Balanced Diversity in Aquaculture Development
"Balanced Diversity in Aquaculture Development" is the theme of Aquaculture Europe 2023 (AE23). This theme surely highlights the potential for aquaculture, already representing the world’s most diverse farming practice, to further grow sustainably utilising the opportunities that lie in diversity.

Food from aquaculture contributes to Sustainable food systems at a local and global level. Since global aquaculture production is dominated by a few dozen species, major efforts are being made to promote species diversity. To succeed, we need responsible use of resources, circular food systems, improved efficiency, and increased resilience against future challenges such as diseases and climate change. All issues that require further diversification in aquaculture also beyond species level. AE2023 will provide a great opportunity for discussing new and innovative ideas to address challenges and opportunities as well as up scaling already proven concepts and solutions of diversification in aquaculture industry.

What makes EAS annual events unique is bringing together scientists, industry leaders and entrepreneurs, governmental bodies, and regulators from all over Europe and sharing the same passion for aquaculture. This year theme of diversification will be reflected in the 32 scientific sessions over 3 days ranging from genomics to socioeconomics, covering the full scope of European aquaculture scientific disciplines and species. AE2023 will also feature an international trade exhibition with close to 170 booths, student sessions and activities, satellite workshops and updates on EU research.

In addition, two special events will take place: The AE2023 Industry Forum entitled “TRANSITION: Towards new technologies and new markets” focus on freshwater aquaculture especially targeted towards farmers from Austria, Germany, Switzerland, Hungary and Czech Republic. A unique opportunity to learn more from and about freshwater aquaculture for all AE23 delegates.

This year’s program AE23 Innovation Forum is dedicated to new innovations on the theme of balancing diversity within aquaculture and the wider blue economy. The Innovation Forum includes a series of specific pitching sessions, showcasing research driven innovations as well company-driven initiatives that lead to innovation for the benefit of the entire sector. The program is exciting for all of us with a passion for knowledge that is used by and make an impact for industry and society.

This year we are expecting close to 2000 attendees with more than 540 oral presentations. Results presented as Eposters will also receive special attention at this year’s conference - and the last slot in each session before the breaks is dedicated to a “Poster Focus.” More than 600 scientific abstracts were received and these have been reviewed by the session chairs and integrated into an impressive programme by Bela Urbanyi (MATE, Hungary) and Nikos Papandroulakis (HCMR, Greece) as AE2023 Program co-chairs. Thank you for your hard work! I’d like also to thank our Steering and Local Organising Committees who gave their time and efforts to make AE2023 possible as for my colleagues on the Board of the EAS with several newly appointed directors. A big thanks also to our Gold Sponsors Biomar, Session Sponsors DSM and support from Meeting Destination Vienna. We are also grateful for the communication channels offered to us by our Media Partners. I hope you will enjoy the event, the people, and the science. I’m excited about the diverse aquaculture program we have for you, and I look forward to seeing you all in Vienna!

Bente E. Torstensen – EAS President 2022-2024

Blue mussels (*Mytilus edulis*) are often recommended in integrated multitrophic aquaculture (IMTA) systems to extract particulate waste from finfish production (Cranford et al. 2013), but it is debated significant mitigation can be obtained by direct assimilation of fish farm waste (Sanz-Lazaro & Sanchez-Jerez 2017). The performance of IMTA in open water systems is highly influenced by the spatial arrangement of the system and local environmental factors. Therefore, it is essential to evaluate the potential mitigation within the local environmental and spatial constraints (Kerrigan and Suckling 2018; Reid et al. 2020). The mitigation effect depends on the dispersion of waste from the fish farm to the mussel farm and the exposure time of the mussels to the waste, which depend on currents and settling velocity of the waste particles (Reid et al. 2020).

As vertical transport dominates the particulate waste distribution around fish farms, it has been suggested that higher mitigation can be achieved by locating the extractive species below fish farms (Filgueria et al. 2017), and studies have explored IMTA with extractive species at the seabed (Nederlof et al. 2020). However, the living conditions at the seabed vary considerably during the course of a production cycle, especially in sheltered areas (á Norði et al. 2011). Another approach to extract particles in the vertical waste stream is to suspend the extractive species below the fish farm, but this has received little attention.

![Study site and conceptual drawings](image)

**Fig. 1** Study site (a and b) and conceptual drawings of the modelled spatial locations of the Atlantic salmon farm and the blue mussel farms (c and d).

(Continued on next page)
To support the decision basis in future implementation of blue mussels to mitigate commercial fish farm impacts, a model was developed to assess the assimilation of fish farm waste by blue mussels at an operational fish farm. The waste production was modelled based on feed data, analysis of the commercial feed used, and the spatial arrangement of the net pens (Fig. 1b). Dispersion was modelled according the local hydrodynamics and assimilation of particulate waste by blue mussels was modelled according to two spatial blue mussel/salmon farm configurations; the approach with blue mussels at the surface at the long side of the fish farm (Fig. 1c) and an alternative approach with the blue mussel farm submerged directly below the net cages (Fig. 1d).

The general design of the fish farm is widely used in salmon farming and to investigate if the mitigation potential would be higher at other farms with different hydrodynamic settings, a sensitivity analysis was conducted on the current speed. A sensitivity analysis was likewise performed on the density of blue mussels as the density of mussels on passive spat collectors can be highly variable. Size and settling velocities of fish faecal particles are highly variable and depend on feed ingredients, fish size and hydrodynamics (Reid et al. 2009); and in general, the information on the size fractionations of waste particles is scarce (Nederlof et al. 2022). Thus, a sensitivity analysis was also conducted to investigate how the fraction of slowly settling particles influenced the mitigation performance of the blue mussel farms.

TESTING ENVIRONMENTAL DNA-BASED DIAGNOSTICS FOR MULTI-PATHOGEN GILL DISEASE ASSOCIATED WITH CARP EDEMA VIRUS INFECTION IN COMMON CARP

M. Adamek1*, T. Krebs1, F. Teitge1, M. Zawisza2, G. Bröcker1, A.C. Miebach1, D. Steinhagen1, K. Rakus2, V. Jung-Schroers1

1University of Veterinary Medicine Hannover, Bünteweg 17, 30559 Hannover, Germany
2Jagiellonian University, Gronostajowa 9, 30-387, Krakow, Poland
E-mail: Mikolaj.Adamek@tiho-hannover.de

Introduction
Recently, environmental DNA (eDNA) analysis has been recognised as a tool for monitoring the presence of pathogens in aquaculture. eDNA-based diagnostic appears to be particularly suitable for the detection of mucosal pathogens in fish. Gill and skin diseases are often multi-pathogenic including co-infections with viruses, bacteria and parasites. For example, carp edema virus, an immunosuppressive poxvirus that infects the gills and causes koi sleepy disease (KSD), often occurs with co-infections with ectoparasites such as Ichthyobodo necator and the bacterium Flavobacterium branchiophilum, making diagnosis and treatment difficult. Furthermore, the disease occurs in common carp and koi that are less accessible and cannot always be sacrificed for sampling (e.g. high-value ornamental koi or common carp broodstock). We therefore tested the applicability and robustness of eDNA-based methods for the detection of pathogens associated with KDS.

Materials and methods
To test eDNA-based methods for rapid detection of KDS, water samples, gill swabs and gill biopsies were collected during disease outbreaks and experimental infections and stored frozen at -20°C. Several centrifugation speeds and different pore size filters were used to select the best method for concentrating pathogens from water. Detection of carp edema virus, Ichthyobodo necator and Flavobacterium sp. was performed by qPCR after DNA extraction using Qiagen DNA mini kit.

Results
Filtration (0.20 µm and 0.45 µm) appeared to be the most reliable method for concentrating the pathogens associated with KDS outbreaks. The detection of CEV, I. necator and Flavobacterium sp. was possible at very early stages of infection and the CEV concentration increased rapidly on day 4 onwards when the first clinical signs were visible. Furthermore, the DNA of all pathogens could be detected in the water for at least 8 days after removal of infected fish.

Conclusions
Concentration of all pathogens involved in multi-pathogen gill disease associated with carp edema virus infection was possible with a single water filtration procedure using a e.g. 0.20 µm syringe filter. eDNA-based diagnosis could therefore be a very efficient method for detecting outbreaks of KSD, flavobacteriosis and ichthyobodiosis, at least in relatively small water bodies such as small ponds or tanks.
LIVE ATTENUATED VIRUS VACCINE PROTECTS THE SKIN BARRIER AND GILL FUNCTION FROM DISRUPTION CAUSED BY Cyprinid herpesvirus 3

Introduction
Epitheliotropic viruses can be particularly dangerous in the aquatic environment, which is osmotically and microbiologically hostile to fish. If the pathogen is able to disrupt the mucosal barrier, the breach can lead to severe secondary effects, such as disruption of the osmotic balance or induction of secondary infections. We used a live attenuated virus vaccine against cyprinid herpesvirus 3 (CyHV-3) to investigate which aspects of non-direct protection are important in the aquatic environment and to fill the remaining knowledge gaps on how these vaccines effectively protect fish against the deadly disease caused by CyHV-3.

Materials and methods
Common carp were vaccinated against CyHV-3 using a double-deletion vaccine virus KHV-TΔDUT/TK in the absence or presence of a mixture of common carp beta-defensins 1, 2 and 3. Fish were challenged with a hyper-virulent Polish isolate of CyHV-3 2.5 months after vaccination. Blood, skin, gill and kidney samples were collected at 2, 7, 14, 28 days post vaccination and challenge for monitoring of immune responses by SNT, RT-qPCR using Fluidigm and disease related pathology.

Results
Vaccination induced mild clinical signs, low viral load and slight up-regulation of cd8 and igm gene expression in vaccinated fish, while blood neutralising activity increased from 14 days post-vaccination. A challenge infection with CyHV-3 induced severe disease with 80-100% mortality in unvaccinated fish, whereas no mortality was observed in vaccinated fish and the viral load was >1000-fold lower. Histological analysis showed that vaccination protected against pathological changes in the skin and gills. In the skin of non-vaccinated fish, T and B cell responses were severely downregulated, inflammatory and stress responses were increased upon challenge, whereas vaccinated fish had enhanced neutrophil, T and B cell responses. Disruption of skin and gill barrier elements (tight and adherence junctions, desmosomes, mucins) led to a severe osmotic imbalance and an uncontrolled increase in skin and gill bacterial load, which most likely exacerbated the pathology.

Conclusions
Using a live attenuated virus vaccine, we show that increased neutrophil, T and B cell responses provide protection against CyHV-3 infection and preserve skin integrity and gill function, supporting successful protection against secondary bacterial pathogens and osmotic disruption, enabling vaccinated carp to cope with the hostile aquatic environment.
BAD NEWS - GOOD NEWS SITUATION: SALT TREATMENT OF KOI SLEEPY DISEASE DELIVERS BOTH: LONG PERSISTENCE OF CARP EDEMA VIRUS AND SUCCESSFUL PROTECTION AGAINST CEV RE-INFECTION

Introduction
Carp edema virus (CEV) is a highly virulent fish poxvirus that frequently causes a very severe koi sleeping disease (KSD), leading to high mortality in carp populations. Its worldwide spread is due to the international trade in koi and carp. In Germany, the virus has repeatedly been found in consignments of completely asymptomatic fish. In addition, some fish farmers and ornamental fish keepers have experienced repeated outbreaks of the disease without introducing new fish. This raised several questions about the ability of the virus to persist in populations following salt treatment and the effectiveness of natural immunity following this treatment.

Materials and methods
To answer these questions, a combination of case studies documenting the outcome of salt treatments in koi and farmed carp and experimental infections were used. Virus load was measured by qPCR and the development of clinical signs was measured by observing behaviour, gill pathology and blood Na+ and ammonia concentrations. Immune responses were evaluated with qPCR and immunocytochemistry.

Results
Salt treatment was found to be highly effective in preventing most of the morbidity and mortality associated with KSD. The main mechanism of action of salt treatment was confirmed to be the prevention of osmotic disorders by stabilising blood sodium concentration and the prevention of ammonia intoxication by facilitating gill excretion of ammonia. Results from the monitoring of the KSD outbreak showed that over 25% of the fish sampled remained CEV positive for five months without clinical signs. Further studies were carried out on carp rescued from a fish farm in Saxony, Germany. Experimental reinfections of these fish three months after recovery showed that they were protected against reinfection. Compared to naive fish infected with CEV, the naturally immunised fish did not develop the clinical signs of KSD, including pathophysiology and immunosuppression. Conversely, reinfection resulted in increased expression of gzma, zap70, cd4 and igm, which are normally downregulated during KDS.

Conclusions
The long persistence of CEV may explain its successful global spread. On the other hand, the protection against reinfection conferred by increased T-cell and B-cell responses gives hope for the development of effective vaccines against CEV and other poxviruses affecting fish.
DISCOVERY OF A NILE TILAPIA STRAIN WITH RESISTANCE TO TILAPIA LAKE VIRUS DISEASE - FROM IMMUNOLOGY TO CONSIDERATIONS FOR IMPLEMENTATION IN AQUACULTURE

Introduction
The occurrence of viral diseases that cause very high mortality can disrupt aquaculture production. This recently happened in Nile tilapia aquaculture with the emergence of a disease caused by tilapia lake virus (TiLV), which has dramatically affected tilapia farms around the world. In areas where the virus is endemic, three strategies can be used to limit the losses caused by infection: 1) improved biosecurity, 2) vaccination programmes, 3) selective breeding to increase resistance. To explore the third strategy, we investigated the resistance to TiLV in three genetic strains of tilapia reared in Germany. We used two strains originating from Nilotic regions (Lake Mansala (MAN) and Lake Turkana (ELM)) and one from an unknown region (DRE).

Materials and methods
Nile tilapia juveniles were infected with TiLV by intraperitoneal injection or cohabitation. Immune responses were measured using a Fluidigm array and correlated with viral load and pathological changes.

Results
Infection by injection resulted in 100% fish mortality in all three strains. However, when using cohabitation, we found that the ELM strain did not develop clinical signs of infection and had almost 100% survival. The other two strains showed severe clinical signs and a much lower survival rate of 29.3% for the DRE strain and 6.7% for the MAN strain. Disease resistance in tilapia from the ELM strain correlated with a lower viral load in both mucosal and internal tissues. The lower viral spread was associated with a stronger mx1-based antiviral response in the early phase of infection in the ELM strain. In addition, lower pro-inflammatory responses in the resistant strain may further contribute to its protection against disease-associated pathology.

Conclusions
Obtained results suggest the possibility of using TiLV-resistant strains as a cost-effective ad hoc solution to the TiLV challenge. However, it is important to note that fish of the resistant strain still had a significant viral load in the liver and brain 28 days after infection and could become persistent virus carriers, potentially transmitting the virus to naive populations. Therefore, the resistant strain should be used as part of an integrated approach that includes biosecurity, diagnostic and vaccination measures as appropriate.
IS IT POSSIBLE FOR THE TILAPIA LAKE VIRUS TO HOST JUMP TO SALMONIDS DUE TO THERMAL STRESS CAUSED BY HEATWAVES IN EUROPE?

M. Adamek1*, M. Matras2, W. Surachetpong3, K. Rakus4, M. Stachnik2, J. Bauer1, A. Falco5, V. Jung-Schroers1, C. Piewbang6, S. Techangamsuwan6, S. El Rahman7, R. Paley8, M. Reichert2, D. Steinhagen1

Introduction
Many salmonids are thermally sensitive and are therefore particularly vulnerable to thermal stress caused by rising temperatures during summer heat waves. We hypothesised that the combination of thermal stress and the presence of a new viral pathogen could lead to a potential host jump of the pathogen if the fish are susceptible. Tilapia Lake Virus (TiLV) can be considered as one of the most dangerous emerging viruses affecting warm water aquaculture. This pathogen has a global distribution and a host range that remains to be defined, but preliminary in vitro data indicate that the virus replicates in a variety of cell lines, including those derived from salmonids. Therefore, the aim of this study was to evaluate the potential of TiLV to infect salmonids in a range of water temperatures that can be reached during summer heatwaves in continental Europe.

Materials and methods
The susceptibility of several cell lines was assessed in different temperatures. The susceptibility of juvenile rainbow trout and brown trout to infection with TiLV was investigated in infection experiments based on cohabitation of both species with infected fish or intraperitoneal (i.p.) injection of the virus at elevated water temperatures of 20°C and 25°C. The behaviour, pathology, virus load and antiviral responses were measured.

