of European sea bass and provide the consumer some differentiated fillet-rich in LC-PUFA.

Materials and methods

Six isolipidic diets (**Table 1**) were formulated targeting differential FA profiles. A control commercial-based diet (CTRL) was formulated with sardine and rapeseed oil as main lipid sources, with expected EPA+DHA levels of 2%. A positive control (SARDINE), targeting 3% EPA+DHA levels, included 8.5% sardine oil and 4.5% rapeseed oil. Three other experimental diets, were formulated to totally replace sardine oil by alternative sources rich in LC-PUFA, also targeting 3% of EPA+DHA: ALGASALMON with 9.9% salmon oil and 3.1% algae oil; ALGARAPE and ALGASOY with 4.4% algae oil and 8.6% rapeseed or soybean oil, respectively. A sixth diet was formulated to include 7.9% sardine oil, 4.7% rapeseed oil and a 2% blend of micro and macroalgae, also targeting 3% of EPA+DHA.

European sea bass individuals (initial body weight of 118g) were fed the experimental diets for 54 days. The trial was carried out in a recirculation aquaculture system (RAS) with water temperature at 20 °C. By the end of the trial, all fish were individually weighed to determine growth performance and feed efficiency. Fish were sampled for evaluation of nutrient utilization, whole-body and flesh FA content. Lipid quality indexes estimated from FA profile, concerning possible effects on human health, were also evaluated.

Results

All diets were equally well-accepted by the fish, no differences being found on feed efficiency or growth performance. A linear relationship between FA profile in tissues and in the diet suggested that EPA and DHA are retained in the muscle.

Although no differences were found in muscle total lipid content, the FA profile of sea bass fillet generally reflected the FA profile of diets. The muscle of fish fed ALGASALMON presented the highest PUFA n-3/n-6 ratio and ALGARAPE and ALGASOY the lowest, mostly due to the high linoleic acid content. EPA and DHA levels in muscle are presented in **Figure 1**. Muscle from fish fed ALGARAPE and ALGASOY had significantly higher DHA contents (231 and 218 mg $100g^{-1}$, respectively) when compared to CTRL, SARDINE and ALGABLEND diets. At end of the trial, all dietary treatments resulted in muscle EPA+DHA values that were within the recommended levels for human consumption to decrease the risk of cardiovascular diseases (> 250 mg $100g^{-1}$). A trend for ALGARAPE and ALGASOY to be more effective in increasing muscle EPA+DHA levels was observed, but without any statistical significance.

(Continued on next page)

Table 1. Lipid sources, expected EPA+DHA and estimated variation in formulation cost of the diets.

	CTRL	SARDINE	ALGASALMON	ALGARAPE	ALGASOY	ALGABLEND
Ingredients (%)						
Sardine oil	5.0	8.5	-	-	-	7.9
Rapeseed oil	8.0	4.5	-	8.6	-	4.7
Soybean oil	-	-	-	-	8.6	-
Salmon oil	-	-	9.9	-	-	-
Algae oil	-	-	3.1	4.4	4.4	-
Blend of algae	-	-	-	-	-	2.0
EPA+DHA (%)	2.0	3.0	3.0	3.0	3.0	3.0
Increased cost (%)	-	6	16	17	17	41

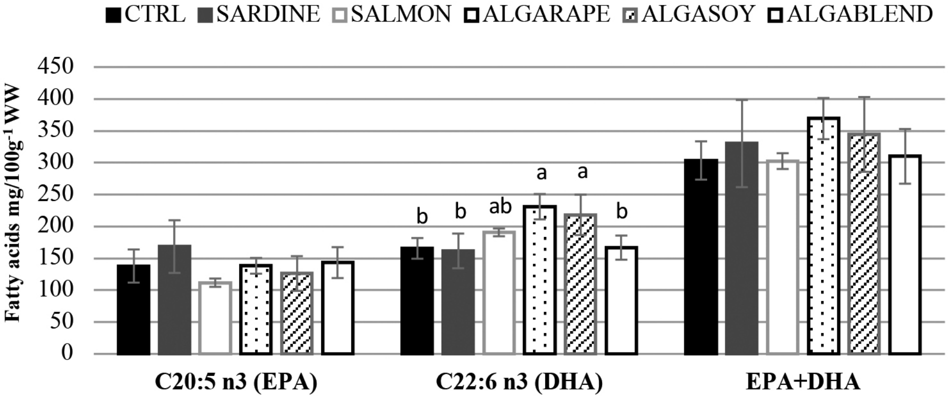

Figure 1: Muscle EPA, DHA and EPA+DHA content of sea bass fed the experimental diets for 54 days. EPA – eicosapentaenoic acid; DHA – docosahexaenoic acid. Values are presented as mean ± standard deviation (n = 4).

Discussion and Conclusion

The present study shows that it is feasible to include alternative lipid sources to increase the sustainability of diets for sea bass, without affecting growth performance and nutrient utilisation.

Taking into account the final muscle content of EPA and DHA, it can be concluded that the combination of pricy n-3 LC-PUFA sources with more economic and/or eco-friendly lipid ingredients, such as salmon by-product oil and algae is a viable solution for replacing sardine oil in feeds for European sea bass. Overall, the present study showed the feasibility of achieving good levels of DHA and EPA in the final product.

[1] Next Tuna GmbH, Londoner Str. 3, 60327 Frankfurt am Main, Germany / C-Feed AS
Brattørkaia 17B 7010 Trondheim Norway

Introduction

Next Tuna GmbH is planning, the first of its kind, production facility for Atlantic Bluefin Tuna (*Thunnus thynnus*) at the shore of the Mediterranean Sea. (see as well https://www.nexttuna.com/)

An essential part of Next Tuna's mission is to follow a sustainable production approach. A part of this approach is the application of an integrated multi trophic aquaculture (IMTA) system to treat/polish the run-off water from the state-of-the-art recirculation aquaculture facility.

Since the use of multi trophic nutrient extraction is mainly known as a marine add-on application to net-pen aquaculture, Next Tuna wants to apply this technology in a more concentrated, intensive application under fully controlled conditions.

Approach

Based on a desktop study, the work is focusing exclusively on the IMTA as application for final effluent polishing and nutrient extraction prior to effluent discharge into the sea. The expected incoming loads (volumes and nutrient concentrations) are given and based on long term experience with RAS. The available space for the IMTA application within the Next Tuna production facility is already earmarked and needs to be filled with the most suitable concept. The recirculation aquaculture part of the production facility is only seen as the source of nutrients for the IMTA. The added value of the IMTA production and its costs are discussed but are not the main scope of this work.
The scope of work is to identify:

1. The right combination of primary production species (algae or higher plants) and the suitable filter feeding shellfish for the multi trophic application based on available literature and ongoing international projects on IMTA.
2. Based on the findings form point 1, develop a system layout and calculate expected effluent nutrient concentrations based on known incoming nutrient loads.

Results

Within the framework of the project we:

1. Identify the most suitable combination of plants and shellfish for the planned application
2. Dimension a most suitable system for the most effective nutrient extraction under the given circumstances.
3. Calculate expected values of nutrient concentration after the IMTA application.

Discussion

The developed intensive IMTA application is benchmarked against experiences and expectations known for net-pen applications of the IMTA approach.
The intensive form of IMTA application is discussed with potential risks and management recommendations.

SAFE SEAWEED BY DESIGN: SUPPORTING THE SEAWEED SECTOR TO ENSURE SEAWEEDs ARE SAFE FOR HUMAN CONSUMPTION and THE ENVIRONMENT

Sander van den Burg, Sophie Koch & Jon Barlow

Wageningen Economic and Research
Droevendaalsesteeg 4, 6708 PB Wageningen, the Netherlands
E-mail: sander.vandenburg@wur.nl

Introduction

The increased global demand for food and feed combined with a changing climate confronts societies with the challenge to explore new sources of food and feed. In recent years, there has been significant interest in the potential contribution of seaweeds to the future food systems.

The growth of the global seaweed sector, already a source of income to farmers in moderate and tropical regions and now expanding to other regions, is fuelled by the development of (new) applications of seaweeds in food, feed, cosmetics and pharmaceuticals (Buschmann et al. 2017). Seaweeds not only can help meet future food demand – locally and abroad – they can also play an important role in stimulating food production on land and at sea, and contribute to the provision of ecosystem services, including climate mitigation. On land, marine resources can assist with improving soil quality and terrestrial production system efficiency, for both crops and livestock (Abbott et al. 2020; Seghetta et al. 2017). At sea, marine resources can increase nursery habitats and provide valuable ecosystem services such as CO_2 and mineral fixation, nutrient recycling, and long term carbon storage (Froehlich et al. 2019; Duarte et al. 2017).

It is crucial to ensure the further development of the seaweed sector is safe, for human consumption, for the environmental and for workers, as concerns are raised about the impact of large scale cultivation on the marine ecosystem (van der Meer, 2020), food safety (Banach et al, 2020).

Objective

This study aimed to support the development of a safe seaweed sector by providing protocols for safe seaweed production. Based on literature review, interviews with experts and a pilot, the Safe Seaweed by Design project aims to deliver science-based safety protocols. The protocols identify key risks and support the selection of appropriate methods for risk assessment. The study concludes with recommendations for business and government to advance the role seaweeds.

Methodology

The study pulls together information from various data sources. The first phase involves a review of literature on risk associated with seaweed production. This review was validated with expert interviews and a survey. Subsequently, the study teams developed and tested draft protocols in a pilot, conducted in Norway.

Intended output

The results from the study will support development of seaweed application in future food systems. Protocols are designed to be taken up by the sector, including seaweed producers and processors.

MODELLING SEAWEED CULTIVATION ON THE DUTCH CONTINENTAL SHELF

L. Vilmin and L.A. van Duren

[1] Deltares, Boussinesqweg 1, 2629 HV Delft, The Netherlands
Email: luca.vanduren@deltares.nl

Introduction

While Saccharina latissima seaweed is currently cultivated in the Netherlands at a small scale, there is a major drive towards increasing sustainable offshore cultivation. Future wind farm areas are seen as potential development locations. Figure 1 indicates the operational wind farms and designated areas for wind energy development at the time of the start of this research (development areas have meanwhile changed).

Harvesting seaweed leads to nutrient removal from the ecosystem. If this is done on a large scale, this can subsequently affect phytoplankton primary production, the basis of the marine food web. In this study, we investigate the spatial variability in ecosystem responses to seaweed cultivation in the Dutch North Sea in designated wind development areas. We focus on the interaction of seaweed and phytoplankton productivity with respect to nutrients and the effect of size, location and distribution of farms.

Approach and results

We integrated a module simulating seaweed nutrient uptake and growth dynamics into a fully coupled 3D hydrodynamic-water quality model of the North Sea. We ran different cultivation scenarios over a production year and compared them to a run without seaweed cultivation. Results showed that offshore locations are slightly more productive for seaweed cultivation than those closer to the coast, and that it is beneficial to split the cultivation area into relatively small plots. Growth of total seaweed biomass is mainly driven by temperature and light, since the fronds do not run out of reserves before harvest. Extreme upscaling of seaweed production to 25% of all Dutch designated offshore windfarm areas would have a strong impact on the ecology, with local decreases in spring phytoplankton production as high as 30%. The effect on nutrient concentrations and phytoplankton primary production is directly related to the size of the farms. Even at this stocking density, target yields were still achieved, indicating that production carrying capacity is not yet reached. However, at this level it is likely that there is an effect on ecological carrying capacity. What is acceptable or desirable in terms of nutrient removal and impact on phytoplankton primary production requires a societal debate, but models such as these can feed this discussion.

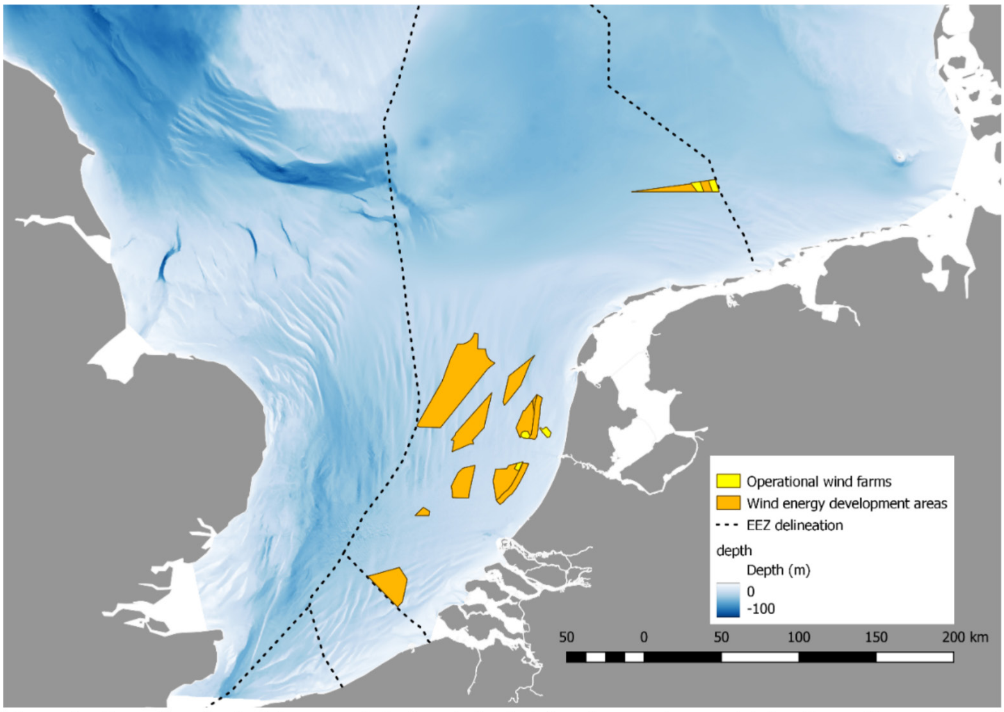

Figure 1: Operational wind farms and designated wind development areas (at the time of carrying out this research).

(Continued on next page)

The effects of large farms can extend far downstream. For example, seaweed cultivation over ~25 km2 at Borssele leads to a decrease in spring primary production >5% over more than 3,000 km2, all the way North from the Dutch Wadden Islands. Therefore, the location of seaweed farms with respect to each other is also an important factor to consider when upscaling seaweed production. Placing a new seaweed farm in the area of influence of another one can lead to higher local reductions in nutrient concentrations and phytoplankton primary production.

Outlook

The scenarios presented here are hypothetical. When sufficient field data is available, the seaweed module should be further calibrated and validated for Dutch waters to endorse the reliability of its predictions. This model could then be used to refine our estimates of the ecological carrying capacity of the Dutch North Sea for seaweed cultivation.

"THE USE OF SOY PRODUCTS AS A REPLACEMENT FOR FISHMEAL IN AQUA DIETS "

J.E. van Eys*

USSEC – United States Soybean Export Council; GANS Inc.
16305 Swingley Ridge Road, Suite 200, Chesterfield, MO 63017, U.S.A.
jvaneys@ct.ussec.org

On a world-wide scale it is estimated that fed aquaculture supplies 125 MMT or 70 % of the total aquatic production. It is expected that this production, as well as the proportion of total aquaculture production, will increase with approximately 2 % per year until 2030 (OECD/FAO, 2021). The associated annual production of commercial aqua feed is estimated at more than 51 MMT and fish meal production is estimated at 5.4 MMT (OECD/FAO, 2021). The supply of fishmeal - an ingredient considered essential in many aqua diets - is limited, leading to high prices of the fish meal and consequently the feed produced with it. Alternative sources of protein (amino acids) have been considered and tried in a large range of diets. These include animal co-products and plant proteins; principal among the latter is soy since it is the main plant protein being produced and its nutritive value in terms of amino acid profile is most advantageous for most aquatic species.

On a global scale, production of soybeans has increased steadily for more than 100 years reaching close to 370 MMT/yr. (OECD-FAO, 2021). Soybeans are crushed and converted in many ways leading to many different types of soy products that can play an important role in replacing part - or all - of the fish meal in aqua diets.

The main soy co-product is soybean meal (SBM) with an estimated production of more than 265 MMT globally. SBM has been – and is - extensively used in fish feed. In omnivorous fish, accounting for more than 70 % of the global aquaculture volume (Nailor et al., 2021), plant proteins - most notably SBM – have largely replaced fish or animal proteins. In certain species such as carp, catfish and tilapia, SBM may represent as much as 60 % of the total formula (Gatlin, 2013) thus covering almost all of the protein requirements. Soy products have also successfully been included in diets of carnivorous fish where they have been able to replace variable proportions of fish and animal proteins. This includes specific diets for trout as well as various marine fish diets (Powell et al., 2016; Kotzamanis et al., 2020; Velez-Calabria et al., 2021.

Such relatively high levels of SBM are possible, primarily due to SBM's relatively high levels of crude protein and amino acids but also because of its high protein (amino acid) digestibility and its adequate palatability. Among all plant proteins, soy products are recognized for having one of the most balanced amino acid profiles, although their content in sulfur-containing amino acids methionine and cystine may be limiting compared to the established, quantitative amino acid requirements of most fish species (NRC, 1993). Variable amino acid supplementation of soy-containing diets is needed and high-level replacement of FM by SBM (up to 90 %) has been successfully demonstrated in trout diets supplemented with valine, lysine, methionine and taurine without apparent decrease in growth or intestinal health status. (Velez-Calabria et al., 2021). Similar responses with additional improvements in carcass quality have been obtained with supplemental taurine in specific marine species (Kotzamanis et al., 2020). As a matter of fact, in many species the replacement of fish or animal proteins by soy proteins is hampered by an inadequate understanding of the digestible amino acid requirements for these species and age groups within species.

In the case of properly crushed SBM, amino acid digestibility is generally high although considerably differences among species have been shown. In fish and shrimp the digestibility of the soy protein fraction has been found to be high and generally close to 90 %, (e.g. Gatlin, 2013; Brezas and Hardy 2020; Kumar et al., 2020; Galkanda-Arachchige et al., 2020). Much of the variation in digestibility of SBM is related to quality and especially the degree of heat treatment.

Following a correction for the specific amino acids, higher levels of inclusion of soy products in fish and shrimp diets are limited by the presence and possible effects of the residual anti-nutritional factors (ANF). This is especially true for fry and juvenile fish which are exceptionally sensitive to ANFs. These components – present to variable degrees in soy product – have been associated with intestinal inflammations (enteritis) in commercial fish species leading to reduced absorptive capacity, increased mucus secretion, hyperpermeability, and leucocyte infiltration. Directly or indirectly, they have also been related to pro-inflammatory cytokine genes expression and changes in the composition and population of gut microbiota through the supply of nutrients that preferentially support or depress the presence of specific gut bacteria (Kumar et al., 2020).

(Continued on next page)

Partial removal of the heat labile ANF is achieved through toasting or expansion/extrusion. Heat resistant ANFs require alternative methods of treatment such as extraction (as in the case of SPC or ISP). An alternative, efficient and economical method for ANF reduction has proven to be the fermentation of SBM; alone or in combination with enzymatic extraction (Mukherjee et al., 2016; Zhang et al., 2021). These methods, most notably the solid-state fermentation of SBM (FSBM), are rapidly gaining interest allowing the inclusion – or increase in inclusion – of soy in aqua diets. This is especially important for carnivorous fish and shrimp where inclusion of FSBM allowed successful replacement of fish meal and improved performance. Production of FSBM may vary considerably by type of inoculum used and conditions of fermentation. However, these differences in production have not shown consistent, demonstratable differences in performance.

On a world-wide scale it is estimated that fed aquaculture supplies 125 MMT or 70 % of the total aquatic production. It is expected that this production, as well as the proportion of total aquaculture production, will increase with approximately 2 % per year until 2030 (OECD/FAO, 2021). The associated annual production of commercial aqua feed is estimated at more than 51 MMT and fish meal production is estimated at 5.4 MMT (OECD/FAO, 2021). The supply of fishmeal - an ingredient considered essential in many aqua diets - is limited, leading to high prices of the fish meal and consequently the feed produced with it. Alternative sources of protein (amino acids) have been considered and tried in a large range of diets. These include animal co-products and plant proteins; principal among the latter is soy since it is the main plant protein being produced and its nutritive value in terms of amino acid profile is most advantageous for most aquatic species.

On a global scale, production of soybeans has increased steadily for more than 100 years reaching close to 370 MMT/yr. (OECD-FAO, 2021). Soybeans are crushed and converted in many ways leading to many different types of soy products that can play an important role in replacing part - or all - of the fish meal in aqua diets.

The main soy co-product is soybean meal (SBM) with an estimated production of more than 265 MMT globally. SBM has been – and is - extensively used in fish feed. In omnivorous fish, accounting for more than 70 % of the global aquaculture volume (Nailor et al., 2021), plant proteins - most notably SBM – have largely replaced fish or animal proteins. In certain species such as carp, catfish and tilapia, SBM may represent as much as 60 % of the total formula (Gatlin, 2013) thus covering almost all of the protein requirements. Soy products have also successfully been included in diets of carnivorous fish where they have been able to replace variable proportions of fish and animal proteins. This includes specific diets for trout as well as various marine fish diets (Powell et al., 2016; Kotzamanis et al., 2020; Velez-Calabria et al., 2021.

Such relatively high levels of SBM are possible, primarily due to SBM's relatively high levels of crude protein and amino acids but also because of its high protein (amino acid) digestibility and its adequate palatability. Among all plant proteins, soy products are recognized for having one of the most balanced amino acid profiles, although their content in sulfur-containing amino acids methionine and cystine may be limiting compared to the established, quantitative amino acid requirements of most fish species (NRC, 1993). Variable amino acid supplementation of soy-containing diets is needed and high-level replacement of FM by SBM (up to 90 %) has been successfully demonstrated in trout diets supplemented with valine, lysine, methionine and taurine without apparent decrease in growth or intestinal health status. (Velez-Calabria et al., 2021). Similar responses with additional improvements in carcass quality have been obtained with supplemental taurine in specific marine species (Kotzamanis et al., 2020). As a matter of fact, in many species the replacement of fish or animal proteins by soy proteins is hampered by an inadequate understanding of the digestible amino acid requirements for these species and age groups within species.

In the case of properly crushed SBM, amino acid digestibility is generally high although considerably differences among species have been shown. In fish and shrimp the digestibility of the soy protein fraction has been found to be high and generally close to 90 %, (e.g. Gatlin, 2013; Brezas and Hardy 2020; Kumar et al., 2020; Galkanda-Arachchige et al., 2020). Much of the variation in digestibility of SBM is related to quality and especially the degree of heat treatment.

Following a correction for the specific amino acids, higher levels of inclusion of soy products in fish and shrimp diets are limited by the presence and possible effects of the residual anti-nutritional factors (ANF). This is especially true for fry and juvenile fish which are exceptionally sensitive to ANFs. These components – present to variable degrees in soy product – have been associated with intestinal inflammations (enteritis) in commercial fish species leading to reduced absorptive capacity, increased mucus secretion, hyperpermeability, and leucocyte infiltration. Directly or indirectly, they have also been related to pro-inflammatory cytokine genes expression and changes in the composition and population of gut microbiota through the supply of nutrients that preferentially support or depress the presence of specific gut bacteria (Kumar et al., 2020).

(Continued on next page)

Partial removal of the heat labile ANF is achieved through toasting or expansion/extrusion. Heat resistant ANFs require alternative methods of treatment such as extraction (as in the case of SPC or ISP). An alternative, efficient and economical method for ANF reduction has proven to be the fermentation of SBM; alone or in combination with enzymatic extraction (Mukherjee et al., 2016; Zhang et al., 2021). These methods, most notably the solid-state fermentation of SBM (FSBM), are rapidly gaining interest allowing the inclusion – or increase in inclusion – of soy in aqua diets. This is especially important for carnivorous fish and shrimp where inclusion of FSBM allowed successful replacement of fish meal and improved performance. Production of FSBM may vary considerably by type of inoculum used and conditions of fermentation. However, these differences in production have not shown consistent, demonstratable differences in performance.

Introduction

Atlantic salmon (*Salmo salar)* is an anadromous salmonid of high economical value globally. Since it is a nutritious food product, Atlantic salmon contributes significantly to economic and employment security in many countries worldwide. With aquaculture being one of the most rapidly expanding food production sectors, the global salmon production in 2019 reached approximately ~2.6 million tons. For salmons, entry into seawater is a crucial part of their life cycle and a critical step in production. A high pathogen pressure in the marine environment combined with a suppressed immune system of the fish results in a higher susceptibility to infections and diseases. Fish welfare is recognized to be essential for high product quality and a good health status. Stressed fish commonly have poor health and performance. Monitoring fish health status by measuring gene expression of biomarkers could be a useful tool to take measures for stress reduction.

Microalgae are considered promising functional feed ingredients, as they have beneficial effects on immune status. However, knowledge on the immune and stress effects of microalgae diets in Atlantic salmon remains limited. Previous research revealed the serious impact feed additives can have on gut health and systemic physiological parameters in salmonid fish. This study aims to investigate the influence of microalgae diets as probiotic feed and the transfer into marine farming systems on the expression of genes functioning as biomarkers for fish health status.

Material & methods

Atlantic salmon were randomly assigned to 18 experimental tanks (28 smolts per tank) in a recirculating aquaculture system (RAS) of Aquaculture Research Station Büsum, Germany. The tanks were filled with brackish water (~ 12 psu). After 8 weeks, the fish were transferred from brackish water to seawater (~ 32 psu). The fish were fed manually to apparent satiation twice daily. The diets were supplemented with different microalgae (8%). The microalgae used were *Spirulina, Chlorella broken, Schizochytrium, Chlorella intact* and *Tetraselmis*. In order to analyze the fish health status, RNA was isolated from five different organs (head kidney, spleen, gills, intestine, liver). Subsequently, the Biomark HD/Fluidigm test system was used for multigene expression analysis.

Results

In our study, we observed inter-individual differences in gene expression between fish fed with the same microalgae diets. In addition, following expectations, the different immune-related organs showed a different immune response. Overall, we recorded no major down- or upregulation of immune-related genes.

Discussion and conclusion

The present study demonstrates that microalgae do not have adverse influences on the immune status of Atlantic salmon and could serve as feed additive in the feeds of Atlantic salmon.

(Continued on next page)

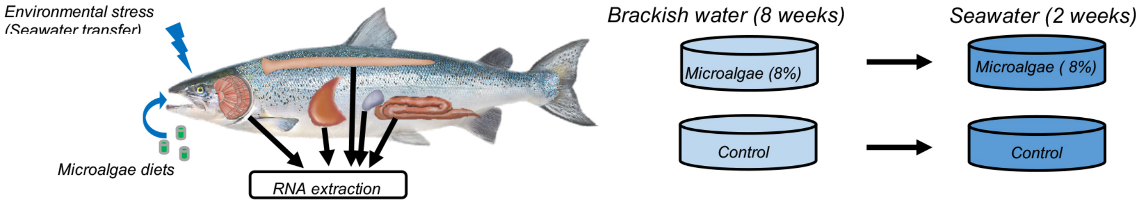

Fig.1. **Schematic representation of the experiment.** The Atlantic salmon was kept for 8 weeks in brackish water and subsequently transferred for 2 weeks in seawater. The fish were fed with microalgae supplemented (8%) diets throughout the whole experiment. In parallel to 5 different microalgae used for the diets, we had one control group. After the trial, the gills, liver, head kidney, spleen and intestine were sampled in order to isolate the RNA and perform a multigene expression analysis.

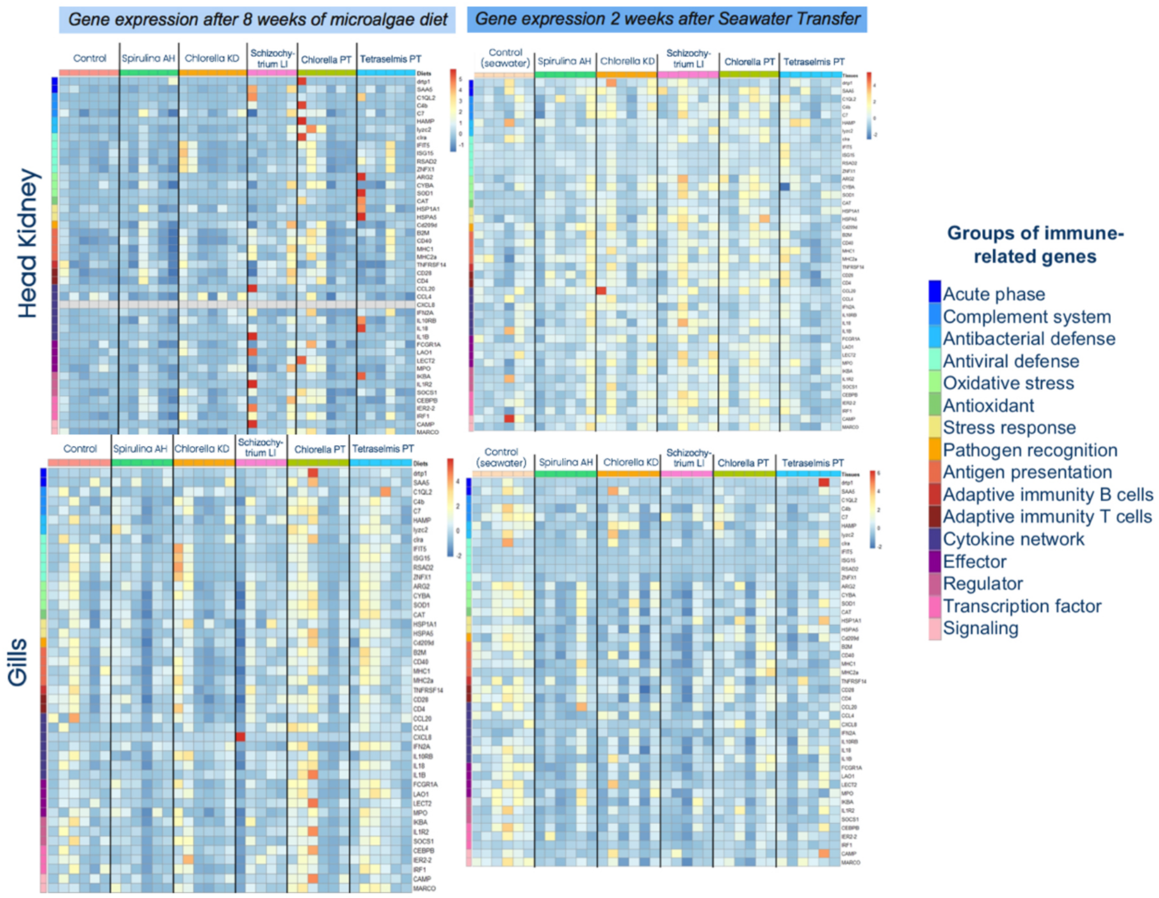

Fig.2. **Heatmaps of gene expression in the Head Kidney and Gills.** On the left side, the results after 8 weeks and on the right side 2 weeks after SWT.

Introduction

There is a rising demand for alternative and sustainable food sources such as seaweed. In order to secure tomorrow's food the European Union is concerned how we can obtain more biomass from the ocean without depriving future generations of their benefits. Seaweed (or macroalgae) are low-trophic marine organisms and meet the criteria when it comes to low environmental impact when cultivated and for their variety of health benefits for humans and animals. Due to the high level of fibres, proteins, minerals (Ca, K, Fe, …), vitamins (B1, B12, …) and antioxidants seaweed would be a good addition to our current diet. According to the Food and Agriculture Organization (FAO), protein required by Europe in 2054 will be around 56 million metric tonnes. Seaweed-derived protein may offer a viable solution. For seaweed to grow, it does not compete with conventional agricultural land and it does not require fresh water and pesticides. In comparison with at-sea cultivation, where seasonality has a huge impact on the quality and quantity of the production, on land cultivation can deliver year-round production of high-value products that are suitable for food applications.

Materials and Method

The red algae *Palmaria palmata* and *Porphyra sp*. were collected from the wild and kept in closed cultivation systems. A series of experiments on lab scale (1 L bottles) and small scale (40 L buckets) were conducted to obtain optimal cultivation conditions (light intensity, light quality, day length, water movement, stocking density and nutrient concentration) in order to maximize the specific growth rate (SGR) of the seaweeds.

Based on the findings from the lab and small-scale experiments a recirculating aquaculture system (RAS) was developed for the cultivation of *P. palmata*. The system consisted of three interconnected tanks with a volume of 1 m^3 each, a first step towards commercial production. The seawater was recycled continuously with a turnover rate of 2400 % day^{-1}. Water exchange was practically zero, except for a small amount of water that was added weekly to compensate for evaporation. UV was used to supress the outgrowth of micro-organisms. On a weekly basis the seaweeds were checked for quality, weighted and growth media was added to the system. In between two measuring days, the system operated autonomously and was followed up remotely by continuous measurements of salinity, temperature, dissolved oxygen and pH using submerged probes. Macro-nutrients in the water, such as nitrate, phosphate and ammonium are essential in the field of aquaculture, but unfortunately they remain hard to measure analytically or require expensive apparatus. In order to be able to follow up the nutrient uptake kinetics of the seaweeds and better understand their nutrient requirements an inexpensive autonomous in situ wet chemical phosphate detector was developed and tested.

Results

On a lab scale maximum growth rates of 8 % day^{-1} and 10 % day^{-1} for *P. palmata* and *Porphyra sp*. were reached, respectively. Under small-scale conditions different strains of *P. palmata* showed similar growth rates. However, the natural cycle of the seaweed (alteration between growth and forming new proliferations) introduced a lot of variation in the data ranging from 2 to 8 % day^{-1}. In the RAS *P. palmata* gave average yields of 600 ± 17.1 g $week^{-1}$ m^{-3} or 3 ± 0.1 % day^{-1}.

(Continued on next page)

Discussion and conclusion

The high growth rates of 8 % day^{-1} that were obtained in the lab and small-scale experiments with *P. palmata* could not be repeated in the RAS. By further optimizing tank dimensions, water circulation, nutrient requirements and light conditions we hope to reach higher yields in the future. Since we now better understand the natural cycle of the seaweed we can exploit this knowledge and develop a cultivation scheme that is adapted to this. Furthermore, we are working on developing new hatchery techniques in order to close the life cycle of both *Palmaria palmata* and *Porphyra sp.* to become self-sustaining and no longer dependent and wild populations. And finally, the idea is to further explore the possibilities for automatization of the RAS system, so labour and energy costs can be reduced significantly.

CAN WE COMBINE GENETICS AND A TWO-STEP TEMPERATURE CONTROL TO MOVE TOWARDS MONOSEX EUROPEAN SEA BASS *Dicentrarchus labrax*?

Vandeputte M.[1], Clota F.[1], Vergnet A.[1], Blanc M.O.[1], Lallement S.[1], Ruelle F.[1], Sánchez-Baizán N., Besson M., Piferrer F., Cousin X., Goikoetxea A.[1], Leitwein M.[1], Allal F.[1] and Geffroy B.[1]

Introduction

The sea bass, *Dicentrarchus labrax,* is an important species for European mariculture, mainly in Mediterranean countries. In this species, females grow faster and reach a higher weight than males. However, most farmed fish batches show a highly male-skewed sex-ratio. The sea bass has a complex sex determination system, combining both genetic (polygenic) and environmental (temperature) influences. Low initial temperatures (<17°C) favor female sex determination. In contrast, temperature in the late post-larval phase has the opposite effect, with cold temperature favoring male differentiation and high temperature (up to 23°C) favoring female differentiation (Clota et al., 2021). However, data on the combined effects of genotype and temperature are lacking. We need to know whether there is genotype-by-environment (GxE) interaction or not, to deploy a strategy towards producing monosex female individuals for production while keeping a balanced sex-ratio for hatchery and selective breeding.

Results

Starting at 1 day and using incremental rearing periods at 16°C (31 to 244 days), followed by an increase to 21°C, we first showed that, while 31 days at 16°C led to 26% of females, increased cold exposure promoted the proportion of females, up to 46% after 74 days at 16°C. Conversely, exposure to 16°C for a period longer than 74 days progressively reduced the proportion of females, reaching a minimum of ≈ 10% after 230 days at 16°C. In a second experiment, we demonstrated that after an initial rearing of fish for 90 days at 16°C, a secondary exposure to four different temperatures (19, 21, 23, 25°C) resulted in different sex-ratios, with more females at higher temperatures (from 30% at 19°C to 49% at 25°C). Then, we examined the genotype-by-environment interaction in both periods, by genotyping fish with a 57K SNP chip, comparing 1) two groups reared at 16 or 21°C during the first 60 days and 2) four groups of fish reared at 19, 21, 23 or 25°C after 90 days at 16°C. The genetic correlation of sex tendencies between the two early temperature groups was very high (0.91 ± 0.09). In the late temperature treatments, the genetic correlations of sex tendencies between the first three temperature groups (19, 21 and 23°C) were close to unity (0.98± 0.16 to 1.00± 0.16), showing little, if any, GxE interaction. Conversely, the genetic correlations of sex tendency at 19, 21 and 23°C with sex tendency at 25°C were lower (0.82 ± 0.21 to 0.91 ± 0.21). Thus, genomic predictions of sex tendency can be reliably performed using data from any temperature treatment, provided the late temperature (after 90 dph) is not higher than 23°C.

The way forward

Based on these findings, we propose a method combining temperature treatments and genomic evaluation of sex tendency to 1) identify individuals with a strong “female” genetic background, including “neomales” sex-reversed by temperature treatments, and 2) use them with adequate temperature treatments to obtain near-monosex batches.

Introduction

Emerging, infectious diseases in shrimp like acute hepatopancreatic necrosis disease (AHPND), caused by *Vibrio parahaemolyticus* are worldwide related to huge economic losses in industrial shrimp production. There is an urgent need to develop innovative AHPND preventive methods that also support sustainable shrimp aquaculture.