Results
TiLV can replicate in vitro in salmonid cells over a wide range of temperatures from 15°C to 25°C. The infection experiments showed that the susceptibility of rainbow and brown trout to the virus was low, considering the ability of the virus to enter the organism. Exposure of these fish to the virus by cohabitation did not result in high levels of virus in the liver and brain. However, the permissiveness, i.e. the ability of the virus to replicate in the body of the fish, is high because i.p. injection of TiLV resulted in high levels of virus replication in the internal organs.

Conclusions
TiLV has some pathogenic potential in salmonids, which could theoretically be enhanced by climate change and anthropogenic activities. Further studies should determine whether factors affecting the mucosal barrier allow the virus to spread to the already permissive, thermally sensitive salmonid species.
EFFECTS OF SOYBEAN MEAL (SBM) DIETARY INCLUSION ON THE INTESTINAL MORPHOLOGY OF JUVENILE RUSSIAN STURGEON (*Acipenser gueldenstaedtii*)

Introduction
In recent years, sturgeon farming has been one of the most rapidly growing branches of aquaculture. While the production of sturgeon larvae does not present many technical difficulties, it is very costly, not only due to the relatively long administration of natural food, but also due to high prices of commercial feeds, which are largely a resultant of expensive components.

Feeds with plant protein sources have long been the subject of research in many fish species, including sturgeon fish. Studies carried out so far on *Acipenser schrencki* and its hybrid with *A. baerii*, in which the animal protein component was replaced with soy protein concentrate, showed negative effects on immunity, gastrointestinal tract morphology and growth (Jiang et al., 2018; Wei et al., 2019). Therefore, the aim of this study was to determine the effect of using soybean meal at 10% and 20% relative to animal components on the morphology of the gastrointestinal tract of juvenile Siberian sturgeons (*Acipenser baerii*).

Material and methods:
The study was carried out as part of the project no. 0001–6521.1-OR0700001/17/20 founded by Operational Program ‘Fisheries and Sea’ (2014–2020) financed by the European Maritime and Fisheries Fund. Siberian sturgeon larvae were maintained in RAS (recirculating aquaculture systems). From 20 dph (days post hatching), feeding with one of three experimental feeds was initiated: a control diet with no soybean components (P0), a diet in which 10% of the animal components were replaced with soybean (P10), and a diet in which 20% were replaced (P20). The dietary experiment lasted 7 weeks. After this time, the fish were slaughtered and their digestive tracts were collected for histological examination. Analysis of digestive tract morphology was carried out on 8 individuals from each group. Paraffin-embedded tissues were stained with haematoxylin and eosin (HE) and Alcian blue with Schiff’s periodic acid reagent (AB/PAS) to differentiate mucosal cells. The morphometric analysis was carried out according to Kasprzak et al. (2019). Microscopic analysis was carried out using a Nikon Eclipse 90i microscope with a camera and NIS Elements software (Tokyo, Japan). Statistical differences were calculated in Statistica (Statsoft, Tulsa, USA) using a parametric ANOVA test with Fisher post hoc test.

Results
In all individuals, the intestinal folds in both examined sections were well-organised, containing not only enterocytes without signs of degenerative changes, but also mucosal cells with a normal structure. At the bases of the intestinal folds, numerous cells were undergoing mitotic division. Enterocytes showed well-developed, visible microvilli. In the spiral section, enterocytes were characterised by an enlarged, transparent supranuclear part with clearly visible absorptive vesicles. However, the morphometric analyses carried out indicate that fish from the control group had the most favourable intestinal morphological parameters.

Conclusion:
The histological analysis indicates that the use of soybean components at both 10 and 20% protein replacement adversely affects the morphology of the digestive tract of juvenile Siberian sturgeon, impairing the ability to absorb nutrients and, as a result, generating lower growth rates.

Introduction
Fish is a high quality food, apart from its protein contents; it is also rich in vitamins and contains variable quantities of fat and minerals for human health (Bard et al., 1976). Fish is often recommended for cardio-vascular disease patients because of its unique fat, which is composed mainly of Omega-3 polyunsaturated fatty acid.

Materials and Methods
The food and feeding habits of *Tilapia mariae* in Akomoje River reservoir, Abeokuta, Ogun State, Nigeria, were examined between the months of August and December 2019. A total number of 125 fish specimens were collected on monthly basis from the commercial landings of fishermen around the water body.

Results
The results of monthly variation in food items show that Bacillariophyta, Chlorophyta, Cyanophyceae, crustacean, detritus, plant tissues, and unidentified food all occurred in varying quantities from August to December 2019. Bacillariophyta (diatoms) was the most important food item in the stomach of Tilapia mariae accounting for 14.72% and 78.10% by numerical and frequency of occurrence methods, respectively. Cyanophyceae constituted 11.43% in number and 59.63% in occurrence as the next food item in order of importance. Crustaceans occurred least in order of importance with 2.34% in numbers and 27.12% in frequency of occurrence.

**Figure 2**: Distribution of food items in the stomach of *Tilapia mariae* from Akomoje water Reservoir.
IDENTIFICATION AND VALIDATION OF SELECTED PATHOGEN RECOGNITION AND IMMUNE RESPONSE MRNAS IN THE FRESHWATER AFRICAN CATFISH *Clarias gariepinus*

Aloysius Adibe¹,²*, Margaret Crumlish², Jimmy Turnbull² and Simon MacKenzie²

Department of Fisheries and Aquaculture, Nnamdi Azikiwe University P.M.B. 5025 Awka, Nigeria
Institute of Aquaculture, University of Stirling, FK7 4LA Stirling, United Kingdom
Email: a.c.adibe@stir.ac.uk

Introduction

African catfish *Clarias gariepinus* is the dominant aquaculture species in Nigeria with over 160000 tonnes output per year (Dauda et al., 2018) and 2 million tonnes global output (FAO 2022). It is also intensively farmed in Ghana, Cameroon, Kenya, Mali, South Africa, Brazil, Netherlands, Hungary, Italy and Syrian Arab Republic (FAO, 2022). Disease outbreaks from pathogenic bacteria cause huge economic losses affecting all production systems with the Gram negative bacteria *Aeromonas hydrophila* the aetiological agent of motile aeromonas septicaemia (MAS) outbreaks in Clarias catfish (Jiang et al., 2016). Very little is known about host-pathogen interactions in Clarias species. The objective of this study was to identify mRNAs involved in pathogen recognition and response in *C. gariepinus* to provide new knowledge supporting the development of innovative disease control strategies.

Materials and methods

The study was approved by the Animal Welfare Ethical Review Board of the University of Stirling. The Clarias catfish were sourced from a stock population bred at the Institute of Aquaculture (UoS) and housed in a 300 litre stock tank, in a recirculation system on a 12:12 light:dark cycle and water temperature of 28 ± 2 °C. All fish were fed twice daily with commercial pellets at 2% bodyweight per day. Water quality parameters including temperature, dissolved oxygen, ammonia, nitrate and pH were recorded daily. A total of 18 fish were used for this experiment with 3 fish samples taken from each treatment group (TG1 = vaccinated and TG2 = non-vaccinated/control fish groups) at 24 hours, 72 hours and 41 days post vaccination. The fish were vaccinated by intraperitoneal injection using a whole cell, inactivated (heat killed) preparation of *Aeromonas hydrophila* mixed at 3:7 ration with commercial adjuvant Montanide. Blood, head kidney, spleen, liver and gill were aseptically removed from *C. gariepinus* and transferred into 1.5 ml tubes with RNA preservation buffer. (Continued on next page)
Seven immune genes were selected based on their related functions in pathogen recognition (Nucleotide-binding oligomerization (NOD1 and NOD2), toll like receptor 3 (TLR3)), pathogen perception and integration (Major Histocompatibility Complex (MHC2)) and inflammatory response (interleukin 1β, Cyclooxygenase-2 (COX2) and Myeloperoxidase (MPO)). Predicted sequences of the genes from different species of animal (figure 1) were sourced through nucleotide query on https://www.ncbi.nlm.nih.gov and aligned using MEGA-X 10.1.8 software. The primer sets for each gene were designed from the conserved regions of the aligned sequences using https://www.ncbi.nlm.nih.gov/tools/primer-blast/ and purchased from commercial company.

Total ribonucleic acid (RNA) was extracted from 100 mg head kidney and spleen tissues using TRI Reagent® (Sigma-Aldrich T9424) following the manufacturer’s protocol. Extracted RNA products were subjected to purity check and quantified using electrophotometer (Thermo Scientific Nanodrop 2000c) and the integrity tested on 1% Agarose gel electrophoresis. A pool of RNA was made with 1 µl of RNA from each tissue sample and first stranded DNA was synthesized with QuantiTect® Reverse Transcription kit according to the protocol from the manufacturer. The PCR for all the mRNAs were optimized with MyTaq™ mix using the manufacturer’s description at temperature gradient of 51–65 °C and integrity checked on 1% Agarose gel electrophoresis. Optimized genes were successfully cloned using Nucleospin Gel and PCR clean up kit (Fisher Scientific 1507/001) as described by the manufacturer and the extracted plasmid DNA were sequenced by a commercial company. Sequences obtained were confirmed on https://blast.ncbi.nlm.nih.gov/Blast.cgi?PROGRAM. The genes were validated using Clustal Omega multiple sequence alignment tool (https://www.ebi.ac.uk/Tools/msa/clustalo/) by aligning sequences against their respective primer sets.

Results and discussion
Seven sequence specific primer pairs were successfully designed and optimized (table 1). All the primers (except for IL1β) were designed, optimized and validated for the first time in the *C. gariepinus*. Going forward, the validated mRNA target sequences will be used to assess their distribution and expression in tissues of the fish through real time qPCR. They will also be used to determine the pathogen recognition pattern of the fish by comparing results from vaccinated and non-vaccinated groups.

*fafonso@fmv.ulisboa.pt

Introduction
The production of mollusks in Portugal has a very high economic and social importance. The Portuguese mollusk production is represented by various species of greater socioeconomic significance such as the Portuguese oyster, *Crassostrea angulata* and the Pacific oyster, *Crassostrea gigas*.

In general, the consumption of these species has been increasing and as such their production as well. The production of these species faces some threats, such as the appearance of diseases. Several pathogenic agents can cause lesions and diseases both in wild and farmed oysters. *Ostreid herpesvirus* (OSHV -1 and OsHV-1 μvar) has been the cause of important mortalities in Pacific oyster, in several countries, including in Portugal. Lesions are not specific of this virus and may include, namely, discoloration of the digestive gland, presence of vacuoles in the cytoplasm of epithelia of the digestive gland diverticula and necrotic lesions in several tissues, mainly in gills epithelium and connective tissue.

Furthermore, hemocitosis and intracytoplasmatic inclusion bodies can be observed in most affected tissues.

Materials and Methods
The presence of OsHV-1 and OsHV-1 μvar in Portuguese and Pacific oysters was surveyed from 2018 to 2022. Oysters (adults) were sampled from five different sites on the Portuguese coast (water temperature: 18-20ºC; salinity: 30-34 ppm). Portuguese oysters from Sado estuary (n=159) and Mira estuary (n=66) and Pacific oysters from Formosa lagoon (n=234), Alvor lagoon (n=90), and Aveiro lagoon (n=371).

For the detection of this pathogen, we followed, since the first time the pathogen was detected in Portuguese waters (2011), the protocol set out in Commission Regulation (EU) No 175/2010 of 2 March 2010, Part B of Annex I for the DNA extraction method and PCR analysis.

For histopathology, the tissue samples were fixed in Davidson’s fixative for 48h, dehydrated, embedded in paraffin and cut with a microtome (3-5 µm thick), then stained with Hematoxylin and Eosin (H&E).

Results
Slide analyses for histopathology of both oyster species revealed the presence of various ciliates such as *Trichodina sp.* in gills and in mantle epithelium and *Ancistrocoma sp.* in the digestive gland tubules and in the connective tissue, both with a moderate prevalence. The copepod *Mytilicola sp.* was observed in the intestine lumen of both oyster species. It was also observed hemocytosis in connective tissue, edema and metaplasia in the digestive gland and tissue necrosis. In the population from Mira estuary the prevalence of these lesions was slightly higher, except for individuals with metaplasia.

The lesions observed in the epithelium of the digestive gland, hemocytic infiltration and necrosis may be related to different pathogenic and/or environmental agents. In all populations analyzed in this study, the presence of the virus was not identified.

Discussion and conclusion
The first reported mortality outbreak of oysters occurred during the summer of 2012 in south coast of Portugal, in Pacific oyster populations and was related with the presence of a herpes-like virus. In 2011 was detected for the first time the presence of the microvariant (μvar) genotype of OsHV-1 in *C. angulata* produced from a broodstock collected in Sado estuary and then transferred to the Formosa Lagoon (Batista et al., 2015). This disease reached the highest impact in oyster production during 2017, when mortalities rates between 60 and 100% were registered in Alvor (south) and Aveiro lagoons. Since then, reports of massive mortalities related with the presence of OsHV-1 have been declining.

(Continued on next page)
Environmental factors, as well as bad practice management methods, namely the high animal densities in oyster tables and the intensive handling of animals in unfavorable environmental conditions, can contribute to increasing the virulence and propagation capacity of this opportunistic virus.

It is fundamental to implement biosecurity measures to prevent the spread of diseases, namely controlling the transport of animals and equipment from different countries and regions. Furthermore, regular monitoring, identification and characterization of pathological processes in oysters are important measures for sanitary control. These measures all together, as well as the collaboration of producers, have been contributing to the control and spread of Ostreid Herpesvirus in Portugal.

Introduction
Siberian sturgeons are considered as one of the most prolific fish species. This is mainly because of its relatively rapid growth in maturity which, by producing caviar in shorter period of time, ensures sooner come back of investment. Among diverse factors affecting the feed efficiency, emulsifiers play an important role. In this study, Lipogest®, a synthetic emulsifier, was tried on Siberian sturgeons. Lipogest® is a bile salt-based emulsifiers and promotes formation of small size lipid droplets and aid fat digestion.

Materials and Methods
The current study was done on 750 Siberian sturgeons (mean weight 250±20 grams) on a period of 84 days. Fish were divided into five treatments (each in three replicates). Treatments consisted of 0 (control group), 0.5, 0.8, 1 and 1.5 g of Lipogest® per kg of basic diet (BEYZA 21®). To exclude the role of Lipogest®, the control group were fed on mere basic diet. On the last day of study fish were weighed under anesthesia and the results were analyzed by SPSS.

Results
According to this study, all treatments showed significant changes compared to control group. Control group showed the least feed efficiency. While group 1 and 1.5 g/kg Lipogest® showed the most which was 7% improvement in compare with control group). SGR and FCR was also affected by different dosages of the additive. The results showed that both reached its best in 1 g/kg Lipogest® which was 6% and 1.5% respectively better than control group. Based on the results the difference between 0.6 and 0.7 of Lipogest® was not significant. So, the recommended dosage for adult Siberian sturgeon based on our results is 0.6 gram/kg of diet.

Conclusion
Lipogest® significantly increased the feed efficiency and SGR AND decreased FCR of Siberian sturgeons in the current study within suggested ranges (best at 1 g/kg of food). Since dose 1.5% did not significantly affect the feed efficiency, for economic purposes dose 1% may be more reasonable. This additive also has shown good results in carnivores fish such as rainbow trout and seabass and herbivores tilapia, with significant changes in growth performance in compare with control group.
DIETARY OREGANO (*Origanum vulgare*) ESSENTIAL OIL IMPROVED RESISTANCE TO *Aeromonas hydrophila* INFECTION IN STERLET STURGEON (*Acipenser ruthenus*)

*sara.ahani@yahoo.com

Introduction

With regard to side effects of antibiotic therapy, there is an increasing attention to herbal plants as a substitute for synthetic medications. The oregano plant (*Origanum vulgare*), because of its antioxidant, antimicrobial and anti-inflammatory features, has been surveyed in different fish species and proved to have significant effects in improving immune system and accelerating growth rate. In this study, the effect of oregano essential oil is examined in sterlet sturgeon for the first time.

Materials and Methods

Diets were fortified with five levels of Oregano essential oil (0, 2, 5, 8, 10 g/kg). Two hundred and twenty five sterlet sturgeons (25±1 g) were divided into five treatments (in 3 replicates) and fed with the diets for twelve weeks. At the end of feeding trial, the activity of liver enzymes (SOD, CAT, MDA) was assessed. After a fifteen-day-challenge, the cumulative mortality rate with *Aeromonas hydrophila* was recorded.