Exposure to non-lethal heat shock (NLHS) of Pacific white shrimp (*Litopenaeus vannamei*) and brine shrimp (*Artemia franciscana*) induced the expression of endogenous heat shock proteins and activated the innate immune system, resulting in enhanced disease resistance against *Vibrio* infections. Thus, exposure to NLHS might be a strategy for protecting animals and their progenies against AHPND and possibly other infections. However, its practical application in industrial shrimp farming is cumbersome. Also, temperature shifts are often detrimental and can negatively affect the physiological and immunological balance. Therefore, the administration of Hsp-inducing compounds as an alternative to NLHS exposure has been proposed.

Kumar et al., (2018) showed that the plant derived polyphenolic compound phloroglucinol perhaps might be used as a biocontrol agent as it increased the resistance against *V. parahaemolyticus* AHPND infection in axenic brine shrimp and the giant freshwater prawn (*Macrobrachium rosenbergii*) by inducing endogenous Hsp70.

In the current study, using brine shrimp as an animal model, we tested whether phloroglucinol exposure of the parental generation at early life stages could induce heat shock proteins and elicit an AHPND- resistant phenotype in the offspring.

Materials and methods

Parental brine shrimp were treated with phloroglucinol, starting from day after hatching 1 (DAH1) until DAH16, to ensure that the uterus, which normally develops by 3 weeks and carries the cysts/embryos, was not directly exposed to the compound. Controls were untreated (Fig 1).

Adult parental females (CF0 and TF0) produced next-generation CF1 and TF1 larvae and, under suboptimal conditions, CF1 and TF1 cysts. Adult CF1 and TF1 females produced CF2 and TF2 larvae and, under suboptimal conditions, CF2 and TF2 cysts. Subsequently, adult CF2 and TF2 females produced CF3 and TF3 larvae and, under suboptimal conditions, CF3 and TF3 cysts. The F1, F2, and F3 larvae and cysts were never exposed to phloroglucinol.

Next, all cysts were hatched simultaneously for a common garden experiment. The age- and size-synchronized axenic 1-day old brine shrimp larvae were used for: a *V. parahaemolyticus* challenge assay, immune gene expression analyses (RT-qPCR), DNA methylation assays and histone modification assays.

Results

Phloroglucinol treatment of parental brine shrimp significantly increased the resistance of their progeny for 3 subsequent unexposed generations (F1, F2 and F3) against bacterial infection with a highly virulent *Vibrio parahaemolyticus* AHPND strain.

Challenged (AHPND) offspring (TF1 and TF2) originating from treated parents showed a significant upregulation of immune-related genes compared to challenged offspring from non-treated parents. We found no link between global DNA methylation and the increased resistance in offspring against AHPND infection. However, H3 hyper-acetylation and hyper-methylation probably played a role in transgenerational (F1, F2) inheritance of the phloroglucinol-induced, AHPND disease resistant phenotype. Results showed that epigenetic reprogramming is likely to play a role in the underlying mechanism.

(Continued on next page)

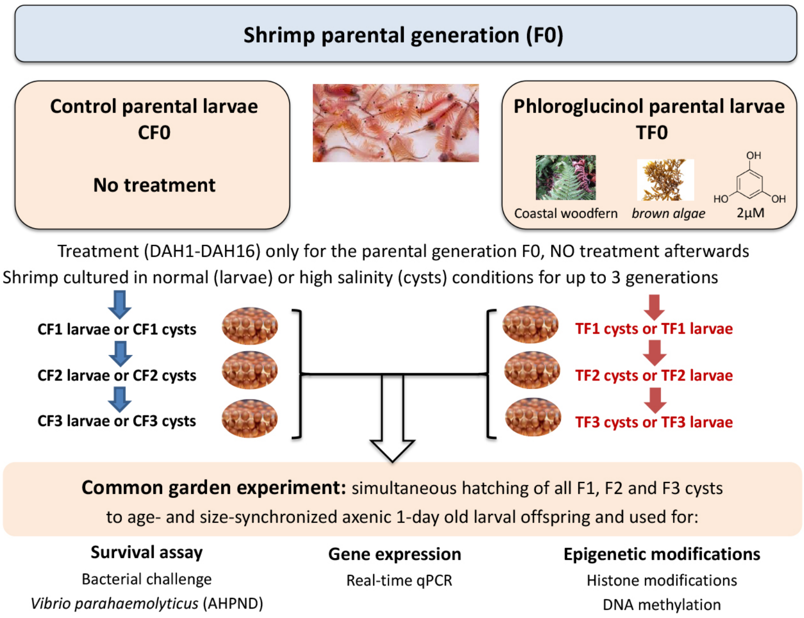

Figure 1. Schematic overview of the experimental setup.

Conclusions

Here, using axenic brine shrimp (*Artemia franciscana*) as a model system, we showed that phloroglucinol treatment of the parental animals at early life stages resulted in transgenerational inherited increased resistance in their progeny against *V. parahaemolyticus* AHPND infection. In the future, parental priming might be used for brood stock management to produce more robust, disease resistant progenies in crustaceans. The principle of trained immunity might be used in shrimp aquaculture as a novel strategy for creating broad-spectrum protective innate immune response against economically important pathogens

Introduction

The expansion of aquaculture production has been associated with the need of rapid growth in aquafeed production. Forage legumes are promising candidates and highly valued feed components for both ruminants and monogastric livestock due to their relatively high protein, balanced amino acid profile and energy values compared to cereal grains. However, their use in feed is still limited by the presence of several antinutritional factors (ANFs) that decrease enzyme activity and the absorption of minerals and other nutrients (Francis et al., 2001). Exogenous enzymes have the ability to improve the digestibility of many ingredients, by breaking down the complex cell wall structure that encapsulates nutrients presents in plant based feed. Aim of the present study was the *in vitro* evaluation of forage legumes treated with different processes with exogenous enzymes and conditions.

Materials and methods

Lupinus albus, *Cicer arietinum* and *Favino faba* whole seeds were grinded to produce legume meals, and evaluated for their nutritional value. Samples were treated under different condition processes (moisture, temperature, time and pH) and enzyme combinations. Briefly, 4 commercial enzyme products were assessed i.e. xylanase, phytase and two multienzymes complexes. Two different moisture levels (8 and 45%) and thermal treatments (25 and 50°C) were evaluated. Process duration was either 25 or 240 min and in selected processes pH was reduced with the addition of citric acid. All legume products were evaluated for their protein content after treatment, trypsin inhibitors (TUI) (Liu et al., 2021), phytic acid and free phosphorus (P) (spectrophotometrically).

Results and discussion

ANFs combine with nutrients and act as inhibitors by reducing nutrients bioavailability. Specifically, phytic acid hinders the activity of enzymes, which are necessary for protein degradation in the intestine and stomach (Kies et al., 2006). Phytic acid normally constitutes 0.2%–2% of the dry weight in cereals and legumes with 60%–90% of the total phosphorus present bound to phytate (Feizollahi et al., 2021). The use of exogenous enzymes increase digestibility of nutrients and bioavailability. Additionally, cooking of pulses is a commonly used process that highly improved the nutritional value of foods by reducing their ANFs (Patterson et al. 2017). The results showed positive effect of enzymes, thermal treatment, high moisture level and acidic pH in nutritional and ANFs examined (Table 1). In *Lupinus albus* meal multi-enzyme product along with high moisture level (45%) and thermal treatment (50°C) resulted in lower trypsin units inhibited (0.40 TUI/mg sample) and phytic acid content (0.23%), while free P increased from 0.08 to 0.34%. *Cicer arietinum* showed lower TUI/mg sample in same treatment conditions and enzyme process as *Lupinus albus*. However, free P was higher and phytic acid lower when phytase-xylanase was added. Treatment with a combination of phytase-xylanase had positive effect in *Favino faba* meal reducing TUI from 4.38 to 0.20 /mg sample. Moreover, free P content increased with the same enzymes and treatment conditions but only in acidic pH (5.5).

Introduction

The fast growth of aquaculture together with the limited availability of dietary fishmeal (FM) has forced the feed industry to search for alternative and more sustainable dietary protein sources. To face the challenges of replacing increasing levels of FM by plant protein sources, low levels of plant- and animal-protein hydrolysates can be incorporated into fish diets, providing bioactive peptides with benefits beyond their nutritional value, including antioxidant, immunomodulatory and antimicrobial activities (1). Currently, fish processing industries discard large quantities of fish skin and bones. These by-products can be valorised and originate new added-value products with functional properties, contributing to a circular economy (2). In order to select the best candidates to be included in aquafeeds, the aim of the present study is to have an in-depth comprehension of the bioactive potential of distinct hydrolysates obtained from fish processing by-products.

Materials and methods

Discarded skin of blue shark (*Prionace glauca*) was processed in order to obtain 3 different fractions: 1) total skin (TS); 2) a collagenic fraction (C); and 3) a non-collagenic fraction (NC). Each fraction was then hydrolysed using two different enzymes (alcalase and bromelain), resulting in 6 different hydrolysates: 1) total skin hydrolysed by alcalase (TSHA), 2) total skin hydrolysed by bromelain (TSHB), 3) collagenic fractions hydrolysed by alcalase (CHA), 4) collagenic fractions hydrolysed by bromelain (CHB), 5) non-collagenic fraction hydrolysed by alcalase (NCHA), 6) non-collagenic fraction hydrolysed by bromelain (NCHB). These nine experimental fractions (hydrolysed and non-hydrolysed) were analysed *in vitro* to unreveal their antioxidant capacity through 2′-azinobis-3-ethylbenzthiazoline-6-sulphonic acid and oxygen radical absorbance capacity ($ABTS^{+\bullet}$ and ORAC, respectively). The antimicrobial activity of hydrolysates was also tested *in vitro* by assessing the bactericidal and bacteriostatic potential against several pathogenic bacteria with high impact on fish health, well-being and aquaculture production (*Vibrio anguillarum, Vibrio harveyi, Vibrio parahaemolyticus, Aeromonas hydrophila, Yersinia ruckeri, Edwardsiella tarda, Tenacibaculum maritimum, Photobacterium damselae*). All the results obtained from each hydrolysed fraction were compared with the non-hydrolysed one.

Results and Discussion

Overall, all hydrolysates and non-hydrolysates fractions displayed good bactericidal activity against the bacteria tested, excepting for *E. tarda,* which was killed just by CHB. On the other hand, only NC was not effective against *Y. ruckeri*. Regarding *V. parahaemolyticus,* the three fractions hydrolysed by bromelain (TSHB, CHB and NCHB) displayed the highest capacity to kill this bacterium (98, 90, 78%, respectively). For the bacteriostatic activity, the tested hydrolysates presented the highest bacteriostatic activity against *Vibrio* genera. Concerning the $ABTS^{+\bullet}$ assay, all fractions hydrolysed by alcalase displayed higher antioxidant capacity when compared with non-hydrolysed fractions and hydrolysates by bromelain. Similarly, hydrolysates by alcalase displayed the best results for ORAC assay.

(Continued on next page)

Conclusion

All fractions displayed between 10 and 98% of bactericidal activity against the species tested but were unable to kill *E. tarda* (expecting CHB*)*. Overall, enzymatic hydrolysates obtained by alcalase presented high bacteriostatic activity, while bromelain hydrolysates demonstrated the best bactericidal potential, with the most promising results being observed against *Vibrio* genera. Additionally, hydrolysates demonstrated high antioxidant capacity. Overall, the *in vitro* studies showcased those hydrolysates obtained from total skin, collagen and non-collagen fractions using the enzyme alcalase, are promising ingredients to include in aquafeeds. Moreover, the use of such functional feeds could promote both fish growth and health while being sustainable at social, economic, and environmental levels and contributing to the one health concept. But further studies *in vivo* are still warranted to ascertain the full potential of these products in aquafeeds.

ECOLOGICAL INTENSIFICATION AND CIRCULARITY IN POND AQUACULTURE

Pond food web and natural foods

Important advantages of pond systems include that they are self-cleaning, produce a significant amount of natural foods and recycle nutrients. These advantages are dependent on a well-functioning food web in the pond. To mineralize and recycles wastes through the pond's food web, sufficient energy (e.g. carbon (C)) and nutrients (e.g. phosphorous (P), nitrogen (N)), the latter in the right proportions, need to be available. When this is the case, waste accumulation will be minimal, and the majority of the fed nutrients will be retained in herbivorous/omnivorous species (e.g. tilapia, major carps, small indigenous fish species) grazing on natural foods. Feeding pelleted feed with a low (31% protein/kg DM) and high (24% protein/kg DM) C:N ratio in ponds, Nile tilapia fed the high C:N ratio feed consumed more natural foods, compensating for the lower nutrient content in the feed. Fish fed the high C:N ratio diet retained 87% of the fed nitrogen, compared to 59% in fish fed the low C:N ratio diet (Kabir et al., 2019, Figure 1).

Ecosystem approach to aquaculture and ecological intensification

According to the FAO ecosystem approach to aquaculture (Soto et al., 2008), ecological aquaculture is imbedded in the surrounding ecosystem which (cit.) 'contributes to sustainable development, equity, and resilience of interlinked social and ecological systems'. In an ideal society, ecological aquaculture occurs when the physical, production, social and ecological types of carrying capacity intertwine harmoniously (Weitzman and Filgueira, 2020) (Figure 2). In turn, numerous, more or less similar, definitions of 'ecological intensification' were proposed from a human utility perspective, focusing on (cit.) 'the use of ecological processes and functions to increase productivity, [that] strengthen ecosystem services and decrease disservices' (Aubin et al., 2019). Although not the intention, by defining ecological intensification in this way, there is a risk to downgrade the intrinsic value of the production ecosystem.

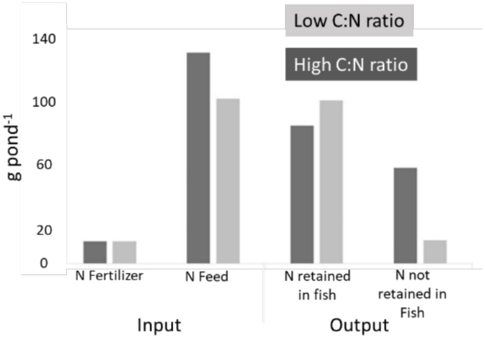

Fig 1: Effect of dietary C:N ratio on N input, N-output and N-balance in pond (modified from (Kabir et al., 2019)

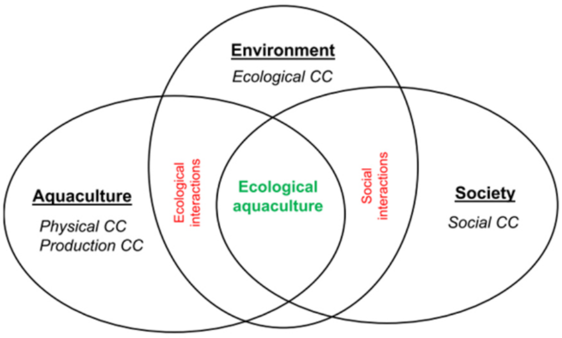

Fig. 2: How 4 types of **carrying capacity (CC)** jointly define ecological aquaculture. (Weitzman and Filgueira, 2020).

(Continued on next page)

Pond culture: a tool to recycle nutrients and optimize nutrient use efficiencies

To make aquaculture fully sustainable, more attention must be put of Ecological CC. A healthy pond ecosystem traps as much as possible bio-available macro and micro-nutrients and recycles them through the food web. During our experiments ponds retain more than 90% of the P input during the full culture period at harvest. The latter sometimes also happens for N. However, the amounts N and P retained in fish biomass turn out to be highly variable, fluctuating between 15 to 85%. Much more research is needed. At present, we lack sufficient insight to predict accurately optimal nutrient use efficiencies, including for nitrogen and phosphorous. Research should focus on recycling waste nutrients through the food web through culture organisms. Important research questions are how the types of feed influence on-farm nutrient use efficiencies and food web health, and how to maximize nutrient recycling through biomass gain of culture species in pond farming systems. The latter is our best bet to maintain the pond ecosystem productive and healthy and to contribute to food systems that produce withing planetary boundaries.

Introduction

Enabling surrogate offspring production in fish is an emerging question and an interesting perspective for different objectives. Interspecific or intraspecific germ stem cell grafting may mitigate reproductive barriers, reduce generation time, help manage or recover broodstock, and enhance aquaculture productivity.

In this study, we explored the feasibility of germ stem cells (GSC) grafting in the European sea bass (*Dicentrarchus labrax*), a key European aquaculture species.

Material and Methods

We prepared two types of fish:

First, we produced 9 batches of sterile recipient sea bass larvae by triploidisation using the pressure shock method (Peruzzi et al. 2000). The ploidy level of the recipient fish was controlled by flow cytometry.

Second, 112 adult sea bass donors held in a recirculated system at constant temperature and photoperiod to avoid sexual maturation were sacrificed to recover the testis or ovary used to extract the GSC used in this study.

Preparation of the GSC was carried out by enzymatic and mechanical dissociation of gonads. Each tissue fragment was weighed and put in a digestive medium based on the cell culture medium L15 (Leibovitz) complemented by enzymes. Gonadal fragments were incubated in the digestive medium and placed at 20°C on an orbital agitator for 5h30. At two time points the pieces of gonads were mechanically dissociated by back and forth pipetting with a 10 ml pipette. Then, cells were centrifuged for 15 min at 500G and placed in a culture medium to stop digestion, and kept on an orbital agitator overnight. Just before the transplantation of the cells, tissues were mechanically dissociated using a potter and filtered with 180 µm and 50 µm mesh. Finally, cells were centrifuged, counted and diluted at 200.000 cells/ml.

Larvae of recipient batches were injected at 20, 30, 60 and 90 days post hatching (dph). 11 batches were injected with spermatogonia and 3 batches were injected with ovogonia (only at 30 dph). Recipient larvae were anesthetized with tricaine and approximately 5000 cells including GSC were injected into the peritoneal cavity of each recipient under binocular magnifier using a CellTrams microinjector and a Leica micromanipulator. Some of the injected cells floating in the abdominal cavity were expected to randomly attach to the abdominal wall. Injected larvae (200 larvae per group) were transferred into a recirculated system and left to recover for 3 days, then reared following the standard protocols.

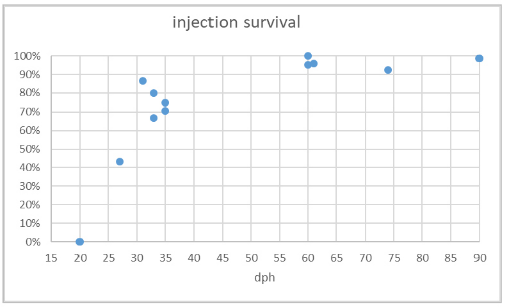

Fig 1. Survival rates after injection. Survivals recorded three days after injection of the GSC.

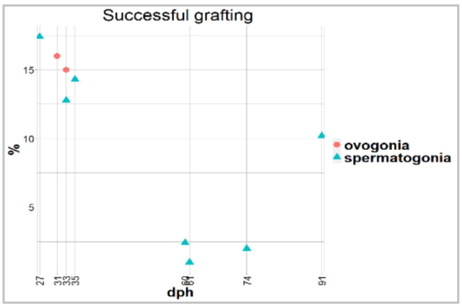

Fig 2. Successful GSC grafting rates. GSC grafting determined by flow cytometry at 1 year.

(Continued on next page)

To determine the best age for the injection, the survival rate was followed during the first three days following the injection and the success rate of GSC grafting was determined at 1 year. 100 fish of each group were sacrificed at that time to compare the ploidy levels of their gonads with that of a blood sample, using flow cytometry analyses. Gonads and fins of fish showing different ploidy levels were genotyped for thirteen microsatellite loci in order to find different allele contributions between the recipient's somatic tissue and the gonads. At 3 years the remaining recipient fish kept in maturing condition were sacrificed to observe their gonads. The gonads showing development or non-linear development were analysed using flow cytometry to compare their ploidy levels to that of the fins.

Results and Discussion

Post-injection survival rates were low at 27 dph (43%) but increased up to 100% at 90dph (668 mg) as shown in figure 1. Analysis of the survival rates after injection suggests that sea bass larvae are too small and too fragile to be injected before 30 dph (15 mg).

Our data also shows that the percentage of successfully grafted recipients varied from 1 to 17% with the best grafting success obtained for the recipient larvae injected from 27 to 35 dph (fig. 2). Interestingly, no difference was observed between testicular and ovarian cells grafting success at 30 dph.

Further investigations will include reproduction of injected recipients fish to control the viability and the functionality of the gametes derived from the grafted germ stem cells.

Our study confirms that GSC grafting is possible in sea bass despite the impossibility to inject newly hatched larvae. This biotechnology opens new possibilities for innovative applications aimed to: (i) conserve and regenerate the whole genetic characteristics (mitochondrial and nuclear genomes) of original and/or selected populations (Lareyre et al 2018), (ii) generate viable double haploids, (iii) create monosex populations.

Introduction

Pikeperch is increasingly considered for commercial farming in recirculation aquaculture systems (RAS) in European aquaculture. In addition to its growing commercial importance, research on the genetic and genomic composition of the percid fish has also gained momentum. With the recent publications on the genome [1] and transcriptome [2], systematic exploration of functional genomics is feasible, especially in the context of relevant commercial traits. Here, the identification and characterization of regulatory elements like micro RNAs (miRNAs) represents another important part of the puzzle to explore, understand and improve the full scope of the performance of economically important traits in this fish species. Micro RNAs are short non-coding RNA molecules that play an important role in the transcriptional and post-transcriptional regulation of their target transcripts. They are involved in the regulation of multiple developmental and physiological processes like growth, the immune system, or stress response [3]. Data on miRNAs in teleost fish are still limited, with only 16 out of the over 26,000 species present in miRBase (05, April 2022; http://www.mirbase.org/). So far, there is no available information on miRNAs in pikeperch. We have identified and characterized the miRNA repertoire of pikeperch using deep sequencing and miRDeep analysis. Furthermore, we investigated specific expression patterns of the miRNAs in different tissues and developmental stages of this percid fish.

Material & Methods

Juvenile pikeperch stages, fingerlings and adult individuals used in this study were bred and reared in RAS system at the State Research Centre for Agriculture and Fisheries Mecklenburg-Vorpommern (Hohen Wangelin, Germany). A total of 20 samples including pools of eyed eggs, yolk sac larvae (2dph and 15 dph), and larvae (26dph) as well as spleen of two fingerling stages (3g and 35g) and liver, gills, head kidney, and spleen of adult fish were used for deep sequencing. An additional of 20 samples (a total of 40 samples) were used for real-time qPCR expression analysis.

The mature 5p (red) and mature 3p (purple) miR as well as details on the counts of reads mapped to the precursor sequence are given.

(Continued on next page)

Total RNA was isolated from the samples by use of the mirVana miRNA isolation kit (Invitrogen), followed by Library preparation according to the manufacturer protocol using only RNA samples with RIN values ≥ 7 and the Illumina TruSeq Small RNA Library Preparation Kit (Illumina). RNA libraries were sequenced on the Illumina Genome Analyzer IIx sequencing platform. High quality reads were used for miRNA identification applying the miRDeep2 software package. The present version of the pikeperch genome assembly (GeneBank accession number: GCA_008315115.2) was used as reference genome. Predicted miRNA precursors with a miRDeep2 score ≥ 1.0e+2 were used in the downstream analysis, including annotation and estimation of tissue specific miRNA expression, as described elsewhere [4]. Real-time qPCR expression analysis of a set of predicted highly expressed miRNAs was performed by using the Biomark HD system (Fluidigm).

Results

Initial miRDeep analysis identified a total of 240 pikeperch miRNA genes with 375 corresponding 5p and 3p mature miRNAs in the different developmental stages of pikeperch meeting the threshold for the miRDeep score mentioned above (Fig.1). Of these, we could classify 234 as orthologs to evolutionary conserved miRNAs while seven are potential novel miRNAs. Furthermore, expression analysis revealed miRNA specific expression pattern across investigated developmental stages and tissues.

Discussion & Conclusions

In order to investigate and improve economically important traits in pikeperch for optimising its rearing conditions, it is necessary to gain basic knowledge of the genetic and genomic composition of this species. Our study provides the miRNA repertoire in pikeperch and supplies their specific expression patterns. Among these are miRNAs that may be of particular interest to the aquaculture industry as they are regulating economical important processes like metabolism, growth and resilience.

Introduction

Traditional flow-through oyster hatcheries and nurseries generally depend on local water sources, which limits the amount of suitable locations, and increases the risk for unwanted organisms and disease outbreaks. A closed recirculating aquaculture system (RAS) for the production of early stage bivalves has been reported, but literature is scarce. A RAS provides a controlled environment that minimizes water consumption, increases waste management, mitigates the summer mortality syndrome and is the ideal setting to produce specific-pathogen-free oysters. A RAS also enables production in regions where natural seed cannot be collected or where (clean) seawater is scarce. This project developed an indoor RAS for oyster spat. Animal growth was evaluated and compared to a closed, static system (batch). This study is the first to report growth of cupped oyster spat in a RAS.

Materials & Methods

Two trials of five weeks each, were carried out using nursery-stage Pacific oyster (*Crassostrea gigas*). All spat was obtained from a local oyster farm, De Oesterput bvba (Ostend, Belgium). Growth experiments were performed using different initial sizes and feeding regimes (table 1). One and two RASs were used in the first and second experiment, respectively. Each RAS held 500 L of filtered natural seawater, and included a drum filter, protein skimmer, header tank and three rearing tanks of 90 L each. The flow rate was 38 L h^{-1} per rearing tank, or ten times the tank volume per day. A batch system with 100% renewal rate every second day, was used as control and consisted of three rearing tanks of 90 L. Each rearing tank held one PVC cylinder basket, with a depth of 80 mm and a bottom mesh with 1 mm mesh size, that held 35 grams of spat. The water temperature was set at 19°C. All rearing tanks received a percentage of the oyster wet weight in dry weight live microalgae at a 1:1:1 composition of *Tetraselmis chuii*, *Chaetoceros muelleri* and *Isochrysis galbana* (table 1). All microalgae were obtained from Proviron (Hemiksem, Belgium). Total oyster biomass was kept constant by removing the grown biomass weekly. Shell length (SL), individual wet (WW) and dry weight (DW), as well as individual dry shell (SW) and dry tissue weight (TW) were measured weekly, and the specific growth rate (SGR) was calculated. Total ammonia nitrogen (TAN), calcium (Ca) and carbonate (CO_3) concentrations were monitored multiple times a week.

Results

1. Oyster growth

Overall, the results from the spat weight and length measurements indicate no or only a small difference between animals grown in batch and those grown in a RAS receiving 1.50% DW microalgae. An example can be seen in figure 1. In the first experiment, the SGR for WW is 44% and 41% per week for spat grown in the batch system and the RAS respectively, representing almost a doubling in total weight every two weeks.

2. Water quality variables

TAN concentrations were low throughout both experiments, never exceeding the value of 0.5 mg L^{-1}. A drop in CO_3 was observed in the RAS in both experiments, more so than for Ca (figure 2). Ca and CO_3 occupy around 95% of the shell composition, hence the drop in these substances is in line with the (relative fast) oyster spat shell growth. This observation is rarely mentioned in literature on bivalves in closed systems, and requires more in-depth investigation on the amount, the frequency and the form in which Ca and CO_3 consumption should be compensated for in a RAS for bivalves.

Table 1: treatments and initial spat length and weights for both trials.

Trial	System	DW microalgae (%)	Initial SL (mm)	Initial SW (mg)	Initial TW (mg)
1	RAS	1.50	4.05	6.2	1.4
	Batch	1.50			
2	RAS 1	1.50	2.64	2.1	0.4
	RAS 2	0.75			
	Batch	1.50			

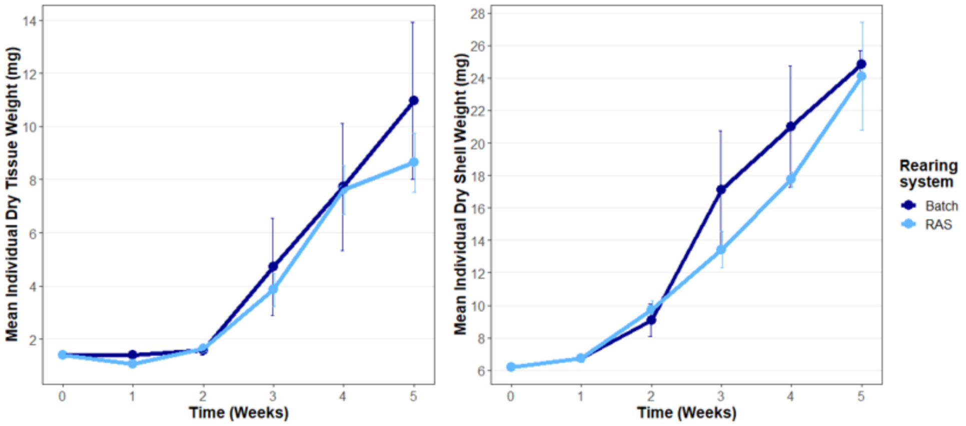

Figure 1: results from the first trial show that TW (left) and SW (right) increase at a similar trend in both rearing systems.

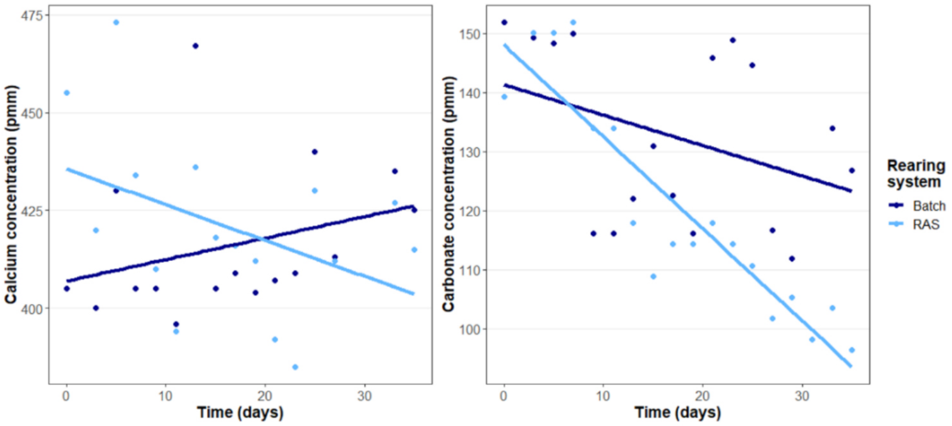

Figure 2: results from the first trial on the change of calcium (left) and carbonate (right) concentrations over time.

Conclusion

The results from the growth measurements demonstrate that a RAS environment is suitable for growing oyster spat. Oyster shell mineral requirements require more investigation to finetune Ca and CO_3 addition to RAS. Overall, the results so far indicate that a RAS could be a valuable alternative for future bivalve nurseries.

Challenges and opportunities

In further experiments, we will investigate the compensation for carbonate and calcium, as well as the potential for rearing the larval stadia and other oyster species (*e.g*. the European flat oyster, *Ostrea edulis*) in a RAS.

Introduction

The production of high quality and healthy fish larvae and juveniles is an important target for the successful and competitive growth of the aquaculture industry. Still, most marine fish larvae produced under intensive rearing conditions are known to be affected by several afflictions, including low survival rates and a high incidence of skeletal anomalies. Amongst other factors, nutrition has a key role in skeletogenesis. While taking advantage of an industrial setting, we performed the nutritional optimization of a commercial-type larval feed in terms of vitamins and minerals, that can be potentially be used as a tool to mitigate skeletal anomalies relevant for fish welfare and production.

Materials and methods

A series of larval fish nutritional trials were performed, using as base feed formulas, commercial larval fish feed products available from SPAROS Lda. Several nutritional feed component modifications were performed: Ca:P ratio; Inorganic Vs. Organic mineral forms; Dietary levels of Mn and Zn; Selected B-Vitamin supplementation; Choline removal from premix. Growth (Dry weight, standard length, relative growth rates (RGR)), survival, economic (feed conversion ratio (FCR)) and bone status (Figure 1) criteria were assessed.

Results

The omission of calcium supplementation, that can have a potential antagonist effect on the bioavailability of other minerals and/or nutrients, from the premix used in larval feed lead to the observation that a low Ca:P ratio, ranging between 0.5 and 0.7, is adequate to support a high survival and growth performance in Senegalese sole post-larvae, without compromising bone development and skeletal formation.

The replacement of inorganic mineral forms (sulphates) of Cu, Fe, Mn and Zn by their organic glycinate-chelated forms, did not generate marked beneficial effects on somatic growth and bone development in Senegalese sole post-larvae fed high quality commercial microdiets.

Dietary levels of Mn (90 $mg.kg^{-1}$) and Zn (130 $mg.kg^{-1}$) could help improve larval survival, decrease the severity of vertebral malformations, and increase the deposition of Mn in bone.

B-Vitamin supplementation (B1, B6 and B12) to larval feeds brings no clear advantage in attempting to enhance the growth performance and bone status of Senegalese sole larvae.

Although choline supplementation to vitamin premixes can decrease their stability, it is still necessary when feeding Senegalese sole larvae as, it's removal can reduce growth criteria.

Conclusion

The conclusions obtained throughout this work demonstrate that mineral and vitamin levels and/or forms in commercial formulas are adequate for proper growth and bone development. Still, there is room for further nutritional optimization of inert microdiets when the potential beneficial effects of beyond requirement levels are considered and their impact on bone, immune and stress coping status of early-stage marine fish.

Introduction

As the aquaculture industry continues to grow, aquafeed production must rely on alternative ingredients to fishmeal, which is unsustainable both from an environmental and economic perspective. Plant ingredients are a major alternative dietary protein source, however, dietary plant-based proteins present some constraints, such as high fiber content and anti-nutritional factors, which can limit nutrient digestibility (Sinha et al., 2011). Some biological processes can be applied to improve the nutritional quality of plant feedstuffs, such as Solid-State Fermentation (SSF). SSF is a cost-effective and eco-friendly biotechnological process that relies on fungi to digest the substrate, producing fungal biomass and increasing nutrient bioavailability (Soccol et al., 2017). Applying mathematical models, *a posteriori* to a feeding trial can be useful to assist the interpretation of the results, allowing to infer whether the observed performance is fully explained by the nutritional or environmental factors taken into account by the models or if there are unknown factors worthy of being explored that might have contributed to the results.

Materials and methods

This work explored the effects of SSF plant-based diets on the zootechnical performance of European sea bass (*Dicentrarchus labrax*). For that purpose, a mixture of soybean, rice bran, sunflower seed, and rapeseed meal (25% each) was fermented with *Aspergillus niger*. Then, four isoproteic (42%) and isolipidic (18%) diets were formulated including a non-fermented mixture and the SSF mixture at 20% and 40% (diets 20M, 20SFF, 40M, and 40SSF, respectively; Table 1). Triplicate groups of 20 fish, with an initial body weight of 10±0.02g, were fed for 50 days at 21°C in a recirculating system (RAS). After the *in vivo* trial, the same experimental conditions recorded throughout the trial were used to run simulations with the FEEDNETICS^{TM} nutrient-based model (SPAROS, Lda.). The main objective was to evaluate whether the fish performance observed in the *in vivo* trial is well predicted by the model, in order to infer whether there are unknown nutritional factors worthy of being explored in future research.

Results and Discussion

The *in vivo* growth performance was higher in fish fed with the 20M, 20SSF, and 40M diets, while feed efficiency was higher in fish fed with the 20M and 20SSF diets and significantly lower in fish fed with the 40SSF diet (Table 2). A clear suppression of feed intake was observed for the SFF diets, however, due to probably better nutrient availability, the 20SSF diet resulted in a relatively good growth performance, which is also reflected in high feed efficiency. The same was not observed for the 40SSF diet.

Overall, FEEDNETICS^{TM} predicts similar performance as it was observed in the *in vivo* trial, except for the dietary treatment 40SSF where the deviation between the simulated and observed values (here estimated as the MAPE) is higher compared to the other treatments (Figure 1). In this case, the model overestimates the observed growth. This leads us to infer that the reduced performance of the 40SFF diet is probably not fully explained by a decrease in diet palatability. There must be another factor that contributed to this loss of performance, that is affecting nutrient availability and/or utilization. The plausibility of this hypothesis is also supported by a reduced feed efficiency observed at the end of the *in vivo* trial.

Conclusion

In overall terms, the diets with the SFF mixture induced lower growth performance and feed intake on European sea bass. However, a positive effect on feed efficiency was observed for inclusion levels of 20% SFF. In turn, inclusion levels of 40% SFF did not show to improve feed efficiency, and the model results suggest that a factor other than the loss of palatability may have contributed to the loss of performance. Future research on SFF mixtures should focus on trying to compensate the loss of palatability and on identifying the causes related to the loss of performance when higher inclusion levels of SFF mixtures are considered.

Introduction

Aquafeeds production has been increasing as a result of the ongoing increase in aquaculture production. However, this industry faces several challenges, mainly regarding production sustainability. The inclusion of vegetable ingredients and agroindustrial by-products is an excellent option to reduce aquafeeds' carbon footprint and promote a circular economy. However, vegetable ingredients display some disadvantages, such as the presence of anti-nutritional factors, higher fiber content, and poor palatability. Some biotechnological processes have been applied to this type of ingredient to mitigate these constraints. Solid-state Fermentation (SSF) is an eco-friendly and cheap biotechnological process in which fungi digest the substrate and reduce the presence of anti-nutritional compounds, enhancing the nutritional value of SSF products. Moreover, these secondary metabolites, antioxidants or β-glucans, may enhance fish's immune innate system. As it follows, this study aims to evaluate the oxidative stress status, inflammatory and metabolic gene expression, and gut microbiota modulation in European sea bass juveniles fed diets with a SSF plant-feedstuff mixture inclusion.