Results

The results of the trial revealed that oregano essential oil increased the immunity levels of sterlet sturgeon. The levels of CAT and SOD in fish fed with 10 g/kg oregano significantly increased compared with other treatments (p<0.05). Also, the 2 and 5 g/kg groups did not show a significant difference compared with the control group (p>0.05).

After challenging with *Aeromonas hydrophila*, cumulative mortality decreased significantly as the dose increased (p<0.05). The results of the experiment showed positive effects of oregano essential oil in improving the antioxidant defense capability and increasing survival rate of sterlet sturgeon challenged with bacterial infection.
CAN WE TRUST DIGITAL PHENOTYPING FOR ESTIMATING WHOLE BODY FAT IN ATLANTIC SALMON? LARGE-SCALE GENETIC VALIDATION PROVIDES PROMISING RESULTS

Introduction
Maintaining an optimal level of body fat is essential for the survival in Atlantic salmon, but higher levels can result in costly harvest waste and economic losses. Breeding programs could in principle, incorporate whole body fat as a trait and thus contribute to more sustainable and cost-efficient fish farming. However, high throughput and cost-effective methods for phenotyping whole-body fat in thousands of fish are currently lacking. The reference Folch lipid extraction method (Folch et al., 1957) is destructive, highly laborious, and expensive. Two rapid non-invasive methods, namely the Distell fat meter which is a highly portable dielectric spectrometer (DS) and a new semi-automated Near-infrared (NIR) system offer the possibility to change this but require further validation. To address this issue, we conducted a large-scale genetic validation study on thousands of Atlantic salmon with the goal of 1) comparing the accuracy and reliability of digital NIR and DS methods for estimating total body fat; and 2) examining the pattern of total body fat across three different life phases in Atlantic salmon.

Materials and Methods
The large-scale genetic validation study is done on ~3000 Atlantic salmon belonging to 35 fish families of 2017-year class at MOWI Genetics, Norway. From fertilization the families were reared in separate trays, while from the eyed egg stage families were pooled and reared in a common garden tank. At an average body weight of 40 grams fish were PIT tagged with a fin clip taken for genotyping with MOWI’s customized single nucleotide polymorphisms SNP array which contains 55735 SNP markers.

In August 2020 at an average body weight of 48.9 (SD= 7.9) grams, the fish were transported to the freshwater facility of Nofima Research Station for Sustainable Aquaculture, located at Sunndalsøra (62°40N 8°31E), Norway. After a three-week acclimation period, the fish were sorted into 3 phase (Parr, Pre-Smolt and Post-Smolt) groups as shown in figure 1.

The Whole-body fat traits were recorded on different numbers of participating fish in different phases through reference Folch lipid extraction, DS and NIR spectroscopy. Genetic, Biometric, spectroscopic and chemical measurements were taken at all life stages. The DMU software and Rdmu package were used for genetic estimates and multivariate analysis (Madsen et al., 2014).

Results
Both the NIR and DS methods showed strong agreement with the reference method (r_p= 0.80 -0.88). Moderate to high genetic estimates were obtained for whole body fat estimation through NIR and DS as presented in the table 1 below.

We found substantial variation in total body fat across the different life phases, with an average of 11.32 ±1.23 % in parr, 33.80 ±2.6 % in pre-smolt, and 14.98 ±1.27 % in post-smolt fish. The genetic and phenotypic agreement between whole-body fat in different phases are presented in table 2. A significant decrease in phenotypic and genetic correlation was observed between fresh water and sea water stages.

Conclusion
For the first time, genetic parameters are presented for whole-body fat in Atlantic salmon in multiple life phases. The substantial genetic estimates demonstrate significant potential in selective breeding for whole-body fat, but cognizance must be taken of the life phase. The genetic validation proves the capability of non-invasive DS and NIR methods for measuring whole body fat at different life stages without killing or filleting, and their usefulness depends on the user’s specific needs and preferences.

META-ANALYSIS OF GENOME-WIDE ASSOCIATION STUDIES OF AMOEBCIC GILL DISEASE RESISTANCE IN ATLANTIC SALMON

Afees Ajasa1,2*, Solomon Boison3, Hans Magnus Gjøen2 and Marie Lillehammer1

1 Nofima (Norwegian Institute of Food, Fisheries and Aquaculture research), PO Box 210, N-1432 Ås, Norway

Email: afees.ajasa@nofima.no

Introduction
Amoebic gill disease (AGD) is becoming a growing concern to the salmon industry in Northern Europe due to its increasing incidence and resulting consequence on fish health and welfare. Genetic variation of resistance to this disease is documented (Ajasa et al., 2023), and resistance can thus be improved by selective breeding. Genome-wide association studies (GWAS) of AGD can help unravel the genetic basis of resistance to the disease, and identified QTLs can be used for marker or gene-assisted selection. Most of the GWAS on AGD resistance (Aslam et al., 2020; Boison et al., 2019; Robledo et al., 2018) have until now not identified QTLs reaching genome-wide significance for resistance to this disease. Many of these studies are lacking a sufficient sample size (i.e. < 1500) which may limit the power to detect QTLs. A useful approach that can increase the power of detecting QTLs is combining several GWAS through meta-analysis. In this study, we conducted a meta-analysis GWAS of AGD resistance in six Atlantic salmon populations in Norway.

Materials and methods
The dataset consists of categorical gill score records (0-5) of six Atlantic salmon populations collected during natural field outbreaks of AGD. The six populations were all genotyped with custom 55k SNP array. Quality control procedures included removing markers and samples with call rate < 95%, minor allele frequency < 1%, and Hardy Weinberg p value (Fisher’s exact test) < 10^{-25}. Finally, only samples with > 0.25 and < 0.45 heterozygosity were retained so as to limit the impact of poor-quality samples (Weale, 2010). After quality filtering, 50,456 SNPs remained, which was used for further analysis. We performed genome-wide association analysis (GWAA) on each of the six populations independently using the model described below, applying the software GCTA (--mlma option) (Yang et al., 2011):

\[
y = xb + Zu + e
\]

where \(y\) is a vector of gill scores, \(x\) is a vector of SNP genotypes (coded 0|AA, 1|AG, 2|GG), \(b\) is the allele substitution effect of the SNP, \(Z\) is an incidence matrix relating the phenotype to the residual polygenic effect \(u\), and \(e\) is a vector of the residual environmental effect. \(u \sim (0, G\sigma^2_u)\), \(e \sim N(0, I\sigma^2_e)\), where \(I\) is an identity matrix, \(\sigma^2_e\) is the residual variance, \(G\) is the genomic relationship matrix, and \(\sigma^2_G\) is the additive genomic variance. The resulting summary statistics from the GWAA were then combined using the sample weighted Z-score method of the METAL software (Willer et al., 2010). Bonferroni correction of 0.05/number of SNPs (50456) was used to correct for multiple testing. Chromosome wide significance level was derived from 0.05/average number of SNPs per chromosome (1740).

Result and discussion
Two QTL regions on chromosomes 2 and 12 were identified in this study (Figure 1). The most significant region was located on chromosome 12, with the most significant SNP in this region located at 61,580,655 bp. We identified 6 protein-coding genes within 100kb region of this SNP.

Conclusion
We identified novel QTLs with strong signals that have not been identified in previous studies. Further studies will be conducted to fine-map causal variants in the regions identified.

DESIGN, VALIDATION and VERIFICATION of a MOVING BED BIOMEDIA REACTOR (MBBR) UNIT a CASE STUDY: 220 m³/h

Manolya Akdemir Çolpan

'MAT Filtration Technologies
e-mail: manolya.colpan@matglobal.tech

Total Ammonia Nitrogen (TAN), which occurs due to various reasons especially fish defecation and death, is crucial for life and bring about death of living creatures. Therefore, it is very important to reduce the amount of TAN in water and it is called as Nitrification process. In a system inhabited by living organisms, even a very low amount of TAN can have fatal consequences. For this reason, it is very important that the system responds to the requirement with pinpoint accuracy.

Design validation gains meaning by evaluating the designed system in terms of Computational Fluid Dynamics (CFD). Within the scope of this evaluation, after deciding on the final three designs with validation, prototypes were manufactured, and the error margin of the validation part was evaluated as verification.

Within the scope of the study, the dimensioning of the system depending on the biological load was created and structured with the approaches in the literature. Life Cycle Inventory Assessment (LCIA) and Life Cycle Cost Assessment (LCCA) studies on the MBBR unit to ensure the principle of eco-design were structured during the design phase and optimization studies on the system were carried out in this way within the scope of sizing.

The aim of the study is to produce a user-friendly technology that complies with the eco-design directive, is environmentally friendly and has low energy consumption compared to its counterparts. With the result obtained in this context, it has been confirmed with experimental results that water consumption is reduced by 90%, the loss of nitrification bacteria is minimized, and the nitrification process is carried out in a quality manner. The margin of error of CFD and experimental studies was obtained as 3.4%.
BEHAVIOURAL CHANGES AND HISTOPATHOLOGICAL EFFECT OF GLYPHOSATE AQUATIC HERBICIDE (FORCE UP) ON TISSUES OF SUB ADULT AFRICAN CATFISH (Clarias gariepinus)

This experiment determined the toxicity and behavioural changes of glyphosate aquatic herbicide (Force up) on African catfish Clarias gariepinus sub adult. A total of 120 live and apparently healthy Clarias gariepinus sub adult measuring 18.3-30cm standard length and average weight of 123g was randomly distributed into twelve (53.5cm X 33cm X 34cm) glass tanks of 60litres capacity. Each were filled with 20litres aerated bore-holes water and six treatment in triplicate was set up for the experiment. Ten (10) Clarias gariepinus sub adult was distributed randomly in triplicate per treatment for experiment involving the sub adult Clarias gariepinus. The toxicant was introduced at different concentrations (0mg/l, 40mg/l, 70mg/l, 100mg/l, 130mg/l, 160mg/l) in triplicate per treatment. Fish mortality and behavioral changes was monitored and recorded for the first 24hours, 48 hours, 72 hours for the next 96hours. The inability of the fish to respond to external stimuli was used as an index of death. Dead fish were removed immediately with a scoop net to avoid contamination due to rotting. Behavioral changes exhibited by the fish include erratic swimming, air gulping, loss of reflex, molting, discoloration, barbel deformation and excessive mucus secretion in fish exposed to higher concentration of glyphosate aquatic herbicides. Histopathology of the organs after 96 hours in the liver shows nuclear vacuolization (NV) with irregular shaped nuclei, moderately damaged tissue and hepatocyte (H) regeneration which indicates that recuperation is still possible. The effect of the toxicant on the skin reveals there was cellular abnormalities, shrinkages, hypertrophy of tissue, absence of dermal layer and necrosis. The 96h LC50 of glyphosate aquatic herbicide (Force up) to Sub Adult African Catfish Clarias gariepinus is 123.784mg/l with the maximum safe concentration ranged between 1.24mg/l to 12.38mg/l, the safe level of a compound is derived by multiplying the 96h LC50 with an application factor of 0.01-0.1. Such application factor are applied to acute toxicity test data to estimate the concentration that is safe for chronic exposure. The results of the study revealed that Glyphosate aquatic herbicide (Force up) is toxic to fish organs and causes histopathological changes in different organs such as skin and liver; therefore, indiscriminate use by farmers should be discouraged particularly in aquatic bodies.
DOES THE FISH TANK HISTORY HAVE AN INFLUENCE ON THE MICROBIAL DIVERSITY IN RECIRCULATING AQUACULTURE SYSTEMS (RAS) AND HOW TO LIMIT THIS INFLUENCE?

Introduction

Aquaculture is undergoing rapid development worldwide (FAO, 2020), but the sustainability of aquaculture systems is more and more questioned in view of the many changes taking place (climate, animal welfare, antibiotic resistance, etc.) (Sudarshan et al., 2021). To reduce their dependence on the surrounding unstable environment, the Recirculating Aquaculture Systems (RAS) have been developed. Those systems allow to reuse 90-99% of water but also to create an optimal growth environment for fish (temperature, nutrients, etc.). The functioning of RAS is highly dependent on the equilibrium between fish and microbial communities (e.g.: biofilter, associated biodiversity) (Kamali et al., 2022). This equilibrium could become more complex to achieve with the development of the polyculture in RAS (Thomas et al., 2020).

The fish microbiota (tract, skin, and gills) is highly diverse, including bacteria, fungi, viruses (Merrifield and Rodiles, 2015; Dulska et al., 2020; Dai et al., 2021) and is affected by intrinsic factors including trophic level, fish species (mainly linked with gastrointestinal tract morphology and diet) and environmental factor as season and captive-state (Egerton et al., 2018). Fish have an intimate interaction with their surrounding environment resulting in a shaping effect on water microbial communities (Fourrier et al., 2022). This study suggest also that the RAS history (linked with biofilm memory) seems to influence water microbiome. A reliable protocol is required to stabilize and equilibrate initial microbial communities before studying the effects of fish communities on microbial communities.

An experiment was performed to select a standardized procedure to obtain tanks with a microbial diversity as close as possible regardless of the history of the tanks. The objective here is not to have a perfect disinfection of the tanks, but rather to have a starting situation (t0) in the tanks that is as similar as possible either by homogenizing the filtration substrates or either by replacing them, limiting variability due to fish rearing.

Materials and methods

We compared 3 disinfection/homogenization modalities (M) using 4 replicates for each. That’s why 12 tanks were selected based on their rearing history of different fish species over the past 3 years.

1. M1: Emptying and filling of the tanks after cleaning (raw cleaning),
2. M2: Raw cleaning, homogenization of active biofiltration substrates between fish tanks, standard protocol disinfection which consists of chemical treatments (hydrogen peroxide and chloramine T) and physical treatments (high temperature and drying) (protocol currently used at the Aquaculture Experimental Platform PEA of the University of Lorraine).
3. M3: Same as M2 but using new and inactive biofiltration substrates.

The experiment lasted 30 days and water was sampled (days 0, 16, 23 and 30) to access physico-chemical parameters of water and microbial communities dynamic. The physicochemical parameters of water: temperature, dissolved oxygen, pH, NH4+, NO2- and NO3- will be measured during the experiment. The microbial diversity of tank water (sampled on days 0, 16, 23 and 30) was assessed by metabarcoding approaches. Sequencing (Miseq 2x300 bp) was performed at the GIGA Institute (University of Liège) and bioinformatic analysis was performed using FROGS and R software.

Results

We observed a significant effect of the treatment on the dynamic of the microbial communities. The most homogenous starting point in all replicates was obtained using the second modality M2. The results allowed us to select the most reliable tested protocol that can be used to study microbial communities regardless of the tank rearing history.

INTRODUCTION
We see a growing trend that mariculture is growing out of sheltered, near-shore areas and moved to locations further offshore. There are several advantages applying this solution. Better fish welfare, less conflicts with interests in the ocean space as well as possibility to scale up output volume without compromising environmental sustainability are some of them. As the world’s population grows, the options for producing enough food are becoming limited. The oceans offer a vast opportunity to meet this demand with sustainable, safe and efficient offshore fish farming. Adding safety to offshore fish farming projects is mainly ensured by providing uniformity, transparency, and predictability and thereby reducing project risk. We need to be ensured that facilities for aquaculture can handle harsh environment and still contain the fish safely.

MAIN APPROACH
The main areas of concern when it comes to ensuring safe and reliable offshore fish farming units may be categories into: Asset integrity, personnel safety, fish welfare and prevention of fish escape.

Asset integrity includes structural strength, stability, mooring, technical arrangement, and solutions on board together with reliability of essential equipment installed.

Personnel safety is mainly addressing arrangement for emergency escape and fire safety. This included lifesaving appliances, launching equipment and similar as well as fire detection and -extinguishing. It is common to apply well know maritime codes as acceptance criteria for personnel safety. SOLAS is a good example followed by local flag- or shelf states interpretation of requirements embedded in this maritime code.

Fish welfare and requirements related to this varies depending on local authorities. It is essential to verify the reliability of technology utilized to monitor environment of the fish. Instrumentation indicating oxygen level, temperature, salinity, turbidity is subject for special attention. Maximum acceptable level of biomass is also a crucial parameter that needs to be monitored.

Fish control or prevention of escape is the main function of a fish farming unit. Structural integrity of net system and ropes together with capability of fish transfer systems are crucial items in fish control. Flexible net systems utilized in rigid high volume steel fish farming installation has proven to be exposed to fatigue and need to be attended to in particular. Wear and tear of net due to cleaning and handling is also a concern. Several of reported incidents related to fish escape happens while handling of fish – for example crowding due to de-licing or transfer. Equipment contributing to these operations needs to be specially attended to.