Materials and methods

A plant-based mixture composed of soybean, rice bran, sunflower, and rapeseed (25% each) was fermented with *Aspergillus niger* 2088 CECT for 7 days at 25 °C to obtain mycoprotein enriched biomass and enzyme production. Four isoproteic (42%) and isolipidic (18%) diets were formulated to contain 20% and 40% of the unfermented (Mix) and fermented mixture (SSF Mix): 20 Mix, 20 Mix SSF, 40 Mix, and 40 Mix SSF, respectively. A growth trial was conducted for 50 days in a recirculating water system, with European sea bass juveniles (*Dicentrarchus labrax*; initial body weight of 10g). The experimental diets were randomly assigned to triplicate groups of fish. At the end of the trial, three fish from each tank were randomly sampled after 4 hours of the first meal, and liver, intestine, and muscle were collected for oxidative stress and lipid peroxidation analysis, and liver and intestine for gene expression by RT-PCR. Another two fish from each tank were sampled at the same time, and intestinal mucosa and digesta were collected for posterior PCR-DGGE (denaturing gradient gel electrophoresis) fingerprints obtention.

Results

In the intestine, catalase (CAT), glutathione reductase (GR), and glucose 6-phosphate dehydrogenase (G6PDH) activities were unaffected by the inclusion level, nor by SSF. Glutathione peroxidase (GPX) was higher in fish fed the 40% mix diets. SSF increased superoxide dismutase (SOD) activity in fish fed the 20% SSF diet. Concerning the inclusion effect, SOD activity of fish fed the 40 Mix SSF was lower than 20 Mix SSF. Liver glutamate dehydrogenase (GDH), and aspartate aminotransferase (ASAT) activities were not affected by the diet composition. Alanine aminotransferase (ALAT) activity was higher in fish fed with 20% Mix diets. Liver CAT activity was higher in fish fed the 40% Mix diets, while GR and G6PDH were lower in fish fed the fermented diets, irrespective of the Mix inclusion level.

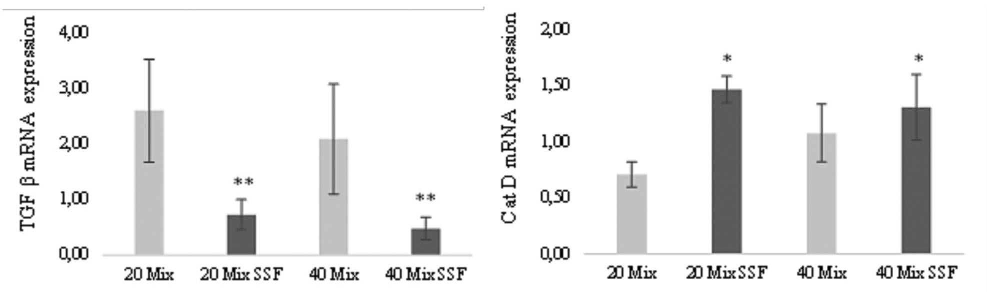

Fig. 1 - Quantitative expression of gut's transforming growth factor beta (TGF β), and liver's cathepsin D (Cat D) of European sea bass juveniles fed dietary treatments

(Continued on next page)

Values are presented as mean ± SEM (n=9). SEM: pooled standard error of the mean. A Two-way ANOVA was used to analyze the effect of inclusion level and SSF. The * indicates significant differences between SSF and non-SSF diets ($P \leq 0.05$) ; *$P < 0.05$; **$P < 0.01$.

Hepatic SOD activity was higher in fish fed the 40 Mix SSF diet compared to the 20 Mix SSF diet. Concerning the SSF effect, SOD activity increased when fish were fed the 20 Mix SSF compared to fish fed the 20 Mix diet. The intestine, liver, and muscle lipid peroxidation (LPO) were not affected by dietary treatments.

Caspase 3, interleukin 8, interleukin 10, tumor necrosis factor α, and insulin-like growth factor 1 gene expression was not affected by the diet composition. Transforming growth factor β gene expression was lower, while cathepsin D expression was higher in the SSF diets (Fig. 1).

PCR-DGGE fingerprints of fish fed the experimental diets showed that SSF increased the average intestinal number of operational taxonomic units (OTUs), microbial richness, and diversity. This was confirmed by the analysis of the sequenced gel bands that showed the appearance of numerous *Bacillus* spp. in fish fed with the SSF diets. The inclusion level increased microbial diversity when fish were fed the 40% vegetable mixture diets.

Conclusion

Overall, oxidative stress and lipid peroxidation of the intestine, liver, and muscle were unaffected by dietary treatments. SSF appears to have immunostimulant properties, due to the decrease of TGF when fish were fed the SSF diets. SSF of plant feedstuffs mixture had beneficial modulatory effects on intestinal microbiota, by promoting the abundance of *Bacillus* spp., which may produce antifungal compounds and enzymes, and may help fungal digestion in fish's gastrointestinal tract.

NUTRITIONAL EVALUATION OF DIETS INCLUDING A SOLID-STATE FERMENTED PLANT-FEEDSTUFF MIXTURE WITH *Aspergillus niger* FOR EUROPEAN SEA BASS (*Dicentrarchus labrax)* JUVENILES

Vieira, L. *[1,2], Filipe, D. [1,2,3], Magalhães, R. [1,2], Ferreira, M. [3], Ozorio, R. [2], Oliva-Teles, A. [1,2], Belo, I. [3], Peres, H. [1,2]

Introduction

Modern aquaculture relies on plant feedstuffs as the main alternative to unsustainable and expensive ingredients, such as fishmeal. Fish meal is the most complete ingredient for fish nutrition, lacks anti-nutritional factors, is highly digestible, and has a balanced amino acid profile, but it is no longer used as the main ingredient due to its unsustainability. On the other hand, plant feedstuffs are cheaper ingredients but present some constraints such as poor palatability, high fiber content, imbalanced amino acid profiles, and anti-nutritional factors. These limit aquafeeds' digestibility, feed efficiency, and overall fish growth performance. Biotechnological processes, such as Solid-state Fermentation (SSF), may be used to improve the nutritional properties of plant feedstuffs. SSF is a cheap and eco-friendly process that relies on fungi to digest the substrate, thus increasing nutrient bioavailability by producing fiber-degrading enzymes and fungal biomass. This study aims to evaluate the nutritional effects of including a solid-state fermented plant-feedstuff mixture in aquafeeds for European sea bass juveniles.

Materials and methods

A plant-based mixture (Mix: soybean, rice bran, sunflower, rapeseed; 25% each) was fermented with *Aspergillus niger* 2088 CECT (Colección Española de Cultivos Tipo) for 7 days at 25 °C to obtain mycoprotein enriched biomass, and carbohydrase production. Four isoproteic (42%) and isolipidic (18%) diets were formulated to include the fermented and non-fermented mixture at 20% and 40% (diets 20SSF, 20M, 40SSF, and 40M, respectively). A growth trial was performed in a recirculating water system (RAS) at 21 °C. Triplicate groups of 20 European sea bass juveniles (*Dicentrarchus labrax*; initial body weight of 10g) were fed each experimental diet for 50 days. At the end of the trial, fish's growth performance, feed intake, and feed efficiency were evaluated. Three fish from each tank were randomly sampled after 5 hours of the first meal, and the intestine was collected for digestive lipase, amylase, and total alkaline proteases activity determination. Blood was collected from the caudal vein with heparinized syringes, centrifuged at 10000 rpm for 10 minutes, and plasma was collected for total protein, glucose, cholesterol, and triglycerides determination.

Results

During the trial, mortality was low and was increased by dietary SSF. Irrespective of SSF, the growth performance of fish fed with the 40 Mix diets was lower than with 20 Mix diets. Regarding the SSF effect, growth performance of fish fed with 40 SSF was lower than that of the respective unfermented diet. Feed intake decreased with SSF and was lower when fish were fed the 40 Mix and 40 Mix SSF, compared to the 20% inclusion level. Feed efficiency, and protein efficiency ratio were significantly increased with the fermented inclusion in 20 Mix SSF and 40 Mix SSF. Nitrogen intake decreased when fish were fed the 20 Mix and 40 Mix fermented diets. Nitrogen retention decreased within the 40% inclusion level when fish were fed the 40 Mix SSF diet. Irrespective of the fermentation, nitrogen retention of fish fed with a 40 Mix SSF diet was lower than with 20 SSF (Table 1). Whole-body ash and lipid contents were unaffected by dietary SSF. Regarding the inclusion level, whole-body dry matter content increased when fish were fed a 20% Mix diet, rather than at 40%. Irrespective of the inclusion level, fish fed the 20 Mix diet had higher dry matter than 20 Mix SSF. Dietary SSF increased whole-body protein in the 20 Mix SSF diet and decreased in the 40 Mix SSF diet. Gross energy content was affected by the inclusion level, being higher when fish were fed the 20% inclusion diets. Amylase activity decreased when fish were fed the 20 Mix diet compared to the 40 Mix diet, irrespective of the SSF. Concerning the SSF effect, among the 40% inclusion level, fish fed the 40 Mix SSF had lower amylase activity compared to the respective non SSF one. Lipase activity increased when fish were fed the 20 Mix SSF, regardless of the inclusion level. Regarding the inclusion level, fish fed the 40 Mix diet had higher activity than the 20 Mix diet. Total alkaline proteases decreased when fish were fed with 20% inclusion level diets, irrespective of SSF. Regarding the SSF effect, fish fed with non-fermented diets had higher activity of proteases. Plasma metabolites cholesterol, total protein, and triglycerides were unaffected by dietary treatments. Regardless of the inclusion level, serum glucose was higher in the 40 Mix SSF diet compared to the respective unfermented one.

(Continued on next page)

Conclusion

SSF reduced overall growth performance in 40% inclusion and was not affected in 20SSF. Feed intake decreased in 20SSF, but feed efficiency increased. Protein efficiency ratio increased in 20SSF, which coincides with a higher whole-body protein deposition. Inclusion of 40SSF revealed a lower growth, feed efficiency, and protein retention. Plasma metabolites were not affected by dietary SSF. Overall, 20SSF reveals to be an interesting diet, allowing for more efficient use of the diet, reducing costs, and in a short feeding period without compromising fish's growth. Nevertheless, more studies are needed to explore the effects on growth performance of lower fermented inclusion levels, SSF with non-sporulating fungi, or to evaluate the potential of including extracts from this SSF mixture, to determine SSF's nutritional effects without fungal spores.

[3]Menzies Health Institute Queensland, Griffith University, Gold Coast, 4222, Queensland, Australia.

This study aims to characterize the strain A12 isolated from a competitive exclusion culture derived from the intestinal contents of Nile tilapia (*Oreochromis niloticus*) and determine the probiotic potential regarding the antibacterial activity, hydrophobicity, and molecular identification and annotation using whole-genome sequencing and comparison to other isolates of the same species. The functional annotation of genes associated with probiotic activity was established. A12 showed antibacterial activity against *Streptococcus agalactiae* and *Aeromonas hydrophila*. Using the ANIb, ANIm, and Tetra indices (calculated in JSpeciesWS), A12 was identified as *Lactococcus lactis* A12. The pangenome analysis of Roary revealed that these bacteria possess unique genes that must be characterized in future research to determine if they are involved in adaptation to the fish environment. Annotation of the genome revealed the presence of essential genes involved in the biosynthesis of amino acids, vitamins, bacteriocin-like proteins, adhesion genes, and carbohydrate metabolism. Consequently, *in vitro* and *in silico* evaluation of the probiotic potential revealed a promising opportunity to use the selected A12 as probiotics in tilapia culture; however, in vivo experiments at various production scales are required.

PILOTING OF A SOFTWARE TOOL DESIGNED TO CALCULATE THE ENVIRONMENTAL PERFORMANCE OF MEDITERRANEAN AQUACULTURE PRODUCTS

David Villanueva*, Ane Ugena, Maite Cidad, Saioa Ramos

Email: dvillanueva@azti.es

Introduction

Fish represents a significant part of the global food provision, accounting the 20% of the animal protein consumed by humans (Carvalho & Guillen, 2021). Since the past few decades, aquaculture has been subject to a significant production growth, which is reflected in a rise of the global aquaculture production of 527% from 1990 to 2018 (FAO, 2020). In 2019 there was a production of over 2 million fish tones in the Mediterranean from which 43% was aquaculture production (FAO, 2020).

In 2013 the European Commission (EC) proposes the Product Environmental Footprint (PEF) method as a common way of measuring environmental performance (COM2013/179/EU). This method establishes the Life Cycle Assessment (LCA) methodology to measure environmental performance of products represented by 16 environmental impact categories. Within this framework in 2018 the LIFE+ AQUAPEF project was launched with the aim to facilitate the environmental footprint calculation of Mediterranean aquaculture products. An important outcome of this project is the development of a software tool specifically designed to help the Mediterranean aquaculture sector to calculate the environmental performance of their products, complying PEF methodology, in specific the Product Environmental Footprint Category Rules (PEFCR) for marine fish. The study presented in this manuscript, describes the piloting stage of the software tool in several seabass and seabream producer companies within the Mediterranean aquaculture sector. Results allows to identify benefits and challenges of using the software tool in a regular basis within the aquaculture sector.

Approach and Methodology

In order to validate the efficiency and usefulness of the software tool, it was tested by several companies from different countries (Greece, Italy, Spain and Cyprus) of the Mediterranean aquaculture sector.

The tool transforms company specific data, gathered by the user, into 16 environmental impact categories recommended by the International Reference Life Cycle Data system (Fazio et al., 2018). This process is carried out based on secondary data coming from public databases that are EF-compliant tendered by the EC. Before loading data into the tool, the user needs to collect the information that will conform the inventory data to be used by the tool to perform the LCA. To facilitate this data collection, the user was provided with questionaries that ask for the specific information that should be collected in the tool. The software tool was developed following the methodology described in de Marine Fish PEFCR. It works via web; hence, the user can access to it in any computer with internet connection only using its username and password. The tool gathers the information of the main steps of the Mediterranean offshore aquaculture sector: feed production, juvenile production, growing in open sea-cages, preparation, and distribution. Moreover, it also considers retailer stage, consumption and end-of-life based on average data. Results obtained from the tool are based on the stablished functional unit that is 1 kg of edible fish product and covers the life cycle of the product from “cradle to gate”.

Workshops and training sessions were carried out to present the tool to the companies and to transfer them the minimum knowledge required to use the tool. Besides those activities, the companies were allowed to test the tool by their own during a period, after which more feedback were received.

Results

The companies in general shown great interest on the tool and found it useful for their activities. Furthermore, companies communicated their feedback for the tool, where the next topics were identified: i) the ability to cover all the activities of the value chain including external suppliers while protecting sensible information shown to be useful, ii) validation of the methodology used, iii) visibility of the methods and databases that are used for the calculations, and iv) tool being translated to different languages used within the European Mediterranean was highly appreciated. Feedback related to tool usability, specifically about tool design, information content and how this information is shown and/or distributed within the user interface were also communicated.

Other subjects like the validity of the tool when other species than seabass and seabream are intended to be studied, and how the social and economic impacts can be included in the tool, arise during the piloting stage.

(Continued on next page)

Conclusion

Based on the feedback received from the companies that participated on the tool piloting, three main topics were addressed: i) sensible data confidentiality and security, which was ensured by the appropriate protocols from the server provider and by giving specific access permissions to each participant of the value chain; ii) training required, even though the tool user-interface was developed in a "friendly" way to allow the use of it by any member of the company, the experience after piloting the tool in a "real-life situation" suggest that the ideal user must possess some knowledge of LCA and domine the company operations related to fish production, this topic was addressed by including resources in the tool like video tutorials and info-boxes and by organizing training sessions with the companies; and iii) tool certification, companies are concern about the possibility of being required by the EU to present a valid PEF report in the future, reason why the need of a certified tool becomes important.

To validate the tool, not only in the production of seabass and seabream in the Mediterranean aquaculture sector, but also for its usefulness when dealing with other species and aquaculture areas outside the Mediterranean, the replicability stage is currently being carried out. During this stage the tool is being tested with producers of salmon, and croaker, located in Atlantic waters like the north of Spain and Norway.

PERFORMANCE CHARACTERIZATION OF A DIFFUSED AERATION BASIN FOR CARBON DIOXIDE REMOVAL IN RECIRCULATING AQUACULTURE SYSTEMS

Brian Vinci* and Laura Bailey

The Conservation Fund, Freshwater Institute, 1098 Turner Rd, Shepherdstown, WV 25443 (USA)
E-mail: bvinci@conservationfund.org

Introduction

Fish produce carbon dioxide (CO_2) as a normal outcome of aerobic metabolism and excrete this gas through their gills into the surrounding water. In recirculating aquaculture systems (RAS) with high stocking densities, dissolved CO_2 accumulates to unsafe levels unless some form of carbon dioxide control is used. Properly designed CO_2 control unit processes are needed to maintain safe levels of dissolved CO_2 in RAS culture tanks at high stocking densities. Typical CO_2 control unit processes include force-ventilated columns with or without packing media, shallow diffused aeration basins, and passive ventilation trickling biofilters. Force-ventilated packed columns can remove 40% to 60% of dissolved CO_2 from RAS water when properly designed. However, pumping is required to transport water to the top of force-ventilated packed columns. Pumps require capital investment, 24/7/365 operating costs, routine maintenance, and have a relatively short depreciation period. Therefore, it is critical to maximize CO_2 removal efficiency to minimize the water flow that must be pumped when using a force-ventilated packed column. Alternatively, unit processes that remove CO_2 using less energy can be utilized if design criteria are established. The objective of this project was to characterize the dissolved CO_2 removal performance of a low head or gravity flow CO_2 control technology and develop the associated design criteria for use in RAS mass balances and engineering.

Materials and methods

This project studied a diffused aeration basin that uses diffused air as the CO_2 stripping gas in a relatively shallow basin. Diffused aeration basins are often used in current RAS designs immediately after a moving bed biofilter. Water gravity flows from the moving bed biofilter into the diffused aeration basin with no water pumping required. This study evaluated diffused aeration basin hydraulic loadings (407, 611, 814, and 1222 lpm/m^2), influent CO_2 levels (10, 15, and 25 mg/L), and diffused air flow (G:L of 2 and 5) to characterize CO_2 removal efficiencies in a research-scale aeration basin that was 1.2 m by 0.9 m by 0.9 m deep (1 m^3). The project setup consisted of an influent tank using a low head oxygenator to inject CO_2 to achieve the desired influent dissolved CO_2 levels and a diffused aeration basin with pump and sump for returning treated water to the influent tank. OxyGuard International A/S portable CO_2 sensors monitored the dissolved CO_2 in the influent tank and after the diffused aeration basin as it returned to the low head oxygenator. Diffused air for aeration was provided by a regenerative blower and air manifold at the bottom of the aeration basin.

Results

The results of the study will be reported along with recommendations for optimizing the design of diffused aeration basins in RAS. Preliminary example results are shown in Figure 1.

(Continued on next page)

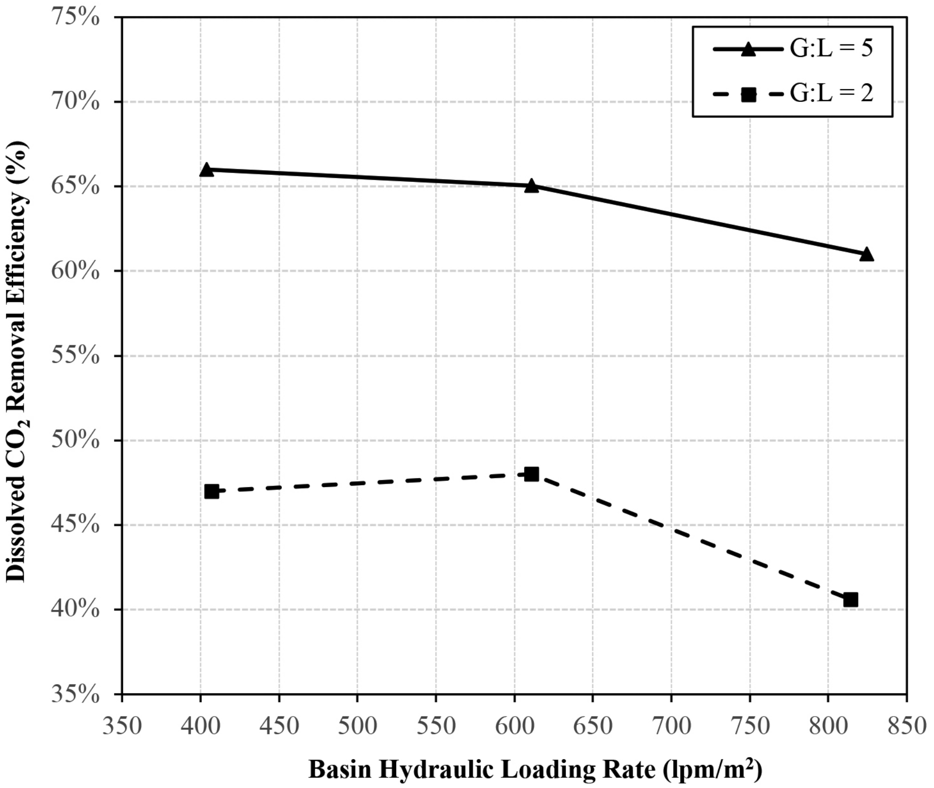

Figure 1. Dissolved CO_2 removal efficiency for a research-scale diffused aeration basin treating an inlet CO_2 concentration of 25 mg/L at a high air flow rate (G:L = 5) and a low air flow rate (G:L = 2).

EVALUATION OF A VELOCITY ASSIST INLET FOR IMPROVEMENT OF HYDRODYNAMICS IN COMMERCIAL-SCALE DUAL DRAIN FISH TANKS USED IN RECIRCULATING AQUACULTURE SYSTEMS

Brian Vinci[1*], Khurram Shahzad[2], and Curtis Crouse[1]

[1]The Conservation Fund, Freshwater Institute, 1098 Turner Rd, Shepherdstown, WV 25443 (USA)

Introduction

One type of fish tank used in recirculating aquaculture systems (RAS) is the Cornell-style dual drain circular tank. Cornell-style dual drain fish tanks have two drains: a bottom center drain, and an elevated sidewall drain. Cornell-style dual-drain tanks are advantageous because the rotational velocity caused by the inlet water injection creates a self-cleaning effect. In operation, a Cornell-style dual drain tank functions as a swirl separator with waste solids collecting at the tank center and flowing out the bottom center drain. These fish tanks also provide a relatively uniform environment for the fish, with minimal gradients in dissolved oxygen (Davidson & Summerfelt, 2004).

In a typical Cornell-style dual drain circular tank, the injection of treated RAS water causes a rotational velocity that is highest at the tank perimeter and decreases toward the tank center. Recent research indicates increased water velocities provide performance benefits for Atlantic salmon post-smolts raised in fish tanks (Timmerhaus et al., 2021). To achieve these benefits, an additional inlet can be installed on separate pumped loop that removes water from the fish tank and re-injects it to provide increased water velocities. This internally pumped "velocity assist" inlet aims to increase water velocities available to larger post-smolt and harvest-size salmon in commercial-scale Cornell-style dual drain circular fish tanks. This study sought to evaluate the effect of the velocity assist technique by testing combinations of three different water flow rates and three different nozzle head loss configurations for a velocity assist inlet in a semi-commercial scale RAS used for land-based growout of Atlantic salmon with the intent of determining optimal combinations for increasing water velocities at minimum energy.

Materials and methods

The velocity assist technique was empirically tested by the addition of a pumped velocity assist loop with adjustable inlet in a 150 m^3 Cornell-style dual drain circular tank that is part of the semi-commercial scale RAS at the Freshwater Institute (USA). Empirical water velocity sampling of the currents in the tank were carried out for all combinations of the following: ~30% of the main flow as velocity assist flow (1136 lpm), ~50% of the main flow as velocity assist flow (2271 lpm), ~60% of the main flow as velocity assist flow (2763 lpm) and low (0.14 bar), medium (0.33 bar), high (0.56 bar) velocity assist inlet nozzle headloss. Water flow was adjusted by changing the number of pumps operating and adjusting a control valve. Nozzle headloss was adjusted by changing the number of 2.54cm openings on the inlet. Water velocity measurements were collected using a SonTek Argonaut-ADV 3-axis Doppler velocity meter at three depths across two cross-sections once steady state conditions were achieved for each combination of flow and headloss (Figure 1). Water velocities were also characterized for operation of the tank without the velocity assist inlet in operation.

Results

Preliminary results indicate that operation of the velocity assist inlet improved velocity profiles in the 150 m^3 Cornell-style dual drain circular tank over the base case without a velocity assist inlet. Higher velocities were observed throughout the tank with higher velocity assist inlet water flow and nozzle headloss. The complete results of the evaluation will be presented along with recommendations for optimizing the velocity assist technique in commercial-scale fish tanks for RAS.

Conclusions

The use of a velocity assist inlet effectively decouples the control of tank water velocities for improved fish welfare from the primary inlet flow and allows for more control as fish increase in size.

THE EFFICACY OF VARIOUS CHEMICALS IN THE DISINFECTION OF DUSKY KOB (*Argyrosomus japonicus*) EGGS AND HATCHERY WATER

NG Vine[1], AD Maapea[1] and BM Macey[2,3]

[1]Department of Zoology & Entomology, University of Fort Hare, Alice, 5700, South Africa

Introduction

Dusky kob (*Argyrosomus japonicus*) has been identified as a promising food fish in the South African marine finfish industry. To support industry growth, existing hatcheries frequently sell or donate excess eggs to neighbouring farms, raising concern over the potential transfer of infectious disease agents. Chemical disinfectants are frequently used to prevent transmission of diseases, but their application has shown large variations between finfish species and very little is known about the efficacy and impact of disinfectants on dusky kob eggs or larvae. Bacterial diseases are particularly prevalent in finfish farming, constituting about 55% of infectious disease outbreaks compared with viruses, parasites and fungi. Since little is known about the microorganisms, particularly bacteria, associated with dusky kob and their rearing systems in South Africa, this study aimed to assess the efficacy of various chemicals in disinfecting dusky kob eggs and the rearing water and their subsequent impact on larval development.

Materials and methods

Microbial samples were collected from dusky kob eggs and hatchery water from Pure Ocean (Pty) Ltd, a commercial dusky kob farm in the East London Industrial Development Zone (ELIDZ) of South Africa. Dusky kob eggs and hatchery rearing water were exposed to four different chemical disinfectants for 5 min at difference levels: povo-iodine at 30 mg/L (PI30); formaldehyde at 2000 mg/L (F2000); chloramine-T at 25 mg/L (CT25); and hydrogen peroxide at 200 mg/L (HP200), and compared with a control where no disinfectant was added. Following treatment, eggs samples were rinsed with autoclaved seawater, water samples filtered to concentrate bacteria, the eggs were homogenized and then tenfold serial dilutions of both concentrated bacteria and egg samples were plated on a general media commonly used for growth of marine bacteria (TSA) and a *Vibrio* spp. selective media (TCBS).

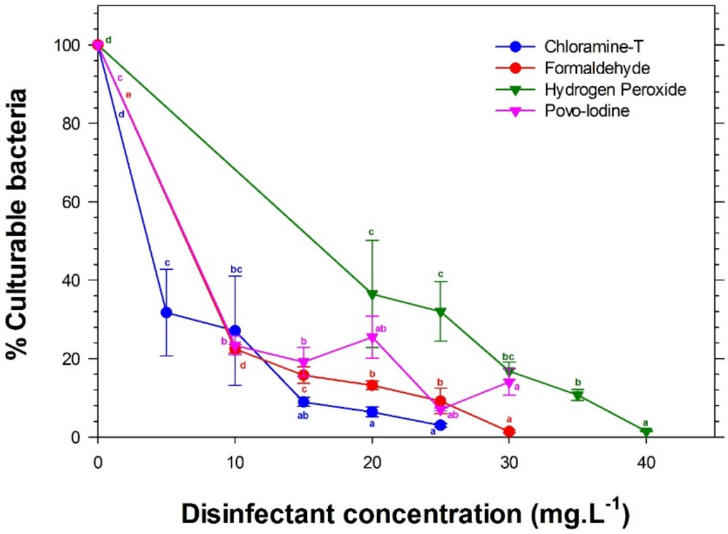

Fig 1: Effect of varying the concentration of each chemical disinfectant (a. Chloramine-T; b. formaldehyde; c. hydrogen peroxide; d. povo-iodine) on the number of culturable bacteria in seawater.

(Continued on next page)

Results

All chemical disinfectants tested in this study were able to reduce the number of culturable bacteria associated with hatchery rearing water and on dusky kob eggs. Treatments with povo-iodine at 30 mg/L (PI30); and formaldehyde at 2000 mg/L (F2000) significantly decreased bacterial growth on TSA media by 43 and 88%, respectively, while chloramine-T at 25 mg/L (CT25); and hydrogen peroxide at 200 mg/L (HP200) only decreased bacterial growth by 3 and 10%, respectively. Similarly, PI30 and F2000 decreased the growth of *Vibrio* species by 79 and 75%, respectively, while CT25 and HP200 decreased *Vibrio* spp. by only 12 and 14%, respectively (Figure 1). None of the chemical disinfectant appeared to have any adverse effects on larval development as no significant differences were recorded in any of the larval development parameters of dusky kob between any of the treatments and the control (no disinfectant).

Discussion

This study showed that all tested disinfectant agents were capable of reducing the culturability of bacteria in seawater in a dose dependent manner. However, povo-iodine (30 mg/L) and formalin (2000 mg/L) were shown to be more effective at reducing the number of bacteria associated with dusky kob eggs following a 5 minute exposure period. None of the tested disinfectants had an adverse effect on early larval development, suggesting that these disinfectants have potential for treatment and control of bacteria associated with seawater and eggs in dusky kob hatcheries.

THE WELFARE OF TAGGING: THE EFFECT OF CHRONIC STRESS ON WOUND HEALING AND WELFARE IN ATLANTIC SALMON (*Salmo salar*)

M.I. Virtanen*, M.F. Brinchmann, and M.H. Iversen

Faculty of Biosciences and Aquaculture, Nord University, BODØ, 8026, Nordland, Norway
E-mail: miiro.i.virtanen@nord.no

Introduction

To provide fish a voice to communicate feelings, needs and worries within its population requires the use of technology that can analyse and interpret multiple forms of data which can be processed into actions for providing better welfare. This can be done with new age tagging technology, however, the tagging process can not cause welfare to be compromised if this form of communication is to be valid. This study aims to document how chronic stress is visible through primary, secondary, and tertiary stress responses and their effects on the visible wound healing cascade and fish welfare.

Materials and methods

266 Atlantic salmon (*salmo salar*) were distributed into 9 indoor tanks (1.0 m^{-3}) with continuous flow of seawater with salinity 33.5‰, temperature of 7.3 ± 0.3 °C, and oxygen level of 97.7%. 24 hour light regime, with dry feed dispensed automatically in excess was provided during the experiment and acclimation phase lasting 68 days was present. Three experimental groups (in triplicate, total of nine tanks) were used: (1) Control, (2) Wound, and (3) Wound + Stress. Sampling was done once per group every week starting from week 0 (pre-stress) to week 8. The control group had no manipulation done, the wound group had a dummy tag surgically implanted into the abdominal cavity, and the wound + stress group had the same surgical implant as the wound group while also being subject to a daily crowding stressor by lowering the water in their tank to increase density from 30 kg/m3 to 315 kg/m^3 lasting roughly 30 minutes. Primary and secondary stress responses were measured from the blood plasma including CRH, ACTH, dopamine, and cortisol from the primary and glucose, lactate, magnesium, calcium, chloride, and osmolality from the secondary. Tertiary stress responses such as weight, length and fin erosion of 5 different fins were used.

Results

Primary stress responses with most significance are shown in Fig.1, secondary stress responses had few significant differences between the three groups with no conclusion drawn. For the fin erosion the wound + stress group suffered significant erosion in fins after week 3. Using the wound + stress group to rank severity of fin damage, the order of most damaged at week 8 compared to week 1 is as follows, pectoral, pelvic, anal, caudal, dorsal. There was positive correlation between the aggregated fin score of the pelvic, pectoral, and anal regions and plasma in wound + stress group (r_s= 0,700). No such correlation was shown in the control (r_s= -0,714) and wound (r_s= -0.407) group. While for the wound healing (Fig.2) the inflammation of the wound in the wound + stress group was larger and slower healing than the wound group. Also the inside wound was larger and healed slower in the wound + stress group than the wound group.

Discussion & Conclusion

The present experiment studies the effect tagged Atlantic salmon experience during chronic stress, and how the fish respond to daily crowding stress in terms of allostatic response, overall welfare and visible wound healing. The main observations from the study are: (1) Wounded individuals do not suffer from chronic stress; (2) Wound + stressed individuals suffer from allostatic overload type 2 with an increase of ACTH starting at week 4 to an increase in baseline levels of plasma starting at week 6; (3) Fin erosion is significant in stressed fish where damage to fins occurs well before the allostatic overload, indicating a possible use of fin erosion as a pre-indicator of stressful conditions; (4) Stressed individuals suffer from a larger inflammation period in weeks 1-2 while also their inside wounds heals slower than unstressed wounded fish, suggesting a neuroimmunoendocrine regulatory feedback; (5) Choice of suture can result in better welfare for tagging studies; (6) Internal wound healing is slower in stressed fish and plays a key role in understanding tag retention. (7) Unstressed fish do not suffer compromised welfare when tagging is introduced and they are allowed to recover, while tagging with daily stress compromises welfare, indicating the need for good aquaculture practices to be used post tagging to establish a healing opportunity.

Line within ovals represents mean wound length (A1 Fig.3.). A red line indicates not all replicates within that week had wound width (B1 Fig.3.) = 0.0cm, a blue line indicates all replicates within that week had wound width = 0.0cm. Lower sections: Inside wound healing width and length, represented the same as the top section. Significance between groups represented as * = P ≤ 0.05, ** = P ≤ 0.01.

SUSTAINABLE EXPLOITATION OF FARMED LUMPFISH – FOOD NEOPHOBIA'S INFLUENCE ON INTRODUCING NEW FISH SPICIES IN A NEW MARKET

Gøril Voldnes, Nofima

Nofima, P.B. 6122, 9291 Tromsø, Norway
goril.voldnes@nofima.no

Introduction

The challenges with sea lice in the salmon aquaculture industry have resulted in various amounts of measures to remove lice from the salmon in the net pens. Among the measures taken, the use of cleaner fish placed together with the salmon to eat lice from the salmon, have become an effective way to reduce the amount lice. The increased popularity of using cleanerfish (lumpfish and different wrasse species) have further resulted in a new industry, farming of cleanerfish. The production of lumpfish for this purpose has grown, significantly the last years, from just above 400 thousand fish in 2012 to nearly 36 million in 2020 (Source: Directorate of Fisheries).

A challenge with the use of lumpfish for eating lice is that they stop eating lice when they reach about 200-300 grams. The industry has however paid limited attention to the after-use of this fish, meaning that millions of fish goes to waste or in best case are used for ensilage when taken out from the salmon pens. Our aim was to find a more sustainable after-use for this resource. The most sustainable solution for the fish was in our opinion to.

Our aim is to find a suitable market for human consumption of farmed lumpfish. Challenging task as introducing new products in itself is challenging, and this fish have in addition a history that may cause even more challenge. The fact that the lumpfish have been used to eat lice for salmon in early life stage can be problematic for some consumers.

Theoretical background

The current trends towards globalization and cultural diversity have led to an increased demand for non-traditional food not only in Western countries but also in homogenized Asian societies. However, people vary considerably in their willingness to try new foods, with some individuals showing great pleasure in eating new foods and others showing strong aversions to them (Ritchey et al., 2003).

Introduction of new food are in itself a challenging task, and introducing new food to a new market, may be even more challenging. Food neophobia is defined as the unwillingness or refusal to eat or the tendency to avoid new foods (Pliner and Hobden, 1992). This food neophobia results in high failure rates for innovative and novel food products (Barrena and Sanchez, 2012).

Food neophobia (FN) is generally characterized as a personality trait, a continuum along which people can be placed in terms of their tendency to accept or avoid new foods (Pliner and Salvy, 2006). Since FN can influence preferences toward novel foods (Tuorila et al., 2001), understanding its potential impact on consumers' food selections is an important issue for food product developers and marketers. Food neophobia can impact scores on product evaluations, particularly for novel products (Henriques, King, & Meiselman, 2009).

A systematic review of Food Neophobia studies the last 30 years (Rabadan and Bernabéu, 2021) showed that most studies were conducted in developed countries, mainly in the US and Europe. It is important to include several countries as differences have been reported between countries, such as between Koreans and American (Chung et al., 2012) and between well-educated and wealthy people from Western and emerging countries (Brunner and Nuttavuthisit, 2019). In emerging countries, this consumer segment was more conservative (more neophobic) about food, while in developed countries this segment showed lower levels of FN. According to Rabadan and Bernabéu (2021) specific attention should be paid to fast-growing countries in Asia, where society and food consumption are changing rapidly as results shows that FN in societies decreases with increased income, education, and urbanization (Koivistu and Sjöden, 1996; Meiselman et al., 2010; Predieri et al., 2020; Prescott et al., 2002; Beltrán et al., 2016; Schickenberg et al., 2008), Beyond economic development, the cultural background of a country seems crucial to explain the level of FN of its inhabitants (Rabadan and Bernabéu, 2021).

(Continued on next page)

FN is interesting to investigate as it has a negative effect on the willingness to try new or unfamiliar products (Fernández-Ruiz et al., 2013) which is essential when aiming for introducing a new seafood species to a new market. Olabi et al. (2009) indicate that it would be challenging for food companies to launch foods that are ‘‘highly novel non-traditional foods’’ into markets with high food neophobia levels and to assess whether these markets would require the elements of more aggressive marketing campaigns, such as the provision of a high number of free samples and free coupons (Olabi et al., 2009).

No research found investigating neophobia of industrial buyers, important gate-keepers…

Thus, our aim is to investigate FN of industrial buyers in South Korea.

Methodological approach
A pilot study conducted in Norway testing lumpfish in different milieus revealed a more positive perception of eating the fish in different Asian milieus. Thus, we chose two different Asian countries for further investigation: South Korea and Vietnam. Lumpfish were sent from Norway to Seoul and Nah Trang and distributed to different industrial buyers (number). They were given the task to evaluate the fish and make dishes they found suitable for the fish and their cultural cuisine. The product test was followed up with in-depth interviews asking questions about their perceptions about the fish; the appearance, texture, smell, size, and taste. We also asked about their perceptions regarding the fact that the fish have been used to eat sea lice from the salmon in the aquaculture industry. The interviews were conducted via teams and…

Results
The results of the product test and interviews revealed quite negative perceptions about the fish.
Lumpfish
Not for eating. Big trend in skin care for women – so maybe processed info collagen powder or somewhat
Maybe spicy stew. Separate skin because it’s too thick.
Should be filleted because of how it looks. Used for fritter dish.
”we have many uglier fishes, but this is different from ugly – its scary”
“it wont be easy to sell”
“I felt a bit uncomfortable. Actually I was very uncomfortable. I was doubtful if I can cook it deliciously.”
“It definitely didn’t have a mouthwatering look”
It did not make a favorable impression”
“To sell the lumpfish round, honestly, the skin color is not favorable and there are too much inedible part.”
“Delivering factual info to the consumers will be keen”
“It would take time to persuade people”
“need supporting evidence that it is not harmful to eat”

The name cleaner fish itself would give some sort of repulsion to people. Korean would never eat fish with this name. That doesn’t suit Koreans’ cultural sentiments. Even I as a chef feel uncomfortable as well.
“No one knew about Pantagonian toothfish before it got popular.”
“We are continuously looking for new fish and new dish.”
The amount of seafood catch in Korea keeps decreasing, I can see an opportunity for them. It is worth to try.
Positive: “Consumers are always looking for something new”
Opposite: “ Koreans are very conservative people. They don’t like unfamiliar things. They don’t even consider at all if thing are new and not familiar. It is extremely difficult to penetrate the market with a new item”

“In China it, it seems that things sell anyway. Koreans don’t like new items. They would check through the internet first, for example lumpfish, it they look at the picture of lumpfish on the internet, they would say “Nope, no way”
“Whomever the first penguin is, he must put a tremendous effort. Otherwise, its almost impossible.”

when entering into a market with a more neophobic cultural background, marketers may focus on how their non-traditional foods can be made to be more adaptable and familiar to local markets by using well-known food ingredients and familiar spices (Choe and Cho, 2011).

THE ROLE OF TRACEABILITY AS AN ENABLER RESILIENCE, EFFICIENCY, AND SOCIAL AND ENVIRONMENTAL SUSTAINABILITY IN GLOBAL SHRIMP SUPPLY CHAINS

Ron Volpe

PSQR
Frederiksborggade 15, DK-1360, Copenhagen, Denmark
Ron.volpe@psqr.eu

Introduction

Consumer demand for seafood, including shrimp, has never been higher. Shrimp supply chains, both aquaculture and wild caught, are complex and opaque ecosystems of supply chain actors that bring product from many countries to consumers and restaurants around the world. Lack of transparency and data sharing across these actors creates a myriad of very serious problems for seafood companies, consumers, workers, and the environment, problems that are often created due to lack of investment in technology rather than the lack of available technology.

During the 20-year period from 2000 and 2020 the global shrimp market nearly doubled from 17.7B to $33.8B, an increase of 90%. Looking forward, by the year 2028 the global shrimp market is projected to grow another 60% to $53.63 billion in 2028 at a CAGR of 6.81%.

Market Dynamics

1. High demand (30 years in a row)
2. Declining *wild* shrimp and prawn populations due to overfishing
3. Large and growing number of farmed shrimp operators and *farmed* shrimp and prawn supply (55% of the shrimp on the market are from farmed operations versus 45% wild caught)
4. Significant consolidation and M&A activity of large, global, seafood companies (10 seafood companies represent 36% of the global production) with profit margins of 25%-35%.
5. Retailers with average profit margins of 35%-45%
6. Massive cost reduction pressure on downstream supply chain players (fishermen, processors, farmers) to support higher margins for large seafood companies and retailers who have the leverage to demand leaner financials
7. Not unlike food in general, the regulatory profile of the industry is relatively loose, particularly in the countries where much of the world's production comes from.

In this presentation I will specifically identify how granular and end-to-end traceability can impact positive change and performance in the following five areas.

1. Unsustainable Practices
2. Bycatch (Wild Caught)
3. Slave Labor (Wild Caught)
4. Overfishing (Wild Caught)
5. Mangrove habitat destruction (Farmed)
6. Overuse of antibiotics (Farmed)
7. Social Costs (Farmed)
8. Disease as a result of poorly circulating farm tanks (Farmed)
9. Slavery (Wild Caught & Farmed)
10. Waste
11. Mislabeling
12. Supply Chain Resilience
13. Operational Efficiency and costs/profit margins

I will also introduce the concept Social Contracts within global supply chains, and discuss the need for enhance interoperability across the systems of supply chain partners

SLEEPING WITH THE FISHES: USING BRAIN ACTIVITY TO ASSESS INDUCTION TIMES OF FIVE ANESTHETHICS IN RAINBOW TROUT (*Oncorhynchus mykiss*)

N. Kallstenius[*], A. Gräns[†]

[*] University of Gothenburg, Medicinaregatan 18A, 405 30 Gothenburg, Sweden
[†] Swedish University of Agricultural Sciences, Medicinaregatan 18A, 405 30 Gothenburg, Sweden
E-mail: nicklas.kallstenius@bioenv.gu.se

Introduction

Assessing the induction of anesthesia often relies on visual observation of the animal[1]. However, evidence shows that visual indicators are not always reliable[1-3]. A more conservative method to assess insensibility is analysis of electroencephalogram (EEG) where visually evoked responses (VERs) from visual stimulus are recorded, and absence of these are considered a reliable sign of insensibility[3]. A recent study revealed an alarming mismatch between visual consciousness indicators and brain activity[2]. They showed that rainbow trout (*Oncorhynchus mykiss*) might perceive their surroundings for several minutes after being immobilized following CO_2- stunning, highlighting the importance of measuring brain activity when assessing sensibility[2]. Here, we apply a non-invasive method of acquiring brain activity data to identify the required dose of five anesthetics to render rainbow trout insensible[4].

Materials and methods

A silicone cup equipped with electrodes[1] was secured onto the head of lightly sedated rainbow trout (636.8 ± 16.1 g) to record EEG, and a light flashed twice per second to evoke visual responses. A wireless recording system[5] in the experimental tank and an overhead camera allowed non-invasive heart rate measurement and visual observation. Once the fish was calm and clear signals in the investigated variables were established, one of five anesthetics was added to the tank at 2-3 different dosages (see Fig. 1). Induction lasted for a maximum of 10 minutes or until VERs were abolished. After quick transfer to clean water, recovery lasted for a maximum of 15 minutes, or until observable consciousness and VERs were regained. Visual consciousness indicators were considered lost when the fish had fully lost equilibrium and swimming ability. The data for time until loss of VERs and visual consciousness indicators were analyzed using the Kaplan-Meier method and a log-rank (Mantel-Cox) test.

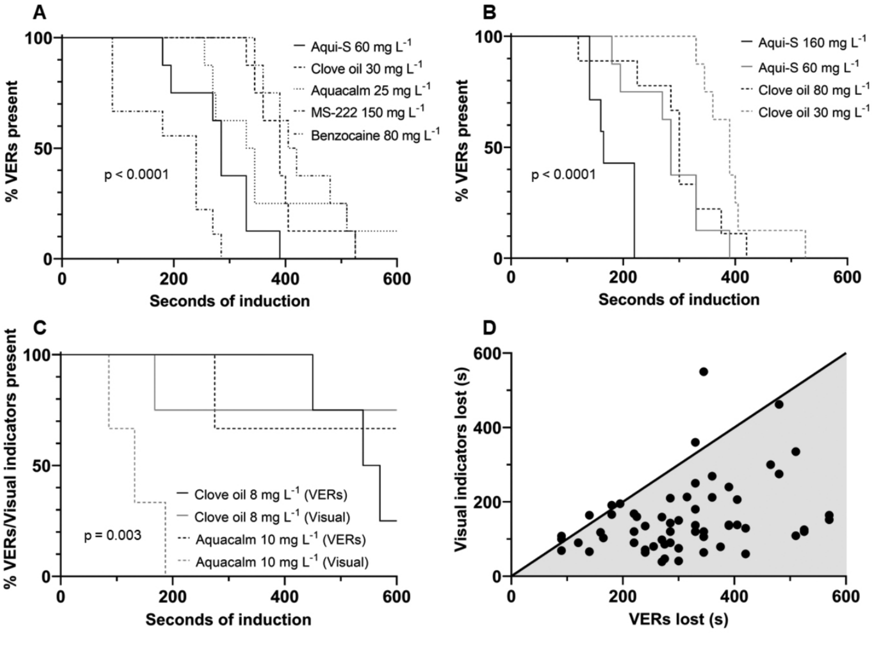

Fig. 1. Induction times of narcosis using five compounds, and the relationship between VERs and visual indicators. A. Time to loss of VERs with five commonly used compounds. B. Time to loss of VERs with different doses of Aqui-S and clove oil. C. Time to loss of VERs and visual indicators using clove oil and Aquacalm. D. Time to loss of VERs versus loss of visual consciousness indicators across groups. The black line illustrates a 1:1 relationship, and data points in the gray area represent a welfare hazard.

(Continued on next page)

Results and discussion

This is the first comprehensive evaluation of various common anesthetic compounds using non-invasively acquired brain activity data. We show that the induction to narcosis differs between compounds in terms of required time and dose, and that there is substantial individual variation (Fig. 1A-B). We further show a clear mismatch between the loss of VERs and visual consciousness indicators (Fig. 1C-D), and thus support the notion that basing assessment of anesthesia induction on visual indicators alone can be a welfare hazard[4]. Aquacalm showed the most pronounced mismatch (see Fig 1C). Our data further indicate that clove oil and Aqui-S may interfere with visual processing in rainbow trout. VERs were abolished in observably conscious individuals given clove oil, and some individuals anesthetized with clove oil or Aqui-S regained observable consciousness before VERs during recovery. This suspected sight loss represents a potential welfare hazard and indicates that VERs may not be suitable for assessing consciousness when using these compounds. All compounds caused cardio-ventilatory depression, which causes hypoxemia[6]. Benzocaine also occasionally induced involuntary defecation. In conclusion, we show that anesthetizing fish is associated with considerable welfare hazards and propose that species-specific evaluations based on appropriate methods are needed for developing reliable and ethically acceptable standards.

GROWTH AND MINERALS COMPOSITION OF CULTIVATED SUGAR KELP IN THE NORTH OF NORWAY: SITE SELECTION, DEPTH AND SORI ORIGIN

Xinxin Wang*, Marthe Blikra, Tor Evense, Dagbjørn Skipnes, Philip James

Nofima AS, P.O. Box 6122, NO-9291, Tromsø, Norway
Email address: xinxin.wang@nofima.no

Introduction

In Norway, as in many parts of Europe, kelp cultivation is a relatively new industry. Interest in the cultivation of kelp is also increasing in the north of Norway. To cultivate kelp efficiently, understanding the physical and biological factors that affect survival and growth as well as developing appropriate production strategies will be among the keys to success. In the present study, *S. latissima* was cultivated at two sites (Kraknes and Rotsund), 90 km apart, in Troms, northern Norway (69-70 °N) in 2020. The effect of site, depth and sori origin (Kraknes and Rotsund) on *S. latissima* growth, biofouling, minerals and potentially toxic elements (PTEs) content was studied. This is the first study on mineral content of *S. latissima* cultivated in the Artic in Norway and the first investigation into the effect of sporeling translocation on the growth and quality of this species.

Materials and methods

S. latissima sporelings were incubated for 8 weeks in seawater in two flowthrough cylinders in the Nofima seaweed hatchery in Tromsø. Seawater temperature were kept at about 10°C in the first 6 weeks and then gradually decreased to ambient seawater temperature. When the sporelings reached an average length of approximately 0.5 cm they were deployed in at Kraknes and Rotsund sites. Environmental factors, growth, biofouling were monitored during the cultivation period from March to August. Major elements (calcium, potassium, magnesium, sodium and phosphorus), potential toxic elements (arsenic, cadmium, lead, mercury) and iodine contents of *S. latissima* were analyzed.

Results and Discussion

Cultivation sites had the strongest effect on the growth and quality of cultivated *S. latissima* even within a small geographical area. Large variations in the frond length and wet weight were observed between sites. The site with lower seawater temperature and no fresh-water influence had better growth and later outbreak of epibionts. Sori origin also had a significant effect on the growth, *S. latissima* produced from Kraknes sori had higher frond length and wet weight irrespective of grow-out site and grew best at their own site. This indicates inherent genetic difference in growth traits, as well as local adaptation to the natal environment for optimal growth.

The iodine content in general was high and increased with cultivation depth, and the results showed lower iodine content at the freshwater influenced site (Rotsund). The heavy metal content varied significantly between sites and sori origin and were lower than the recommended maximum level for food supplements in EU regulations.

The present study shows that both growth and mineral content vary profoundly within the same geographical region and it thereby underlines the importance of thorough site selection and using local traits with high growth rates for seeding and cultivation to achieve maximum biomass, higher quality and economic viability.

The children and youth are the future of sustainable aquaculture and the ocean, in ASTRAL we recognise this hence an education campaign within the ASTRAL project is being developed and targeted at primary and secondary school students in Nigeria. This campaign aims to gather the importance of safe and nutritious aquaculture seafood also addressing climate change resilience and ocean influence. The campaign involves several schools across 3 states namely Lagos, Ogun and Oyo reaching a total of 450 students.

ASTRAL (All Atlantic Ocean Sustainable, Profitable and Resilient Aquaculture) is a Horizon 2020 project with the objective to promote Integrated Multi-Trophic Aquaculture (IMTA) farming system while increasing social awareness towards the consumption of sustainably produced seafood across the Atlantic countries. To target the young generation, the ASTRAL school campaign among other objectives aims at creating awareness and increase the knowledge base of children and youth on the following: the importance of safe and nutritious aquaculture seafood, IMTA, the benefit of the Atlantic Ocean and the Blue Economy, Climate change mitigation and resilience, ocean influence, aquatic pollution as well as the role and responsibility of the young generation on Ocean protection.

To achieve the ASTRAL goals, the objectives were communicated to different primary and secondary school teachers and students. These schools were adopted as ASTRAL schools forming ASTRAL School Clubs to make learning fun outside the regular curriculum objective of human capital development of the project. Some of the activities of these clubs are Do-it-yourself activities such as setting up small fish farms in the school and their homes(aquariums), creative drawing and video images, telling stories and essay writing on the subject matters. Other activities include educating on waste management (talks on pollution), awareness on recycling and upcycling (developing products from waste) and organizing clean-ups in schools, streets, parks and beaches.

There has been visitation by these schools on excursions to tour aquaculture farms and IMTA models in NIOMR. Researchers are also saddled with the responsibility of engaging these students in their schools.

ASTRAL Schools Clubs participated in the Children Day's 2022 Symposium at NIOMR. With 85 students and 21 teachers from 7 schools within Lagos metropolitan. There were talks from researchers on nutritious aquaculture seafood and the benefits, of care for the ocean.

The impact evaluation of these activities will be done through a competition among the schools on different occasions to achieve the ASTRAL aim. Further information on ASTRAL project can be found at www.astral-project.eu/

This project has received funding from the European Union's Horizon 2020 research and innovation programme under grant agreement No 863034.

REPRODUCTIVE POTENTIAL AND POPULATION PERSISTENCE OF PACIFIC OYSTERS *Crassostrea (Magallana) gigas* IN A MACROTIDAL ESTUARY

S. Ward[1]*, D. Smyth[1], B Winterbourn[1], M. Hayden- Hughes[1], S. Malham[1], R. Corner[1], A. Woolmer[2], L. Le Vay[1]

[1]Centre for Applied Marine Sciences, School of Ocean Sciences, Bangor University, Wales, UK [2]Tethys Oysters Ltd.
Burry Port, Wales, UK
Email: *sophie.ward@bangor.ac.uk

Introduction

While production of Pacific oysters *Crassostrea* (*Magallana*) *gigas* is approved across the UK under licence, currently there are only two oyster farming areas in Wales. Development of aquaculture is embedded in the objectives of the Welsh National Marine Plan, and national objectives for its sustainable expansion support economic development in rural coastal communities. However, potential colonisation of intertidal habitats by oysters, as seen along the south coast of England, is an issue of concern in coastal management and biodiversity conservation. Policy development regarding the future of Pacific oyster aquaculture is pending further information about the current status of *C. gigas* populations. Such information includes the extent to which reproduction of farmed oysters may act as a source of self-sustaining escaped (feral) populations across marine habitats, especially those comprising designated conservation features. The Welsh coast is an interesting case study for the potential for range extension of feral Pacific oysters, as environmental conditions may be marginal for successful reproduction and recruitment (and hence the risk of reproductive escape from aquaculture farms may be relatively low). In this study, we considered the potential for sustainable expansion of Pacific oyster aquaculture within the macrotidal estuary at Milford Haven (south Wales, UK).

Materials & Methods

Densities of intertidal *C. gigas* oysters in the Milford Haven waterway were re-assessed at five sites previously surveyed in 1998, using quadrat survey and timed searches. For each site, a Gunderson population model was used to estimate abundance of Pacific oysters, based on available area of suitable substrate for larval settlement (Phase 3 EUNIS biotope codes), with a correction factor for post-settlement mortality. The potential for recruitment from spawning events within Milford Haven was investigated using hydrodynamic- and larval dispersal modelling of potential transport and dispersal of larvae released from a range of locations, and under contrasting river flow scenarios. UK Meteorological Office AMM7 forecast model climate projections for past (1990-2018), present-day (August 2020 to August 2021) and future sea surface temperatures (2020-2099) were calibrated using monthly observed mean sea temperature data (1991-2007). The reproductive potential of oysters was assessed using a degree days formula, with thresholds for spawning and larval development of 600 and 825 cumulative degree days above 10.55°C, respectively (Mann, 1979).

Results & Discussion

The intertidal feral Pacific oyster population in the Milford Haven has not increased over the 23-year interval between surveys, at 3,209 (0.11 m^{-2}) and 2,949 (0.10 m^{-2}) in 1998 and 2021, respectively. This was despite dispersal modelling showing that oysters in the estuary could be self-recruiting to some extent, with relatively high retention of larvae within the estuary, originating from the more upstream release sites (Figure 1). We found that, given the well-mixed macrotidal conditions, seawater temperatures are only sufficient to support sporadic spawning events, with even more limited larval settlement. Sufficient degree days for maturation and spawning occurred in only 3 of the 18 years considered (1990-2018).

Maximum summer seawater temperature conditions may constrain successful settlement to fewer years than degree-day calculations, as peak temperatures rarely reach the threshold (>18-20°C) required to trigger spawning events. Low summer seawater temperatures would also be expected to support relatively low larval development and settlement success (Rico-Villa et al., 2009); in no past modelled years were total degree days sufficient for spawning and settlement. Future seawater temperatures in Milford Haven may become sufficient for more frequent spawning and settlement, although it is not possible to determine timescales for when these thresholds may be reached. While the prevailing conditions on the Welsh coast are currently at the limit for successful reproduction of Pacific oysters, projected future range expansion across NW Europe (King et al. 2021) and larval transport pathways from more southerly populations on the coasts SW England (Wood et al. 2021) may support recruitment to the south Wales coast, even while regional conditions still limit reproductive expansion.

(Continued on next page)

Introduction

Yeasts can convert organic side streams into high value protein and have become one of the most promising alternative feed ingredients for aquaculture and specifically salmonid fish (Agboola et al., 2021)extensive studies exist on the role of yeast cell wall components in modulating health responses of fish. However, research on its use as a major protein source in fish diets is still in its infancy. The current review collates, synthesises and discusses the prospects of five major yeast species as future protein ingredients with respect to their nutritional adequacy in fish. Nutritional quality of Saccharomyces cerevisiae, Cyberlindnera jadinii, Kluyveromyces marxianus, Blastobotrys adeninivorans and Wickerhamomyces anomalus and their use as replacement for fishmeal and soy protein in the diets of Atlantic salmon and rainbow trout are discussed based on three protein quality indices: chemical score, essential amino acid index and ideal protein concept based on the first limiting amino acids, methionine. The crude protein contents of yeast (40–55%. The range of side streams which may be used for yeast cultivation is broad and different yeast strains thrive in different culture conditions. *Saccharomyces cerevisiae* and most other terrestrial yeast do not tolerate high salt concentrations, rendering marine side streams unsuitable for cultivation of these yeasts. *Candida sake*, on the other hand, is a cold water marine yeast adapted to high salt concentrations and thus can utilize processing side streams of marine biomass. Similar to other yeast used as additives in feed, low levels of *C. sake* have been shown to have immune stimulating effects in the Indian prawn.

The aim of the present study was therefore to cultivate *C. sake* on herring brine (processing water of the herring industry) and to evaluate *C. sake* as a nutrient source and immunostimulant in feed for rainbow trout (*Oncorhynchus mykiss*).

The cultivation substrate was comprised of 50% pre-salting brine from North Sea herring and 10 % molasses. After freeze drying, a sub-sample of the product was exposed to an additional heat treatment (105°C). The experimental diets were formulated to substitute a fish meal-based control (C) diet with 20% *C. sake* (Y20), 20% heat-treated *C. sake* (YE20) or 3% *C. sake* (Y3). All diets were extruded, and fish were fed twice daily for 10 weeks. Measurements of weight and length were taken monthly. After finalizing the feeding trial, 61 fish from C and Y3 diet, were intraperitoneally injected with either LPS or PBS. Fish were sampled for tissue both at the end of the feeding trial and 12- and 24-hour post injection. The tissue samples included: blood, liver, head kidney, spleen, and intestinal mucosa. Additionally, samples of both proximal and distal intestine were used to assess intestinal nutrient uptake and barrier functions *in vitro*.

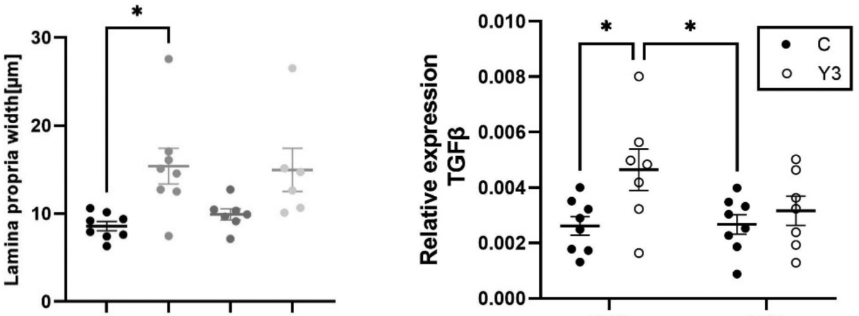

Fig 1. Left: Histological results; Average lamina propria width in distal intestine of juvenile rainbow trout fed either control (C), 3% *C. sake* (Y3), 20% *C. sake* (Y20) or 20% heat treated *C. sake* (YE20). *Right: qPCR results;* relative expression of TGFβ for rainbow trout injected with either PBS or LBS and fed either C or Y3 diet. * = p-values <0.05, bars = mean ± SE.

(Continued on next page)

Results

The *C. sake* product contained 54% protein and 13% fat including 1% DHA and 1.1% EPA. The results of the feeding trial revealed no effect on specific growth rate, feed conversion, condition factor and fat deposition in any of the diets. An increase in lamina propria width was observed in the distal intestine of fish fed the Y3 diet (Fig 1. left). Other parameters of intestinal health including other morphological measures and electrophysiology were unaffected by *C. sake* inclusion. Heat treating *C. sake* improved the apparent digestibility coefficient (ADC) of dry matter by 7% and gross energy (GE) by 2.7%, but reduced the overall amino acid ADC by ca. 3%. The ADC of *C. sake* for crude protein, crude fat, amino acids and GE was generally above 80%. LPS simulation had no effect on mRNA concentrations of selected immune genes, but increased levels of TGFβ in the 3% diet compared to the control fish were observed (Fig 1. right).

Discussion

The present study demonstrated the viability of cultivating *C. sake* on herring brine. Additional heat treatment of the yeast biomass increased dry matter and gross energy digestibility of the feed, possibly do to the rupture of long, for salmonids indigestible, polysaccharides (Agboola et al., 2021)extensive studies exist on the role of yeast cell wall components in modulating health responses of fish. However, research on its use as a major protein source in fish diets is still in its infancy. The current review collates, synthesises and discusses the prospects of five major yeast species as future protein ingredients with respect to their nutritional adequacy in fish. Nutritional quality of Saccharomyces cerevisiae, Cyberlindnera jadinii, Kluyveromyces marxianus, Blastobotrys adeninivorans and Wickerhamomyces anomalus and their use as replacement for fishmeal and soy protein in the diets of Atlantic salmon and rainbow trout are discussed based on three protein quality indices: chemical score, essential amino acid index and ideal protein concept based on the first limiting amino acids, methionine. The crude protein contents of yeast (40–55%. The amino acids content, and ADC however decreased after heat treatment indicating endothermic breakdown of amino acids. However, the heat treatment of 105°C is rather mild considering extrusion temperatures of generally above 100°C. Thus, other mechanisms causing the lower ADC may be involved. *C. sake* inclusion of 3% resulted in an increase in lamina propria width indicating immune stimulation and possibly infiltration of lymphocytes (Gisbert et al., 2013). While lamina propria width is a common histopathological indicator of intestinal inflammation (enteritis), no effect was observed in fish fed either diet with 20% yeast inclusion. This suggest that the increased lamina propria width most likely is not due to enteritis but rather a stimulation of the gut associated immune tissue. The 3% *C. sake* inclusion also increased transcription of TGFβ in the proximal intestine further suggesting an immune stimulating effect. This effect was LPS independent, and no other immune genes were affected.

Conclusion

The production of *Candida sake* using herring brine was successful and yielded a product containing over 50% protein and 3% omega-3 fatty acids. *C. sake* inclusion in feeds for rainbow trout did not affect growth and feed utilization. Due its nutrient profile and the sustainable production using industry process water, *C. sake* has great potential as an aquafeed ingredient. Downstream processing techniques increase the bioavailability of complex carbohydrate but alternative techniques, such as autolysis, may be more suitable than heat. Three percent yeast inclusion may alter gene expression and intestinal morphology. However, additional research is needed to understand the implications of these mild effects on innate immune response and disease resistance in rainbow trout.

THE REUSE OF BIOFLOC MATURE WATER IN SHRIMP CULTURE OF *Litopenaeus vannamei* IN SUPERINTENSIVE BFT SYSTEM

W, Wasiesky Jr*; K., Menestrino; L., Borges; D., Krummenauer; M, Holanda

Universidade Federal do Rio Grande, Rio Grande, Rio Grande do Sul, Brasil
E-mail: manow@mikrus.com.br

Introduction

In the biofloc technology culture system (BFT System) the water reuse, with a well-established microbial community where nitrification it is already taking place and in a presence of nitrate, is important to obtain a better stability of nitrogen compounds throughout a new production cycle. Krummenauer et al., (2014) reported that a minimum inoculum of 25% accelerated the formation of microbial aggregates in the BFT system. However, information on the minimum inoculum from the reuse of water rich in mature bioflocs is limited. The proposed of this study is evaluate the zootechnical performance and water quality parameters in treatments with different levels of inoculum (mg L^{-1}) in order to determine the minimum inoculum necessary for a rapid stabilization of nitrogen compounds in a new culture cycle of *L. vannamei*.

Material and Methods

The study lasted 45 days, until the nitrification cycle was completed in the control treatment with the detection of nitrate in the culture water. The experiment was carried out in 18 tanks with a volume of 400 liters, in six treatments, with different initial concentrations of total suspended solids (inoculum): 0 mg L^{-1}, 2.5 mg L^{-1}, 5 mg L^{-1}, 10 mg L^{-1}, 20 mg L^{-1} and 40 mg L^{-1}. During the experiment no water changes were made, unless the nitrite level exceeded 20 mg/L. In this case 30% of total volume was changed with previously chlorinated and de-chlorinated seawater. *L. vannamei* juveniles were stocked with an initial weight of 0.8g±0.1, at a density of 400 shrimp m^{-3}. The animals were fed twice a day at 08:00h and 17:00h with specific commercial ration containing 38% crude protein. The water with mature bioflocs, it means, that already had undergone the complete nitrification process until the appearance of nitrate, was collected from a raceway with *L. vannamei* culture in progress. Sugarcane molasses, with about 36% of carbon in its composition, was used as a source of organic carbon in the experimental units when the ammonia exceeded 1 mg L^{-1}.

Results

There was no significant difference between the physicochemical parameters of water, except for nitrogen. Ammonia and nitrite were higher in the control and lower in the treatments with the addition of inoculum, and nitrate showed an inverse pattern, it was lower in the control treatment and higher in the inoculum treatments (Figure 1).

More sugarcane molasses and water changes were used in the control treatment. The use of molasses was inversely proportional to the inoculum concentration, the higher the inoculum concentration, the lower the use of molasses. Regarding the zootechnical performance of shrimp, survival was lower in the control treatment, followed by the 2.5 mg L^{-1} treatment. In treatments 5, 10, 20 and 40 mg L^{-1}, survival ranged from 93 to 95%. Final weight was higher in treatments with lower survival and the opposite was observed for FCR (Feed conversion rate). Biomass and productivity were higher where inoculum was used, with better results in the 5 mg L^{-1} treatment.

Discussion

The use of a mature inoculum with a well-established nitrification process at the beginning of the culture was essential to avoid the oscillation of nitrogen compounds, as occurred in the control treatment without inoculum. This stabilization of nitrogen compounds directly reflected the better zootechnical performance of shrimp and the lower use of water and molasses to maintain water quality. Shrimp survival was low in the control treatment and 2.5, due to prolonged exposure to high concentrations of ammonia and nitrite that exceeded the safety level proposed by Lin & Chen (2001, 2003), of 3.95 mg L^{-1} and 25.7 mg L^{-1} respectively.

Conclusion

The results demonstrate that an inoculum concentration of 5 mg L^{-1} used in the starting of the culture of *L. vannamei* in a biofloc system, maintains water parameters more stable, uses fewer inputs of water and molasses and obtains a better zootechnical performance of shrimps.

Introduction

One of the limiting factors for aquaculture development is the lack of fish meal for the composition of the feeds. Biofloc Technology Culture Systems (BFT) is characterized by zero water exchange and super-intensive culture of shrimp in enclosed raceway type (Krummenauer et al., 2014). This type of system is considered environmentally friendly and avoids nutrient rich waste from polluting coastal waters. In the last years several authors have been reporting that in BFT systems is possible to decrease the total amount of protein based on fish meal in the feeds. And besides, some of these researchers have been working to decrease the fish meal concentration in the feeds (Tacon & Forster, 2003; Tacon & Metian, 2008)”given”:”Albert G J”,”non-dropping-particle”:””,”parse-names”:false,”suffix”:””},{“dropping-particle”:””,”family”:”Forster”,”given”:”Ian P”,”non-dropping-particle”:””,”parse-names”:false,”suffix”:””}],”id”:”ITEM-1”,”issued”:{“date-parts”:[[“2003”]]},”page”:”181-189”,”title”:”Aquafeeds and the environment : policy implications”,”type”:”article-journal”,”volume”:”226”},”uris”:[“http://www.mendeley.com/documents/?uuid=85e0efcf-2656-47c1-adbd-c0513ba70163”]},{“id”:”ITEM-2”,”itemData”:{“DOI”:”10.1016/j.aquaculture.2008.08.015”,”ISBN”:”0044-8486”,”ISSN”:”00448486”,”PMID”:”8800584”,”abstract”:”The finfish and crustacean aquaculture sector is still highly dependent upon marine capture fisheries for sourcing key dietary nutrient inputs, including fish meal and fish oil. This dependency is particularly strong within compound aquafeeds for farmed carnivorous finfish species and marine shrimp. Results are presented concerning the responses received from a global survey conducted between December 2006 and October 2007 concerning the use of fish meal and fish oil within compound aquafeeds using a questionnaire sent to over 800 feed manufacturers, farmers, researchers, fishery specialists, and other stakeholders in over 50 countries. On the basis of the responses received, it is estimated that in 2006 the aquaculture sector consumed 3724 thousand tonnes of fish meal (68.2% total global fish meal production in 2006. As a new strategy for shrimp production in BFT system, the present work aimed to analyze the effect of the use of a Fish Meal Analog (FMA) in shrimp feeds in substitution to Fish Meal, in the culture of *Litopenaeus vannamei* in BFT systems. The present study aims to evaluate the inclusion of different percentages (0%, 50% and 100%) of fish meal analog, formulated with by-products from the bovine and poultry industries in its composition in *L. vannamei* culture in clear water and in biofloc system.

Table 1. Means (± SD) of performance of *L. vannamei* fed with diferents levels of fishmeal analog in diets in clear water (CW) and biofloc (BFT) system

	CW0%	**CW50%**	**CW100%**	**BFT0%**	**BFT50%**	**BFT100%**

(Continued on next page)

Material and Methods

The experiment was carried out at Marine Station of Aquaculture of Federal University of Rio Grande (FURG/ Rio Grande - Brazil). The study was conducted in eighteen experimental units with 0.15 m^3 each one, for 50 days. The system used for both treatments was the water recirculation, which consists in two matrix tanks with 7 m^3 of water each one, one containing clear water (CW) and the other biofloc system (BFT), where each matrix tank supplied water to others nine tanks, totalizing six treatments in triplicate: CW0% commercial feed in clear water; CW50% commercial feed with addition of 50% fish meal analog; CW100% commercial feed with addition of 100% fish meal analog, all of these in biofloc water (BFT). The density of storage was of 400 shrimps m^{-3}, with initial weight of 1.1 ± 0.5g. The statistical method of analysis of variance (ANOVA) was used to analyze water quality and production parameters (Zar, 2010).

Results

There were no significant differences in water quality parameters among treatments. Survival was highest in the BFT100% treatment and lowest in CW0% and CW50%. Final weight was highest in clear water (CW treatments), without statistically differing from CW50%, BFT0% and BFT50%. The highest final biomass was observed in treatment BFT0, without differing from treatments BFT50%, BFT100% and CW0%. The highest yield was observed in treatment BFT0%, without differing from treatments BFT50%, BFT100% and CW0%. FCR (Feed Convertion Rate) and WGG (weekly weight gain) didn't show significant difference among treatments (Table 1).

Discussion

All water quality parameters were within acceptable standards for *L. vannamei* (Crawford et al., 1999) cultivation and the inclusion of FMA did not change this standard.The higher survival in the BFT treatments, evidences the positive effect the biofloc system has on the cultured animals (Ray, 2012). Even using the fishmeal analog at a 100% level there was no significant difference in FCR among treatments, indicating acceptability of the feed containing fish meal analog to shrimp. The set of zootechnical performance parameters indicate that the substitution of fishmeal by the fishmeal analog may be more interesting in the biofloc system than in clear water.

Conclusion

It is possible to reduce the levels of fishmeal in the feed up to 100% in biofloc system without compromising the zootechnical parameters of the *L. vannamei*, as well as the water quality of the culture system.

FISH SLUDGE – A PROBLEM OR A RESOURCE?

Steinar Wasmuth*
Bioretur AS

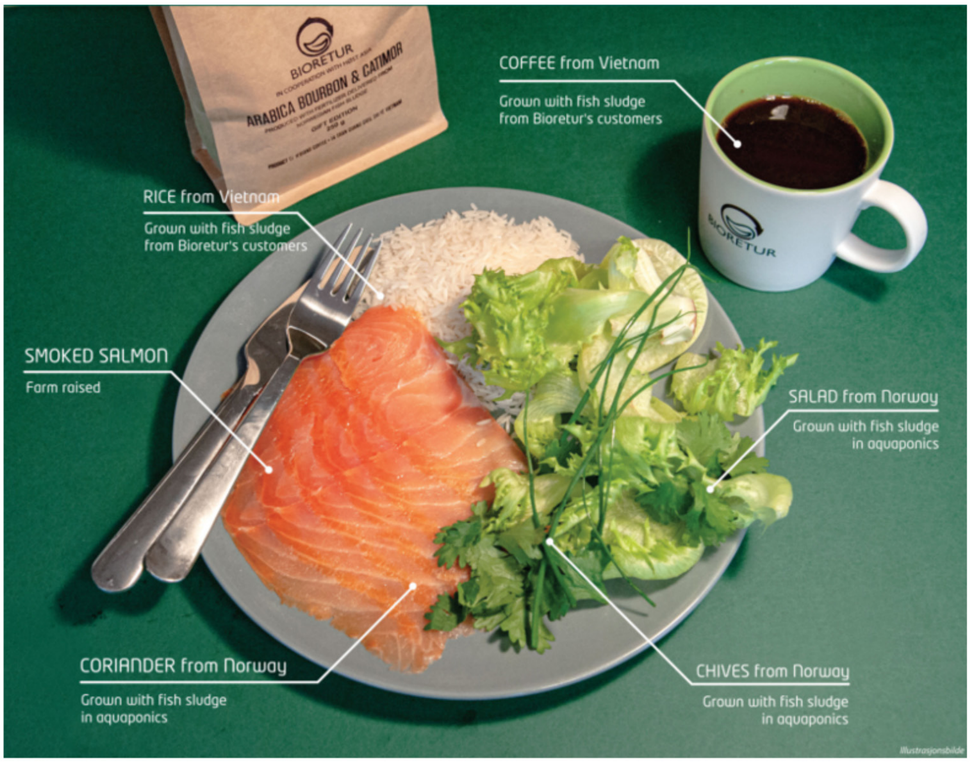
Nesttunvegen 102, 5221 Nesttun
NORWAY
steinar@bioretur.no

Fish sludge from land-based aquaculture facilities can be considered The Elephant in the Room, if this problem is not addressed and handled it can be a barrier for new land based project and further growth in marine food production. Fish sludge consists of feces and food waste from the production in the aquaculture facility, and is high on phosphates and other important minerals that is essential for sustaining life on the planet. Fish sludge also contains heavy metals such as zinc (Zn) and cadmium (Cd) and can thus not be used as is for fertilizer without special treatment and regulations. To be able to reach the climate goals, reuse of minerals such as phosphorus in a circular economy is essential, and we can simply not continue to waste thousands of tons of fish sludge every year.