The four different items are considered equally important for safe and sustainable fish farming offshore. These elements are also closely interconnected where integrity of one may support several others.

CONCLUSION
There is a significant potential to utilize competence from traditional offshore and maritime industry to help operators of exposed fish farming units to identify operational risks by applying technical rules and requirements from classification. As opposed to the offshore oil and gas industry, classification may not be obligatory in aquaculture, but it turns out that many developers and operators nonetheless choose to follow class requirements and recommendations.

Combining the well-known classification concept from maritime industry with balanced aquaculture-based requirements provides a robust and cost-efficient solutions to reducing risk in operation of offshore fish farming installations.
INDUSTRIALIZATION OF OCEAN FISH FARMING CONTRIBUTING TO BOOST SUPPLY OF MARINE PROTEINS – SOLUTIONS AND CHALLENGES

INTRODUCTION
All aquaculture market projections uncover a dramatic supply-demand imbalance in the next two to three decades. Focusing on fin fish supply specifically uncovers that output level is close to a saturation point for traditional areas with sheltered aquaculture. Currently the response to this situation is the fact that fish farming is growing out of sheltered, near-shore areas and moved to locations further offshore together with several new land-based RAS/flow-through plants being established around the world. A number of innovative solutions is being tried out in offshore fish farming in the process of industrialization. The objective is a higher output volume of fin fish combined with improved fish welfare. As the world’s population grows, the options for producing enough healthy, sustainable food are becoming limited. Several interesting solutions for efficient, large-scaled fish farming in offshore/exposed environment are in the pipeline.

MAIN APPROACH
There are several advantages applying the solution with advanced, high volume fish farming installations to increase supply of marine proteins. Better fish welfare, less conflicts with interests in the ocean space as well as possibility to scale up output volume without compromising environmental sustainability - to mention a few.

The numerous concepts planned and implemented may be split into three main categories: Open trusswork with traditional net or grating, semi-closed units and at last closed aquaculture installation. The first may be split into two where most are operating at the ocean surface while an increasing number of designs have the option of submerged position to avoid splash-zone issues at rough sea states. These have all a number of advantages and weaknesses that have to be considered and evaluated. The various solutions ability to perform depends on a long list of aspects. The essential parameters to be taken into consideration assessing performance are among other things:

- Oxygen level in sea water. Essential for fish welfare is the ability to keep continuous O2-level above lower limit in all parts of the fish farming installation. In-depth analysis has to be performed to ensure no “dead pockets” where the fish density at periods of low water circulation may be too high.
- Crowding and live transfer of fish. These are processes that cause significant stress and physical strain. Again, resulting in reduced resistance towards diseases, etc and may lead to great losses of fish combined with low fish welfare. The industrialized solutions applied for offshore fish farming often utilized advanced mechanical systems to facilitate these processes, failure will lead to operational interruption and fish escape.
- Dead fish handling and ensilage processing. Typically, automated processes that involves much less manual handling compared to traditional sheltered methodology where these task are not carried out at the pen, but rather on the feed barge, etc.
- Logistics of supplies and goods going both on and off the fish farming installation result in several and more advanced marine operations compared with traditional fish farming. Higher sea states with more dynamics in both supply vessel and offshore fish farming installation is a major risk contributor to be mitigated when emergency preparedness is planned.
- Personnel safety. Personnel safety is mainly addressing arrangement for emergency escape and fire safety on board. This included lifesaving appliances, launching equipment and similar as well as fire detection and -extinguishing. In addition, other common safety items such as falling objects, working at heights and pinching/crushing have to be taken into account.

Other similar issues such as hygiene and cleaning as well as feed handling & -control could also be included discussing the total operational performance of a high-volume fish farming installation.

CONCLUSION
To address and mitigate issues mentioned above there is a significant potential to utilize competence from traditional offshore- and maritime industry to support operators of exposed fish farming units in design and tuning operational modes for efficient production. The industry is currently very much exploring possibilities and collecting experience from the various concepts being planned and put in operations. This learning journey is an important phase in the development of offshore fish farming to become a significant contributor in feeding future generations with sustainable and healthy marine proteins.
A MULTIPLEXED, TILED PCR METHOD FOR RAPID WHOLE-GENOME SEQUENCING OF INFECTIOUS SPLEEN AND KIDNEY NECROSIS VIRUS (ISKNV) IN TILAPIA

Shayma Alathari*, Richard Paley, Charles Tyler and Ben Temperton.

INTRODUCTION

Tilapia farming is one of the most important sectors in finfish species cultured worldwide and of major importance to global food security, with total global production estimated at more than 6 million tonnes in 2018 (FAO; Martínez-Cordero et al. 2021). Infectious spleen and kidney necrosis virus (ISKNV) has been identified as an agent of high morbidity and mortality, threatening tilapia aquaculture. ISKNV was detected in Lake Volta, Ghana, in September 2018 and spread rapidly, with mortality rates between 60 and 90% and losses of more than 10 tonnes of fish per day resulting in the closure of more than 50 farms and the disruption of the livelihoods of the communities along the lake (Okai 2021). Understanding the spread and evolution of viral pathogens is important for control strategies. With the information obtained from genomic surveillance and epidemiological data, it is possible to reconstruct chains of transmission (Quick et al. 2020), (Gardy et al. 2015). Here, we assess the epidemiology of an ongoing epidemic of ISKNV in Nile tilapia in Ghana by developing a tiled-PCR sequencing approach for whole-genome sequencing of ISKNV to enable field-based, real-time genomic surveillance. Additionally, this method was used as a monitoring scheme and an alternative to destructive sampling, by concentrating viruses from the water of floating cages. Despite the low mutation rate of dsDNA viruses, 20 single nucleotide polymorphisms (SNPs) accumulated during the sampling period, with two non-synonymous SNPs were seen in the major capsid protein. Droplet digital PCR identified a minimum requirement of template in a sample to recover 50% of an ISKNV genome. Overall, tiled-PCR sequencing of ISKNV provides an informative tool to assist in disease control in aquaculture (Alathari et al. 2023).

METHODS AND MATERIALS

This study was performed on samples collected from seven farms in Lake Volta/Ghana, during an outbreak of ISKNV between October/2018–May/2022. Furthermore, water samples were collected to test the feasibility of this method in the field. Primers were designed with the PrimalScheme (v 1.3.2) to produce 2kb amplicons spanning the genome, for WGS of ISKNV from infected fish using a tiled PCR approach. Library preparation was conducted on the generated amplicons. Samples were multiplexed and sequenced using the MinION sequencer. A consensus genome was generated according to the ARTIC bioinformatics pipeline (artic.network/ncov-2019/ncov2019-bioinformatics-sop.html). Phylogenetic analysis of ISKNV within the Ghana outbreak of 2018–2022 was performed using Augur and visualised in Auspice. Finally, the number of ISKNV viral templates from 6 ng to 6 × 10^-6 ng was measured using the ddPCR, to determine the minimal input for genome recovery of ISKNV using the tiled PCR protocol.

Figure 1. Phylogenetic placement of ISKNV genomes from Ghana and their associated farms, using Augur bioinformatics toolkit. The horizontal axis indicates divergence relevant to the root of the tree. Clades are labelled A–D. The colour of the tips represents the date of sample collection; the number and location of mutational events are shown in the diversity panel below.

(Continued on next page)
RESULTS AND DISCUSSION
In this study, we were able to recover up to ~96% of the ISKNV genome, directly from fish samples collected from Ghana during the outbreak, using the tiled PCR protocol. Approximately 137 SNPs were detected, when compared with the original reference genome, and it has shown that changes were sufficient to detect a phylogeographic signal during this outbreak. Some of these non-synonymous mutations were associated with the MCP, ATPase gene and OFR022. Phylogenetic analysis of ISKNV within the Ghana outbreak of 2018–2022, performed using Augur and visualised in Auspice, showed the initial outbreaks in Lake Volta clustered into four distinct clades, and each clade had a mix of samples from different farms. To evaluate the optimal concentration of ISKNV needed for genome recovery using the tiled PCR method, we measured the number of ISKNV viral templates. The minimum requirement to recover 50% of an ISKNV genome was ~2410 viral templates. This work shows that PCR tiling approaches used successfully to track the evolutionary rate, signatures of host adaptation, and transmission patterns of RNA viruses (Quick et al. 2016) can also be applied to monitor infections of large dsDNA fish viruses. Thus, this method can be utilised as a surveillance tool for other viral infections threatening the growth of the aquaculture industry.

FUTURE RESEARCH
Further studies will include determining the sensitivity of our developed protocol for different viruses affecting the growth of aquaculture. We have tested this method on Tilapia Lake Virus (TiLV) samples- an RNA virus affecting tilapia in several continents. This work provides a platform from which it is feasible to replicate the Artic-Network “lab-in-a-suitcase” approach to disease tracking and management in aquaculture in remote and resource-limited locations. With appropriate training and guidance, this workflow represents a suitable framework for local authorities in lower- and middle-income countries to contain and track different viral diseases in their localities.

Introduction

Carbohydrates are an excellent cost-friendly energy source for fish, and they have been used to improve growth performance and reduce dietary protein levels. However, the aquaculture industry has frequently overused high dietary carbohydrate levels, which has caused metabolic disturbances in fish. This deleterious effect is often diagnosed at the end of the production cycle, affects fish health and causes significant losses to farmers. In this context, β-glucan, which is broadly known as an immunomodulator, may ameliorate the deleterious effects caused by high levels of dietary carbohydrates. Therefore, we investigate the effect of dietary β-glucan on the reduction of metabolic disturbances in Nile tilapia fed with a high carbohydrate diet.

Material and methods

A total of 352 juvenile Nile tilapias (25.39 ± 0.83 g) were fed with isoproteic (280 g kg⁻¹ PD) and isoenergetic diets (3130 kcal kg⁻¹) containing low amounts of carbohydrates (CHO-L 270 g kg⁻¹) or high amounts of carbohydrates (CHO-H 620 g kg⁻¹) with four levels of β-glucan (βG; 0, 1, 3 and 6 g kg⁻¹) for 10 weeks. We evaluated the productive performance, plasma glucose, serum triglycerides, hepatosomatic index, total liver and muscle lipid, hepatic glycogen, innate immune responses, hepatic activity of hexokinase, glucokinase, pyruvate kinase, glucose-6-phosphate dehydrogenase, malic enzyme and liver histopathology (not all data discussed here). The data were verified regarding normality (Kolmogorov-Smirnov test) and homoscedasticity (Brown-Forsythe test) of variances. Thereafter, the results were analyzed using two-way ANOVA with CHO and βG levels as factors followed by Tukey’s test to identify differences among the treatments. When the interaction was found between the factors, a One-Way ANOVA was performed to compare the βG groups and a t-test to compare the CHO levels. The effects of the treatments were considered significant at a 5% probability. All the analyses were done using the ExpDes.pt package (Ferreira et al., 2018) in software R®, version 3.5.1.

Results

Fish fed with a high carbohydrate diet had significantly increased productive performance (Weight gain – figure 1A and Feed conversion ratio - 1B) and lipogenesis, presenting higher muscular lipid (1C), hepatosomatic index (1D), hepatic activity of glucose-6-dehydrogenase phosphate, and malic enzyme. Additionally, histological analyses indicated expressive cytoplasm vacuolization. The innate immune responses such as leukocyte respiratory activity (1E), complement and lysozyme were also significantly decreased for the high carbohydrate diet, indicating the occurrence of immunosuppression in fish. These results also indicate impaired metabolic functioning, however, β-glucan ameliorated metabolic stress.

Figure 1. Weigh gain (A), Feed conversion ratio (B), Muscle lipid (C), Hepatosomatic index (D) and Leukocyte respiratory activity (RAL) of Nile tilapia juveniles fed for 10 weeks with diets containing different levels of carbohydrates (CHO-L vs. CHO-H; 270 and 620 g kg⁻¹, respectively) and β-glucan (βG: 0, 1, 3 e 6 g kg⁻¹). Capital letters indicate statistically different means between carbohydrate levels (P < 0.05). Lowercase letters indicate statistically different means between glucan (P < 0.05). Values are means ± 1 standard error (S.E.).

Conclusion

β-glucan mitigated the metabolic disturbances caused by the high levels of carbohydrates in the diet of Nile tilapia. This finding indicates that besides having an immunomodulating effect, β-glucan also has metabolic functions/benefits such as reducing glycolysis and lipogenesis.

SYSTEMATIC REVIEW OF ENABLING AND CONSTRAINING FACTORS FOR THE DEVELOPMENT OF ORGANIC AQUACULTURE IN THE EU

S. Alfonso1*, I. Jahrl2, S. Quiédeville2, P. Carbonara1, G. Lembo1

1 Fondazione COISPA ETS, Bari, Italy
2 Research Institute of Organic Agriculture (FiBL), Frick, Switzerland
E-mail: salfonso@coispa.eu

Introduction
Although global aquaculture is setting production records, the organic aquaculture still represents a niche market. Indeed, the total organic aquaculture production of EU-27 is only accounting for 6.4% of the total production, and this appears to be not sufficient to fit the objectives of at least 25% of the agricultural land by 2030 according to the EU’s Farm to Fork Strategy. Historically, the organic aquaculture sector has faced many difficulties hampering the development of the sector as e.g., technical difficulties in production, lower profitability, limited market demand, strict regulations or competition with other certification schemes (EUMOFA, 2022). In this study, we have conducted a meta-analysis of the available literature to investigate the enabling but also constraining factors on the organic aquaculture development in the EU. We focused particularly on the main farmed species, including freshwater and marine species (i.e. shellfish, salmon, trout, carp, sea bass and sea bream).

Materials and methods
Impact factors (IFs) were retrieved from the 82 documents reviewed, which include scientific papers, national, European reports and classed them as enabling or constraining as presented in the documents. List of IFs able to support/constrain the development of the EU organic aquaculture used in this study was defined according to Michelsen, (2001). Briefly, the IFs (n=59) were defined to encompass the interrelationship between the farmer and the institutional environment by conceptualizing society to be composed of three parts: the state (based on political authority), the market (based on economic competition) and civil society (e.g. based on civil solidarity within families, social groups) at micro-, meso- and macro level (Michelsen, 2001).

Each mentioning of IF was coded according to the document content and to the way the factor was defined in the document: “Supporting” or “Constraining” with three sub-categories which were “Supporting/Constraining but insufficient”, “Supporting/Constraining” or “Very Supporting/Constraining”. In more details, an IF was coded as “Supporting/ constraining but insufficient”, when the authors did not explicitly refer to the IF as supporting or constraining but when this was implicit or when there was some specific caution about the IF made by the authors. IF was coded as “Supporting/ constraining” when the authors explicitly referred to the IF as supporting/constraining. An IF was coded as “Very supporting/ constraining” when the authors explicitly referred to the IF as main supporting/constraining factor to the development of organic aquaculture.

Results and discussion
We have identified 470 impacting factors (IF) as supporting or constraining to the development of organic aquaculture in the EU. Overall, the five most mentioned supporting factors to the development of the organic aquaculture in the EU were the “consumer demand and/or willingness to buy” (n=35), the “marketing strategies for organic products” (n=24), “accessibility to communication and marketing” (n=20), “consumer attitude & belief” (n=19) and “innovation in farming” (n=17). Other significant supporting factors (n>10 mentions) highlighted are related to the “price relation between organic and conventional products” (n=14), “offer of organic products/sortiment” (n=12), the “need of research effort, funds for organic research and development” (n=12), “private label and criteria” (n=11), “need for clearer and simpler organic farming regulation/rules” (n=10), “public awareness” (n=11), and “environmental benefit and ecosystem services” (n=10) and the “availability of incentives (e.g., eco-premium)” (n=14) (Figure 1).

At the contrary, the most mentioned constraining factors to the development of the organic aquaculture in the EU were the “(quality) requirements for organic products and/or price” (n=32), the “price relation between organic and conventional products” (n=29), the “high bureaucracy level in organic farming regulation/rules, including high cost for certification” (n=18), the “unavailability of organically produced inputs (e.g. animals, seeds, feeds)” (n=16), the “competition and/or confusion with other labels (e.g. MSC, ASC, label rouge)” (n=15), “consumer demand, willingness to buy” (n=15) and the “lack of public awareness” (n=13) (Figure 2).

(Continued on next page)
In conclusion, results showed a certain demand for aquaculture organic product does exist and is expected to growth in the EU. There still are, however, important constraining factors to the development of the organic aquaculture, i.e., quality requirements for organic products, harmonization of the standard for certification, competition with other sustainable labels (e.g., ASC, MSC) and the price relation between organic and conventional products. Strong effort from the EU policy will be needed in term of incentives, simplification of regulation, harmonization of standard, effective marketing strategies and availability of research funds to support innovation. In addition, institutions to support organic aquaculture need to be built at different policy levels in collaboration with different stakeholders to promote sound development of the organic aquaculture sector.

Acknowledgments
This research was supported by OrganicTargets4EU funded by the European Union (Grant no. 101060368) and by the Swiss State Secretariat for Education, Research and Innovation (SERI) (Grant no. 22.00155).

Introduction

Limiting the spread of classical and emergent microbial infections in aquaculture is a challenge the scientific community is increasingly aware of, looking for new efficient preventive and therapeutic approaches. Several synthetic antimicrobial agents have been used to control bacterial infections in shellfish and fish cultured worldwide. However, around 90% of aquatic bacteria are resistant to at least one antibiotic, threatening human health shortly (Elbashir et al., 2018).

Marine species compose around half of the total global biodiversity, and considering their unique living environment (composition, close contact with microbes, and properties, e.g., antibacterial, antiviral, antitumoral), these organisms have gained substantial importance as a “gold mine” for the search of new natural bioactive compounds (Cheung et al., 2015). Therefore, in the BIOPTAL “Bioactive Octopus peptides with potential for aquaculture” Marie Skłodowska-Curie project (https://cordis.europa.eu/project/id/101026577), we are focused on high-throughput protein search from an under-explored marine reservoir of peptide diversity – the common octopus (Octopus vulgaris). O. vulgaris is one of the most demanded cephalopod species for human consumption and represents a challenge for aquaculture farming. Octopuses routinely edit their RNA sequences to adapt to their environment (Alon et al., 2015), meaning that some pertinent bioactive compounds with antimicrobial or other relevant properties to several industries, such as aquaculture, must only occur under particular environmental conditions. Unraveling putative bioactive compounds from O. vulgaris can help develop novel therapeutic solutions for several marine species to fight the appearance and persistence of multidrug-resistant bacterial strains (e.g., the pathogenic gram-negative bacterium, Vibrio parahaemolyticus, found in marine and estuarine environments which causes a varying degree of illness including gastroenteritis) in the aquaculture sector. Thus, aiming to detect natural compounds highly expressed under challenging conditions and stimulate bioactive peptide secretion to produce different kinds of compounds involved in host defense mechanisms, we accomplished an in vivo bacterial challenge with V. parahaemolyticus and generated the O. vulgaris proteome to investigate the differential expression of several antimicrobial and toxins-related genes in the skin, posterior salivary glands (PSGs), and hemocytes of the common octopus.

Materials and methods

Ten adult specimens of common octopus were obtained from the Mediterranean Sea (Valencia, Spain), maintained in the Marine Fish Facility at the University of Murcia (Spain), and randomly distributed into two groups: i) control group (unchallenged, immersion with sterile sea water) and ii) bath-challenged with V. parahaemolyticus (challenged, immersion with a sub-lethal bacteria concentration). After 6 h bath-challenged with the bacteria, octopuses were humanely sacrificed (Fiorito et al., 2015) and dissected. Hemolymph, skin, and PSGs fragments were collected to obtain the proteome of these tissues and hemocyte cells. Digestion of the samples was performed with trypsin/LysC overnight following SP3 – solid-phase-preparation (Hughes et al., 2019), and the concentration of the resulting peptides was measured by fluorescence. The shotgun proteomics analysis of the two tissues and cells was performed by injection of peptides in a nano-LC (Ultimate 3000, Thermo Fisher Scientific, Bremen, Germany) connected to a Q Exactive Hybrid Quadrupole-Orbitrap mass spectrometer (Thermo Fisher Scientific, Bremen, Germany). The LC-MS/MS raw data were analyzed by Proteome Discoverer SP1

(Continued on next page)
3.0 software (Thermo Fisher Scientific) for protein identification against the following databases UniProtKB/Swiss-Prot, UniProtKB/Swiss-Prot Tox-Prot, Starpep (Aguilera-Mendoza et al., 2019), and a comprehensive non-redundant antimicrobial peptides (AMPs) database (Almeida et al., 2020) together with a database of common contaminants from MaxQuant.

Results and discussion

AMPs present great diversity considering their structure, activity, mode of action, and genetic origin (Almeida et al., 2020). These peptides are widely distributed among prokaryotes, animals, and plants, establishing the first line of defense against microorganisms (bacteria, viruses, parasites, and fungi) as part of their primary immune system. A previous proteomics study of unchallenged O. vulgaris from eastern Atlantic waters (Portuguese waters) suggests the putative production of AMPs by O. vulgaris PSGs as part of their primary immune system (Almeida et al., 2020). That study revealed that the O. vulgaris PSGs antimicrobial repertoire is composed of AMPs found in relatively high abundance, such as ubiquitin-derived peptides (cgUbiquitin), histone-derived peptides (buforin-II, H2A, and H2B), peptides similar to bovine pancreatic trypsin inhibitor (BPTI/Magainin), among others (Almeida et al., 2020). In this project, we are implementing a high-throughput approach for discovering new antimicrobial and immunomodulatory peptides potentially expressed under challenge (V. parahaemolyticus) from tissues and cells of O. vulgaris. We are looking specifically for differential expression of the previously mentioned AMPs and other AMPs not yet characterized in this species. Our results (work in progress) will help shed light on the underexplored antimicrobial repertoire of the common octopus, uncovering potential new peptides and simultaneously elucidating the role of glands, skin, and hemocytes in the species’ molecular environmental adaptation, which remains poorly known (Fingerhut et al., 2018), opening the opportunity to develop alternatives to fight the synthetic antimicrobial resistance problem currently impacting several industrial sectors such as aquaculture.

Conclusion

This study offers a comprehensive proteomic view to enlarge the understanding of the common octopus’s adaptive mechanisms, broadening the knowledge on the first line of defense against multi-antibiotic resistant bacteria affecting the aquaculture sector. The information provided by this study represents a pilot prospect that could help optimize culture conditions and disease prevention procedures affecting aquaculture-relevant species.

Acknowledgments

This project has received funding from the European Union’s Horizon 2020 research and innovation programme under the Marie Skłodowska-Curie grant agreement No 101026577 (D.A.).

Introduction

Aquaculture represents one of the most promising sectors in the global food industry, driven by the rising demand for increased production. Among the species garnering significant interest in the Mediterranean area is the cephalopod common octopus (Octopus vulgaris), known for its short life cycle and high reproductivity. However, a major challenge faced in its aquaculture is the emergence of infections caused by bacteria that have developed resistance to commonly used antibiotics, leading to substantial economic losses and jeopardizing the survival of the animals 1. In invertebrates, such as cephalopods, stress triggers an innate immune response, encompassing cellular and humoral reactions, as they lack an adaptive immune system 2. To enhance animal welfare in aquaculture and gain insights into the immune defense mechanisms of cephalopods, it becomes essential to study defense mechanisms in the skin, which features a mucus layer in the epidermis acting as a barrier against pathogens 3, and the plasma, which carries substances that support the immune response 2. Thus, to better understand cephalopod immunity, we conducted tests to identify potential differential responses in the expression of immune-related genes in the posterior salivary glands (PSGs) and assessed immune-related parameters and the bactericidal activity in the skin mucus and plasma of the Octopus vulgaris upon a bacterial challenge with the pathogen Vibrio parahaemolyticus. By investigating these aspects, we aim to shed light on the immune defense mechanisms of the common octopus and potentially discover new strategies to strengthen disease resistance in aquaculture production.

Materials and methods

Ten adult O. vulgaris specimens, previously acclimatized, were randomly divided into two experimental groups: i) unchallenged and ii) challenged group subjected to immersion with a sublethal concentration of V. parahaemolyticus. After a 6-hour bath-challenge, the animals were anesthetized and euthanized to collect PSGs, skin mucus, and hemolymph samples. The immune response of Octopus vulgaris was assessed by studying the gene expression in the PSGs and evaluating several immune-related parameters in skin mucus and plasma. In particular, PSGs samples were used to evaluate the expression of the following genes by RT-qPCR: i) immune-related genes – heat-shock protein 90 (hsp90), toll-like receptor (tlr), peptidoglycan recognition protein 3 (pggr3), C1q binding protein (C1q), β-actin (β-act); ii) stress-related genes – superoxide dismutase (sod), peroxiredoxin-5 (prdx5), lysosomal-trafficking regulator (lyz) and clotting factor C1 (C1-like), and iii) antimicrobial peptide (AMP) genes –ubiquitin-40S ribosomal protein S27a (rps27a) and histone H4 (h4). To study the humoral response, innate immune parameters such as protease, antiprotease, lysozyme, peroxidase, esterase, and alkaline phosphatase activities were measured in skin mucus and plasma samples to assess potential differences between the unchallenged and bacterial-stimulated animals. Finally, the bactericidal activity in skin mucus and plasma samples was evaluated against V. parahaemolyticus, V. anguillarum, V. alginolyticus, V. harveyi, Escherichia coli, and Photobacterium damselae subsp. piscicida.

Results and discussion

The expression of immune-related genes in PSGs showed variations between both experimental groups for rps27a, prdx5, lyz, and C1q genes, which were down-regulated in the challenged group compared to the unchallenged one. The rps27a downregulation could suggest that the presence of bacteria may exert an inhibitory effect on the antibacterial function associated with the ribosomal protein, as reported by Hurtado-Ríos et al. (2022) 4. Prdx5 showed a significantly lower mRNA expression in challenged octopi, as observed in the research conducted by Castellanos-Martínez et al. (2014) 5.

(Continued on next page)
their study, this gene was found to be repressed in infected hemocytes with Aggregata octopiana. In contrast to the findings of Vizcaíno et al. (2023) and Castellanos-Martínez et al. (2014), where the expression levels of lyz and C1q increased in octopi hemocytes under stressful conditions, in the present study, we observed a decrease in the expression of both genes within the challenged group. The immune-related parameters measured in the plasma and skin mucus did not indicate variations among the unchallenged and challenged groups. This fact could be due to the exposure time, which might be insufficient to trigger a local and systemic response, as reported by other authors considering several challenges. Finally, no variations were observed between the experimental groups in the bactericidal activity measured in the skin mucus and plasma against the six marine pathogenic bacteria tested. This finding aligns with our results and previous studies, which have indicated that significant changes in bactericidal activity are typically observed after five days of challenge. Thus, the relatively short 6-hour challenge period employed in our study may not have provided enough time for the substantial accumulation of natural compounds exhibiting significant bactericidal activity.

Conclusion

In this study, the expression of immune-related genes in both unchallenged and challenged groups exhibits variations in genes encoding ubiquitin 40S ribosomal protein S27a, peroxiredoxin-5, lysosomal-trafficking regulator and C1q binding protein, which showed a down-regulation in the challenged group. This finding leads us to hypothesize that these genes repression in challenged octopi may occur because of the weakening of the immune system of the specimens, caused by the recent infection with V. parahaemolyticus prior to the onset of the immune response, which has been seen at around five days in other studies. Furthermore, at 6-hours post-challenge, we did not observe variations in the immune-related parameters. Consequently, future studies should consider analyzing these markers at different time points post-exposure to better understand O. vulgaris’s defense mechanism against this multi-drug-resistant pathogen.

Introduction

Global public health is being threatened by multidrug-resistant pathogens fueled by the overuse of traditional antibiotics. To combat this challenge, antimicrobial peptides (AMPs) derived from natural sources are currently being studied as viable alternatives to traditional antibiotics (Browne *et al.*, 2020). AMPs are key components of the innate immune response, with the remarkable ability to target multiple sites in pathogens, reducing the risk of resistance development.

Marine invertebrates, widely distributed and highly diverse, face constant microbial challenges due to altered environments driven by human activities. Their innate immune system, involving cellular and humoral responses, defends them against infections. Cellular immunity employs hemocytes for processes like encapsulation and phagocytosis, while humoral immunity involves hemolymph coagulation mechanisms and AMPs that disrupt microbial membranes. Invertebrates are the primary source of aquatic AMPs contributing with around 40 characterized AMP families (Bertrand and Munoz-Garay, 2019). Within the phylum Cnidaria, a group of primarily marine invertebrates, is the underexplored white-spotted jellyfish *Phyllorhiza punctata* (Scyphozoa, Rhizostomeae), an invasive jellyfish originally from the western Pacific Ocean that’s rapidly spreading through the Mediterranean Sea (Kaminas *et al.*, 2022) even reaching the Northeast Atlantic Ocean (Enrique-Navarro and Prieto, 2020).

The primary goal of this work is to unveil the proteomic profile of the gonads of *Phyllorhiza punctata*, aiming to explore the AMPs produced by this organism and assess their potential as effective alternatives to currently used antibiotics in aquaculture.

Materials and methods

Two adult specimens of *Phyllorhiza punctata* were obtained from Oceanário de Lisboa (Lisbon, Portugal), their gonads were dissected and stored at -80 °C. The proteins from these samples were extracted using two protocols FASP – *Filter Aided Sample Preparation* (Wiśniewski *et al.*, 2009) and ISD – *In-Solution Digestion* with some adjustments, and further processed using a nano-LC coupled to a Q Exactive HF Hybrid Quadrupole-Orbitrap Mass Spectrometer (Thermo Scientific, Waltham, MA, USA). The resulting raw files were searched against three databases consisting of i) AMPs from the starPep database (Aguilera-Mendoza *et al.*, 2019), ii) several proteins from the UniProtKB database, and iii) reviewed venom proteins and toxins from Tox-Prot, together with a database of common contaminants (CRAP: https://www.thegpm.org/crap/), using Proteome Discoverer 3.0 SP1 software. The search parameters for protein identification included precursor and fragment mass tolerances of 10 ppm and 0.02 Da, respectively, allowing up to two missed trypsin cleavage sites, cysteine carbamidomethylation was selected as static modification, while methionine oxidation and asparagine and glutamine deamidation were chosen as variable modifications. Peptide-spectrum matches (PSMs) and peptides were accepted at a 1% false discovery rate (FDR), and peptide confidence was set to “High”.

(Continued on next page)
Results and discussion

Several AMPs share common structural characteristics, like their overall size (~10-100 amino acids), molecular weight (<25-30 kDa), and net positive charge. However, they display a wide variety of structural motifs that, even similar sequences, may have completely different conformatures. Aurelin, a peptide with 40 amino acids, six cysteine residues, and active against gram-positive and negative bacteria, remains the only AMP originally extracted from a jellyfish (Ovchinnikova et al., 2006). In fact, there are very few jellyfish proteomic studies, and the exceptions are mostly focused on studying their venom proteomes (Leung et al., 2020).

In our study, we identified a total of 5,805 putative proteins belonging to 700 protein groups. Out of those, 2,633 proteins distributed among 409 protein groups were found with both FASP and ISD methodologies: 2,603 proteins are led by putative proteins identified against the UniProt database, while the remaining 30 were found against the starPep database. No toxins from the Tox-Prot database were retrieved. Antimicrobial peptides, such as Acipensin 6, Aurein-1.2, and Brevinin-2-RA13, were identified.

Conclusion

Jellyfish studies have critical implications for conservation and environmental awareness. Gaining new insights into the unique molecular properties of the invasive Phyllorhiza punctata contributes to the study of its biotechnological potential and the preservation and conservation of marine ecosystems and their biodiversity.

MODELLING DISSOLVED OXYGEN CONCENTRATIONS IN AN ATLANTIC SALMON SEA CAGE FARM IN NORWAY

M. O. Alver¹, M. Føre¹, H. A. Urke² & J. A. Alfredsen³

1. Department of Engineering Cybernetics, NTNU, 7491 Trondheim, Norway
2. AquaLife R&D AS, Havnegata 9, 7010 Trondheim, Norway
E-mail: morten.alver@ntnu.no

Introduction
Dissolved oxygen (DO) is a key variable in Atlantic salmon sea cages, as sufficient oxygen is needed to ensure good fish welfare and high growth. The effects of insufficient oxygen leading to hypoxia range from reduced appetite, stress responses, reduced feed conversion and growth to acute mortality, depending on how low DO levels are encountered (Oppedal et al., 2011, Remen et al., 2016). Alver et al. (2022) presented a mathematical model of 3D distributed DO levels in salmon cages, seeking to combine our knowledge of the advective and diffusive transport of oxygen, the oxygen consumption by individual fish, and the spatial distribution of the fish, to estimate DO levels as a function of environmental conditions. In this study, the model is used along with an extensive measurement program to investigate oxygen conditions in one of six commercial scale cages containing biomass at a location in Mid-Norway.