Treatment of sludge in land-based aquaculture often consists of mechanical dewatering from 0,1 DS (dry solids) to around 15 % DS before it is transported to a biogas facility. Because the aquaculture sites often are far away from the biogas plants, this means transporting enormous amounts of water every year. This is highly expensive and not sustainable because it results in thousands of transport mileages. The use of fish sludge in production of biogas also results an high volumes of bio rest materials, with concentrated heavy metals.

The Norwegian company Bioretur offers a solution to the fish sluge problem and gives fish farmers access to the best available technology for sludge treatment for the aquaculture industry. At the same time they get a partner who ensures that the sludge is transformed from a problem to a sustainable resource. Bioretur are experts on sludge, and their value proposition is that for a fixed monthly fee they build, operate and maintain the technology of sludge treatment, while the client do what they do best: Produce high quality fish and seafood!

For the fist time, Steinar Wasmuth will present the Bioretur concept in EU.



PHYSICAL AND OPERATIONAL CONSTRAINTS MAPPING FOR EXPANSION OF OFFSHORE BIVALVE SHELLFISH AQUACULTURE

J. Webb[1]*, S. Ward, P. Robins[1], B Winterbourn[1], J. Thorpe[1], P. Bayford[1], S. Malham[1], J.M. Wilson[2], L. Le Vay[1]

[1]Centre for Applied Marine Sciences, School of Ocean Sciences, Bangor University, Wales, UK, [2]Deepdock Ltd, Llanfaethlu, Anglesey, Wales, UK
Email: *j.webb@bangor.ac.uk

Introduction

Increasing production and consumption of low-trophic filter-feeding shellfish could contribute to a reduction of food-related greenhouse gas emissions. However, on the supply side, there are many barriers to increasing low trophic marine aquaculture production, including the availability of suitable sites, competition for densely-used inshore waters, sufficient water quality, and regulatory hurdles. Expansion of aquaculture into more exposed coastal sites and more distant offshore waters represents an opportunity for a step change in production, particularly for low-trophic species (Krause *et al*. 2022). While global estimates of potential space available for offshore aquaculture development may be optimistic (e.g., 1,500,000 km^2 for bivalve shellfish production, Gentry *et al*. 2017), access to suitable offshore space will also be subject to a wide range of constraints. Offshore aquaculture development in European waters remains in its early stages, despite several pioneering R&D projects and successful commercial innovation at a range of sites. Both investment decisions and effective marine spatial planning for offshore expansion require an understanding of technical constraints in relation to environmental conditions. We have undertaken a characterisation of the hydrodynamics of UK and adjacent waters relevant for offshore mussel farms and mapped the sea space that is potentially suitable. Given the uncertainty regarding future technical innovation and how this may change operational constraints, we focused on the sub-surface suspended longline systems that are currently widely used in open water shellfish aquaculture.

Methods

Two approaches were applied to identify technical constraint criteria related to submerged mussel longline systems. Data were extracted from published literature identified in a systematic review, following CEE Guidelines for Systematic Reviews in Environmental Management and conducted using Web of Science Core Collection (1970-present). The identified set of key terms referring to offshore bivalve aquaculture were: 'offshore', 'suspended', 'longline' and 'open ocean'. Of 1,029 results, 101 were retained following the application of eligibility and exclusion criteria. Industry expert knowledge was also captured using a questionnaire approach. We surveyed shellfish producers globally to quantify key physical constraints to the installation and operation of commercial shellfish production in exposed and offshore conditions, using sub-surface suspended long-line systems. Based on the results of these approaches, quantification of physical hydrodynamic constraints (e.g., water depth, tidal currents, wave conditions) were combined with key operational constraints, to identify and map potentially suitable areas for shellfish culture around the UK coast.

Results

Review of literature data and operator expert knowledge yielded upper, and in some case lower, values for each environmental variable, giving a range within which existing farms are currently installed and successfully operated. The questionnaire also explored expert knowledge on upper limits that could constrain future expansion to more offshore/exposed sites. The results map a range of scenarios for the potential areas suitable for future expansion (see Figure 1 for an example scenario), testing their sensitivity to the various physical variables applied to the models and their interactions.

(Continued on next page)

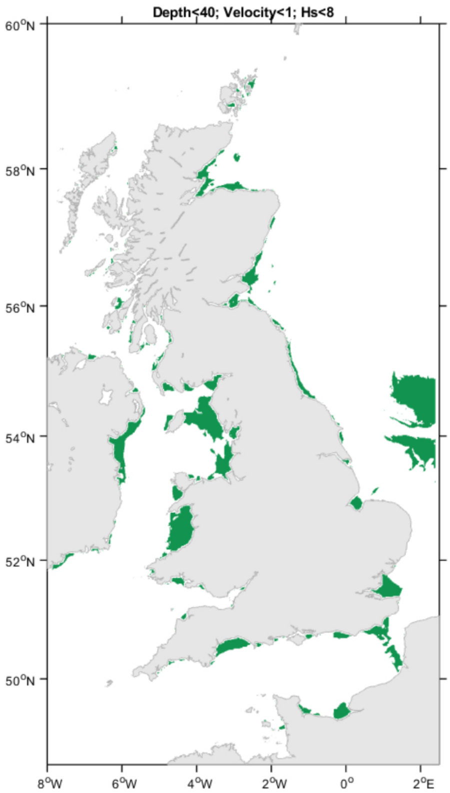


Figure 1. Example of suitable marine space available for offshore mussel longlines (green area) based on three physical constraints only; water depth <40 m LAT, tidal current velocity < 1ms^{-1} and annual peak significant wave height <8 m. In the poster, we present mapping outcomes based on a range of constraint limits and their interactions, showing the sensitivity of modelled outcomes in terms of available suitable space.

HIGH QUALITY EARLY NUTRITION AS A STRATEGY FOR A PRODUCTIVE AQUACULTURE

D. Weissman*[1], T. Raynaud[2]

ADM, Research & Application for Aquaculture, France
ADM Bernaqua/Epicore, Head of Product Management, France
Email : delphine.weissman@adm.com

Early stage in life is a crucial step in fish development and impacts fish quality during their whole lifespan. As a consequence, this period must be managed very carefully. High quality nutrition during hatchery and nursery stage is part of the strategy to maximize fish performance. The ambition to improve aquaculture productivity up to harvest already starts in newly hatched fish.

In many species, it was demonstrated that nutrition at early stage impacts phenotypes during the entire lifespan. For example, piglets weaned too early (Dunshea et al., 2003) or trouts fed too fatty diets in the young phase (Alami-Durante et al., 2014) have their phenotypes modified at slaughtering with fatter body. In addition, key developments of organs happen in early life (Fujimura and Okada, 2007). That's why it is necessary to bring the right nutrients in sufficient amount during this phase. Muscle also starts to be built early in life and nutrition favoring a good muscle structure will promote larger body weight at harvest (Kiesslingetal et al., 2006). Even if the period remains short in comparison to an entire life cycle, the importance of a high quality nutrition should not be minimized as it is part of the strategy to prepare the future of the fish.

In order to demonstrate this statement, an experiment was conducted on tilapia during 236 days, starting from the first feeding. In this experiment, only the feed used during the first month of feeding was modified. One group was fed with a micro-extruded feed produced by marumerisation technology and the second group was fed a standard crumble feed during that period. The two groups were managed the same way and fed the same feed for the rest of the trial. A huge difference in live weight was observed after the first month since live weight was 3.17g and 0.52g ($P<0.0001$) in the groups fed the micro-extruded feed and the crumble feed respectively. The feed fed during the first month not only impacted performances during this period, but also performances up to harvest. Final live weight reached 797g and 683g ($P<0.0001$) after 236 days and fillet yield was 37.1% and 34.5% ($P<0.0001$) in the groups fed the micro-extruded feed and the crumble feed respectively. Survival was also strongly impacted. The benefit of micro-extruded feed using marumerisation technology on fish performances during the first month can be explained by a higher digestibility of the feed, a better stability in water and the possibility to feed the right pellet size adapted to fish mouth size while fish are growing. The benefit observed beyond is clear but needs to be further investigated. It might come from a better development of the fish at early stage leading to more resilient and more efficient animals. This experiment illustrates how the feeding management on the first month of life in tilapia can strongly affects fish performances during this first month and also how it impacts fish performances until harvest, 7 months later.

The importance of early feeding demonstrates why investment on high quality feeds at larvae and juvenile stages is part of the strategy to improve aquaculture productivity. With a positive effect on production efficiency, it is also supporting the reduction of the environmental footprint of the industry. Diversity in farmed aqua species requires early stage feeds to be specifically designed and formulated according to the requirements of each specie including shrimp, freshwater fish, marine fish and salmonid species to ensure precise nutrition.

CONCERNS, CONFLICTS AND CONTROVERSY: UNDERSTANDING DRIVERS OF SOCIAL ACCEPTANCE OF SALMON AQUACULTURE IN NOVA SCOTIA, CANADA

J. Weitzman*, R. Filgueira, J. Grant

Dalhousie University, Halifax, Nova Scotia, B3H4R2 (Canada)
Email: jenny.weitzman@dal.ca

Introduction

Salmon aquaculture is a publicly controversial issue in Canada, with strong opposition being mobilized by certain groups such as environmental NGOs, fishing groups, and residents. Understanding social aspects are increasingly being recognized as important for more sustainable aquaculture management, fostering public trust and creating a positive environment for the growth of the industry (e.g., Krause et al., 2020). The present study was conducted to better understand public perceptions and opinions and identify factors influencing societal attitudes toward salmon farming, using Nova Scotia, Canada as a case study. This study investigated both public and community acceptance to help develop a framework of factors influencing social response to salmon farming.

Methods

This work is supported by two approaches. First, an online public survey aimed to capture the views and opinions of 495 Nova Scotians towards salmon farming. Describe statistics explored the influence of potential motivators on public opinion, including location, individual characteristics, personal value systems, exposure, trust, and perception of risks. Then, an ordinal regression model was fit to identify the most influential factor predicting more negative attitudes to aquaculture. The second approach conducted qualitative interviews with 24 participants across various interest groups within three salmon-farming communities in Nova Scotia to provide a comparative analysis of how locals have experienced aquaculture and identify common dimensions of conflict and controversy. Qualitative coding identified major themes in how locals perceive aquaculture. Major themes were compared across case study areas and across different perspectives on salmon farming.

Results

Survey results reflect a sample of the population largely in opposition, both towards salmon aquaculture as an industry and towards local development in the province. Rural and urban respondents were significantly different in their perceptions and opinions of aquaculture. Models identified five major drivers best predicting more negative views of aquaculture, including: age, environmental value system, salmon consumption patterns, trust in government, and perception of risks. Knowledge and exposure had little influence on opinion but may still help people who are undecided make decisions.

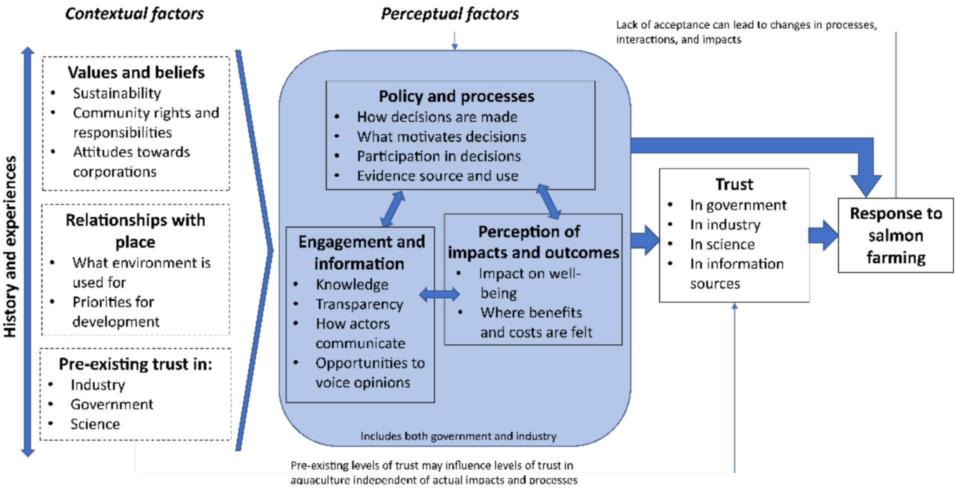

Fig 1. Framework of factors and feedbacks influencing public response (acceptance or opposition) to salmon farming.

(Continued on next page)

Findings from interviews with locals across three salmon-farming communities in Nova Scotia revealed a range of perspectives, experiences, and priorities toward salmon farming. Differences between case study areas revealed that perceptions about salmon farming reflected context-specific differences in history, relationships with place, and wider environmental and social values. Four distinct perspectives towards salmon farming emerged explaining the arguments and perceptions of participants. Contention emerged between the arguments made by supporters and opponents around the role salmon aquaculture plays including as a food system, as a tenant of the environment, as an economic provider, as a user of marine space, and how all are considered in the realm of aquaculture as a system to be governed. Perceptions across case study areas and different perspectives on salmon farming were synthesized to describe a conceptual framework of influencing factors on the social response to salmon farming (Fig 1). Across participants, the issue of trust emerged as a strong predictor of their response to salmon farming. Both trust and public response were dependent on perceptions across three core dimensions related to: 1) how decisions are made, 2) how stakeholders are engaged and informed, and 3) how benefits and costs from aquaculture are distributed.

Discussion

Drawing from this work, we find that social concerns about salmon aquaculture revolve not only around material (e.g., economic) well-being, but highlight the specific importance of relational well-being, being the relationships with family, community, and their environment. This work reveals how perceptions and attitudes are multifaceted, based on arguments around the multiple roles of aquaculture and how it is governed. Multiple perspectives highlight a complex and multi-faceted controversy around salmon farming recognized around the world (Young et al., 2019). Social acceptance of salmon aquaculture is highly tied to public trust and concerns over how the industry is managed. Still, findings reveal that opinion is nuanced across demographic and geographic contexts. Differences across rural and urban areas highlight the need to incorporate both perspectives in understanding conflicts and fostering acceptance. In summary, opposition does not represent a uniform set of experiences, concerns, or conflicts. Responding to opposition will require considering this variability and considering the underlying personal, social, and geographic contexts in which they are embedded.

NOT A QUESTION OF HOW MUCH, BUT OF HOW AND WHERE: REDEFINING CARRYING CAPACITY FOR HOLISTIC ASSESSMENT OF AQUACULTURE

J. Weitzman*, R. Filgueira, J. Grant

Dalhousie University, Halifax, Nova Scotia, B3H4R2 (Canada)
Email: jenny.weitzman@dal.ca

Introduction

As food demands and priorities for aquaculture expansion increase around the world, conflicts around siting, planning, and management have become increasingly complex and require more holistic, integrated approaches to ensure sustainable environmental, social and economic outcomes. The Ecosystem Approach to Aquaculture (EAA) (Soto et al., 2008) outlines a management approach for aquaculture based on promoting equity and resilience of interlinked social and ecological systems. To do so, carrying capacity assessments have been proposed as a useful decision-support tool that could operationalize more interdisciplinary holistic assessments in support of an EAA (Ross et al., 2013). While traditionally carrying capacity for aquaculture is described to be how much aquaculture can be developed without unacceptable impacts on the environment, modern definitions also distinguish that it can be applied to study both physical, production, ecological, and social aspects. A better understanding of how carrying capacity could be developed for holistic assessment of aquaculture can help work toward more effective planning and decision-making in support of sustainable aquaculture governance and an EAA.

Approach

Here we present the results of a research program seeking to define a framework for a holistic assessment of salmon aquaculture. Broadly, the overarching goal of this research was to test whether carrying capacity can be operationalized towards more holistic management and planning. To do so, this work first conducted a comprehensive literature review on carrying capacity to explore the theoretical opportunities to mobilize the concept. Second, best-practice guidelines and recommendations were developed through Delphi consultation with expert practitioners and researchers from around the world. In light of research gaps on social aspects of carrying capacity related to social acceptance, this research also sought to understand the factors driving public and community perceptions of aquaculture, using Nova Scotia, Canada as a case study. Surveys with urban and rural residents across Nova Scotia investigated variables on public opinion to salmon farming, while interviews with residents and local stakeholders across three coastal communities in Nova Scotia explored how variables related to local context and experiences with salmon farming influenced perceptions. Findings across this research program were synthesized to develop a conceptual framework for holistic assessments of aquaculture limits.

Findings

Literature revealed that aligning carrying capacity concepts to more holistic management approaches require an approach that recognizes system complexity, responds to policy needs, applies adaptive frameworks, embraces interdisciplinarity, and curates meaningful information (Weitzman and Filgueira, 2019). In addition to the above, expert best-practices further emphasized the need for clear processes that include all relevant stakeholders (Weitzman et al., 2021). Expert consensus revealed a number of conceptual and knowledge barriers, especially around defining and understanding socio-economic limits and indicators. Results from public survey and interviews revealed differences in perceptions across demographic and geographic contexts. Perceptions also varied across contextual differences in history and experience with aquaculture, relationships with place, and environmental value orientation. The findings from this work revealed trust as a key indicator of social response to aquaculture. Expressions of trust and opinion were multifaceted but linked to arguments around perception of risks and benefits, interactions and knowledge of aquaculture, and procedures and processes.

(Continued on next page)

A way forward

Finding from this work highlight substantial theoretical and practical barriers to applying carrying capacity to more holistic, ecosystem-based management of aquaculture. This research argues that carrying capacity limits are inherently socially determined and thus a critical question of social carrying capacity. Recognizing that social aspects were a major roadblock for holistic approaches to carrying capacity, this research presents a definition of social carrying capacity for aquaculture. Social acceptance research argues that limits of aquaculture determined by society revolve not around a question of how much, but rather reflects a complex discourse around how the industry is managed and where benefits and risks are felt. Therefore, questions of aquaculture limits need to consider not only industry operations and impacts, but also the policies and procedures, and how society is involved and engaged. This, in combination with institutional and procedural barriers suggests that a comprehensive approach to carrying capacity assessment as a tool to further EAA may not be relevant, realistic, or appropriate.

Yet, this research presents a way forward to mobilize the intention and principles behind comprehensive carrying capacity by shifting towards a policy and decision-making lens that reflects more holistic consideration of 'Acceptable Limits of Aquaculture (ALA)'. Rather than replacing carrying capacity assessments, this lens aims to supplement it while adapting a more holistic vision for aquaculture management that accounts for an integrated view of ecological, social, and economic limits.

HOLISTIC APPROACH TOWARDS SAFE AND SUSTAINABLE AQUACULTURE SUPPLY CHAIN

Valeska Weymann

GLOBALG.A.P. Secretariat c/o FoodPLUS GmbH
Spichernstrasse 55
50672 Cologne, Germany
weymann@globalgap.org

OPTIMAL GUIDE TO PRODUCERS FOR GOOD AQUACULTURE PRACTICES AT ALL STAGES OF PRODUCTION

The tendencies on the global markets have been transforming and determining the demand for farmed seafood.

The GLOBALG.A.P. Aquaculture Standard version 6 brings to the market a complete solution for buyers and suppliers, based on current market demands, covering the key sustainability aspects that the animal production for human consumption is required to achieve. Operating since 2004, certified farms feedback reflects that this certification turns into a practical guide to their operations through detailed criteria written in a friendly and clear manner satisfying GLOBALG.A.P. purpose on working hand in hand with producers.

Although the ultimate goal is to obtain certification, the standard is the best tool the aquaculture sector can adopt to properly manage their operations. Currently there are 38 species certified for the finfish, crustaceans, and molluscs with coverage at all continents.

The aspects covered are those stipulated by the FAO Technical Guidelines on Aquaculture certification. With strong governance reliability, including the robust Integrity Program. This pioneering program is the first of its kind in food certification and is designed to ensure consistent delivery and implementation of the standard worldwide. It acts as a feedback mechanism that serves the ongoing improvement of the GLOBALG.A.P. System in all its aspects, promoting transparency and integrity.

The key elements of the GLOBALG.A.P. Aquaculture standard are currently recognized and evaluated.

- Food safety: is the ONLY certification scheme recognized by the Global Food Safety Initiative – GFSI for farming of fish.
- Environment: recognized by the Global Seafood Sustainability Initiative – GSSI Apr 2018.
- Animal Health: the OIE Aquatic Animal Health Code criteria for farms is covered by the standard. The robust Aquaculture Health Plan requirements is a reliable backing that farms give value.
- Animal Welfare: on top of animal health, GLOBALG.A.P. Aquaculture has been recognized as the only international private standard outside the UK that covers animal welfare practices at harvest and slaughter. Further animal welfare innovative criteria is spread for all production stages.
- Workers Occupational Health & Safety: workers are key to efficient operations, appropriate training is included in the requirements.
- Workers Welfare: GLOBALG.A.P. Risk Assessment on Social Practices is compulsory to assess.
- Compound feed used at certified farms shall be verified against the feed safety, responsible sourcing of feed materials, environmental and social criteria stipulated in the recently launched version 3.

The scope covers full production chain verification of: Broodstock, Seedlings, Feed, Farming Post harvest activities up to the point of sale for final consumers.

B2C communication: since the launch of the GGN Certified Aquaculture Label in 2016, the number of labelled products in the market have been doubling every year. The label can be found in many European countries as well as North America and Asia.

GLOBALG.A.P. As a member-based organization, counts with the support of retailer and food service members, supplier members and associate members. Retail members are committed to support safe and sustainable supply at primary production level.

The presentation intends to share to the audience the upgraded holistic approach for both GLOBALG.A.P. Aquaculture and Compound Feed Manufacturing standards.

IMMUNOMODULATATION OF FISH HEALTH BY BETA-GLUCANS

Geert F. Wiegertjes*, Jules Petit

Aquaculture and Fisheries group, Wageningen University & Research, The Netherlands
geert.wiegertjes@wur.nl

Direct effects of β-glucans

Dietary supplementation of fish with β-glucans is commonly associated with immune modulation and is often considered beneficial for fish health. The exact mechanisms of immunomodulation by β-glucans in fish are stull under debate, however. The prototypical C-type lectin receptor (CLR) named Dectin-1 which directly senses the presence of β-glucans in mammals, appears missing from fish genomes. In our studies on common carp, direct immunomodulating effects of β-glucans on macrophages exist, at least *in vitro*, and could be the result of signalling mediated by one or more candidate β-glucan receptors, all members of the CLR family. Also, β-glucan-induced regulation of gene expression profiles typical of the CLR signalling pathway confirm C-type lectin receptors could indeed play a role in the direct sensing of β-glucans in fish.

Long-lived effects on innate immunity

Trained immunity is a form of innate immune memory which can possibly be induced by feeding β-glucans. Given the evolutionary position of fish as early vertebrates with a fully developed immune system, trained immunity should apply and include the ability of fish macrophages to mount heightened responses to a secondary stimulus in a non-specific manner. At least *in vitro*, carp macrophages can indeed be trained by β-glucans. Trained unstimulated macrophages display evidence of metabolic reprogramming as well as heightened phagocytosis and increased expression of the pro-inflammatory cytokines. Trained and re-stimulated macrophages showed heightened production of reactive oxygen and nitrogen species. Trained immunity could play a role in long term health-promoting effects of β-glucans in fish, but requires *in vivo* evidence, which is difficult to provide outside the laboratory.

Indirect effects of short chain fatty acids

Accumulating evidence supports a role for intestinal microbiota and their metabolites in the immunomodulatory effects of β-glucans. Yet, a proven relation in fish between types of diets including β-glucans, and immunomodulation *via* intestinal microbiota and associated metabolites requires more detailed investigations. Initial 16S rRNA sequencing of the active naive microbiota of carp intestine suggests the presence of bacteria with the capacity to degrade and ferment carbohydrates. This suggests that carp intestinal microbiota can ferment dietary β-glucans, a process leading to the production of short-chain fatty acids (SCFA). This important class of metabolites has been shown to affect the mammalian immune system in different ways. We could show that SCFA such as acetate, butyrate, and propionate, have immunomodulatory effects on carp leukocytes, including nitric oxide production and expression of several cytokines, at least *in vitro*.

Role of short chain fatty acid receptors

Not only *in vitro* data but also preliminary *in vivo* observations provide support to a role of SCFA in β-glucan-induced immunomodulation. A single oral gavage of carp with β-glucans modulated the local expression in the intestine of putative SCFA receptors. This could help explain immunomodulation by β-glucan *via* SCFA receptors present on intestinal leukocytes. In mammals, SCFAs can affect host cells via ligation to G-protein coupled receptors (GPR). Using genomic resources and cDNA cloning we identified several coding sequences for *gpr40*-like genes of carp. Phylogenetic analysis shows the carp *gpr40L* genes have a closer phylogenetic relationship to mammalian GPR43 than to mammalian GPR41.

Future developments

A first *in silico* screen of genomes of 25 different fish species largely confirms the observations for *gpr40L* of carp with regards to both, subdivision in three subclasses and conservation of synteny. Our data provide a further step towards an understanding of the function of SCFA receptors and their role in immunomodulation by β-glucans in fish.

THE MOVE TOWARDS CIRCULARITY

Geert Wiegertjes, Yolanda Morales, Roy Koushik, Brian Thomsen

Wageningen University

The Circular Economy and its related Action Plan is high on the European political agenda and the subject of several research initiatives. But how does policy translate to practice and what does circularity really mean for aquaculture? Moderated by Geert Wiegertjes of Wageningen University, this panel discussion will address important questions that need answers, if this concept is to be enshrined in European aquaculture production practices. Panellists: Yolanda Morales, Roy Koushik and Brian Thomsen.

Geert Wiegertjes is professor of the Aquaculture and Fisheries group at Wageningen University, the Netherlands. As head of the research group, his scientific interest in the interaction between fish nutrition and health has broadened to include the multiple aspects of sustainable aquaculture. In his TEDx talk of 2020 he underscored the need for a sustainable production of fish and shellfish products in a world where demands for seafood keep rising. Geert Wiegertjes has been project coordinator and/or training coordinator of three MSCA training networks (FP5, FP7) and work package leader of Imaquanim (FP6), ParaFishControl (H2020) and currently, AQUA-FAANG (H2020). He coordinated TargetFish (FP7), one of the larger research consortia on fish health and vaccination. This year (2022), he announced the Wageningen University & Research (WUR)-wide ambition for WUR to be a major player on research and education in aquaculture and launched Wageningen Aquaculture Research & Education (W-ARE).

Yolanda Morales – ACUIPlus

Yolanda Morales is the manager of the ACUIPLUS cluster in Spain. ACUIPLUS is a group of companies and other stakeholders that promote the competitiveness and sustainability of the value chain of suppliers, including both products and services, and strengthening commercial, research, and innovation processes. and sustainability. ACUIPLUS supports its partners both nationally and internationally, promoting successful strategies, both individually and collectively.

Yolanda has a degree in Business Management and Administration and Master's Degree in International Studies. Her expertise includes revitalizing rural and coastal areas, formulation and implementation of projects in pursuit of rural productive development and the preparation of feasibility studies, market and sectoral strategic plans for economic growth. She is also an expert in design and implementation of CSR policies.

Roy Koushik - University of South Bohemia

Roy Koushik is a circular and sustainable aquaculture system biologist concentrating on the issues of improved resource (nutrients, biomass) use efficiency of Central European fishponds, intensive aquaculture, and farm-to-fork. Presently employed at FROV, University of South Bohemia in Ceske Budejovice.

His expertise includes aquatic animal nutrition, aquaculture environment interactions, climate change, and inland fisheries. He grew up in West Bengal (India) where 'fish for food security' and 'resource circularity for economic reasons' have historical roots.

Brian Thomsen - Danish Aquaculture Organisation

Brian Thomsen is the Director of The Danish Aquaculture Organisation and also holds positions as a member of the Committee for Monitoring the Danish EMFA program, member of the Advisory Board at the National Institute of Aquatic Resources (DTU Aqua), chairman of Agri-Aqua Innovation Denmark and board member of the Danish Seafood Council.

He facilitates and represents aquaculture producers in key European organisations, as Chair of Working Group 3 (Horizontal Issues) of the EU Aquaculture Advisory Council and as Vice-president of the Federation of European Aquaculture producers (FEAP).

Brian has an MSc in chemistry (Technical University of Denmark), an MBA (Heriot-Watt University, Edinburg) an EBA (Via University College, Horsens) and is a Graduate Diploma in Business Organization and Management (Aarhus BSS).

CONCERNS AND RESEARCH PRIORITIES FOR THE WELFARE OF SCOTTISH FARMED ATLANTIC SALMON *Salmo salar* – AN INDUSTRY PERSPECTVE

Timothy R. Wiese*[1], Jimmy F. Turnbull[1], Marie J. Haskell[2], Susan Jarvis[3], Sonia R. Planellas[1]

[1]: Institute of Aquaculture, University of Stirling, Stirling, FK9 4LA, UK.
[2]: (SRUC (Scotland's Rural College),West Mains Road, Edinburgh, EH9 3JG, UK
[3]: Roslin Institute, University of Edinburgh, Midlothian, EH25 9RG, UK.
E-mail: trw1@stir.ac.uk

1. Introduction

Farmed salmon welfare is inextricably linked to the farming practices and conditions within the salmon farming industry (FAWC, 2014; Noble *et al.*, 2018). The intensification of Scottish salmon farming has been associated with increasing demands for the monitoring and safeguarding of farmed salmon welfare. Continued growth of farm productivity, while avoiding adverse effects on salmon welfare, will require the development of effective and time-efficient welfare assessment tools. Farming of Atlantic salmon involves rearing conditions, husbandry practices, responsibilities and welfare considerations that are specific to each production stage (Bergqvist and Gunnarsson, 2013; Noble *et al.*, 2018). When forming opinions on welfare concerns within this context, on-site experience of these various stages can provide important perspectives on current practices and the relevant challenges that are faced. This study involves a survey of the Scottish salmon farming industry, which was conducted to understand current salmon welfare concerns and priorities for research. The survey intentionally focused on industry stakeholders to provide insights into current practices and challenges associated with monitoring and assessing salmon welfare. This survey presents the first collection of opinions from professionals employed across the Scottish salmon farming industry regarding the current state of farmed salmon welfare, and where future research can best benefit salmon welfare and farm productivity.

2. Materials and methods

Multiple iterations of the questionnaire were first piloted through key informant interviews, both in-person and online. The final questionnaire, consisting of 53 questions divided into 6 separate question sections was carried out online. Background variables of participants were also recorded. A total of 61 individuals working in the Scottish salmon farming sector were recruited through the authors' industry contacts, online advertisements, and company mailing lists for the final survey. Participation was also voluntary. Various topics relating to the current state of Scottish farmed Atlantic salmon were investigated, including participants' largest welfare concerns, husbandry practices requiring the most attention for safeguarding salmon welfare, rating the suitability of current welfare measures for on-farm use, and rating the need for certain research priorities specific to on-farm welfare monitoring. For 3 of the question sections, participants were allowed to list and rank their own open-ended responses to prevent bias being introduced to the survey through limiting their responses. For question sections investigating more specific topics, questions were strictly quantitative (either through ratings or rankings) to allow for more in-depth statistical analyses to be carried out using IBM SPSS Statistics. Participants were also allowed to provide comments in addition to their ratings, which were used in a thematic analysis carried out in Nvivo. Where there was no clear consensus in responses to question sections across all participants, we assessed whether any difference in responses were significantly correlated with participants' professional backgrounds.

3. Results

The survey results highlighted the multitude of considerations that have to be made when monitoring and safeguarding salmon welfare. Participants have identified key areas of focus for salmon welfare specific to each major production stage and husbandry practice. Sea lice, gill health, and environmental challenges were of particular importance (Fig. 1 below). The results from this survey have also demonstrated the importance of using an integrated approach to welfare assessments that combines behavioural, physiological, and production-based parameters. Non-invasive, remote monitoring was identified as a priority for further development in welfare assessments, owing to their practical advantages and limited impacts on salmon welfare. Although behavioural measures were highlighted as one of the promising candidates for this role, participants noted that there are still many challenges (both practically and theoretically) that any animal-based welfare measures face. This study has helped highlight how newly developed welfare measures will only be adopted if balanced against the cost of their use.

OPPORTUNITIES AND CHALLENGES FOR UPSCALED GLOBAL BIVALVE SEAFOOD PRODUCTION

David F. Willer*[1], Richard J. Nicholls[2], and David C. Aldridge[1]

[1] Department of Zoology, University of Cambridge, Cambridge, UK
[2] Nomad Foods Europe Limited, Lowestoft, UK
Email: dw460@cam.ac.uk

Summary

Slow growth in the bivalve mariculture sector results from production inefficiencies, food safety concerns, limited availability of convenience products and low consumer demand. Here we assess whether bivalves could meet mass-market seafood demand across the bivalve value chain. We explore how bivalve production could become more efficient, strategies for increasing edible meat yield and how food safety could be improved through food processing technologies and new depuration innovations. Finally, we examine barriers to consumer uptake, such as food allergen prevalence and bivalve preparation challenges, high- lighting that appealing and convenient bivalve food products could provide consumers with nutritious and sustainable seafood options—and contribute positively to global food systems.

This abstract is based upon our recent publication in *Nature Food*, alongside unpublished data from research we have been carrying out with leading academics and global food companies. Please see Willer, D. F., Nicholls, R. J. & Aldridge, D. C. Opportunities and challenges for upscaled global bivalve seafood production. Nat Food 2, 935–943 (2021).

Benefits of unfed bivalve mariculture

To assess the sustainability and nutritional merits of bivalves relative to a current mass-market seafood, we compare bivalves with cod and Alaska pollock, alongside tuna (yellowfin and skip- jack). These wild-caught fish are already a proven resource and will continue to be a key component of consumer seafood, but supply is limited and global food companies are interested in how alternatives for filling the demand gap, such as bivalves, directly compare. In depth sustainability and nutritional analyses will be presented in the oral presentation alongside visual illustration.

Production

We discuss three key challenges to upscaling bivalve production: providing adequate volumes, maintaining sustainability, and ensuring food safety. We outline the emerging opportunities to tackle these challenges. These include new bivalve breeding approaches, feed technologies and grow-out practices; shell valorisation, the use of new species and sustainability regulations; and new depuration approaches including antimicrobial peptides, bacteriophages and chelating agents. We present several figures, including Figure 1, which outline the potential for production increases.

Food Processing

Bringing bivalve-based foods to the mass market will require creating bivalve products that can be easily and safely stored, distributed and purchased by consumers. We discuss the key challenges and opportunities in producing the major types of bivalve food products: fresh in-shell products, frozen de-shelled products, and cooked processed products. These are briefly outlined in Figure 2.

Consumer Uptake

We consider the key barriers to driving increased consumption of bivalves by the mass market and discuss the key opportunities to meet these challenges. We present the results of a consumer survey carried out with Europe's largest frozen food company (Nomad Foods) which can help us understand how to increase mass market demand. These results are compared with other global studies.

Conclusion

Demand for seafood is growing at double the rate of the global population, requiring nutritious seafood to be delivered to this mass market while avoiding damage to ecosystems through overfishing or poorly managed aquaculture. We discuss how through new innovation across production, food processing, and consumer uptake, bivalve shellfish can help meet this consumer demand.

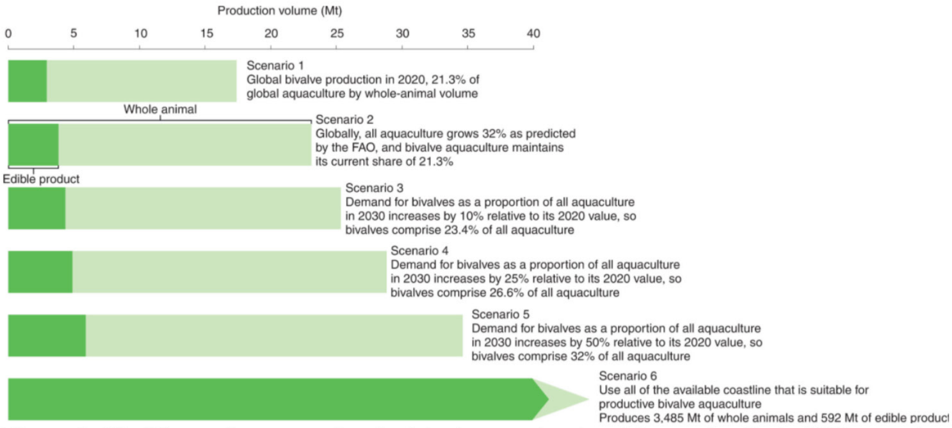

Figure 1. Six illustrative scenarios for bivalve production. Figure details in Willer et al. *Nature Food* 2021.