Materials and methods
The mathematical model is based on an advection-diffusion equation operating on a regular grid with horizontal and vertical resolution of 2 m, with a simplified representation of the fish to compute feed ingestion and oxygen consumption rates. Feeding dynamics are computed based on Alver et al. (2016), and oxygen dynamics based on Alver et al. (2022). Model inputs for temperature, ambient oxygen level, current speed and direction are based on measurements over a 9 day period in June 2022, and model output is compared to measured oxygen levels at 12 points for one of the cages (centre and three points along the edge of the cage, each at 5, 10 and 15 m).

The model is tested when simulating the observed cage only, and when simulating the full farm (Fig. 1). The effect of neighbouring cages partly depleting the water of oxygen needs to be taken into account when simulating a single cage only, and this was addressed with an ad hoc model modification that reduces boundary levels of oxygen dependent on current direction and speed. An additional modification was tested to account for increased biofouling over the study period leading to gradually more damping of the current speed within the cage. The different model varieties were evaluated based on their agreement with measured oxygen.

Results and discussion
Comparisons between simulated and observed DO levels at the sensor positions are summarized in Fig. 2. The model variants are denoted basic (single cage model, no modifications), VAB (single cage model with adjustment to boundary conditions and current damping rate) and VFB (full farm model with adjustment to current damping rate). The basic model has a clear overall positive bias, with a positive trend over the study period. The VAB model has near zero bias and no similar trend, showing that the ad hoc modifications lead to better model fit. The VBF model also significantly reduces the bias and the positive trend, showing that taking the full farm into account clearly improves the overall model fit. All model variants have highest RMSE at 5 m and lowest at 15 m, indicating that dynamics in the upper part of the water column in the cage is the most difficult to capture in the model.

QUALITY AND FISH WELFARE – LINKING CAUSES FOR QUALITY DOWNGRADING AND PRODUCTION RELATED DRIVERS IN NORWEGIAN ATLANTIC SALMON FARMING

René Alvestad*, Chris Noble, Ingrid Måge, and Kristian H. Liland

rene.alvestad@nofima.no

Quality downgrading of fish with quality defects is a considerable cause for economic losses to farmers due to reduced marketability and sales prices, as well as increased processing costs. Several causes for quality downgrading can be linked to adverse welfare states during fish rearing and should therefore be considered as welfare indicators. In this study, we linked the production records of 24 sea cage sites to slaughter records from a processing plant in northern Norway. We quantified the prevalence of proximate causes for downgrading and used ordination and regression-based approaches to model the variation in quality traits due to selected production related drivers. The most important causes for downgrading were ulcers (39 % of downgraded fish), dark spots (17 %), deformities (12 %), and early maturation (10 %). The presence of ulcers was by far the most severe cause for downgrading. Important drivers for overall quality reduction were growth during the seawater stage, seawater temperature (mean and standard deviation), certain cause specific mortality counts, and day of harvest. Ulcers were linked to low seawater temperatures during production.

Our study demonstrates that proximate causes for quality downgrading at slaughter are relevant retrospective welfare performance indicators and provides an overview of how production related drivers can affect slaughter quality throughout the year. It highlights the link between improved welfare and improved production outcomes, as well as the utility of systematic data collection and analysis in aquaculture production.
BIOCHEMICAL COMPOSITION OF MILT AND REPRODUCTIVE PERFORMANCE OF MALE *Clarias gariepinus* BROODSTOCK FED WITH A DIETARY SUPPLEMENTATION OF *Cocos nucifera* POWDER

Folasade D. Amulejoye*1 Olabode T. Adebayo2, Adekunle A. Dada2

Introduction
Good nutrition in aquaculture correlates with better sperm quality and reduced abnormalities in parameters such as sperm count, sperm concentration, and motility (Oke *et al.* 2019). Some plants have been reported to enhance gonadal development, induce maturation and increase growth in fish species (Oke *et al.* 2019). These plants contain inherent active ingredients (sterols, flavonoids, saponins) and nutrients for their actions. *Clarias gariepinus* is a very important freshwater fish in Nigeria that enjoys wide acceptability in most parts of the country because of its ease of cultivation and unique taste, flavour, and texture. World Health Organization encourages the use of medicinal plants to minimize the use of chemicals as fertility enhancers, hence the use of *Cocos nucifera* in this study. The study aims to determine the dietary effect of *C. nucifera* on the biochemical composition of milt and the reproductive performance of male *C. gariepinus* broodstock.

Materials and methods
Sixty male *C. gariepinus* (446.56 g) were randomly distributed into 15 concrete tanks (1×2×1.5m3) at four fish per tank at the Teaching and Research Farm, Federal University of Technology, Akure. Five isonitrogenous diets at 40% crude protein level with different inclusion levels of *C. nucifera* powder were formulated (Table 1). The experimental fish were randomly assigned to five treatment groups (n = 3). The fish were fed at 3% biomass daily spread over two rations (0900 and 1400) for 56 days. The fish were batch-weighed bi-weekly and the water quality was monitored weekly (Temp 26.65±0.02, DO 5.98±0.04, pH 7.85±0.05). At the end of the trial, reproductive indices, hormone level, biochemical indices of milt of the fish, and phytochemical screening of the plant were investigated using standard methods as described by Hussain *et al.* (2018). The total protein, glucose, cholesterol, calcium, and magnesium of the milt were measured using the spectrophotometric method. The concentration of sodium and magnesium was determined with a flame photometer. Data were analyzed with SPSS v22 using one-way ANOVA.

Results
There were significant differences (*P*<0.05) in the values obtained for milt volume, milt count, motility duration and weight of testes of *C. gariepinus* fed *C. nucifera* endosperm residue (Table 2). Testosterone level, % fertility, hatchability, and survival were highest in fish fed CN1.5. All treatments displayed normal biochemical composition. There was no significant difference (*P*<0.05) in most analysed biochemical parameters except for magnesium and sodium (Table 3).

Conclusion
The study showed that the inclusion of *C. nucifera* endosperm powder in the experimental diets improved the milt quality, however it was observed that when *C. nucifera* inclusion level was above 1.5g/kg, the weight of the testes and milt volume decreased. The inclusion level of 1.5g/kg gave the best performance for the milt count, % motility, fertility, hatchability, survival, and testosterone level of *C. gariepinus*.

CHANGE - AN UNDERWATER ROBOTICS CONCEPT FOR DYNAMICALLY CHANGING ENVIRONMENTS

Herman B. Amundsen*1,2, Eleni Kelasidi2 and Martin Føre1

1Department of Engineering Cybernetics, NTNU, Norway
2Department of Aquaculture Technology, SINTEF Ocean, Norway
*E-mail: herman.biorn.amundsen@sintef.no

Introduction
As salmon farm sites are moved further offshore and to more exposed locations, working conditions become increasingly challenging. Farmers therefore aim to automate certain operations to facilitate safer working conditions. Automation and autonomous unmanned underwater vehicles (UUVs) are key elements in meeting this goal, and will contribute to increasing precision in finfish farming operations that in turn will enable the aquaculture industry to advance operational efficiency, safety and thus sustainability [1]. In this paper, an advanced control scheme for UUVs operating in complex environments has been investigated. The proposed scheme is suited for enabling verifiable collision-free navigation in dynamically changing environments. During demonstrations the UUVs were successful in autonomous navigation while successfully avoiding both static and moving obstacles.

This work was financed by the Research Council of Norway through the project: CHANGE – An underwater robotics concept for dynamically changing environments [2].

Materials and methods
The elastic band method has been a suggested method for planning collision-free paths [3] and was included in an adapted guidance, navigation, and control (GNC) architecture shown in Figure 1. The guidance system featured the elastic band path planner and a guidance law. Waypoints and positions of obstacles and the vehicle were used to calculate the control system reference signals. The low-level control system then used these signals and feedback of the vehicle states to calculate the control input for each thruster. Vehicle states were estimated using an Extended Kalman Filter (EKF) based on sensor readings.

Results
Extensive simulation results were obtained using FhSim [4] as shown in Figure 2. In addition, lab and field trials were conducted in the NTNU Marine Cybernetics Lab (MCLab) and the SINTEF ACE full-scale aquaculture laboratory to investigate the performance of the proposed control scheme for obstacle avoidance of UUVs in fish farms. Figure 3 and Figure 4 show some demonstrated case studies with a BlueROV2 vehicle from MCLab and field trials using an Argus Mini in an industrial scale fish farm at SINTEF ACE, respectively. All simulations, lab and field trials showed that the robot was able to avoid both static and moving obstacles during autonomous navigation of UUVs. The results demonstrate that the proposed method worked well at obstacle avoidance, and suggest that the elastic band method is a viable method for underwater collision avoidance in dynamically changing environments.

Conclusion and future work
Management of sea-based fish farms typically entails manual, and often challenging, inspection operations to monitor equipment, structures and biomass, which may result in sub-optimal and costly operations, insufficient maintenance, a general lack of control in daily routines and potential high risks for welfare of personnel and fish. This implies a need for new methods and technology for operations in modern fish farms, especially when moving operations to more exposed locations with more challenging environmental conditions, and new farm designs. The proposed methods and demonstrations show the great potential towards increasing the level of autonomous during daily operations in fish farms.

Introduction
Intensive fish farming involves high population densities and stressful conditions, can lead to disease outbreaks, and may result in the use of antibiotics. However, the development of antibiotic-resistant strains in fish farms has rendered the use of antibiotics ineffective. This has also contributed to a negative perception of the aquaculture industry among consumers (Martinez et al., 2012). In this study we conducted two series of experiments to monitor the antimicrobial activity of microalgal species, isolated from lagoons in Western Greece against four fish pathogenic bacteria (Vibrio anguillarum, Aeromonas veronii, Vibrio alginolyticus, and Vibrio harveyi), using axenic cultures and extracellular assays in two experimental series.

Materials and methods
In this first experiment series, we tested the antimicrobial activity of the axenic microalgae strains: Amphidinium carterae, Asteromonas gracilis, Tetraselmis sp. (red var.), Tetraselmis sp. (palmella), Tetraselmis sp. (red var., Pappas), and Dunaliella salina, at different salinities. The microalgae were cultured under aeration, and their cell numbers were counted using a microscope at the start and end of the six-day experiment (Stanier et al., 1978). Experiments were conducted with and without light, using Chlorella minutissima as a reference microalga (Makridis et al., 2006). In the second series of experiments, supernatants from Amphidinium carterae, Asteromonas gracilis, Tetraselmis sp. (red var. Pappas), Nephroselmis sp., Phormidium sp., Anabaena sp., and Cyanothece sp. were tested against the same fish pathogens (Katircioglu et al., 2006, Jlidi et al., 2022). The optical density was measured at 600 nm at 0, 2, 4, 6, 21, 23, 25, 48, 72, and 168 h after inoculation and calculated the inhibition efficiency using a formula according to Jlidi et al. (2022).

Results and Discussion
In the first series of experiments, all microalgae tested reduced the growth of bacteria compared with the control treatments. The largest differences were observed on the 4th day of the experiment for all microalgae tested, with the best results observed against the pathogen V. anguillarum.

Figure 1. Colony-forming units (CFU) per mL of V. anguillarum in cultures of Chlorella minutissima, A. gracilis, and Tetraselmis species (red var., palmella, red var. Pappas) (a), A. carterae, and D. salina (b), compared with sterile seawater 25 ppt added Walne’s medium (control), through time in light conditions.

(Continued on next page)
In the case of *V. anguillarum* (Fig. 1a,b), the control treatment had a microbial concentration of $33 \times 10^6$ CFU/mL, while in exposure to light, the microalgae *A. gracilis* and *Tetraselmis* species (red var., palmella, red var. Pappas) resulted in a concentration range of $2 \times 10^4$–$89 \times 10^5$ CFU/mL. Similarly, in exposure to light, the microalgae *A. carterae* and *D. salina* resulted in a concentration range of $66 \times 10^4$–$16 \times 10^5$ CFU/mL, compared to the control treatment of $6 \times 10^6$ CFU/mL. In the absence of light, the microbial concentration range for *A. gracilis*, and *Tetraselmis* species (red var., palmella, red var. Pappas) was $3 \times 10^4$–$77 \times 10^5$ CFU/mL, and the concentration range for *A. carterae* and *D. salina* was $78 \times 10^4$–$18,8 \times 10^5$ CFU/mL.

Seven species of microalgae were then tested for extracellular antimicrobial activity, where our experiments with *V. alginolyticus* yielded promising results compared with the control treatment, particularly for the cyanobacteria strains. The inhibitory effect on *Phormidium* sp. and *Anabaena* sp. was observed during the period from 21 to 48 hours, and for *Cyanothece* sp. it was observed during the period from 25 to 48 hours (p<0.05). The samples containing *Tetraselmis* sp. (red var., Pappas) with *V. alginolyticus* showed statistically significant inhibition between 4 and 25 hours. *A. gracilis* showed inhibition at 72 hours, while *Nephroselmis* sp. had a peak inhibition at 48 hours.

Our results with *V. anguillarum* indicate that *A. carterae* demonstrated inhibitory activity between 48 and 72 hours while in the experiment with *Tetraselmis* sp. (red var., Pappas), the growth of the pathogen was inhibited during the period from 6 to 21 hours. The results of our experiments with *V. harveyi* revealed statistically significant inhibition of growth for the *Anabaena* sp. strain between 23 and 25 hours while in our experiments with the *Tetraselmis* sp. (red var., Pappas) strain, inhibition was observed between 21 and 23 hours. *Nephroselmis* sp. exhibited inhibition against *V. harveyi* between 4 and 6 hours.

**Acknowledgements**

This study was supported through the project “Isolation and cultivation of local microalgae species from lagoons with the vision of mass production of antimicrobial substances, fatty acids, pigments and antioxidants” funded by the General Secretariat for Research and Innovation in Greece and EU funds (ref. nr. 5048496).

Introduction
Fish fillet proteolysis is a complex process that involves various biochemical and structural changes post-mortem, along with microbial activity. These changes can result in a decline in fish fillet quality and shelf life, often manifested as muscle softening and the creation of gaps in the myocommata [1]. Proteases responsible for muscle deterioration, namely, calpains, cathepsins and metalloproteases, can originate from both muscle tissue and the digestive system, and their activity is influenced by factors such as stress, temperature, and handling during harvesting and transportation [2], [3]. In Mediterranean aquaculture, species such as Sparus aurata, Dicentrarchus labrax, and Pagrus major are harvested using ice slurry that can cause stress on fish. This stress can exacerbate proteolytic cleavage and muscle softening, leading to further degradation of fillet quality [4]. The need for a more humane method of fish harvesting has led to the application of electro-stunning, suggested by both EFSA and OIE. However, before proceeding with the wide application of electro-stunning in Mediterranean marine fish farming, it is necessary to ensure that fish fillet quality is not compromised [5]. In this direction, the effects of electro-stunning on fish fillet proteolysis and flesh quality are investigated in the above Mediterranean farmed fish species, the gilthead sea bream, European seabass and the red seabream.

Materials and methods
The fish were harvested at the same fish farm in Astakos, Aitoloakarnania, Greece, during three different temperature periods: Warm (August, 25°C), Moderate (June, 21°C), and Cold (February/March, 15.5°C). Three harvest methods were applied: the conventional method of ice slurry and two electro-stunning settings of higher and lower voltage, with the same flow rate. White muscle samples were excised from each fish on slaughter day (Day 0) and on days 1, 2, 5, 7, and 13 post-harvest and were snap-frozen in liquid nitrogen. The activity of Calpain, Collagenase, Cathepsin B, and L was assayed using the Barrett and Kirschke method with minor refinements, and protein content was quantified using the Bradford method. Activity was expressed as fluorescence units change per minute per mg protein. Additionally, white muscle samples at harvest day (Day 0) and on days 7 and 13 post-harvest underwent histological analysis to assess flesh quality [5].

Results
The post-mortem activity of proteolytic enzymes in European seabass, gilthead sebream, and red seabream at different water temperatures and harvest methods was investigated. The results showed that calpain and collagenase activities were activated early post-mortem, and species-specific variations were observed in enzyme activity levels. Cytoplasmic calpains had the highest average activity among proteolytic enzymes, while collagenase activity shared a similar temporal pattern with calpain. Cathepsin B and L also showed a positively correlated activation regardless of the harvest method. Changes in muscle histology caused by the action of proteolytic enzymes can lead to flesh softening and loss of texture. The myofibrils, which make up most of the muscle fiber volume, are particularly vulnerable to degradation by endogenous proteases [1]. In our study, we observed an increase in the average single fiber volume density between days 0 and 7, irrespective of the harvest method used, though this increase was significant in electro-stunned groups. The temperature had a significant effect on enzyme activity and the histological phenotype, with the highest activities observed in the moderate temperature period for all species. Harvest method had a milder effect than the water temperature on enzymatic activities and the histological phenotype.

Discussion and conclusion
In the present study the effect of electro-stunning as a harvest method was investigated on the proteolytic activity and flesh quality of three Mediterranean farmed fish species. It is known that electro-stunning can have an impact on pre-slaughter stress and pH levels, which in turn, may affect the activation of proteolytic enzymes [5]–[8] quality and shelf life of whole fish (gilthead sea bream, European sea bass and red sea bream. The observed variations in enzyme activity among different species of fish, water temperatures, and harvest methods can be attributed to differences in muscle composition, physiological status, and post-mortem metabolism. Previous studies have suggested that this increase may be due to osmotic phenomena resulting from changes in intracellular membrane permeability and disruptions in ion balance in the cytoplasm [5].

(Continued on next page)
These findings suggest that water temperature, species and harvest method have an impact on the histological phenotype due to protease activity and they highlight the importance of developing species-specific humane post-harvest strategies to effectively preserve fish fillet quality ensuring animal welfare.

Introduction

Focusing on circular bioeconomy and solutions for managing finite and scarce resources such as phosphorus are issues that need to be addressed across sectors to obtain food security (Cordell et al., 2009). Land-based aquaculture of Atlantic salmon (Salmo salar) smolt and post-smolt in flow-through and recirculated system results in a large output of aquaculture sludge (Aas and Åsgård, 2017). These nutrient-rich side streams from aquaculture production constitute a valuable resource for cultivation of polychaetes Hediste diversicolor (Wang et al., 2019). The aim of this study was to recycle carbon (C), nitrogen (N), and phosphorus (P) contained in aquaculture sludge by production of polychaetes. Hereby, the bioremediation potential of H. diversicolor was assessed and a nutrient budget for recycling of C, N, and P was established.

Material and methods

Two different experiments, where feed levels were calculated based on estimated nitrogen content of diets and polychaetes, were carried out to investigate our research question. In a first experiment, we studied how the composition of two different diets, smolt sludge (S) and post-smolt sludge (PS) at four different feed levels (5-47% N) affected growth and C, N, and P recovery in H. diversicolor over a feeding period of 30 days. In a second setup, nutrient budgets of individual polychaetes supplied with two different quantities of smolt sludge (5% N, 40% N) were investigated to gain further knowledge on feeding ingestion rates, feces production, respiration, excretion and assimilation of C, N, and P in polychaete biomass. Growth was calculated following Jørgensen (1990). Carbon and nitrogen in polychaetes, sludge, and feces were analyzed using an elemental analyzer. Phosphorus was oxidized with potassium peroxydisulfate and analyzed photometrically as phosphate in the same way as sea water samples containing nitrate, ammonium, and phosphate, using an autoanalyzer.

Figure 1 Carbon, nitrogen, and phosphorus composition of initial polychaetes (n=1), smolt sludge (n=4), post-smolt sludge (n=4) and polychaetes H. diversicolor fed with different levels of smolt sludge (S6-S24 n=4; S45, n=3) and post-smolt sludge (PS6-PS47, n=4) (left) and utilization of carbon, nitrogen, and phosphorus by polychaetes H. diversicolor fed different levels of smolt sludge (S6-S24 n=4; S45, n=3) and post-smolt sludge (PS6-PS47, n=4) (right).

(Continued on next page)
Results and discussion

In the 30-day trial, polychaetes fed with both types of aquaculture sludge were shown to incorporate C, N, and P from their diets into biomass. Specific growth rates increased with increased feed supply for polychaetes fed with both diets, and incorporation of C, N, and P in polychaete biomass was highest at the highest feed levels. C, N, and P contents in polychaetes were not affected by type of diet or feed level (Figure 1, left). Conversion factors of diet C, N, and P into polychaete C, N, and P differed between nutrients but were not significantly different between feed levels. On average, carbon and nitrogen conversion rates amounted to 2-10% and 2-15%, respectively, while values for phosphorus conversion rates were lower at 0.5-1.5% (Figure 1, right). When determining individual nutrient budgets, polychaetes supplied with more feed showed higher ingestion of smolt sludge, however, a smaller relative ingestion rate, suggesting overfeeding. Assimilation rates of C, N, and P were significantly higher in the high feeding treatment compared to the low. Accordingly, relative feces production was higher in the low treatment. Respiration was not affected by feed supply.

Conclusion

The presented findings suggest that *H. diversicolor* can successfully grow on aquaculture sludge. Nutrients C, N and P were incorporated successfully, however utilization rates varied between the three, with P being most poorly utilized. The species can be considered beneficial for bioremediation of aquaculture sludge, however, should not be regarded as the sole solution for efficient recycling of side streams from Atlantic salmon production.

Introduction
The natural sources of marine and freshwater fish have been over-exploited in the last decades, therefore aquacultural fish production’s role in food security is becoming more important which led to aquaculture becoming the fastest growing segment in food industry. At global level freshwater fish production increased from 55.6% to 61.2% in total aquaculture production between 1995 and 2019 (FAO 2021), which shows that freshwater aquaculture has become more significant compared to mariculture in recent years. Aquacultural fish production has to face the challenges of increasing consumption and sustainable production at the same time, which can only be achieved by innovation and high efficiency production. To increase production complete feeds and feed supplements are being used in many cases despite their unsustainable production. Recently, microalgae are being investigated as a potential bulk-feed ingredient for fingerlings and adult fishes (Hodar et al., 2020). The aim of our study was to investigate the effects of microalga supplemented feed on common carp fingerlings (Cyprinus carpio) meat quality. The studies involved the production of freshwater microalgae in open pond systems (Vegetable Trading Centre Ltd.), sample analyses (Bay Zoltán Nonprofit Ltd.), fish feeding tests conducted in fishponds (Szegedfish Ltd.) and the professional supervision of the Institute of Aquaculture and Environmental Safety (MATE).

Materials and methods
The microalgae powder was a mixture of autotrophically open pond-grown unicellular microalgae (Chlorella spp; Scenedesmus spp; Coelastrella spp; Acutodesmus spp). The biomass was concentrated with a flow through centrifuge, dried at 70 °C to constant weight. In the final step the dried microalgae biomass was grinded to a powder (particle size <0.8 mm). The algae supplemented complete fish feed contained 3% w/w alga powder.

The carp fingerlings used during the experiment were kept in 10-hectare natural fishponds.

Fish samples were prepared from whole carp fingerlings, the fish were cut to smaller pieces, then homogenised in a bead beater. Representative portions of the homogenised fish samples were dried to weight constant in a lyophiliser and stored at -20 °C until analysed.

![Fatty acid composition of control and algae fed carp fingerlings](image)

1. Figure: Total fatty acid contents of carp fingerlings during the examined period. Control carp (Cont.); fish fed with a complete diet; algae fed carp (Algae); fish fed with 3% microalga supplemented diet. O-6, O-3: omega 6 and 3 fatty acids, MUFA: monounsaturated fatty acids, SFA: saturated fatty acids

(Continued on next page)
FAME measurements were conducted of given amounts of dried samples, which were extracted in methanol-chloroform-hydrogen chloride at 90 °C, in the presence of an antioxidant. The carboxyl group containing compounds present in the extracted samples were trans esterified to methyl esters. The fatty acid methyl esters present in the chloroform phase were separated with a gas chromatograph and were detected with a mass spectrometer.

The total protein content of the samples was determined by the Lowry method, the color intensity of the solutions was measured with a Helios Alpha UV-Vis Spectrometer.

Results

Our results showed that the total fatty acid content of both control and fish fed with algae supplemented diet was almost identical during the first two sampling (1. Figure). After the 24th of August the total fatty acid contents of fish started to increase rapidly, however, the increase was much greater in the fish samples the had alga supplemented diet, although this difference was only observable until the 20th of October as the samples obtained on the 2nd of December had no significant difference in their total fatty acid contents. We also found that in the beginning, the fatty acid composition regarding saturated, unsaturated, poly unsaturated, omega-3 and omega-6 fatty acids was very similar in control and algae fed carp fingerlings, however the proportions of the fatty acids changed during the examined period. The proportion of saturated fatty acids decreased by about 15%, a similar decreasing trend was observable in the case of omega-3 fatty acids. In contrast to the previously mentioned fatty acids the average proportion of monounsaturated fatty acids increased by 16,1% ±SD 1,0. In general the carp fingerlings which had algae supplemented diet had an average of 34,7% higher total, 38,46% higher unsaturated and 18,65% higher omega-6 fatty acid content compared to control fish during the examined period. The protein content, which is an indicator of meet quality, was also higher due to algae supplemented diet compared to control fish samples.

Conclusions

The fatty acid content of first year common carp fingerlings is increasing during the warm seasons in natural fishponds, probably due to plankton consumption.

The fatty acid composition of first year common carp fingerlings grown in ponds changes, the proportion of saturated fatty acids decreases with the omega-3 fatty acids while the proportion of monounsaturated fatty acids increases.

The 3% w/w microalga powder supplemented diet increased meat protein levels and the total fatty acid content of the carp fingerlings, especially in the case of monounsaturated and omega-6 fatty acids.

Introduction

*Streptococcus agalactiae*, a Gram-positive pathogenic bacterium also known as group B streptococcus, is recognized as a causative agent of zoonosis (Gauthier, 2015). With a broad host range, it is one of the major causes of infection outbreaks in Nile tilapia (*Oreochromis niloticus*) with significant morbidity and mortality, resulting in great economic loss and threatening the development of tilapia aquaculture worldwide (Zhang, 2021). This bacterium species can be subdivided into ten serotypes (Ia, Ib, and II–IX) based on its capsular polysaccharide composition (Poyart et al., 2007), and among these serotypes, Ia, Ib, and III are the most frequent in aquatic animals (Li et al., 2003). The infection leads to septicemia and encephalitis in fish, with noticeable clinical signs including lethargy, erratic swimming, exophthalmia, and ascites (Pretto-Giordano et al., 2010). Our research group recently isolated two distinct serotypes of *S. agalactiae* in Brazil. The first, E8ang2 (serotype Ib), was isolated in the northern state of Paraná, while the second, Maranhão (serotype III), was isolated in the Maranhão state. Upon further investigation, we noticed different patterns of responses to infection in tilapia with these strains. The Maranhão strain induces significant brain damage, resulting in severe signals of erratic swimming and a higher mortality rate in the initial days of infection. In contrast, E8ang2 kills the same number of animals but more slowly and with a lower incidence of noticeable brain-related symptoms. This study aims to characterize the brain transcriptomes of tilapia after infection with *S. agalactiae* and understand the reason for the different outcomes by comparing gene expression profiles between animals infected with strains of different serotypes.

Materials and Methods

This study followed the recommendations established by the Animal Ethics Committee, State University of Londrina (process nº CEUA 45/2017), Brazil. Nile tilapia were randomly divided into three groups: i) control, ii) challenged with the E8ang2 strain (serotype Ib), and iii) challenged with the Maranhão strain (serotype III). The fish were anesthetized and intraperitoneally injected with 0.1 mL/fish of bacterial suspension, whereas the control group fish were injected with an equal volume of broth medium. After bacterial exposure, the fish were monitored daily, and animals that showed signs of erratic swimming were removed from the aquaria and killed by medullary section. The brain was collected and immediately frozen in liquid nitrogen. The RNA was extracted, and 14 Illumina libraries were prepared (4 for Control, 5 for E8ang2, and 5 for Maranhão groups) and sequenced as paired-end reads (150-bp). After quality control and trimming of adapters using the fastp software, the reads were mapped to the Nile tilapia genome using HISAT2 and annotated using featureCounts. The differential expression of genes across treatment groups was determined with DESeq2. Enrichment of KEGG pathways and gene ontology were performed in g:Profiler.

Results

In response to exposure to strains of *S. agalactiae*, several immune response-associated genes were upregulated in the tilapia brain. These genes are mainly related to phagocytosis, cytokine production, and immune cell recruitment, suggesting that the immune response of tilapia to *S. agalactiae* infection is predominantly pro-inflammatory. However, genes involved in tissue repair and oxygen transport were downregulated. Additionally, the energetic demands of the immune response may affect the expression of genes related to the feeding behavior of tilapia during *S. agalactiae* infection.

Comparing the results of exposure to both strains, the animals exhibited an increase in the expression of pathogen recognition-related genes and inflammation-associated genes when exposed to the E8ang2 strain. These results suggest that the E8ang2 strain can be readily identified by the immune system triggering a more robust immune response. Furthermore, the upregulation of genes involved in neuroplasticity indicates a possible faster recovery of the injured tissue in the exposure to E8ang2. Meanwhile, the downregulation of some hormone-related genes may indicate a disturbance in regulating hormonal pathways involved in stress responses.

(Continued on next page)
Overall, our results suggest that the two strains of \textit{S. agalactiae} may elicit different responses from the host immune system and neuroendocrine pathways. The study of this disease holds significant importance for aquaculture and human medicine. Additionally, elucidation of the mechanisms involved in the host–pathogen response is crucial for the success of new therapies. Our research is not only relevant for a better understanding and description of the tilapia immune system, but it also has the potential to provide new insights into the development of prophylactic measures for this species.

The Australian redclaw crayfish has great potential for aquaculture intensification and global market expansion. However, traditional production methods, subfertility, and high embryo mortality could curtail industry growth. This study evaluated sperm quality using optimized conventional and sensitive tools in redclaw crayfish. Healthy and robust male redclaw (n = 33) were collected from the Ross River Dam, Northern Queensland, and immediately subjected to electroejaculation to yield spermatophores for sperm quality assessment. Sperm concentration, count, morphology, viability, DNA fragmentation, and total potential fertile sperm cells (TPFSC) were determined. Under phase contrast microscopy, spermatozoa were visible with an elliptical shape of varying diameters and a tail-like structure. The mean ± SEM of sperm concentration, TPFSC, DNA fragmentation, and sperm viability was 42.5 x 10⁴ ± 5.1 x 10⁴ cells/ml, 23.6 x 10⁴ ± 3.4 x 10⁴ cells/ml, 17.2 ± 2.5 %, and 65.2 ± 3.9 %, respectively. Spermatophore weight was positively associated (p < 0.05) with sperm concentration and TPFSC and inversely associated with sperm DNA fragmentation (p < 0.05). Sperm viability was negatively associated with body mass (p < 0.05) but not spermatophore weight (p > 0.05). In conclusion, the weight of spermatophores provides a guide to sperm quality prior to spermatozoa extraction and may serve as a preliminary indicator of sperm quality. In addition, this study validated species-specific diagnostic tools for sperm quality assessment that may help improve productivity through selective breeding programs in redclaw aquaculture.
THE FIRST LINE OF DEFENSE AGAINST THE TOXIC GAS HYDROGEN SULPHIDE IN ATLANTIC SALMON

Introduction

The need for sustainable and efficient aquaculture production to meet global food demand has led to the development of new technologies, such as recirculating aquaculture systems (RAS). In recent years, advancement in Norwegian land-based aquaculture has been highlighted by the implementation of RAS to produce Atlantic salmon (Salmo salar) in a more controlled environment, thereby addressing recurrent issues such as diseases and escapes. Despite its promise of a superior rearing environment compared to that of the traditional flow-through systems, several challenges have presented themselves, one of which is hydrogen sulphide (H2S)-related mass mortalities. Currently, we have a significant knowledge gap on the physiological mechanisms of how Atlantic salmon respond to prolonged exposure to H2S.

Mucosal organs such as gills, skin and olfactory organs represent the primary barrier against noxious compounds present in the aquatic environment. They can mount strong immune responses against immunotoxins, including H2S. Previously we have shown that mucosal organs of Atlantic salmon exhibit differential sensitivity to transient exposure to H2S. Also, distinct molecular and structural alterations have been observed in these organs after transient exposure to H2S. However, whether these organs exhibit the same sensitivity to prolonged sub-lethal H2S exposure remains to be elucidated. Therefore, this study investigated how prolonged exposure to H2S could impact the barriers at mucosal sites of Atlantic salmon.