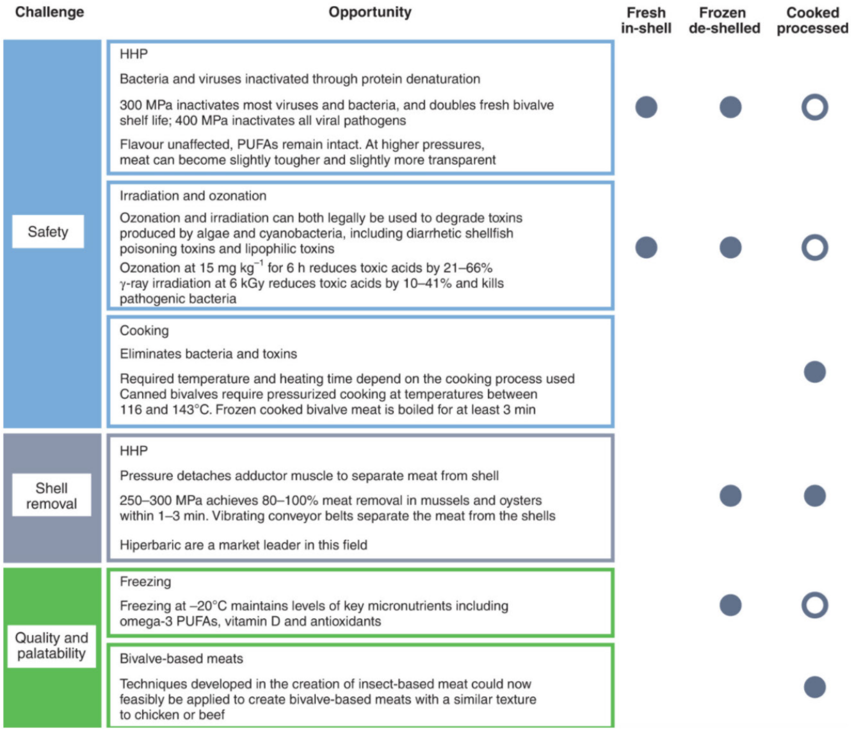

Challenge	Opportunity	Fresh in-shell	Frozen de-shelled	Cooked processed
Safety	HHP Bacteria and viruses inactivated through protein denaturation 300 MPa inactivates most viruses and bacteria, and doubles fresh bivalve shelf life; 400 MPa inactivates all viral pathogens Flavour unaffected, PUFAs remain intact. At higher pressures, meat can become slightly tougher and slightly more transparent	●	●	○
	Irradiation and ozonation Ozonation and irradiation can both legally be used to degrade toxins produced by algae and cyanobacteria, including diarrhetic shellfish poisoning toxins and lipophilic toxins Ozonation at 15 mg kg^{-1} for 6 h reduces toxic acids by 21–66% γ-ray irradiation at 6 kGy reduces toxic acids by 10–41% and kills pathogenic bacteria	●	●	○
	Cooking Eliminates bacteria and toxins Required temperature and heating time depend on the cooking process used Canned bivalves require pressurized cooking at temperatures between 116 and 143°C. Frozen cooked bivalve meat is boiled for at least 3 min			●
Shell removal	HHP Pressure detaches adductor muscle to separate meat from shell 250–300 MPa achieves 80–100% meat removal in mussels and oysters within 1–3 min. Vibrating conveyor belts separate the meat from the shells Hiperbaric are a market leader in this field		●	●
Quality and palatability	Freezing Freezing at –20°C maintains levels of key micronutrients including omega-3 PUFAs, vitamin D and antioxidants		●	○
	Bivalve-based meats Techniques developed in the creation of insect-based meat could now feasibly be applied to create bivalve-based meats with a similar texture to chicken or beef			●

Introduction

Human food production contributes nearly 20% to global greenhouse gas emissions. Diet choices can significantly influence these greenhouse gas emissions. The environmental footprint of aquaculture largely depends on the production method and species cultured. In Europe, rainbow trout *Oncorhynchus* mykiss is one of the main species farmed while land-based flow-throug systems are the predominant production form. By using the streams natural hydraulic gradient such systems are considered to be relatively energy efficient compared to RAS.

In the recent study the ecological footprint of trout production in the temperate climate zone with respect to global warming potential, eutrophication potential, acidification potential, and ozone layer depletion was investigated. Data was collected under the typical farm framework and a cradle-to-gate life cycle assessment was conducted to find the processes contributing the most to the emissions of a typical trout farm. Two further scenarios were than analyzed, with either differing components in the fish feed or a differing amount of photovoltaic systems used on farm.

Material and methods

To estimate the environmental impact of 1 kg live weight (LW) rainbow trout in a traditional flow-through system four impact categories were analyzed: Global warming potential (GWP), Ozone layer depletion (ODP), Acidification (AP) and Eutrophication potential (EP). The impact categories were chosen due to their direct effect not only on the environment but also on human health. Data, which originated from a typical trout farm in South Germany, was considered with respect to energy and material flows. The model farm rears rainbow trout *Oncorhynchus mykiss* from egg to market size in three different river systems. ~500tonnes of trout are produced per year.

The chosen impact categories were analyzed with the software program SimaPro 9.1.1.1, using the CMLIA baseline/EU 25 method. Furthermore, the databases Ecoinvent v. 3.6, Agrifootprint v. 5.0, and Agribalyse v. 3.0 were used. To test for uncertainties, a Monte-Carlo simulation was run in SimaPro with 5000 runs to the 95th confidence interval

The model farm uses feed with 35% fishmeal and ~8% of the production site is covered with photovoltaic systems. The FCR of the fed feed is 0.89 (farmer's calculation)

For the analyses two further models were created. One scenario considering either no fishmeal (No FM) or 61.8% fishmeal (61.8% FM) in the feed, compared to the current model farm (35% FM). Different FCRs were considered for the differing formulations. The other scenario considering either no (No PV) or 100% (100% PV) coverage of the production site with solar panels compared to the current model farm (~8% PV). Here, different amounts of excess energy were considered as well.

Table 1: Results of the evaluated impact categories for the different scenarios (PV = Photovoltaic, FM = Fishmeal, GWP = Global warming potential, ODP = Ozone layer depletion, AP = Acidification potential, EP = Eutrophication potential)

Impact categories	GWP (kg CO_{2eq})	ODP (kg CFC_{11eq})	AP (kg SO_{2eq})	EP (kg PO_{4eq})
No PV	1.81	1.23e-7	0.0068	0.0282
No FM	1.63	7.89e-7	0.0061	0.0272
~8% PV/ 35% FM	1.18	7.89e-8	0.0055	0.0257
61.8% FM	0.84	6.19e-8	0.0054	0.0248
100% PV	0.77	5.92e-8	0.0046	0.0238

(Continued on next page)

Results

The production of 1 kg LW trout is most environmental friendly with a share of 61.8% fishmeal in the feed and a 100% coverage of the production site with solar panels (Table 1). The current model farm (35% FM, ~8% PV) emits around 1.18 kg CO_{2eq}. For the fish feed production itself, the no fishmeal variant emits 1.75 kg CO_{2eq}, while the 61.8% fishmeal variant emits 1.13 kg CO_{2eq}. Main shares of the emissions of feed production come from wheat, soy and fishmeal.

Discussion

The 1.18 kg CO_{2eq} of the recent study are in the lower range of values found in literature of farmed rainbow trout in flow-through system. Compared to terrestrial farming traditional trout production has a comparably low impact on climate. Nonetheless, there is room for improvement. Especially through the use of renewable energy sources and by improvement of feed formulations. Photovoltaic systems can offer the possibility to drastically reduce emissions by the production of excess energy. Additionally, the installation of roofs for PV-systems provides further benefits, such as temperature reduction by shading or the protection against predators. Regarding feed composition fishmeal seems to be the most environmental friendly solution, although this has to be considered carefully. The fish in: fish out ratio decreased within the last years, as fish meal and fish oil are more and more substituted by mainly plant based ingredients. Nevertheless, the increase in aquacultural production lead to a rise in fishmeal use, which can affect wild populations. According to the FAO, more than 50% of marine stocks are fully exploited. Vice versa, the use of some plants as fishmeal replacement can lead to high GHG emissions, mainly related to cultivation, deforestation and land use. Furthermore, some of the mainly used plants in fish feed need to by highly processed to be well digestible for fish.

In summary, it can be stated, that production of *Oncorhynchus mykiss* in Europe could be furthermore reduced by increasing the use of renewable energy sources such as photovoltaic and by reducing the impact of feed as the main single factor for most impact categories. Here, the use of modern technologies such as genetic manipulation of plants or sustainable insect meal could have the potential to decrease the environmental footprint of fish feed production.

ATLANTIC BLUEFIN TUNA (*Thunnus thynnus*, L.) LARVAE ANTIOXIDANT MOLECULAR FUNCTIONS INDUCED BY DIETARY SELENIUM IN ROTIFER *Brachionus rotundiformis*

Introduction

Recently the production cycle of Atlantic bluefin tuna (ABT) has been closed however with low survival at larval stages (Van Beijnen, 2017). Better knowledge of nutritional requirements could be one solution to boost ABT production. Selenium (Se) is an important micronutrient needed to produce selenoproteins involved in the antioxidant metabolism. The Se requirement in ABT remains unknown, but recent studies suggest that rotifers as starter feed do not provide sufficient Se for marine finfish species (Hamre et al., 2008). In general, fish exposed to high levels of stress have higher Se requirements (Küçükbay et al., 2009). Therefore, a supplementation at early stages, sensitive towards changing environmental conditions, might prove especially beneficial in ABT.

Material and Methods

The ABT eggs used in this study originate from ABT broodstock maintained in a floating net cage located at El Gorguel, off the Cartagena coast. From 2 days after hatching, larvae were fed with rotifer (*Brachionus rotundiformis*) grown on Algamac 3050 (Pacific Trading LTD, Kent, England) and enriched with different levels of Se (SelPlex®, Alltech, Meath, Ireland) for 18 h pre-harvest: 0.0 mg/10^6 rotifers (0 µg Se·L^{-1}, Se0), 3 mg/10^6 rotifers (3 µg Se·L^{-1}, Se3), 10 mg/10^6 rotifers (10 µg Se·L^{-1}, Se10), 30 mg/10^6 rotifers (30 µg Se·L^{-1}, Se30) and 100 mg/10^6 rotifers (100 µg Se·L^{-1}, Se100). The performance of ABT larvae was monitored throughout two weeks feeding period and antioxidant and selenoprotein expression was measured as well as Se contents on whole larvae sampled at the end of the trial.

Results

Rotifers accumulated up to 30.05 µg Se·g^{-1} dry weight in Se100, the highest supplementation level. Similarly, ABT larvae had maximum tissue Se concentration (194 ± 38 µg Se·g^{-1} dry mass) in Se100. In ABT larvae total length was highest in Se3, whereas maximum flexion index was reached in Se10. Selenium supplementation increased the expression of selenoproteins glutathione peroxidase 1 (*gpx1*) and methionine sulfoxide reductase 1 (*msrb1*) in Se supplemented treatments compared to the non-supplemented control (Figure 1). The expression of thioredoxin reductase 2 (*trxr2*) and selenoprotein P (*selenop*) also displayed differences between larvae fed supplemented and unsupplemented rotifers, albeit these were minor and varied with supplementation level (Figure 1). In contrast, the antioxidant enzymes catalase (*cat*) and superoxide dismutase (*sod*) showed lowest expression in Se100. The expression of other selenoproteins including iodothyronine deiodinases 1, 2 and 3 (*dio1*, *dio2*, *dio3*) was unaffected.

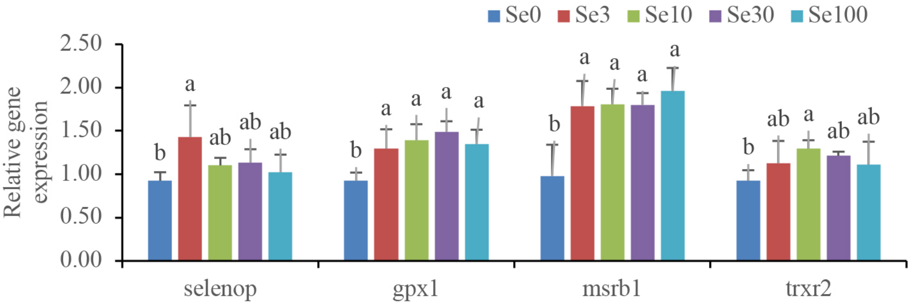

Fig 1. Expression of selenoproteins measured by real-time PCR. Data are normalized to a geometric mean of two housekeeping genes *ef1a* and *bactin* and expressed as fold-changes of mRNA abundance compared with Se0 (Pfaffl et al. 2002). Bars represent means ± SD (n=6). Means not sharing a common superscript letter are significantly different ($p < 0.05$) according to one-way ANOVA on ranks followed by Tukey's HSD. *Selenop*, selenoprotein P; *gpx*, glutathione peroxidase; *msrb*, methionine sulfoxide reductase; *trxr*, thioredoxin reductase.

(Continued on next page)

Discussion and conclusion

Feeding Se enriched rotifers effectively increased Se in ABT larvae tissue. The improved growth observed in Se supplemented treatments might be related to an accelerated development as the flexion index was significantly higher in all Se enriched treatments compared to the non-supplemented control. A similar effect by Se supplementation has been previously described in Senegalese sole (Solea senegalensis) in relation to an enhanced thyroid hormone activity by Se supplementation (Ribeiro et al., 2012). The Se level of 0.10 μg g^{-1} dw measured in non-supplemented rotifers is below known requirements in fish (Antony Jesu Prabhu et al. 2016). In contrast, rotifers supplemented with the lowest Se level (Se3) contained 4.42 μg Se g^{-1}, which might be sufficient to cover requirements for this mineral as selenoproteins displayed maximum expression in ABT larvae fed this treatment. The increased seleno-enzyme production might have contributed towards an improved antioxidant status in ABT larvae, indicated by a transcriptional downregulation of redox sensitive antioxidant enzymes *cat* and *sod*. In conclusion, rotifers without Se enrichment are suboptimal for ABT larvae at first feeding. A dietary Se level of 4.42 μg g^{-1} dw is recommended as it boosted growth performance and improved the antioxidant status in ABT larvae.

Introduction

The proportion of plant-based ingredients being used to replace marine resources in Atlantic salmon feed is in constant growth. Hence, the lipid profile of the diets is changing, situation which can affect the performance and health of fish. The application of nutritional programming in freshwater stages of Atlantic salmon showed benefits in feed efficiency and nutrient retention when using plant ingredients in the stimulus diet compared to marine during first feeding. Moreover, physiological adaptations were described at gene expression level in the vegetable stimulated group after challenged. These changes could have improved the use of nutrients as well as enhance the fish tolerance to vegetable-based feed. However, it is important to determine whether these benefits can be extrapolated to seawater stage and if a "booster" is needed. The aim of the present study is to evaluate the impact of using vegetable-based feed in early stages of Atlantic salmon, on the morphology of liver and intestine of challenged individuals during seawater.

Materials and methods

A nutritional programming trial was performed with Atlantic salmon from six families characterised by high and low pigmentation genotypes. Fish were distributed into four groups and exposed to two stimulus diets; with either marine or vegetable ingredients, both delivered within the first three weeks of exogenous feeding. Fish were maintained with a commercial diet until seawater and challenged again with a vegetable-based feed which was delivered until the end of the trial when they reached harvest size. Samples of liver, to evaluate lipid vacuolization; and intestine for an assessment of circular muscle thickness, enterocyte height and width and number of goblet cells per area of surface, were taken before, during and once the challenge was finalised in seawater.

Results

Prior to the beginning of the challenge, the vegetable stimulated group showed statistically significant higher intracytoplasmic vacuolization in liver, despite been fed with a commercial marine diet during the intermediate phase. On regards of anterior intestine, marine stimulated group presented higher number of goblet cells per area compared to the vegetable group, however, the results were not statistically significant. Further results from intestine morphology and the following sampling point, will be presented.

FARMED LUMPFISH BROOD STOCK - WHAT TO EXPECT?

C.Wittwer

Lofotyngel AS, Stamsund, Norway
Email: cw@lofotyngel.no

Introduction

The Atlantic lumpfish (*Cyclopterus lumpus*) is deployed as cleaner fish to control the sea lice numbers in salmon farming in Norway, the UK, Ireland, the Faroe Islands and Canada (Treasurer, J. W. 2018). The commercial production cycle usually starts with the collection of eggs from wild caught lumpfish which are then incubated on land-based facilities, where larvae can hatch and will grow to juveniles, ready for transport to the salmon sea cages. The use of brood stock lumpfish of wild origin is not only seasonal but can also have an environmental impact and can be a risk to the production facilities by potential transmission of pathogens. A F1 brood stock which is reared in the hatchery can overcome those disadvantages. The objectives of a brood stock project at Lofotyngel AS (former Arctic Cleanerfish AS) in Lofoten, Norway was to determine whether the eggs and larvae from hatchery reared brood stock are of equivalent quality to those produced by wild sourced lumpfish.

Materials and Methods

In 2019, the brood stock for the main trial consisted of 10 females of wild caught (WC) lumpfish and 10 females of 18 months old hatchery reared (HR 1) lumpfish which were selected by their maturation status and were ready for egg collection on the same day. The weight of the females, the volume of hand stripped eggs, egg diameter, developmental stage of embryo, the fertilization rate (F-rate), the hatching rate (H-rate) of larvae, length of larvae at hatch, length of larvae every second week until 35 days post hatch (dph), weight of larvae every second week from 35 dph till 84 dph and the survival rate of larvae (S-rate) were recorded. In 2020 in a second part, the eggs from 10 females of 2.5 years old hatchery reared (HR 2) lumpfish from the same family as the HR 1 brood stock were collected and incubated. Same data as in the main trial was documented. Unfortunately, in this part no records during larvae rearing exist. All data were expressed as mean ± standard deviation (SD) and were analysed with one-way parametric ANOVA followed by Tukey's test. A p-value of < 0.05 was regarded as statistically significant.

Results

There were significant differences between the lumpfish brood stocks (Table 1). The females of the WC brood stocks were significant heavier ($p<0.001$) and produced a higher volume of eggs ($p<0.001$) compared to both HR brood stocks. Between the HR brood stocks, the females of the HR 2 where significant heavier ($p<0.001$) and produced more volume of eggs ($p<0.001$) than the HR 1 brood stock. The WC and HR 2 females showed significantly larger eggs ($p<0.05$) and significant larger newly hatched larvae ($p<0.001$) than the HR 1 females but were not different compared to each other.The F- and H-rate were not different between the brood stocks and were high in all (Table 1).

During the first feeding period (till 35 dph) larvae of the WC brood stock were significantly larger ($p<0.001$), (Table 1). In the on growing period (from 49 dph) larvae from the HR 1 brood stock were significantly larger ($p<0.001$). The S-rate of the larvae was high in both brood stocks at 98.7 % and was not significantly different (Table 1).

Table 1. Comparison of the HR (hatchery reared) and WC (wild caught) brood stock (n=90, except female weight and egg volume is n=20). Data is shown as mean ± standard deviation. Numbers sharing the same letter showing no significant difference (p<0.05).

	WC	HR 1	HR 2
Female Weight [kg]	4.10 ± 0.89 a	1.60 ± 0.45 b	3.4 ± 0.45 c
Egg volume [ml]	588 ± 99 a	250 ± 46 b	435 ± 180 c
Egg diameter [mm]	2.41 ± 0.07 a	2.26 ± 0.08 b	2.44 ± 0.07 a
F-rate [%]	99.9 ± 0.1 a	99.9 ± 0.1 a	99.9 ± 0.1 a
H-rate [%]	90.1 ± 6.4 a	90 ± 6 a	89.9 ± 6 a
Larvae at hatch [mm]	6.41± 0.2 a	6.17 ± 0.12 b	6.37 ± 0.13 a
Lumpfish at 84 dph [g]	1.15 ± 0.17 a	1.47 ± 0.2 b	n.d.
S-rate [%]	98.71 ± 0.05 a	98.71 ± 0.07 a	n.d.

(Continued on next page)

Discussion

The size difference of the females between the brood stocks explains the differences in the produced egg volume as with increasing size of the females, the egg production increases (Fuiman and Werner 2002). The age difference between the brood stocks could be the reason for this size difference. HR females were 18 months and 2.5 years old while wild spawning females are usually 5-8 years old (Davenport 1985). In addition to the age, the HR females were first time spawners. All this facts could also explain the smaller eggs of HR 1 females, as smaller lumpfish females and first time spawners laying smaller eggs than larger and multiple spawners (Fuiman and Werner, Kennedy 2018). Egg size and larvae size is directly related and therefore the HR 1 females produce smaller larvae at hatch (Kjørsvik et al. 1990).

On the other hand egg size has no direct implications for overall egg quality, larval survival and growth (Kjørsvik et al. 1990). Looking at the quality factors of the eggs studied here, fertilization and hatching rate, all brood stocks seemed to have the same quality. Earlier studies showed that hatchery reared lumpfish eggs seemed to have higher nutrient content then wild lumpfish eggs due to the more nutritious diet on farms compared to the natural diet of adult lumpfish (Hamre 2015). They concluded that high nutrient content of the eggs from farmed fish may determine juvenile performance. In this study the performance during start feeding, growth and survival of the larvae, were similar. However, after 49 dph larvae of the HR had a higher growth which could be the result of the nutrient content of the eggs.

Conclusion

Even tough HR brood stocks produced fewer volume of eggs per female than the WC brood stock, a huge advantage is that all eggs are pathogen free and can be incubated and utilized. In contrast a certain amount of eggs from WC brood stocks need to be discarded. The older HR 2 females could be interesting as they produced more volume than the HR 1 females, with similar sized larvae as the WC females. On the other hand, the smaller larvae at hatch did not seem to be a disadvantage as well as larvae were larger at the end of the trial. If the older brood stock has a similar superior growth but with larger larvae at start that could be of big advantage and should be studied further. In addition it would be interesting to see the performance of lumpfish in the salmon cages at the end.

Introduction

Turbot (*Scophthalmus maximus*) is a fast-growing flatfish that has been commercially cultured for more than two decades. Yet several bottlenecks remain in the mass production of high-quality larvae. Early life stages of marine fish development are characterized by variable survival rates, as it is a period extremely sensitive to external conditions. Previous research on dietary curcumin supplementation showed an improvement on growth and health status in Senegalese sole and gilthead seabream larvae (Xavier et al., 2021; 2022). This polyphenol, extract from the roots of *Curcuma longa*, presents high antioxidant properties due to its molecular structure that can interact directly with pro-oxidant molecules (either from the phenolic OH group or from the CH_2 group of the β-diketone moiety). Therefore, the aim of this study was to understand if the supplementation of curcumin could promote turbot postlarvae robustness and ultimately improve growth performance and survival during the hatchery period.

Material and Methods

A growth trial was conducted in 27 days after hatching (DAH) turbot that were fed one of the three experimental diets: a commercial-like diet used as control (CTRL) and the two diets supplemented with different doses of curcumin (CURLOW and CURHIGH). After 23 days feeding experimental diets, fish were sampled to assess growth performance (n = 21), and gut was dissected to analysed redox status biomarkers (n = 8).

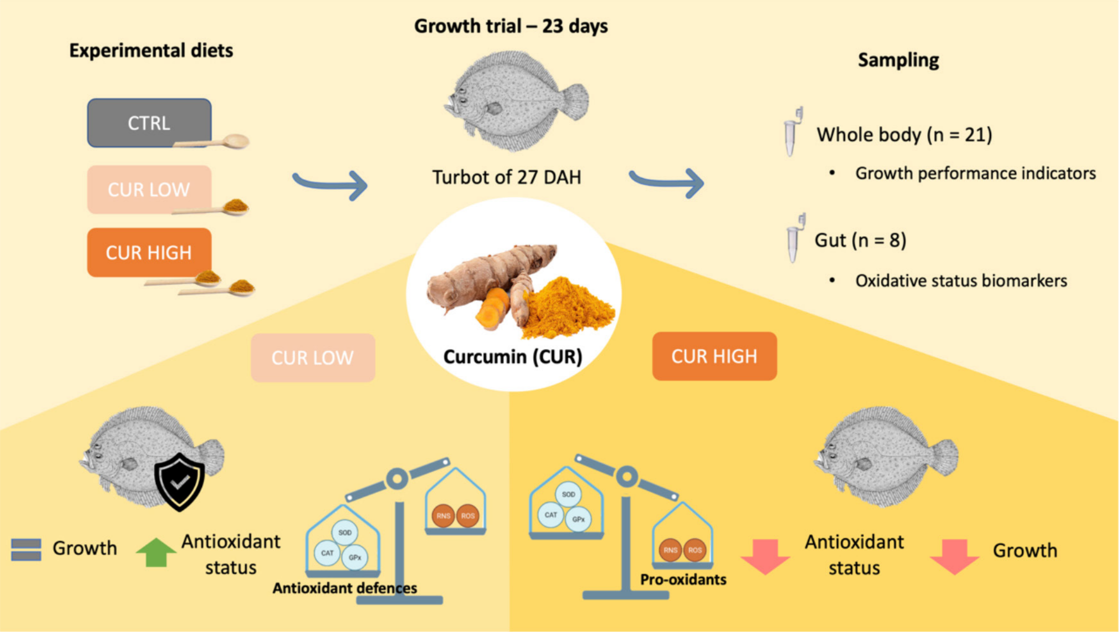

Figure 1. Graphical abstract of the present study.

(Continued on next page)

Results and Discussion

An overview of the experiential trial and main results are present in the figure 1. The higher dose of curcumin CURHIGH decrease turbot growth compared to fish from CTRL ($P < 0.05$). Concomitantly, CURHIGH postlarvae presented higher content of lipid peroxidation (LPO) and activity of catalase (CAT) than CTRL fish ($P < 0.05$). Which may suggest that a higher dose of curcumin is acting as pro-oxidant leading the fish to a state of oxidative stress. The lower curcumin supplementation was not able to promote fish growth performance when compared to CTRL fish. However, the CURLOW fish presented a higher total antioxidant capacity (TAC) when compared to fed CTRL fish ($P < 0.05$). A higher TAC may suggest that curcumin is acting as an exogenous antioxidant, and that in a challenging environment may help fish to cope better with adverse conditions.

Conclusion

The results from the study clearly demonstrate that curcumin presents the ability of acting as both antioxidant and pro-oxidant in turbot postlarvae. The inclusion of a moderate amount of curcumin seems to promote turbot postlarvae robustness through an increase in the antioxidant status. However, further evaluation is needed to identify the optimal inclusion level. Optimal curcumin dietary doses seem to change with fish species, and larval/postlarval age, when comparing the present turbot dataset with results for Senegalese sole (Xavier et al., 2021) and gilthead seabream (Xavier et al., 2022).

Introduction

Wheatgrass juice (a common addition to “smoothies” or as dried food supplement extracts) has become popular in recent years because it contains a variety of nutrients. Production of wheatgrass in aquaponics is rare. The aim of the present study was to test the influence of different aquaponic irrigation water from African catfish (*Clarias gariepinus*) production and various hydroponic substrates on the growth of wheatgrass (*Triticum aestivum*).

Material and methods

Wheatgrass was cultivated in an ebb-and-flood commercial aquaponic system from 30.10.2019 to 19.11.2019 in the FishGlassHouse of the University Rostock, Germany (Figure 1). Three different substrates were used, namely, 100% coconut fiber (C), 70% coconut fiber + 30% perlite (CP), and 50% perlite + 50% vermiculite (PV). Wheatgrass was irrigated by two different effluents from intensive aquaculture unit (IAU) and extensive aquaculture unit (EAU) of African catfish (*C. gariepinus*) recirculation aquaculture systems and tap water with fertilizer (Control) in triplicates. Plant growth indicators and some nutrients were taken and measured in order to evaluate the growth performance of wheatgrass produced in aquaponics.

Results and discussion

Data analysis showed that, regarding irrigation water, total fresh biomass and root dry mass had no significant difference among all groups. Shoot dry mass was significantly higher in fish water groups. Significantly different root length of all groups had the order of Control>EAU>IAU. The significantly highest SPAD-Index was discovered in IAU. Regarding substrates, the highest SPAD-index value was found in PV and not significantly different from CP. The significantly lowest mortality was in PV. Considering interaction of irrigation water and substrates on wheatgrass, the significantly highest value of shoot fresh mass was in PV and EAU combination. Significantly higher shoot length was in IAU and C, PV combination and EAU and CP, PV combination. Root fresh mass was significantly lower in IAU and C, PV combination. Minerals contents had variation due to co-effect of irrigation water and substrates and coconut and vermiculite substrates had positive influence on mineral content. So as vitamins, however, vitamins production reached partly their highest amount in the combination of fish water with different substrates. Abundant microbes including beneficial PGPMs existing in the aquaponic system and organic form of nitrogen in fish units are assumed to lead to higher contents of some nutrients in fish units (Glick, 2012; Palacios et al., 2014).

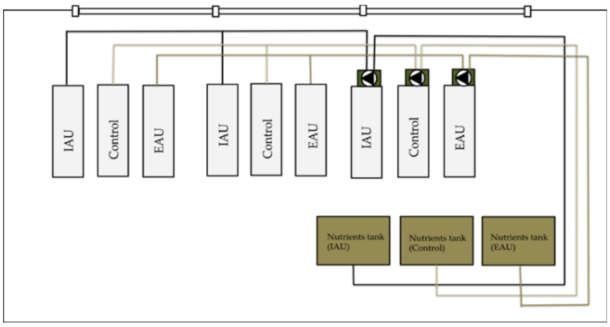

Fig. 1: Scheme of the hydroponics cabin. Bright grey rectangles represent plant tables; green rectangles represent sump tanks; and brown rectangles represent nutrient tanks; “◀”represents pumps.

(Continued on next page)

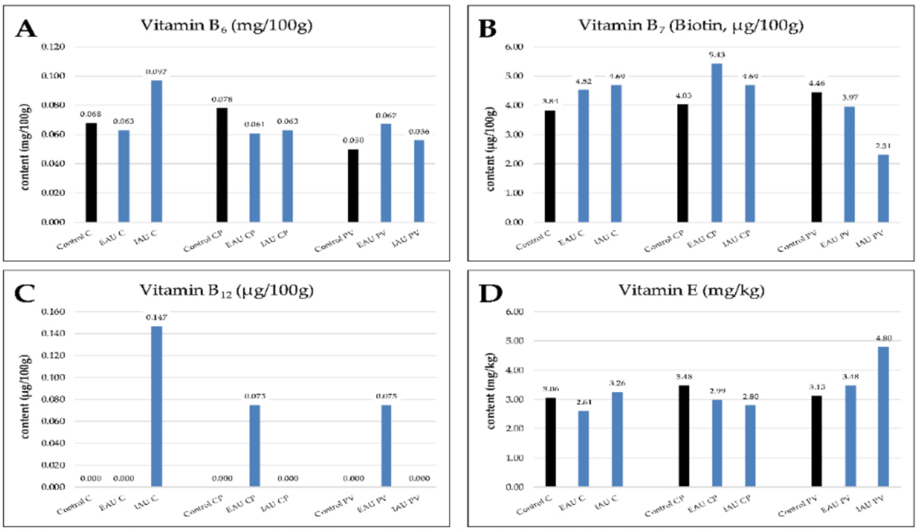

Fig. 2: Wheatgrass vitamin content of A) vitamin B_6, B) vitamin B_7 (Biotin), C) vitamin B_{12}, and D) vitamin E in different experimental groups (control, extensive aquaculture unit (EAU), and intensive aquaculture unit (IAU)); substrates are illustrated as coconut 100% (C), coconut 70% + perlite 30% (CP), and perlite 50% + vermiculite 50% (PV).

This finding showed the potential that aquaponic is a more sustainable way of producing vitamins under aquaponic gardening conditions in future (Palm et al., 2018). Studies of verifying the findings and examining the bacterial populations that inhabit the aquaculture effluents and substrates should be undertaken.

Introduction

Probiotics are "live microbial feed supplements which beneficially affects the host animal by improving its intestinal microbial balance"(Fuller, 1989). Exposing fish larvae to selected probiotics has been proven to improve their health and increase their resilience to pathogens and disease due to the gastrointestinal microbiota dependency on the external environment (Gatesoupe, 1999). Probiotics also compete with pathogens for nutrients and adhesion sites, which help to stimulate the immune system (Gatesoupe, 1999).

Materials and Methods

This trial tested the use of lactic acid bacteria (LAB) on pikeperch (*Sander lucioperca*) larvae during first feeding. The trial included the use of two probiotic treatments and one control (no probiotics). The first treatment exposed the live feed to LAB, while on the second treatment, LAB was used on the live feed as well as in larval tanks. Pancreatic (α-amylase, bile salt-activated lipase, total alkaline proteases) and gastric (pepsin) enzyme activities were determined as well as the microbiome from the larvae and the rearing water during. The trial duration was 18 days and samples of larvae and water were taken at 7, 14, 21 dph from each treatment.

Results

Significant differences were found between treatments in terms of enzyme activity at 7days post hatching (dph) when looking at alkaline protease, amylase, lipase and pepsin. Further significance was found on lipase activity at 21 dph. The use of LAB also had significant differences on the microbiome abundance and diversity on the larvae, as well as on the rearing water. Results showed a significant variation of the microbiome with time, as well as a between treatments. Such effects might be the one of the main factors for the difference on survival between treatments. Larvae exposed to LAB via the live-feed and the rearing water had a significant higher overall survival rate (88%) than the other two treatments at 21 dph. At the same time, larvae exposed to the probiotic treatment had a significantly higher TL (7.34 and 11.82 mm) after 14- and 21-days post hatch (dph) compared to the control treatment (5.99 and 10.67 mm).

Conclusions

The results suggest that the use of LAB in both live feed and rearing water during pikeperch larval stage has a positive effect by enhancing early enzyme activity, controlling microbiome diversity and improving the growth and survival rates.

Introduction

Supply of live feed during fish larval rearing is of key importance to develop intensive aquaculture protocols. Recent work done on pikeperch *(Sander lucioperca*) larvae rearing, have revealed the need to introduce rotifers to their diet during the first feeding stage. The small size of this live feed is the main characteristic that makes them a suitable prey for pikeperch larvae, as opposed to the traditional artemia nauplii. Yet, rotifers nutritional value by itself lacks essential components, such as essential fatty acids. The diet given to rotifers is the main source of essential nutrients required by the larvae to develop.

Material and Methods

This trial compared the effects on pikeperch larvae survival and development from three rotifers diets, (*Nannochloropsis oculata, Chlorella vulgaris*, and a commercial enrichment diet). Three treatments were tested. The first was the control treatment, where larvae were offered rotifers (*Brachionus plicatilis*) fed with *Nannochloropsis occulata* during the first eleven days (15 dph), and unenriched artemia until the end of the trial. The second treatments followed the same feeding protocol as the control treatment, but rotifers (*Brachionus plicatilis*) supplied to the larvae were fed with *Chlorella vulgaris*. *Artemia salina* provided to larvae from the second treatment was not enriched, to assess the potential long-term effects of the *Chlorella vulgaris* supplementation on the larvae fatty acids' composition and survival. The third treatment used rotifers (fed on *Nannoclopropsis*) and artemia, both enriched with Spresso emulsion by Selco (INVE, Salt Lake City, UT, USA).

Results

Larvae fed on *Chlorella* had the highest survival and faster growth. Such result might be due to the highest (10 times higher) concentration of linoleic acid (LA) found in chlorella as opposed to *Nannochlopsis* and the ability that pikeperch larvae have to synthetized LA into docohexanoic acid. The use of chlorella for rotifer feeding could potential be a good candidate to replace other diets, lowering the production cost and increasing pikeperch larval production.

WHAT HAPPENED OVER THE LAST 10 YEARS (2012 to 2021): A BIBLIOMETRIC ANALYSIS OF FISH WELFARE RESEARCH IN EUROPEAN SEA BASS (*Dicentrarchus labrax*)

Hijran Yavuzcan Yildiz[1*], Lambros Kokokiris[2], Elena Mente[3]

*yavuzcan@ankara.edu.tr

This paper describes fish welfare publications on European sea bass, *Dicentrarchus labrax* which is the most produced fish species in the Mediterranean region. To perform the bibliometric analyses, we downloaded the publications from the Web of Science (WoS) database using the keyword combination ‘‘fish welfare and European sea bass” for the period from 2012 to 2022 years. A total of 104 publications were extracted, including 12 reviews and 92 articles. Of the publications, almost all were SCI-expanded (n=102 publications). The visualization analysis in WoS showed that the highest number published in 2021 (n=22) and the lowest in 2014 (n=6). While the University of Algarve (Portugal) is at the top of production in the publications on fish welfare research in sea bass Spain has the highest number of publications. European Commission is the main funding source with a ratio of 32%. The results of this study clearly indicate that although the research on fish welfare of sea bass showed an increasing trend in recent years total number of publications produced the last decade was low. Considering that the importance of fish welfare from the perspective of consumers' perception, production feasibility, and aquaculture sustainability, is high, it is clear that the welfare studies on European sea bass should be increased in the research area of aquaculture.

GROWTH PERFORMANCE OF MEDITERRANEAN FINFISH SPECIES UNDER HIGH TEMPERATURES

Introduction

Although Mediterranean Sea finfish species are becoming important in Saudi Arabia's aquaculture production because of diversifying aquaculture, the farming sector requires a sufficient understanding of the species' thermal preferences and limits. Moreover, High water temperatures have limited the culture species and periods in Saudi Arabia (Figure 1). This study was conducted using three finfish species juveniles (135–155 g), meager (*Argyrosomus regius*), European seabass (*Dicentrarchus labrax*), and greater amberjack (*Seriola dumerili*), to assess their growth performance under high temperatures for three-month-long thermal trials.

Methods

This study was conducted using three finfish species juveniles (135–155 g), meager, European seabass, and greater amberjack, to assess their growth performance under high temperatures for three-month-long thermal trials. Each species trial was performed in triplicates in a recirculating aquaculture system, while three temperature ranges, 24°C–25°C, 28°C–29°C, and 33°C–34°C, were tested, representing the average temperatures in the Mediterranean and Red Seas.

Results

Both meager and European seabass performed similarly between the first two temperatures, indicating that the optimum range lies within that thermal window. Growth performance indicates that it is lower for meager than it is for European seabass. In the greater amberjack, growth performance was similar for the first two temperatures. The temperature of tolerance was 33°C for all species.

Discussion

Consequently, the species appeared to have similar thermal tolerance to the upper end of the tolerance range but with some notable differences in the preferable temperature for optimum performance. This became evident from the husbandry findings and was further corroborated by the growth performance analysis. Both meager and European seabass performed similarly between the 24°C and 29°C, indicating that the optimum range lies within that thermal window. However, growth and FCR indicate that it is lower for meager than it is for the European seabass. In the greater amberjack, growth performance was similar for the first two temperatures. Yet, the high growth rate at 29°C during the second and third month of the trial suggest a high capacity for compensatory growth and the potential to achieve appreciable growth in high-temperature regimes, unlike the other species.

Introduction

Atlantic cod (*Gadus morhua* L.) is one of the most important species for commercial fisheries in the North Atlantic. However, cod catches and spawning stock biomass in the North Atlantic Ocean has declined the last decades, and traditional fisheries may become further reduced due to climate change (IPCC, 2022). This reduced availability of wild cod in the near future has renewed the interest in cod farming (Puvanendran et al., 2022). Cod farming used to be a thriving industry in Norway until it gradually declined from 2008 due to multiple factors. However, selective breeding and new knowledge about production have reinitiated cod farming in recent years. Novel methods and strategies that sensitively measure and predict cod health and welfare, as well as insight into how climate change will affect production, is vital for the sustainable growth of the industry.

Optimal temperature for mature cod is between 6 and 11°C. With temperatures above 15°C, several challenges related to slower growth, impaired swimming, increased stress and reduced haemoglobin oxygen affinity are described, with increased mortality when temperatures reach 20°C. The biological significance of these thermal thresholds is worth a closer look to understand the limitations, opportunities, and possible strategies of adaptation when planning to increase cod farming under climate change (Falconer et al., 2022). For example, water temperatures above 15°C seems to play a significant role in development of francisellosis. Francisellosis, caused by the intracellular bacterium *Francisella noatunensis*, is considered one of the most important disease problems in Norwegian cod farming and was one of the reasons why the industry collapsed around 2010. Current expectations of increased production could cause the disease to re-emerge as a challenge.

Using climate projections from the Intergovernmental Panel on Climate Change (IPCC) we have evaluated potential future temperatures at selected cod farms in Norway. Based on these results we designed a temperature study with Atlantic cod to evaluate biological impact from temperature alone and in combination with a *F. noatunensis* infection.

Methods

The climate projections from IPCC showed that long-term temperatures around 17°C are likely at selected cod farms in the near future. Trial with Atlantic cod was therefore performed at to two different temperature regimes, 12°C and 17°C for 8 weeks. Three weeks into the trial, a *F. noatunensis* infection was carried out.

Samples of skin and spleen were collected at different time-points, and microarray, histology, scanning electron microscopy and immunohistochemistry used to evaluate the impact of temperature on general health, and to determine the pathogenesis of *F. noatunensis* at different temperatures. An *in vitro* model of skin biopsies and scale explants was used to further investigate the functional biology of increased temperature. Migration assays and immunohistochemistry with markers for stress induced genes were used in combination with temperature and oxidative stress exposure of the cells to increase our understanding of combined stressors.

Results and Discussion

Results showed that temperature has a strong effect on skin barrier quality, affecting important functions such as reducing the immune status, proliferation rate and migration capacity, and making the skin less tolerant to oxidative stress. These are vital biological responses in fish skin, as they contribute to keep the fish healthy and robust in the long term. The effects caused by temperature were stronger than those caused by the *F. noatunensis* infection, but the infection had a more severe pathology in fish from the high temperature regime. Fish from the 17°C group showed more severe granuloma formation and developed granulomas at earlier time-points in the spleen, compared to infected fish from the 12°C group. These findings were further combined with the climate model projections to identify risks to existing cod farming areas, and implications for short and long-term cod aquaculture site selection.

(Continued on next page)

Conclusion

Results show that climate change will pose a significant threat to Norwegian cod farming, that important biological functions and responses in cod are severely affected by high temperatures, and that action is needed to sustain production in the future.

Introduction

Plant-derived flours are currently being used as alternative ingredients to fishmeal in aquafeeds. However, most of them are competing for other uses, mainly as food for humans. The cereal industry generates abundant amount of residual by-products that may represent a source of sustainable and low-cost feedstock for fish feeding, presenting limited competition with human food consumption. In this study, four different by-products derived from the cereal industrial processing has been selected and tested to assess their usefulness as potential alternative ingredients in aquafeeds. With this aim, a generalist formulation was designed in order to check those ingredients in three different European fish species (Atlantic salmon, gilthead seabream and greater amberjack). Therefore, the feed formulation was not customized for any of the targeted species. The present report shows the experiments carried out with greater amberjack (*Seriola dumerili*).

Materials and methods

Greater amberjack juveniles (n=141; initial weight 60.50 ± 10.48 g) were randomly distributed in 9 tanks in recirculating aquaculture systems and maintained during 18 days at 22 ºC. Fish were fed with 5 isoproteic experimental diets at a daily feeding ration of 3.5% w/w, distributed in three meals. The experimental diets, manufactured by SPAROS Lda (Portugal), included 7-15% of by-products from cereal industry produced by ROQUETTE (corn germ, corn gluten feed, corn germ meal, and wheat gluten feed) and soy protein concentrate (control). The protein content of these alternative ingredients ranged between 15 and 23%. These ingredients replaced standard cereal flours and krill and squid meals. All diets were marked with yttrium oxide. Growth performance and apparent digestibility were measured at the end of the experiment. Previously, a short experiment was performed with feeding up to satiation to assess the acceptability of the diets. In addition, *in vitro* digestibility of novel ingredients and diets was measured after incubation for 1 and 6 h with intestinal extract of greater amberjack. Apparent digestibility was measured analyzing yttrium in the faeces collected from the *in vivo* experiment using inductivity-coupled plasma mass spectroscopy. Statistical differences were checked by one-way ANOVA followed by Tukey's test using RStudio software.

Results

All experimental diets were well-accepted and the fish grew up in all cases. Voluntary feed intake was similar for all diets, ranging from 4.71 to 5.88 % body weight day^{-1}. Likewise, no statistical differences were detected in final body weight (ranging from 98.5 to 114.7 g) among the experimental diets, including the control with soy protein concentrate. Thus, the weight gain during the 18-day experiment ranged between 63 and 90% of initial body weight.

The *in vitro* protein digestion of the experimental ingredients showed significant differences after 1 and 6 h of incubation ($p < 0{,}05$). However, when the experimental formulated feeds were considered, the differences were significant only after 1 h of incubation and not after 6 h ($p > 0{,}05$) (Table 1).

Discussion

All experimental diets were accepted and were able to support fish growth. Both, the *in vitro* and *in vivo* digestibility analyses of the diets indicated that *a priori* the protein of all the four new ingredients can be digested at similar efficiency than the control by greater amberjack. The problem may be the relative low protein content of these ingredients. A dose-dependent long-term growth experiment with a customized formulation for this fish species with some selected ingredients could confirm the usefulness of these by-products as more sustainable alternative ingredients for fish feeds. In first instance and according to the digestibility results with greater amberjack, wheat gluten feed (Milurex, produced by Roquette Beinheim, France) and corn gluten feed (Corex, produced by Roquette Benifayo, Spain) seems to be the most appropriate as alternative ingredients. Results with the same diets, fed to other species, Atlantic salmon and gilthead seabream, will be reported when available.

(Continued on next page)

Table 1.- Protein *in vitro* digestibility (µmol of amino acids released per mg ingredient or diet) of the novel ingredients and of the diets prepared with these ingredients after 1 and 6 hours of incubation with intestinal extracts from greater amberjack juveniles.

	Ingredients protein digestibility		**Experimental feeds protein digestibility**	
Ingredient	1 h	6 h	1 h	6 h
Corn germ	0.015 ± 0.008^{b}	0.025 ± 0.005^{c}	0.027 ± 0.004^{b}	0.070 ± 0.002
Corn gluten feed	0.016 ± 0.000^{b}	0.018 ± 0.003^{d}	0.030 ± 0.002^{b}	0.070 ± 0.009
Corn germ meal	0.021 ± 0.000^{b}	0.033 ± 0.003^{c}	0.033 ± 0.002^{ab}	0.072 ± 0.001
Wheat gluten feed	0.019 ± 0.001^{b}	0.049 ± 0.003^{b}	0.033 ± 0.004^{ab}	0.073 ± 0.010
Soy protein conc.	0.114 ± 0.001^{a}	0.186 ± 0.005^{a}	0.041 ± 0.004^{a}	0.083 ± 0.004

Data are presented as mean ± SD. Different superscript letters indicate significant differences among diets for each sampling point (One-way ANOVA; $p < 0.05$).

Table 2.- Apparent digestibility of the different diets on weigh basis (ADC) and digestibility of dietary protein (AD protein) by greater amberjack juveniles.

Diet with:	**ADC (%)**	**AD protein (%)**
Corn germ	77.60 ± 1.18	95.68 ± 0.32
Corn gluten feed	78.85 ± 3.11	95.88 ± 0.36
Corn germ meal	77.32 ± 2.59	95.16 ± 0.33
Wheat gluten feed	78.56 ± 2.35	95.41 ± 0.47
Soy protein conc.	76.37 ± 3.80	95.43 ± 0.71

Data are presented as mean ± SD. No significant differences among diets were found (One-way ANOVA; $p > 0.05$).

Introduction

Sea bream (*Sparus aurata*) is one of the most commercially important aquaculture species. The increased use of plant raw materials in the diets contributes to the increase of their phytoestrogen content. Major phytoestrogens found in fish feeds include genistein, daidzein, bioachanin-a and coumestrol (Matsumoto et al. 2004). Phytoestrogens have been found to regulate fatty acid metabolism (D'Souza et al. 2005; Torno et al. 2019) in fishes, thus affecting tissue fatty acid content. The aim of the present study was the investigation of the effect of two diets with different phytoestrogen content on fillet and liver fatty acid composition of sea bream.

Materials and Methods

Two diets, A (protein 44.2%, fat 15.1%, ash 7.3% and moisture 6.4%) and B (protein 44.9%, fat 16.6%, ash 6,9% and moisture 6.5%), were provided by Biomar Hellenic. The phytoestrogen content of feeds was determined by LC/MS-MS. The compounds identified were daidzein (10.4±0.2μg/g for diet A and 2.64±0.06 μg/g for diet B), genistein (3.9±0.2μg/g for diet A and 1.4±0,1 μg/g for diet B), biochanin A (1.14±0.03μg/g for diet A), coumestrol (1.98±0.07 μg/g for diet A and 0.72±0.05μg/g for diet B) and glycitein (0.42±0.05μg/g for diet B). Specimen initial size was 101.4±0.8g. A 12-week experimental rearing was carried out in a Recirculating Aquaculture System (3 replicates/treatment, 12 fish/tank). Fish were fed at satiation twice a day. At the end of the experiment, fillet and liver samples were collected. Fatty acid composition of the tissues and the feeds was determined by GC/FID. Dietary fatty acid profile demonstrated no significant differences.

Results

No significant differences were observed between treatments for fillet and liver lipid content. High phytoestrogen treatment (Diet A) demonstrated significantly higher fillet SFA, liver n-3, n-3 LC PUFA, n-6, EPA and DHA content, than Diet B. On the other hand, Diet B demonstrated significantly higher fillet n-3, n-3 LC PUFA, EPA, DHA and liver MUFA content, that Diet A.

Discussion

Sea bream fatty acid content has been shown to reflect the respective content of the diet (Houston et al. 2017). Nevertheless, the similar dietary fatty acid profiles of the treatments point to the effect of the differences in phytoestrogen content. In the present study, the high phytoestrogen treatment, was characterized by an abundance of dietary daidzein and exhibited lower fillet n-3 LC PUFA content. This may be attributed to the regulatory effect of daidzein on fatty acid oxidation in muscle cells (Kitamura et al. 2020). Genistein on the other hand has been shown to increase DHA and n-3 LC PUFA content in the fillet of sea bream (Torno et al. 2019). This was not the case in the present study, pointing to a potential interaction of phytoestrogens, that needs to be clarified via specialized experimental design. On the other hand, the higher liver DHA and n-3 LC PUFA content was in accordance with data from the aforementioned study, indicating a potential tissue-specific prevalence of the different phytoestrogens. Additionally, biochanin-A (Park et al. 2016) and coumestrol (Zywno et al. 2021) have been shown to regulate hepatic fatty acid oxidation, thus contributing to the need to investigate the combined effects of phytoestrogens. Moreover, treatment A exhibited significantly lower GPT, cholesterol and triglyceride values, as well as a trend for lower LDH and GOT values (Tsopelakos et al. 2021), indicating the previously reported prophylactic effect of phytoestrogens on the liver (Park et al. 2016; Zywno et al. 2021). In conclusion, different dietary phytoestrogen content, affects significantly the fatty acid composition of fillet and liver. Nevertheless, further experimentation is required, in order to clarify the interaction between different phytoestrogens.

Introduction

The readily available and cost-effective plant protein-rich ingredients have become the main protein sources used in aquafeeds to substitute unsustainable marine-derived ones. However, the transition to plant-based diets is more difficult to achieve for carnivorous fish, like salmonids, in which certain plant protein-rich ingredients can cause adverse effects on growth, liver integrity and gut health. In this regard, functional feeds represent an interesting solution to mitigate these drawbacks, even at low dietary inclusion. Conventional feed additives, like nucleotides and sodium butyrate, have been shown to positively modulate immune response by preserving intestinal integrity in salmonids. Furthermore, a new generation of more sustainable ingredients can be intended as feed supplements due to their promising features. The dried microbial biomass of certain microalgae and cyanobacteria represents a source of vitamins, minerals, carotenoids and antioxidant compounds. Differently, the meal obtained by the Louisiana red swamp crayfish (*Procambarus clarkii*), a highly invasive alien species in Europe, can be exploited as an innovative feed supplement converting an ecological problem to a natural source of protein and bioactive compounds such as astaxanthin and chitin. The present study was aimed at exploring the nutraceutical effects of low dietary inclusions of conventional feed additives (nucleotides and sodium butyrate) or innovative potential feed supplements such as Louisiana red swamp crayfish meal (RCM) and dried microbial biomass from intact cells of *Tetraselmis suecica* (TS) and *Artrhospira platensis* (spirulina; AP) in fish meal-free diets during a 104 day feeding trial performed on rainbow trout (*Oncorhynchus mykiss*).

Materials and Methods

Four grossly isoproteic (42%), isolipidic (24%) and isoenergetic (23 MJ/kg) test diets were formulated starting from a basal one, named CV, characterized by a 10:90 ratio between marine (hydrolysed fish proteins used as feed stimulant) and vegetable protein sources. For conventional feed additives, a diet coined CV*plus* was prepared by adding sodium butyrate and nucleotides (0.2 and 0.05%, respectively) to CV. The test ingredients (RCM, TS and AP) were used to replace 10% of dietary crude protein supplied by the major plant protein-rich ingredients of the basal diet CV. A total of 750 rainbow trout (79.7 ± 13.5 g) were randomly distributed into 15 squared fiberglass tanks (1.6 m^3; 3 tanks per dietary treatment). At the end of the trial, zootechnical parameters were measured and samples of blood, liver and distal intestine were carefully collected and properly stored for the following analyses. (i) Histology: a series of histo-pathological indexes were evaluated to assess the gut health status, with emphasis on mucosal fold height and inflammatory influx, and the degree of fat accumulation in hepatic parenchyma. (ii) Fourier Transform Infrared Imaging (FTIRI): to evaluate the biochemical composition of liver tissue, false colour images were created resulting from integration process of IR maps in the spectral regions of lipid, protein, and glycogen components. Spectra were extracted and band area ratios were calculated and statistically analysed. (iii) Real-time PCR: relative quantification of the expression of genes involved in immune response (*tlr1*, *nfkb*, *il1b*, *il10*, and *tnfa*) was performed on distal intestine samples. (iv) Blood chemistry: serum aliquots were stored in dry ice, then metabolites, transaminases and minerals were analysed by spectrophotometric assays. (v) Metataxonomic analyses on intestinal microbiota: faecal content was collected, frozen in liquid nitrogen and then analysed by Illumina Miseq sequencing of V3-V4 region of 16S rRNA gene, using Qiime2 for data analysis.

(Continued on next page)

Results and Discussion

The provision of a diet rich in vegetal protein sources (CV) resulted in a severe impairment of distal intestine morphological and histopathological indexes, without affecting growth performances in relation to the best diets here compared. The CV*plus* diet did not result in a significant improvement of zootechnical parameters and showed only a marginal ameliorative effect on distal intestine health status that remained highly inflamed. Both AP and TS diets reduced microbiota diversity compared to the other groups but showed opposite results in terms of growth and gut. Despite no significant differences with CV and CV*plus* diets, fish fed AP diet showed improved zootechnical performances respect to those fed both RCM and TS dietary treatments, possibly due to an enhanced nutrient uptake and a higher digestible-nutrient intake as respectively evidenced by: (i) a significantly higher supranuclear vacuolization of distal intestine enterocyte; (ii) a higher nutrient digestibility of AP compared to that of TS, characterized by thick and cellulosic cell wall. Accordingly, fish fed TS diet were characterized by depressed growth performances compared to fish given CV, CV*plus* and AP diets and by a stronger selective pressure on microbiota, probably favouring those bacteria with specific cellulolytic activities. However, considering the distal intestine health status, providing TS diet resulted in a well-structured and more developed intestinal absorptive epithelium and led to a significant reduction of inflammatory influx respect to both CV and AP diets. In fact, the AP dietary inclusion was not able to fully contrast the negative side-effects of the vegetable ingredients on gut health, leading to a high degree of basal inflammatory influx. Finally, providing 10% dietary crude protein in the form of RCM did not affect zootechnical parameters compared to those observed for fish given diet CV, despite the high biogenic amines content could have led to a reduction in feed consumption and consequently in growth compared to CV*plus* and AP groups. On the other hand, RCM showed promising results due to its ameliorative effects on gut histological conditions, since it is a source of carotenoids (mainly astaxanthin) with a potential beneficial role on distal intestine. In addition, gut of fish fed RCM diet harboured high percentages of the Proteobacteria genus *Deefgea* (12%), a specific bacterial genus that provides a strong chitinolytic activity. Considering liver, both histological and spectroscopic analyses detected a low hepatic lipid accumulation in fish from all the dietary treatments. Based on blood chemistry analyses, the metabolic status, in terms of total proteins and lipids, were similar in all dietary groups, whereas a significant increasing of minerals content was observed in fish fed RCM, TS and AP diets.

As a conclusion, results from the present study demonstrated that both conventional feed additives and all the novel feed supplements investigated were able to ameliorate responses of rainbow trout when added to a vegetable-based diet.

SEARCHING FOR A SUITABLE COMMERCIAL DIET FOR CARPIONE, *Salmo carpio*, TO SUSTAIN A PROPER GROWTH, WELFARE, AND FILLET QUALITY

M. Zarantoniello*, B. Randazzo, G. Secci, F. Faccenda, F. Fava, G. Parisi, E. Giorgini, A. Belloni, R. Cerri, F. Conti, N. Cattaneo and I. Olivotto

Department of Life and Environmental Sciences, Marche Polytechnic University, via Brecce Bianche, 60131 Ancona, Italy
E-mail: m.zarantoniello@staff.univpm.it

Introduction

Carpione (*Salmo carpio*) is a precious endemism of Lake Garda, particularly refined for its high-quality meat thus representing an important commercial resource for the local community. Initially very abundant, in the last three decades the wild population has been drastically reduced leading to the insertion of carpione in the IUCN list of severely endangered fish species. The possible extinction of this species would result in a biodiversity loss and in economic repercussions. On this regard, the farming of this species has been recognised as a solution to ensure the fish product and thus maintaining the gastronomic tradition. However, little is known about the natural diet of carpione raising a concrete issue for the farmers. Currently, a specific diet has not been yet formulated for the growth-out phase leading to the use of diets intended for other salmonids basing the choice on the best compromise between cost and benefit instead of the nutritional requirements of carpione. For that reason, the aim of the present study was to test four diets in which the protein fraction derived from different origins and evaluate their effects on growth, welfare and fillet biochemical composition of carpione during a 3-month feeding trial.

Materials and Methods

Four isolipidic, isoproteic and isoenergetic diets were formulated. Specifically, a diet in which the protein fraction was mainly constituted by marine-derived ingredients (60%) was used as control (CTRL). The other three diets were formulated by partially replacing marine-derived ingredients with plants-derived ones (70% of the total protein fraction; VEG diet) or with land animal proteins (56 or 68 % of the total protein fraction, named PAP1 and PAP2, respectively). Fish were divided in twelve independent fiberglass tanks (700 L; three tanks per dietary group; 40 fish each) and the diets were administered *ab libitum*, 6 days a week, over the whole feeding trial. The fish physiological responses to each dietary treatment were assessed through a multidisciplinary approach including zootechnical performances, distal intestine and liver histology, gene expression of markers involved in immune and stress response (on distal intestine and liver samples, respectively), physical and chemical analyses of the fillet, and macromolecular composition of liver and muscle samples through spectroscopic analyses (FTIR).

Results and Discussion

Fish from each dietary treatment did not show significant differences in terms of growth performance and feed conversion ratio. However, fish welfare was affected by the dietary inclusion of plants-derived ingredients. In fact, an increase in inflammatory influx (including abnormal presence of melanomacrophages), along with the upregulation of all the inflammatory gene markers analysed on distal intestine samples (*il6*, *il10* and *tnf-α*), were highlighted in fish fed VEG diet. Conversely, CTRL diet did not impair the distal intestine health status, while PAPs diets resulted in a better gut condition compared to the others, consisting in a reduction of inflammatory influx and a significant modulation of inflammatory gene expression. Moreover, the enterocytes supranuclear vacuolization increase in distal intestine from PAPs groups indicates a further improvement in gut functionality in fish from these groups. On the other hand, liver composition was differently affected by the diets tested in the present study. Particularly, while CTRL and VEG groups showed a low degree of lipid deposition in hepatic parenchyma, PAPs inclusion caused a higher, dose-dependent, lipid accumulation in liver tissue, along with a higher amount of total fat in the fillet (as detected by both chemical and spectroscopic -FTIR- analysis), and a consequent *hsp70* upregulation, even if not significant, in liver samples. Since diets were formulated to be grossly isolipidic, these differences can be attributed to the dietary fatty acids composition. Specifically, PAP2 diet showed a higher amount of monounsaturated fatty acids and a higher n6/n3 ratio compared to CTRL and VEG ones, which can be related to the hepatic steatosis onset and the high percentage of fat in the fillet. Moreover, while VEG diet marginally affected fillet fatty acids profile compared to CTRL one, a decrease in EPA (20:5n3) and DHA (22:6n3) content was observed in fillets from PAP1 and, particularly, in PAP2 compared to those from CTRL, consistently with the lower amount of these fatty acids in the corresponding diets. This scenario highlighted a reduced ability of carpione in synthesise long-chain

(Continued on next page)

polyunsaturated fatty acids starting from shorter chain precursors. Finally, the present work revealed a marginal effect of the tested diets on the other quality parameters analysed. Particularly, considering skin colour, the presence of PAPs at different levels induced a discoloration of fish skin respect to CTRL and VEG groups, while the hardness of the fillets was increased in VEG and PAP2 fillets.

In conclusion, the provision of vegetable-derived ingredients affects the gut welfare of carpione comparably to other salmonids fish species, while marine-derived ones (fish meal and fish oil) have been demonstrated to act as adjuvant in counteracting these negative side effects. On the contrary, PAPs used in the present study were able to promote fish welfare by promoting gut health and absorption capacity. However, their use must be further optimized to guarantee an adequate fillet fatty acids profile to achieve the quality traits and the consumers acceptance of the final product.

Introduction

Medicinal plants have been used in fish diets as natural antistress (Adineh et al., 2020). Garlic (*Allium sativum*) is a medicinal plant that belongs to the *Liliaceae* family (Talpur et al., 2012). Eurasian perch (*Perca fluviatilis*) is a newly domesticated species that demonstrated potential for European inland culture last years (Policar et al 2015). The present study aimed to evaluate the effects of garlic powder in feed on resistance to crowding stress in Eurasian perch juveniles.

Materials and Methods

Perch juvenile was adapted for 14-days in a recirculation aquaculture system (RAS), and 1320 juvenile perch were distributed in twelve 185 L tanks (110 fish per tank). Feed was extruded at Exot Hobby s.r.o. (Černá v Pošumaví, Czech Republic). Fish with an initial weight of 25.0±0.4 g were fed a diet including 0 (Control), 10 (G10), 20 (G20), and 30 (G30) g kg^{-1} garlic powder manually based on apparent satiation three times a day at 08.00, 12.00, and 16.00 for 87 days. At the end of the feeding trial, fish were crowded with water level descent, netted, and removed from the water for 30 s, and were then returned to the tank, where the water level of the tank was increased back to the original volume, and the density was reduced. Two fish per tank were randomly selected before stress (Pre-stress), immediately post-stress time 0, time 1, time 6, and time 24 h post-stress. (n = 6 per group).

Results and Discussion

Pre-stress, no significant difference in the level of cortisol among groups was observed ($p > 0.05$). At time 0, the level of cortisol was significantly higher in all garlic groups compared to the control ($p < 0.05$). At time 1, the lowest level of cortisol was observed in G30 significantly compared to all groups ($p < 0.05$). At time 6, G20 showed the lowest level of cortisol among groups significantly ($p < 0.05$). At time 24, significantly lower level of cortisol was detected in all garlic groups compared to the control ($p < 0.05$). The glucose levels in pre-stress and time 0 showed no significant difference among groups ($p > 0.05$). At time 1, glucose levels significantly decreased in G20 and G30 compared to the control and G10. At time 6, levels of glucose decreased in G30 compared to the other groups significantly. At time 24, all groups fed with garlic showed significantly lower level of glucose compared to the control. Garlic powder at levels 5, 10, 15, and 20 g kg^{-1} in the feed of Asian sea bass decreased the level of blood serum glucose (Talpur et al., 2012) significantly, and it can be related to the garlic organosulfur compounds such as alliin (S-allyl cysteine sulfoxide) (Zhai et al., 2018). The use of 2 mg nano selenium and 2 ppm garlic extract decreased blood plasma cortisol and glucose in grass carp (*Ctenopharyngodon idella*) under crowding stress (Adineh et al., 2020). Decreasing the level of glucose in the garlic group can be attributed to the bioactive compounds of garlic including diallyl trisulfide (Han et al., 1995), which were higher in the G30 diet compared to the other diets (Talpur et al., 2012). The present study showed that garlic powder at level 30 g kg^{-1} (G30), can decrease the level of cortisol and glucose one hour after crowded stress compared to control significantly.

Introduction

Sobaity seabream (*Sparidentex hasta*) popularly known as silvery-black porgy, is a commercially important carnivorous fish species in the Arabian Gulf sea region (Mozanzadeh et al., 2017). Knowing that this fish is native from the Red Sea, its suitability to the existing environmental conditions (salinity: 41-42‰; optimum temperature 32°C, based on our earlier research) makes this species a good candidate for aquaculture in the country as well as in the Middle East region. One of the major challenges in aquaculture of this species is to develop less wasteful and economic diets. The commercial success in aquaculture operation of the candidate aquatic species will partially depend on the determination of its optimum feed formulation and feeding schedules during the grow-out. In view of the above, this study was conducted to evaluate the performance of practical formulated feeds in comparison to commercial feed for the juvenile (experiment I) and pre-adult stage (experiment II) of Sobaity seabream *Sparidentex hasta*.

Materials and Methods

In this study, two baseline experiments were conducted for 74 days from the Red Sea (41-42‰ salinity, 24.7-30.7°C temperature) to evaluate the performance of practical formulated feeds in comparison to commercial feed for the juvenile (experiment I) and pre-adult stage (experiment II) of Sobaity seabream *Sparidentex hasta*. The fish (195.22 ± 5.8g for experiment I; 298.6± 18.1g for experiment II) was randomly distributed in triplicates of 450-L circular tanks supplied with filtered seawater from the Red Sea. Two test diets D1 and D2 containing 55 and 51% crude protein, 16.9 and 15.8% crude lipid, respectively, were formulated. Additionally, a commercial diet (Diet_{com} 46% crude protein) was used as a control diet. In experiment I, D1 and D_{com} were compared and in experiment II, D1, D2 and D_{com} were compared. In both experiments, triplicates were hand-fed three times a day.

Results

In experiment I, D1 group showed better growth performance (334.6 g over the 74 days feeding trial) and FCR (1.68) than Diet_{com} group (302.62 g, 2.19 FCR). Fish fed D1 diet showed 10.6% gain in weight than that of commercial diet. The better chemical score (CS) of histidine, arginine, threonine, valine, methionine, lysine, isoleucine and essential amino acid index (EAAI) was found in fish fed D1. In experiment II, the maximum growth performance (538.83 g) and lowest feed conversion ratio (1.69, Fig. 1) was noted in fish fed diet D1. Fish fed D1 diet exhibited 10.1% increase in weight in comparison to commercial diet. The CS of histidine, arginine, threonine, valine, methionine, lysine, isoleucine, leucine, phenylalanine and EAAI was found to be best in fish fed D1. A simple economic analysis exhibited that the feed cost per kilogram of fish production was significantly ($P < 0.05$) lowest in diet D1 (USD 3.18 in experiment I, 2.43 in experiment II) followed by the Diet_{com} (USD 3.39 in experiment I, USD 2.56 in experiment II) and then D2 (USD2.7 in experiment II).

Discussion

In experiment I, Sobaity seabreams fed fish meal based diet D1 presented a higher growth performance compared to fish fed commercial diet, while in experiment 2 the partial replacement of fish meal by plant-based protein in D2 resulted in lower fish performance in terms of body weight compared to D1 and commercial diets regardless the dietary protein contents. This reduction in growth performance may be due to low palatability, protein digestibility, availability of essential amino acid and minerals, and also because of the presence of the anti-nutritional factors (Trushenski et al., 2014; García-Ortega et al., 2015). The reduction in the fish growth of D2 treatment with response to the replacement of dietary fish meal by high inclusion of dietary plant proteins has also been published in other aquatic organisms (NRC 2011).

Conclusions

Based on the results, D1 (55% CP) is recommended for improving the culture of sobaity in the Kingdom of Saudi Arabia.

Introduction

Emerging trends in mariculture, the countries having long coastal shoreline improving the aquaculture industry for culturing different marine carnivorous fishes in marine cages. Gilthead seabream (*Sparus aurata*) is one of the most cultured species in cage nets in the Kingdom of Saudi Arabia for more than four decades (De Francesco, 2014). Aquaculture of this species requires cost-effective, nutritionally-balanced feeds. In view of the above, this study was conducted to evaluate the effect of cost-effective improved diets (ID3 and ID5) and commercial diets (CD) on growth performance, proximate composition of juvenile and pre-adult gilthead seabream (*Sparus aurata*).

Materials and Methods

Two different formulations of ID3 and ID5 with a crude protein content of 50.4% and 48.2% were used for juvenile and preadult, respectively. Additionally, commercial diet (CD with 50.7% crude protein) was also used to compare the performance of improved diets for juvenile and pre-adult stages of gilthead seabream.

Results

Feed conversion ratio (Fig. 1), total feed intake, protein-energy ratio, proximate protein content, and protein retention were significantly higher in juvenile fish fed ID3 than in fish fed CD. No significant differences were found in specific growth rate, condition factor, lipid, and energy retention between fish fed ID3 and CD diets. In the pre-adult gilthead seabream, no significant differences were observed in feed conversion ratio, total feed intake, specific growth rate, protein-energy ratio, proximate composition, protein, lipid and energy retention between fish fed ID5 and CD diets. This study indicates that dietary protein level of 50.4% and 48.2% can improve the growth performance of juvenile and pre-adult fish, respectively. The economic conversion efficiency for the improved diets (ID3 and ID5) in juvenile and preadult was found to be lower than that of commercial diets.

Discussion

The crude protein content of the formulated diets (ID3 and ID5) were higher compared to commercial diets and also higher than dietary crude protein reported previously in the literatures (Guerreiro et al., 2019).

The specific growth rate values (1.21 to 1.23%) obtained with the juvenile gilthead seabream in the present study were higher than those SGR values (0.89 to 1.00%) with the juvenile gilthead seabream reported by Sanchez-Moya et al. (2020). Feed conversion ratio of juvenile gilthead seabream fed ID3 was significantly lower as compared to the fish fed commercial diet (CD).

Previous studies suggested that feed that contains high protein (>49%) and high lipid content (15-22%) results in better FCR (0.94-1.12) and good growth performance (Emre et al. 2013).

Conclusions

Since economic conversion efficiency was lower for ID3 (juvenile) and ID5 (preadult) than the commercial diets, diet ID3 (50.4% protein) and ID5 (48.2% protein) may be recommended for the culture of juvenile and preadult of gilthead seabream, respectively.

Introduction

Biofouling is one of the major problems faced by cage aquaculture farmers worldwide, and its management (costs of chemicals, nets cleaning and repair, and fish escapees) is expensive. Current antifouling practices aimed at preventing or minimizing biofouling growth are predominantly achieved through the use of antifouling agents such as paints and coatings. However, these antifoulants contain toxic substances, which can adversely affect marine organisms and their environment. Therefore, research into alternative environmentally friendly antifouling systems such as the application of ultrasound (US) in marine aquaculture is essential. However, the impact of US on non-target aquatic species, such as commercially important farmed fish, in aquaculture facilities has yet to be extensively evaluated. Therefore, the present study explored and investigated fish cage net cleaning using a US device and its effect on the high-value fishery and aquaculture species European sea bass, *Dicentrarchus labrax* after 12 weeks exposure under commercial culture conditions in Turkey. The effects of applied US on haematology and histology in sea bass liver, skin and gills were evaluated. In addition, feed intake, growth parameters, hepatosomatic index, health and immune responses were monitored.

Material and Methods

A field trial was conducted in a commercial offshore aquaculture fish farm in Izmir, Turkey for 12 weeks. European sea bass juveniles with an initial weight of 49.95±13.30 were raised in operational cages (two test and two control cages; diameter: 30 m, depth: 20 m, stocking density: >50.000). The four cages used in this trial were not protected against fouling (no anti-fouling coating was used) to enable the evaluation of the postulated antifouling effect of the US system installed as a prevention measure in two of the cages (Test (T) cages: T1 and T2) against two untreated cages (C1 and C2) used as control (C). Test cages equipped with US devices were set-up for a fixed range frequency (22kHz +/- 100Hz and 35kHz +/- 100Hz) and operational mode full fire. The impact on farmed sea bass in offshore cages was examined throughout sequential sampling including a reference sampling (d0) before ultrasound system (US) application, after one week (d7), and further in a one-month interval (d37, d67 and d97) of continuous application. Fish behavior (swimming, feed intake) were monitored every day by the fish farm. A total of 200 European sea bass (10 fish/cage) were sampled for further laboratory analyses.

Results and Discussion

This study concluded that the growth and survival of analyzed European seabass in T and C groups were unaffected by a long-term US exposure under aquaculture conditions. Furthermore, histological examination of the liver hepatic parenchyma did not present any distinguishable histopathologic abnormalities or changes attributable to US between T and C groups. A comparison of the results of the blood smears (red and white blood cell, and trombocytes counts) before and after exposure to US did not reveal any major changes, as the counts of the blood cell types of both the first sampling (d0) and the last sampling (d97) were in matching ranges. The application of US as an antifouling method in mariculture systems is practicable and does not cause any noticeable health restrictions in European sea bass (Dicentrarchus labrax), at least at a frequency range of 22kHz - 35kHz (± 100Hz) over a trial period of 3 months. Nevertheless, final histological evaluation of sea bass skin and gills are pending!

As stress response can differ between species, the end product should be tested in other commercially important species as well in order to proof the safeness of system and tune fine it for each species and condition.

This study is part of the EU-project “Smart System for the Prevention of Biofouling on Aquaculture NETs by Ultrasonic Wave Technology” (NetWave), and it has received funding from the European Union’s Horizon 2020 research and innovation programme under grant agreement No 958776.

EFFECTS OF ASTAXANTHIN FROM CORYNEBACTERIUM GLUTAMICUM ON GROWTH PERFORMANCE, MUSCLE PIGMENTATION AND HEALTH STATUS OF JUVENILE RAINBOW TROUT *Oncorhynchus mykiss*

Introduction

Colouration of fish, especially salmonids, is an important quality criterion for consumers. In nature, salmonid fishes get their muscle colouration through their natural prey, such as small crustaceans, which normally contain Astaxanthin (Asx). In aquaculture, the colouration can be achieved by supplementing Asx to the formulated diets. Asx can be produced synthetically or through natural vectors, such as microalgae or bacteria. Asx is not only responsible for the coloration of the fish, but can also have impacts on the antioxidant activity of fish (Sheikhzadeh et al. 2012). Therefore, in this trial, we investigated the effects of Asx from *Corynebacterium glutamicum* and compared it with other sources of Asx on growth, muscle pigmentation and health status in juvenile rainbow trout.

Material and Methods

Feed enriched with Asx from different sources was investigated in juvenile rainbow trout with an initial weight of 25 ± 3.6 gr. Five feed groups were examined in quadruplicates (C: without Asx supplement (control); SA30: synthetic Asx; PA30: natural Asx supplement, Panaferd©; AA30: algae-based Asx, *Haematococcus pluvialis*; BA30: bacteria-based Asx, *C. glutamicum*). Forthy fish per replicate were fed for 8 weeks and growth was monitored at experiment onset, after four weeks and at the termination. Ten fish per replicate were sampled in the end of the experiment for muscle and liver Asx content determinationt by HPLC. Fillet colour were determined visually by DSM SalmoFan card scores. In addition, whole body composition, organ indices and haematological responses were assessed.

Results and Discussion

Final Results are pending. However, the first results from mid-term sampling (after 4 weeks) showed clear differences on growth and pigmentation of fillets of rainbow trout fed with different Asx source supplement diets. Although the pigmentation of bacteria-based Asx fed groups were very promising as other Asx source fed groups, the growth was lower than other experimental groups. However, conclusions are not possible since the full data set is not available yet. Preliminary results are presented in Table.1 and Figure. 1.

This research was supported by the ERA-NET BlueBio COFUND Project SIDESTREAM [Gran ID 68], cofounded through national funds provided by the the Funding by the German Federal Ministry of Education and Research (BMBF), FKZ161B0950B.

Introduction

Clawed Fork Weed *Furcellaria lumbricalis* (Hudson) J.V.Lamouroux is a species native to the waters of the Baltic Sea, which formed rich communities on the bottom of the Puck Lagoon (Southern Baltic) until the 1960s. As a result of severe anthropopressure from exploitation by dredging, rapidly increasing levels of eutrophication and industrial pollution, between 1970 and 1980, the lagoon's environment was severely degraded, which ultimately led to the disappearance of the weed population. *F. lumbricalis* has been observed again in the waters of the lagoon since 2019 and the population is gradually increasing its range.

Due to the fact that this taxon has a very high commercial potential and is exploited in another area of the Baltic (Estonia) any information on the biology and ecology of the taxon is extremely valuable. In this study, we will present the results of an experiment to explore the ecological requirements of the current *F. lumbricalis* population in relation to temperature and salinity in the context of biomass growth.

Materials and methods

F. lumbricalis was collected from a beach near the waterline in June and October 2021 in the vicinity of Rewa (54°40'18.18 "N; 18°32'19.39 "E). After being transported to the laboratory, the tissues were cleaned of overgrowing plant and animal organisms and organic and inorganic particles. Only undamaged specimens, visually in the best possible condition, were selected for the experiments. Before starting the experiment, the initial weight of specimens was determined, after draining excess water. The experiment was carried out on plants acclimatised to the experimental conditions for a period of 7 days. The study was carried out in an aquarium flow-through system, consisting of three circuits with four aquaria in each (tank dimensions: 50 x 35 x 30 cm; volume: 50 l).

Light of four, different intensities of photon flux density was used for the experiment, i.e.: 50, 110, 170 and 200 μmol photons m^{-2} s^{-1} and three water temperature values, i.e.: 10, 15 and 20 °C. Each experimental treatment was performed in three independent replicates by placing 2 dm^3 glass tanks inside each aquarium. Three to four specimens of about 2.91 g m.m were placed in each tank.

The plants were maintained in a 1.5 l culture solution with a salinity of 7 PSU, prepared on the basis of artificial Marine seawater with the addition of nutrient solution. The experiment lasted for a total of 50 days and biomass measurements were taken when the culture medium was changed, i.e. every 7 days. Based on the results of the biomass measurements, the Daily Growth Rate (DGR) was determined.

Results

At 10 °C, the DGR rate varied from -1.59 % to 3.58 % on average. The highest values were observed on the 15th day of measurements (from 1.80 % for light of 50 μmol photons m^{-2} s^{-1} to 3.58 % for light - 170 μmol photons m^{-2} s^{-1}), while negative values of the index occurred on the 22nd day after the start of the experiment. Considering the magnitude of the light, the highest values of the DGR rate occurred in high light of 200 μmol photons m^{-2} s^{-1}, even on the last day of the test, despite the high necrosis of the fronds, the DGR was 1.0 %. On the last day of measurement, only at light 110 and 50 μmol photons m^{-2} s^{-1} the DGR index had a negative value.

At 15 °C, the DGR index ranged from -4.19 % to 4.58 %, with the highest values on the 15th day of measurement (from 1.63 % for a light of 50 μmol photons m^{-2} s^{-1} to 4.58 % for a light of 170 μmol photons m^{-2} s^{-1}). Negative values of the index occurred after the 22nd day of the experiment, at which time fragmentation of the fronds was observed. Considering the light intensity, *F. lumbricalis* had the highest growth values falling mainly on the 15th day of the test, with subsequent measurements, positive values of the DGR indicator were observed mainly in the low light of 50 μmol photons m^{-2} s^{-1}.

(Continued on next page)

At 20 °C, the DGR ratio ranged from -12.98 % to 5.41 %. The highest values were observed on the 15th day of measurement (1.82 % for light of 50 μmol photons m^{-2} s^{-1} to 5.41 % for light of 200 μmol photons m^{-2} s^{-1}), and negative values of the index were observed 22 days after the start of the experiment. It was then that strong necrosis and decay of the fronds was observed. After day 29 of the experiment, there was a strong loss of biomass in each light variant.

In all temperature variants (10, 15 and 20 °C), maximum DGR values occurred at aquaria with high light (170-200 μmol photons m^{-2} s^{-1}), and minimum values occurred at low light (50 μmol photons m^{-2} s^{-1}). The first fronds decomposition and the successive decrease in biomass always occurred between days 15 and 22 of the experiment. The lowest DGR rates were determined for *F. lumbricalis* in circulation with a water temperature of 20 °C.

Conclusions

The growth of *F. lumbricalis* was most influenced by temperature, followed by light. The most optimal conditions for growth with respect to water temperature were in the range of 10-15 °C, and for light in the range of 170-200 μmol photons m^{-2} s^{-1}. Maintaining cultures at high temperature combined with high light led to high fragmentation and necrosis of the fronds.

The use of artificial seawater for laboratory cultures and the treatment of *F. lumbricalis* prior to experiments was shown to be an insufficient way to avoid overgrowth of organisms and culture tanks by unwanted organisms.

Introduction

8-Hydroxydeoxyguanosine (8OHDG) and dityrosine (DIY) are specific biomarkers of DNA and protein damage from oxidative stress, respectively (Valavanidis, et al. 2009; Malencik, et al. 2003). Nowadays, 8OHDG analysis in fish is mostly performed with these specific kits/antibody methods (Oğuz, et al. 2018; Gyimah, et al. 2020; Alak, et al. 2017). However, the selectivity of ELISA in trace concentrations can be compromised from cross-reactivity with other co-occurring analogues, while simultaneous determination of 8OHDG and DIY with a single assay is currently not available. With this background, an extraction methodology tailored to UPLC®–ESI (electrospray)–MS/MS analysis was developed in the present study for the simultaneous determination of 8OHDG and DIY and was applied in tissue samples (skin, gills, dorsal fin, and liver) that were collected from Atlantic salmon parr individuals reared in an experimental recirculating aquaculture system (RAS) treated with peracetic acid.

Materials and Methods

The skin, gills, dorsal fin and liver were collected from 234 Atlantic salmon parr (4 x 234 = 936 samples) at the Tromsø Aquaculture Research Station in Kårvik, Norway (Mota, et al. 2022). The tissue samples were thawed in room temperature and a portion of ~100 mg of each tissue sample was transferred into a 15 mL PP tube. Samples were fortified with 15 µL of 1000 ng/mL isotope labeled IS-mixture followed by the addition of 600 µL MeOH containing 1% ammonium formate (w/v). Thereafter, the samples were vortex mixed (30 s) and ultrasonication (30 min) was performed followed by centrifugation (5 min, 3500 rpm). The supernatant was collected and transferred into a new 15 mL PP tube. Two different cleaning methods were tailored to the extraction protocol. Finally, the extarct was transferred for UPLC®-MS/MS analysis.

Results

The relative recoveries of 8OHDG and DIY were 101±11.1 % and 104±12.0 %, respectively, ensuring the accuracy of the extraction and quantification. The inter-day precision (method reproducibility, RSD %, N = 18) at the fortified concentration of 10 ng/mL were 5.62 and 5.18 % for 8OHDG and DIY, respectively. The chromatographic separation was carried out using a gradient elution program with a total run time of 5 min. The limits of detection (LODs) were 0.11 and 1.37 ng/g wet weight (w.w.) for 8OHDG and DIY, respectively. To demonstrate the applicability of the developed method, it was applied in 907 tissue samples that were collected from Atlantic salmon parr individuals reared in an experimental land-based recirculating aquaculturesystem (RAS) treated with peracetic acid. The detection rates of both target analytes were > 70% in the tissues, except from the low detection rate of 8OHDG reported in the liver samples (24%). Moreover, the possibility of using dorsal fin as an alternative matrix for the minimally invasive assessment of oxidative stress in Atlantic salmon parr was introduced.

Conclusions

A methodology tailored to UPLC®-MS/MS was developed for the determination of two oxidative stress biomarkers, 8OHDG and DIY, in gills, skin, dorsal fin, and liver tissue of Atlantic salmon parr. The method was applied successfully in 907 fish tissue samples from Atlantic salmon, and both biomarkers were detected in most samples. Moreover, correlations of the biomarkers across tissues were uncovered, introducing the possibility of using dorsal fin as an alternative matrix for the minimally invasive assessment of oxidate stress in Atlantic salmon parr.

Introduction

For the rapid expansion of the aquaculture sector, the feed industry is using amongst others plant ingredients as alternatives to replace fishmeal and -oil (FAO, 2016). However, the inclusion of low-quality plant ingredients as fishmeal alternatives will mostly result in decreased digestibility of these diets, as most plant ingredients contain anti-nutritional factors (Sinha et al., 2011). Shifting to plant-based feed with good nutrient digestibility is of importance for the aquafeed industry and long-term sustainability of the aquaculture sector.

Dietary fat is the most energy-dense macronutrient (proximately 39.5 kJ/g) in feed to fulfil the energy and fatty acid requirements of animals for maintenance and growth (Hardy & Kaushik, 2021). For good fat digestion processes, proper emulsification in the gastrointestinal tract needs to take place, whereby bile acids play a role. Fishmeal contains bile acids, while plant ingredients lack these bile acids, especially plant ingredients with high non-starch polysaccharide (NSP) contents. NSPs are far less digestible compared to fishmeal and also interferes with other feed macronutrients, overall resulting in decreased nutrient digestibility (Sinha et al., 2011). In addition, NSP are believed to enhance bile-acid losses, due to binding with faces, more faces production and deconjugation by the gut microbiome (Staessen et al., 2021). Therefore diets containing high NSP level are usually considered as low-quality diets. Replacing fishmeal with low-quality plant ingredients may therefore hamper fat digestion. It is hypothesized that dietary supplementation with emulsifiers can improve (fat) digestion in fish, especially for diets lacking fishmeal and being high in NSP content. This study assesses the potential to improve digestibility and performance of Nile tilapia by the supplementation of two types of emulsifiers (bile acid or a commercial emulsifier), which was tested with two types of diets; a diet with a low NSP content and a diet with a high NSP content.

Materials and methods

This experiment involved a six-week growth trial with Nile tilapia (*Oreochromis niloticus*). Six diets were tested in a 2 x 3 factorial design with 3 triplicates. The first factor is the quality of the diet, created by differences in NSP level (low versus high NSP level). The second factor is 3 types of emulsifier supplementation (Non; 0.5g/kg bile acid ; 0.5g/kg commercial emulsifier). The commercial emulsifier, Excential Energy Plus which is composed of 21% ethoxylated castor oil, was provided by Orffa (orffa.com). In total six diets were tested: Diet 1: Low NSP, without supplement; Diet 2: Low NSP + bile acids; Diet 3: Low NSP + commercial emulsifier; Diet 4: High NSP, without supplement; Diet 5: High NSP + bile acid; Diet 6: High NSP + commercial emulsifier. During the growth trial fish (average initial weight 48.37 ± 0.63 gram) were fed twice daily at apparent satiation. Faeces were collected during the last week of the experiment, to study nutrient digestibility.

Results

Our results showed a significant effect of NSP levels, but no effect of emulsifier on fish performance. Dry matter, fat and carbohydrate digestibility were all affected by the interaction of NSP levels and emulsifier supplement (Table 1). Fat ADC was the most strongly affected by emulsifier supplement and the interaction (Figure 1). In fish fed the low NSP diet, both bile acid and commercial emulsifier improved fat ADC, but no effect was found for the high NSP diet. These results indicate that the supplementation of bile acid/emulsifier can improve fat digestibility in Nile tilapia, but the effect seems to be dependent on the diet quality.

Introduction

Aquaponics (integration of aquaculture and hydroponics) is gaining renewed interest in enhancing food security. Several limitations, including energy and resource demand, nutrient imbalances, and waste management, have, however, limited their widespread application (Goddek et al., 2019; Somerville et al., 2014). Efficient onsite treatment of aquaponics waste and its conversion to nutrient and energy sources may be advantageous. Zhu et al. (2021) demonstrated that plant wastes (e.g., roots and inedible parts) from aquaponics could be treated with high efficiency using anaerobic digestion (AD). Similarly, this is also the case for AD of fish sludge from RAS (Quinn et al., 2016; Yogev et al., 2020). The resulting biogas can be combusted to produce electricity and heat, while the remaining nutrients in the supernatant can be applied as fertilizer (Zhu et al., 2022). The carbon cycle and footprint of the aquaponics systems, especially the carbon dioxide, which is a significant contributor to global warming, have not yet been considered by other studies. This study aimed to investigate the performance of a novel off-grid aquaponics system with zero water and waste discharge, focusing on the carbon cycle and energy recovery that was achieved by the addition of onsite anaerobic treatment of the solid waste streams.

Materials and Methods

The experiments were carried out in a desert aquaponics facility located in a greenhouse with RAS and an adjacent net-house containing deep water culture hydroponics beds at Ben-Gurion University of Negev, Israel. The design of the near-zero waste aquaponics system was based on four treatment loops. Catfish (*Clarias gariepinus*; n=264) was stocked with daily feeding of 2% of the total stocking biomass. Lettuce seedlings (*Lactuca sativa cv. Noga*) were introduced on the floating rafts of hydroponics. Following a stabilization stage, the system was closely monitored for four months. An input-output model to support balances concerning the carbon cycle and footprint in the near-zero waste aquaponics was developed.

Results and discussion

Fish tank water was recirculated via a solid removal unit and nitrification reactor, from which 66% was recycled to the fish tank directly and 34% indirectly through the hydroponically grown plants. Fish stocking density was 15.3 kg/m^3 and over time reached approximately 40 kg/m^3 where it was maintained. Typical fish performance was observed with a survival rate >97% and a feed conversion ratio of 1.33. Results show that 1 kg of feed per day was able to produce about 0.75 kg of fish and support 33.8 kg of fresh lettuce. Fish sludge and plant waste were anaerobically treated, energy was recovered, and the nutrient-rich supernatant was recycled to the plants to enhance production. Lettuce production was up to 5.65 kg/m^2, significantly higher than previous reports, largely because of high nutrients reuse efficiency from the anaerobic supernatant that contained 130 and 34 mg/L N and P, respectively. Of the feed carbon, 24.5% was taken up by fish biomass. Fish solid wastes contained 38.2% carbon, of which 91.9% was recovered as biogas (74.5% CH_4). Biogas production was 0.84 m^3/kg for fish sludge and 0.67 m^3/kg for dry plant material. CO_2 sequestration was 1.4 higher than the feed carbon, which reduced the system's carbon footprint by 64%. The energy consumption per ton of fish stocked in this system is expected to be 84.4 kWh/day, and the potential energy recovery from the waste via AD will be about 83.7 kWh/day, with 85% energy use efficiency of CHP from the biogas to support about 84% of the energy demand for its operation. This study is the first to demonstrate highly efficient fish and plant production with near-zero water and waste discharge and with energy recovery that can potentially supply the system's energy demand.

Conclusions

A near-zero waste desert aquaponics system, which combined aquaponics and anaerobic digestion technologies into a closed system with a small environmental footprint, was successfully demonstrated. The current study is the first to demonstrate a significant recovery of water, energy, and nutrients from aquaponics waste streams. Alternatively, seen from a broader perspective, this concept would allow fish and vegetable production in nontraditional agricultural land, such as rural areas with insufficient electricity supply or in urban environments close to the customer.

Introduction

Aquaculture is currently the fastest growing animal food production sector, driven by the increased human consumption and market acceptance. Of the major constrains to sustainable production by aquaculture is the incorporation of fish meal and fish oil (FMFO) from capture fisheries, as key ingredients in fish feed in general and in carnivorous fish in particular. FMFO provides essential nutritional components such as amino acids, phospholipids, and fatty acids (such as the omega-3 LC-PUFA docosahexaenoic acid, DHA, and eicosapentaenoic acid, EPA) for optimal development and growth. The FMFO industries are one of the few major animal industries, which still rely on hunting-and-gathering technique. Thus, most fish rendered into meal and oil are captured at sea, which is unsustainable. By this practice millions of tons of FMFO is produced worldwide, posing a significant associated environmental damage. The annual supply of FMFO is presently 6.0 to 6.5 million tons.

Microalgae are primary producers of high-valued biomolecules, such as lipids, proteins, pigments, polysaccharides, LC-PUFA, all with beneficial health-related properties and can therefore serve as a sustainable alternative to FMFO in fish nutrition. n-3 LC-PUFA, EPA and DHA, which are produced by certain microalgae, have immunomodulatory properties and therefore hold major health benefits for humans and fish.

The aim of this study was to investigate the use of microalgae as a substitute for FMFO for feeding barramundi (*Lates calcarifer*), a carnivore fish. Microalgae with specific composition of *n*-3 LC-PUFA were selected to provide the required composition of these fatty acids in the fish feed.

Methods

Microalgae-formulated diets (NI and NIP) containing a combination of *Nanochloropsis oceanica* (N), *Isochrysis galbana* (I) and *Porphyridium purpureum* (P), and no added FMFO were prepared. The diets combining the different microalgae species were constructed to achieve 50% crude protein and c*a*. 11% lipid, by the following composition: NI - containing 7.5% N; 12.5% I; NIP diet - containing 7.5% N; 12.5% I; 3.13% P; and a commercial control diet which contained fish oil. The dietary trial was conducted in a RAS system where juvenile Barramundi (*Lates calcarifer*), with an average weight of 24 ± 0.9 g were stocked in 250 L tanks (1.4 kg/tank). Each dietary group consisted of three replicate tanks (total of nine experimental tanks). Fish were fed with the experimental diets for a period of 8 weeks at 2% of their body weight once a day.

Fish weight was monitored weekly and at the end of the trial fish were sampled and used for the following analyses: 1) whole body proximate composition (moisture, ash, protein, fiber and total lipid contents); 2) blood samples were collected for plasma immunoassays (lysozyme, antiprotease, and myeloperoxidase activities); 3) qRT-PCR based gene expression analysis from head kidneys and blood leukocytes; 4) Histological analysis of internal organs; 5) Microbiome analysis of the gut. In addition, 15 fish from each tank (45 fish per treatment) were challenged with *Vibrio harveyi* by intraperitoneal (IP) injection (100 μl of 10^8 cfu ml^{-1}). Mortality was monitored for 10 days.

Results

Fish fed the microalgae-based diets demonstrated significantly better growth performance (Figure 1a,b). Microalgae-supplemented diets also led to significantly higher survival following bacterial challenge. Immunoassays carried out on fish plasma samples revealed enhanced lysozyme and antiprotease activities in fish fed NI and NIP diets as compared to control. Further analyses of the samples collected are underway.

Our results demonstrate that the mixture of microalgae meal used in this study can improve growth metrics and boost immune defense. We demonstrate that the LC-PUFA rich algal meal can be used in diets of barramundi as an alternative ingredient to fish oil. Our research efforts is a step towards eliminating dependence on fish meal oil, and to improve sustainability of the farmed fish.

Introduction

Fish production by recirculating aquaculture systems (RAS) is rising. As fish recover only about 20-30% of the applied feed as biomass, a novel reactor which assimilates the excreted nitrogen into microbial biomass was developed (Yogev and Gross, 2019). This novel reactor reduces the environmental impact of water treatment by nitrification and the discharge of nitrogen through effluents, as done in conventional RASs, as well as enables utilization of the high-valued nitrogen by production of high-protein microaerophilic microbial biomass (MMB) as a feed ingredient. Since feed is the most expensive component in aquaculture, this approach holds an economic potential.

Methods

For the production of MMB by the RAS assimilation reactor, an external carbon source is required to achieve a minimal C:N ration of 15, for which wheat, sugar (SUG) and semolina (SEM) were used. MMB was harvested daily, oven dried (50 ºC), powdered (Fig 1) and used as a feed ingredient for barramundi (*Lates calcarifer*) in two separate trials:

Trial 1: experimental diet was prepared by replacing 20% (w/w) of commercial barramundi feed with dry MMB (wheat as a carbon source) and commercial feed as control.

Trial 2: four reconstructed diets containing different biofloc levels of 15 and 25 % from semolina and sugar as carbon sources were used (15% SEM, 25% SEM, 25% SUG and un-supplemented control).

The trials were conducted in 100 L plastic tanks stocked with barramundi (average weight 27± 0.9 g) at a density of 20 kg/m^3, in three replicates. Feed was applied at 2% body-weight per day. Fish were fed for a period of 8-10 weeks, during which their growth was monitored.

At the end of the trial, the whole-body proximate composition, serum immune function, gene expression were analysed. Fifteen fish from each treatment were challenged with *Vibrio harveyi* to examine their disease resistance.

Results

Survival was 100% in all treatment groups. In both studies, weight gain was significantly ($p < 0.05$) higher in control-fed barramundi as compared to biofloc-fed groups and negatively correlated with the inclusion levels. Feed conversion ratio (FCR) in all treatment groups ranged between 1 to about 2. It did not significantly differ between the treatment and control groups in trial 1 (1.36 and 1.09, respectively; $p>0.05$) but in the 25% biofloc diet in trial 2, FCR was significantly elevated as compared to 15% biofloc and control food (2.03, 1.41 and 1.19, respectively; $p<0.05$). Fish composition was not affected by the different diets.

(Continued on next page)

Figure 1: Biofloc preparation for incorporation in the feed (left to right): Wet biofloc after centrifugation (supernatant discarded); Oven-dried biofloc (50 ºC); Ground biofloc.

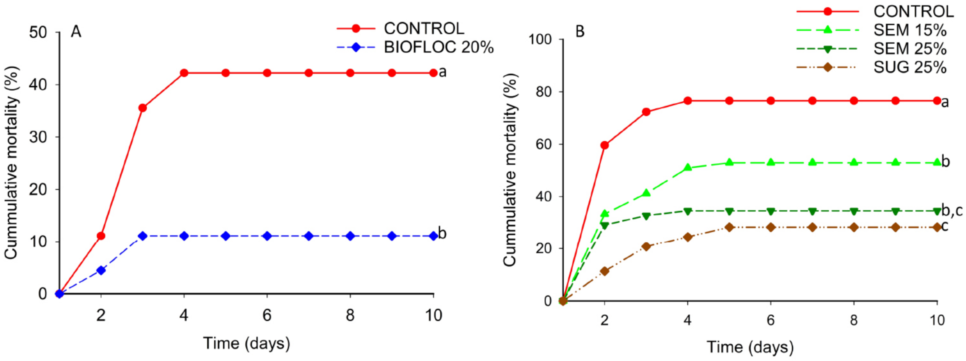

Figure 2: Mortality of fish challenged with V*ibrio harveyi* in trials 1 (A) and 2 (B). Data presents daily cumulative mortality of fish fed with control and treatment diets (n=3 replicate tanks, 15 fish per tank).

Biofloc inclusion improved barramundi resistance to bacterial infection, and higher survival was noted in both trials (Fig 2). Analysis of fish sera showed higher activities of immune factors including myeloperoxidase and lysozyme as compared to control-fed fish in both trials. Results of qPCR revealed significantly higher expression of five immune-related genes (galectin, C-type lectin, hepcidin, lysozyme and complement) in the kidneys of the biofloc-fed fish.

Results demonstrate that biofloc can be used as a feed ingredient in carnivorous fish. Selected levels should be considered to optimize production based on growth and survival performances.

Introduction

Microalgae exhibit tremendous potential to be an environmentally sustainable solution for bioremediation as they have the capacity of efficiently recovering nutrients from agricultural wastewaters, while simultaneously producing high value bioproducts with various biotechnological application[1,2]. *Chlorella vulgaris, Scenedesmus quadricauda* and *Haematococcus pluvialis* are three widely cultivated freshwater microalgae strains with established commercial exploitation due to their high added-value biomass which we have shown to be effectively cultivated in hydroponic effluents.

Material and Methods

Three widely cultivated strains, *Chlorella vulgaris 211/11B* (CCAP)*, Scenedesmus quadricauda 276/21* (CCAP) and *Haematococcus pluvialis 34/7* (CCAP) were grown under steady conditions (temperature: 24±1˚C, photoperiod: 12:12h L:D, light intensity: 150 μmol photon $m^{-2}s^{-1}$) for 5 days and inoculum re-cultivated in three different culture media: L1 (control medium), PR (hydroponic effluent) and PR-L1 (hydroponic effluent enriched with the micronutrients mixture used to create the nutrient medium L1). Moreover, two aqueous (CVW and SQW) and two ethanolic (CVE and SQE) extracts were prepared by freeze-dried biomass of *C. vulgaris* and *S. quadricauda,* respectively. Total biochemical characterization was determined to all extracts. *In vitro* protective role of the extracts against H_2O_2 induced Caco2 cells was estimated by MTT assay. Subsequently, total RNA was isolated from Caco2 cells exposed to H_2O_2 after a pre-incubation with CVE (0.5μg/ml) and SQW (1μg/ml) extracts. Antioxidant defense pathway and inflammation related genes were selected for analysis.

Results

Our results revealed that all microalgae species included in this study were able to efficiently grow in hydroponic water effluents utilizing the available nutrients (Fig.1)

The biochemical characterization of custom produced extracts from the respective biomass (Table 1) highlighted its potential to be used as bioactive supplement in many applications. To this end, the ability of these extracts to protect Caco2 cells against H_2O_2 induced oxidative stress was demonstrated (Fig.2)

Moreover, the observed protective effects could be clearly attributed to the modulation of the transcription of several human genes involved in oxidative stress responses, by both the CVE and SQW microalgae extracts (**Table 2**).

Conclusions

All the strains when cultivated using the PR and PR-L1 media exhibited similar and sometimes even higher growth rates. CVE and SQE extracts present greater antioxidant activity, flavonoid and pigment content. CVE (0,5 μg/ml) present no cytotoxicity on Caco2 cells and upon 24 hours incubation enhanced viability of H_2O_2-treated cells to 103% whereas SQW (1μg/ml) enhanced viability of H_20_2 treated cells up to 92%. Transcriptome analysis of Caco2 cells pre-treated with CVE and SQW followed by H_2O_2 induced oxidative stress revealed significant alternation at oxidative stress and inflammation related genes expression.

Introduction

Globally, aquaculture is the fastest growing agri-food sector and it is increasingly seen as the primary activity to meet the growing consumer demand for fish. Up to now, European seabass (sp. *Dicentrarchus labrax*) and Gilthead seabream (sp. *Sparus aurata*) are the most commonly farmed species in the Mediterranean Sea, with a production of 464,000 tons and USD 2.24 billion in 2019 (FAO, 2020). However, intensive fish farming, implies environmental concerns related to the consumption of feed, the emission of nutrients and organic compounds into the water and, sometimes, the consumption of pesticides and antibiotics for pest and disease control (le Feon et al., 2021). Developing sustainable aquaculture is a priority in the current economic and social context. Therefore, aquaculture production systems must change to improve environmental performance and decrease energy consumption. To achieve these objectives, a holistic perspective is needed considering the impacts generated by production, and Life Cycle Assessment (LCA) approach is considered the most suitable tool for analyzing such a wide spectrum. In this study, LCA was applied to assess the environmental impact related to Seabass and Seabream farming of an off-shore plant located in Central Italy.

Materials and method

The selected functional unit (i.e., the reference unit of the study to which all the inputs and outputs should be referred) was 1 ton of Seabass and 1 ton of Seabream at the fish farm gate. Moreover, the different feeds supplied were analysed and the impact of 1 ton of different feeds calculated. The system boundary includes the production of feed and other production factors consumed (e.g., fuel, electricity), the rearing operations and all the emissions related to the process (e.g., phosphorous and nitrogen emissions due to the metabolism of the fish during the entire production cycle). The inventory data was collected in a commercial aquaculture plant in Central Italy. Primary data refers to the consumption of different feeds based on the sizes of fish, energy and fuels while secondary data was used with regard to the emissions of N and P compounds from fish (Cho et al., 1991), fry production (Garcia Garcia et al., 2019) and feed composition (estimated with a centesimal analysis based on the content of proteins and fats). Background data about cages and other capital goods as well as about the component of the feed were retrieved from databases (Ecoinvent® and Agrifootprint). The environmental profile of the production system was analysed with the Recipe Midpoint (H) method, taking into account 12 different impact categories.

Results

For European Seabass and Gilthead Seabream, the environmental results, for most of the considered impact categories, showed that aquafeed is the main environmental hotspots. The species analysed show the same results as regards the analysis of contributions. For the Climate Change impact category, aquafeed impacts about 60% of the total impact, while for marine eutrophication the emissions of N compounds accounts for 95% of impact. Infrastructures have an high impact in the human carcinogenic toxicity (75%) and mineral resource scarcity (59%). Comparing the two species, Seabass has higher impacts in all impact categories than Seabream: this is mainly due to the higher FCR of Seabass than Seabream (respectively 2.4 and 1.9), which also results in higher emissions of nitrogen compounds per kg of fish produced. In addition, Seabass has a higher average mortality rate (20% vs 8% for Seabream): therefore, a greater number of fry is necessary to obtain the same production. Finally, the feeds that contain a greater quantity of fish meal and fish oil, supplied to smaller sized fish, have the highest impacts.

Conclusions

This study confirmed that aquafeeds management is the main responsible for most of the impacts. Measures that optimize the production and use of fish feed are necessary and can positively affect the environmental performances of aquaculture sectors. Similar results, both in absolute terms and in terms of relative contributions, are reported by other studies (Aubin et al., 2009; Abdou et al., 2017). To date, the large amount of protein and lipids required for fish growth is mainly provided by fishmeal and fish oil from freshly caught fish stocks. Therefore, it is essential to optimize and modify diet formulation

(Continued on next page)

as well as to study alternative feeding strategies in order to lower FCR. In addition, aquaculture requires a very high consumption of fossil fuels (both for the mobility of ships and for the supply of feed and fry); for this reason, following the example of the SIMTAP system developed during the project SIMTAP (Self-sufficient Integrated Multi-Trophic AquaPonic systems for improving food production sustainability and brackish water use and recycling), new diets characterized by limited transportation impacts and by the use of locally produced raw materials, combined with the maximization of the use of renewable energy (e.g. solar energy) and alternative protein sources (e.g. microalgae) can represent other effective impact mitigation strategies. Finally, besides the environmental performances also the economic and social ones should be evaluated for a more comprehensive assessment of the process sustainability

Introduction

The estimation of the carrying capacity (CC) is a fundamental process in integrated environmental management, policy making, and decision making. Aquaculture carrying capacity has been studied since the 1960s to allow estimation of the production limits of aquaculture projects and, hence, their maximum economic performance within sustainable limits for the local environment. One major drawback of these approaches is that they can provide CC estimates after a fish farm is installed and operates in a certain location (ex post approaches). This work approaches the estimation of CC using a Bayesian/CHAID model of profiling information on the environmental quality, geomorphology, and human activities on the adjacent coastal area (land side) using as an indicator the trophic state of the marine area in terms of chlorophyll-*a* concentration (upper meso- trophic).

Material and methods

Eight marine cage farm sites in Greece (Sterea Ellada region; Figure 1) were selected, for the collection of a variety of physico-chemical data: temperature, salinity, dissolved oxygen (DO), dissolved inorganic nitrogen (DIN = ammonium - NH_4^+ +nitrates - NO_3^- + nitrites - NO_2^-, soluble reactive phosphorus (PO_4^{-3}), total nitrogen (TN), total phosphorus (TP), chlorophyll-a (Chl-a), suspended particulate matter (SPM), total organic carbon (TOC), particulate organic carbon (POC), particulate organic nitrogen (PON) and particulate organic phosphorus (POP). Water samples were taken at 1 m below the surface and 1 m above the bottom, on a monthly basis, during the period March 2015 - May 2016. Moreover, geomorphological data (depth, watershed, fetch, openness, coastal area, exposure and water retention time), a farm operational parameter (biomass), and a social parameter (local inhabitants) were also used.

Results

The application of the Bayesian–CHAID algorithm, based on the monthly data of all parameters measured, showed that the CC of the studied fish farm areas (measured as the maximum cultivated biomass so that the eutrophication level remains always at the upper mesotrophic level or below), is affected by the following parameters (ranked from most important to least important): particulate nitrogen, salinity, silicates and suspended particulate matter and the overall relationship found for the biomass carrying capacity is:

$$\text{Biomass at CC level} = +473.762[\text{Chl-a}] - 6856.64[\text{PN}] + 9.302[\text{Salinity}]$$
$$- 473.5[\text{Si-SiO4}] + 341.864[\text{SPM}] - 207.046$$

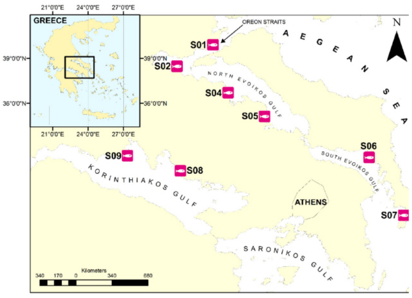

Figure 1. Farm sites location

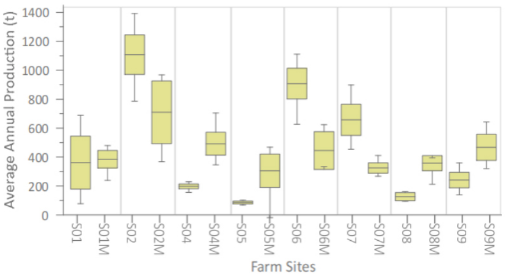

Figure 2. Annual average actual production and the model predictions for each farm site (letter M in y-axis labels denotes the model estimates).

(Continued on next page)

The application of the model to the current farm sites shows that from the 8 farms studied, only S01 should maintain their level of annual production to achieve the environmental goal of a eutrophication level up to 3 (upper mesotrophic). Of the rest farms S02, S06, and S07 should reduce their average production, while farms S04, S05, S08, and S09 can easily increase their average production and almost double it (Figure 2).

In addition, the analysis performed allowed us to estimate the maximum levels for each factor to maintain a eutrophication status up to the upper mesotrophic level which are:

particulate nitrogen < 0.018 mg/L, silicates < 0.137 mg/L, salinity > 38 psu and
SPM > 0.815 mg/L

Conclusions

The use of the Bayesian–CHAID model for the estimation of the maximum CC of a given coastal area for cage fish farming includes factors related to natural pressures on the coastal area. Most of the PON originates in inland waters as a result of the human production of food and energy and occur in the plankton [2], salinity is affected by the section area and governs the plankton species survival [3], silicates concentration depends on river out flows and affects the diatoms concentration [4] and SPM is related with the adjacent land and land-originating effluents and is consider a potent driver for plankton growth [5].

The analysis performed allowed us to estimate the maximum levels for each factor to maintain a eutrophication status up to the upper mesotrophic level

A significant utility from the specific model application is the creation of a formula which can be used by anyone with different levels of education or expertise (for example, public administrators).

Introduction

Water quality is a limiting factor in fisheries management and significantly impacts fish health and production level. When water quality has deteriorated, it is necessary to focus on its treatment and thus prevent potential losses caused by the introduction of pathogenic agents into the breeding environment. In recent years, it has become more and more challenging to have sufficient, safe water available to fill large-volume storage pond systems. Sophisticated treatment of pathogen-laden water from adjacent stocked locations appears to be an economic element in the entire rearing process. Chlorine-containing preparations (Chloramine T and Calcium hypochlorite) and preparations based on peracetic acid appear to be suitable disinfectants for water treatment and the elimination of pathogens. All three disinfectants do not leave residues in the environment. Although they have a low therapeutic index, which indicates the ratio of the concentration of the preparation causing death in fish (LC50) to the dose causing a therapeutic effect (EC50), their residual amounts in water can be used for preventive treatment of fish. The goal of the study was to verify the effectiveness and efficiency of water disinfection treatment in order to reduce the infectivity of the burdened environment, and the morbidity of the fish kept. The health status of the fish was evaluated on the basis of the hematological and biochemical parameters of the fish, as well as the parasitic and bacterial examination of the fish after exposure to disinfectants.

Material and Methods

A total of 60 fish with an average weight of 25 g was divided into 12 aquariums (5 fish per aquarium) with a water volume of 20l. Fish were exposed to the effects of selected disinfectants for three days, as follows:

- Control group – 3 aquariums - fish left in clean tap water
- CHT group – 3 aquariums - fish exposed to chloramine T at a dose of 20 mg/l
- KPO group – 3 aquariums - fish exposed to 1 mg/l peracetic acid
- CH group – 3 aquariums - fish exposed to 1.5 mg/l of calcium hypochlorite

The application of Chloramine T and calcium hypochlorite to the water was made immediately before placing the fish in the aquarium. The KPO application was carried out once a day, three times in total.

After three days of exposure, blood was taken from the caudal vessel of the fish, then they were killed, and a bacteriological smear of the skin and a parasitological examination were performed. The obtained results were statistically evaluated.

Results

By evaluating the hematological parameters, only an increased hematocrit was recorded in the CHT group compared to the control. The most statistically significant changes in biochemical indicators were also recorded in the CHT group, where Glu, ALP and PHOS were different. The parasite examination revealed a positive effect of all used disinfectants on the reduction or elimination of the parasites found, with the exception of the parasite *I. multifiliis*. The CH group showed the lowest efficiency against parasites. Semiquantitative bacterial examination showed a statistically significant reduction of bacteria in the CH and KPO groups compared to the control.

Conclusion

Considering the analysis results, KPO appears to be the universal disinfectant, having an effect on both parasitic and bacterial colonization with a minimum of observed side effects on the fish organism.