Materials and Methods

A group of Atlantic salmon post-smolts (35 ppt) were reared under three H2S level conditions – 0 µM/L (Control), 0.05±0.02 µM/L (Low) and 0.12 ±0.02 µM/L (High) – for 12 days. Each treatment group had 3 replicate tanks (Figure 1). After the exposure period, samples from the gills, skin and olfactory organ were collected for gene expression analysis, histology and RNAscope/in situ hybridisation. Moreover, mucus samples from the gills and skin were also collected for proteomics analysis.

Results and Discussion

The prolonged exposure to H2S led to changes in gene expression, mainly affecting genes crucial for stress response, xenobiotic detoxification and immunity (Figure 2). Multi-tissue analysis revealed that the gills and olfactory organs were highly sensitive to H2S where more than half of the genes analysed were altered by both H2S doses. The expression of these marker genes showed minimal variations in the skin. These transcriptional profiles were not in agreement with previous transient exposure studies suggesting that the differential sensitivity of mucosal organs to H2S was influenced by the duration of exposure. Mucosal structural integrity remained favourable following H2S exposure since histological and morphological analyses did not show any relevant changes in H2S-exposed fish compared with the control group. RNAscope identified and localised the transcripts important for sulphide detoxification in mucosal organs, including suox, sqor1, and sqor2. High throughput proteomics of gill and skin mucus revealed significant changes in mucosal proteome following H2S exposure. 129 and 160 proteins were differentially altered in gill and skin mucus, respectively. Reactome pathway analysis revealed significant alterations in ribosomal processes and reactive oxygen species detoxification in the skin mucus, while drug metabolism was affected in gill mucus. Gene Ontology analysis further elucidated that some of the substantially affected proteins were crucial for toll-like 9 signalling and hydrogen peroxide catabolism, while affected proteins in gill mucus were important for lipoprotein metabolic process and regulation of endocytosis.

(Continued on next page)
Conclusion

Overall, the results demonstrate that prolonged exposure to sub-lethal doses of H\textsubscript{2}S altered the mucosal defences of Atlantic salmon. The mucosal changes were reflected in the gene and protein expression profiles of molecules important for stress, immunity and xenobiotic metabolism. Nonetheless, H\textsubscript{2}S exposure revealed no substantial structural changes in mucosal organs. These results indicate that Atlantic salmon are capable of coping with low levels of H\textsubscript{2}S, but it remained to be investigated whether this inherent mechanism at mucosal sites can persist for longer period. The study significantly advances our understanding of how Atlantic salmon interacts with H\textsubscript{2}S at mucosal surfaces.

Introduction
Contemporary feed formulations, which predominantly use plant protein sources and minimize marine ingredients, often result in reduced taurine content. Previous works on Senegalese sole (Solea senegalensis) juveniles have shown that dietary inclusion of high levels of plant protein sources to replace marine ingredients resulted in adverse effects on lipid metabolism (Richard et al., 2017; Aragão et al., 2023). Taurine supplementation to these high-plant diets mitigated part of the adverse effects, leading to better lipid utilization (Aragão et al., 2023). Therefore, the objective of this work was to evaluate the metabolism of triolein in Senegalese sole juveniles of two different sizes, considering dietary formulations with different protein sources and lipid levels, and the impacts of taurine supplementation.

Material and Methods
The different experiments performed used two basal diets: a marine ingredient-rich diet (FM), containing 69% of marine ingredients (fishmeal, fish soluble protein concentrate, squid meal and fish gelatine), and a plant protein-based diet (PP), in which plant protein sources replaced 85% of proteins from marine origin. Taurine content in PP and FM diets was 0.08 and 0.43%, respectively. The PP diet was further supplemented with taurine (PPT), resulting in a dietary content of 1.40%. All diets were isonitrogenous (55% crude protein, CP) and isolipidic (8.6% crude fat, CF). Additionally, based on the FM and PPT formulations, fish oil was increased at the expense of gelatinized pea starch, resulting in diets with similar CP content (55%), but with a CF content of 16.8% (FMF and PPTF, respectively).

Senegalese sole were adapted to these diets for 8 to 12 weeks and when presenting 11.9 ± 1.0 and 19.3 ± 5.5 g, metabolic trials were performed. For the metabolic trials, six fish per treatment were tube-fed with the respective diet labelled with 14C-triolein and after tube-feeding the fish were placed in metabolic chambers with seawater and oxygen. After 24 h, samples were collected to analyse the effect of the different variables (fish size, protein source or taurine supplementation) on lipid evacuation, catabolism and retention. Details on the method may be found in Aragão et al. (2023).

Results and Discussion
The results showed that, when considering all the fish solely based on their size, the percentage of triolein evacuated increased concomitantly with fish size, when fed the low-fat diets (Table 1). However, when analysing each treatment separately, only fish fed the PP diet exhibited an increase in the proportion of triolein evacuated with increasing fish size (Table 1). Looking at the influence of diet, no significant differences were observed in the evacuation of triolein among fish of the same size. In terms of catabolism, the overall results indicated that the proportion of triolein that was catabolised decreases as fish size increases (Table 1). Upon closer analysis, it was noticed that larger fish presented lower triolein catabolism when fed PP diets, irrespectively of taurine supplementation (Table 1). Nonetheless, no significant differences were found in the percentage of triolein catabolised in fish of the same size among the various dietary treatments. Interestingly, the retention of triolein retention was not affected by the fish size (Table 1) or dietary treatment.

Comparing the use of low versus high-fat diets, in overall terms, the proportion of triolein evacuated was unaffected by the fish size (Table 2). However, when examining each dietary treatment separately, the percentage of triolein evacuation increased concomitantly with the increase in fish size when these were fed high-fat PP-based diets supplemented with taurine (PPTF; Table 2). Irrespective of the fish size, the proportion of triolein that was evacuated was higher in fish fed high-fat diets compared to those fed low-fat diets, regardless of the protein source. Additionally, the overall catabolism of triolein decreased as fish size increased and this was particularly evident in fish fed the taurine-supplemented PP-diet (PPT; Table 2). In terms of retention, no significant differences were found among treatments for overall fish. However, in fish fed the high-fat FM (FMF) diet, the proportion of triolein retained increased concomitantly with fish size (Table 2). Interestingly, dietary protein source and lipid content did not affect the catabolism and retention of triolein among treatments at each fish size.

In conclusion, the evacuation of triolein in fish fed the PP diet shows an increase as fish size increases, but the dietary inclusion of taurine mitigates this effect. Additionally, irrespective of the protein source, high-fat diets lead to higher triolein evacuation in fish of both sizes. In general, it is evident that triolein catabolism decreases with an increase in fish size. Careful must be taken, as triolein retention increases with fish size when fed high-fat FM diets, which may affect the quality of the fish.

**Introduction**

Antimicrobial resistance is a major health issue of this era, affecting the lives of millions of people worldwide. Alternative solutions have been proposed, such as the use of host defense peptides (HDPs), which are vital components of innate immunity, with antibacterial, antifungal, antiviral, and antiparasitic, as well as immunomodulatory properties (Mladineo et al., 2023; Shi et al., 2022). In particular, anisaxins, a cecropin-like helminthic HDPs from the zoonotic marine nematodes, *Anisakis simplex* and *Anisakis pegreffii*, have shown high efficacy against clinical and referent human bacterial Gram-negative isolates (Rončević et al., 2022).

**Materials and methods**

In order to evaluate the immunomodulatory properties of HDP anisaxin-2S (A-2S), the blood of the common carp *Cyprinus carpio* have been drawn from four groups of fish: i) specific pathogen free fish (SPF); ii) fish infected by the myxozoan *Spaherospora molnari* blood stages (BS); iii) fish infected by *S. molnari* blood stages and immunosuppressed (IS+BS); and iv) non-infected immunosuppressed fish (IS). Blood collected at four time points (T0, week 2, 3, and 4) was separated by Ficoll, and white (WBC) and red blood cell (RBC) suspensions were *in vitro* stimulated by A-2S. Flow cytometry was used to measure cellular changes and reactive oxygen species (ROS) production. Gene expression of innate immunity targets (*il6, il10, il1b, tnfa, infγ*) was quantified by qPCR and log-transformed relative gene expression data was used to test the statistical difference. Data were analysed in Prism 9 and presented as mean values ± SD.

**Results and discussion**

*S. molnari* infection decreased the number of RBCs in the blood by approximately 10% (100 × 10⁶ RBC/mL), with a significant difference observed 2 weeks post-infection (wpi). In infected immunosuppressed fish, a steep decline in erythrocytes (loss of 84%) was observed 3rd wpi onward. On the contrary, non-infected but immunosuppressed fish exhibited mild but significantly higher numbers of erythrocytes. The decrease of erythrocytes during late-stage infection was accompanied by a release of the erythroblasts. This indicates a strong interaction of *S. molnari* and WBC/RBC as reported earlier (Korytár et al., 2020). High activity of both pre- and mature RBC in the IS group suggests that in the absence of the lymphocytes, erythrocytes contribute to an immune response in a much larger range (Fig. 1). All groups treated with A-S2 showed higher ROS production, in particular the IS+BS group, inferring the immunomodulatory role of this HDP (Fig. 2).

**Conclusions**

Immunomodulatory properties of the A-2S to the immune response in infected fish are promising, especially if we consider the fact that anisaxin predominantly stimulates red blood cells which are the most abundant population in the blood.

Introduction
Understanding immune response is of utmost relevance for all farmed animals. In turbot aquaculture, infectious diseases are caused by a broad spectrum of well-studied pathogens, from viruses and bacteria to different parasites (Aramburu et al., 2022). Knowledge of the transcriptomic basis for immune responses, both at general and pathogen-specific levels, is essential for a comprehensive understanding of host defence in turbot and can be helpful for other flatfish species. Moreover, dynamic changes in chromatin accessibility influence gene expression by granting or preventing binding by transcription factors (TF) and the transcription preinitiation complex (Herrera-Uribe et al., 2020; Jiang & Mortazavi, 2018). This work, framed in the AQUA-FAANG project for the functional and regulatory annotation of the six main species of European pisciculture, aims at establishing a regulatory map of the innate immune response of turbot through the immunostimulation of live (in vivo) and head kidney-extracted primary leukocytes (in vitro) using mimics of viral (Poly I:C) and bacterial (inactive Vibrio spp) infection.

Material and Methods
The immune challenges were carried out by i.p. injection (in vivo) and cell stimulation (in vitro). Head kidney and cell cultures were collected and frozen after 24 hpi, to be later used for RNAseq, ATACseq and ChIPseq procedures. Libraries were sequenced, with the resulting data being processed using nf-core pipelines (https://nf-co.re/).

A reference head kidney transcriptome was constructed from RNAseq data retaining genes when i) TPM > 5 and ii) present in at least two replicates in any of the conditions tested. The transcriptome was used as the reference to define differential expressed genes (DEGs) using DESeq2 (P < 0.05), and the resulting DEGs lists were subjected to gene ontology (GO) enrichment analysis (P < 0.05, GO terms with > 3 genes) using ShinyGO (http://bioinformatics.sdstate.edu/go/).

ATACseq and ChIPseq peaks were filtered following the Irreproducibility Discovery Rate method (https://github.com/nboley/idr) to obtain Highly Reproducible (HR) peaks for each condition and mark. Chromatin state discovery and characterization for the in vivo and in vitro experiments was modelled using ChromHMM (http://compbio.mit.edu/ChromHMM/) and the HR-peaks. Differential histone modification regions and differentially accessible regions were identified with DiffBind (https://bioconductor.org/packages/release/bioc/html/DiffBind.html; P < 0.05) using the unfiltered peaksets. Both HR-peaks and differentially accessible regions were annotated using HOMER’s annotatePeaks function (http://homer.ucsd.edu/homer/index.html).

DEGs showing differential accessibility in their promoter regions (-1000 to -100 bp) were identified from the intersection of differentially accessible regions and the DEGs list, for each comparison. Transcription factor motif analysis was carried out for each condition using HOMER’s findMotifsGenome.pl function. A turbot-specific blacklist of high-signal and low-mappability regions for ChIPseq analysis was generated using the ChIPseq controls to avoid artifacts and noisy regions.

Results
We identified 8,797 DEGs across all in vivo and in vitro conditions from a total filtered transcriptome of 12,152 genes. A significant enrichment of transcriptional activation immune response pathways was observed, such as the IFN-gamma pathway (particularly in PolyI:C stimulation) in upregulated DEGs, and metabolic pathways and cell cycle in downregulated DEGs.

(Continued on next page)
We constructed a regulomic atlas of immune stimulation in turbot using highly reproducible peaks of open chromatin regions (52,585 HR peaks) and three histone marks: H3K4me3 (14,741 peaks), H3K27ac (10,584 peaks) and H3K27me3 (33,843 peaks). Two different chromatin state models of 10 and 8 states (in vivo and in vitro respectively) were identified characterized by their transcription start site regions, potential enhancers, repressed polycomb and low signal regions. Roughly, 6.98% of the turbot genome was included in the blacklist of high ChIP signal/low mappability regions, mostly comprised of telomeric and centromeric regions.

The differential binding analysis revealed significant differences in chromatin accessibility and H3K4me3-binded regions when comparing immune stimulated samples against the controls (particularly for Vibrio stimulation), with less differential binding for H3K27ac and H3K27me3. To identify potential genes with high DE and differential aperture, we identified the open chromatin, H3K4me3 and H3K27me3 differentially binded peaks annotated as promoter regions and compared them with the corresponding DEGs list (Hypergeometric distribution test, P < 0.05), showing high significance for the upregulated, differentially accessible genes for both marks and ATAC.

An analysis of the known transcription factor (TF) motifs identified in each of the peaks revealed a high representation of TF families associated with IFN regulation (IRF), defense and stress response (bZIP), cell cycle and differentiation (ETS), hematopoiesis (bHLH) and angiogenesis (Homeobox).

**Conclusion**

Our results provide the first chromatin state description of immune stimulated turbot as well as an overview of the genomic resources generated in the AQUA-FAANG project, providing brand new information on the regulomics of the species across different conditions.

Introduction
Low trophic aquaculture, such as bivalve species, can be candidate species for the minimization of environmental impact of worldwide growing aquaculture, while providing consumers with high quality and nutritive seafood. Nowadays, mussels are cultured suspended mainly in raft and longline systems, using ropes made of non-biodegradable fossil-based plastics, which use could result in augmenting marine litter and microplastics entering the oceans. The EU BIOGEARS project addresses the challenge of minimizing the use of fossil-based plastics by developing alternative biobased and compostable ropes, biogears. The aim of this study is to assess and compare the sustainability of two biogears prototypes vs. commercial fossil-based rope counterparts in mussel offshore longline productions, under technical, economic and environmental perspectives.

Material and methods
Two biogears ropes prototypes (B1 and B2) were developed based on compounds of commercially available biopolymers and manufactured with industrial processes to be fit-for-purpose, with technical and mechanical properties similar to commercial counterparts, for mussel productions. For the technical assessment, the upscaling of their potential implementation by minimizing technical risks at rope production and the aquaculture performance phases were studied. For aquaculture validation, a one-year mussel longline production was performed using biobased B1 and B2 ropes and commercial fossil-based rope counterparts (GROPE). In the economic assessment, the costs and benefits of the use of biogears in mussel aquaculture were analysed along the value chain, comparing them to fossil-based ropes (market trends of raw materials, rope processing costs, aquaculture production, and End of Life (EoL) options). Additionally, the eco-efficiency indicator of the ropes was calculated (ISO 14045:2012). In the environmental assessment, rope biodegradation trials and the environmental profile via Life Cycle Analysis (LCA) methodology (ISO 14040/14044) were studied.

Results and discussion
Technical assessment: Biobased ropes promoted similar mussel growth but higher mussel productions per rope linear meter (85% in B2 and 23% in B1) with respect to the fossil-based rope counterpart (4.29 kg/m). Overall, mussel abundance per rope linear meter decreased over the experimental period in all types of rope, and especially in fossil-based ropes. Mussel quality was not compromised by using biobased ropes, as similar Condition Index, meat yield, proximal composition and fatty acid profiles were observed among experimental groups. Mechanical properties (Load at Break and elongation) of biogears decreased in the first two months of the sea tests, although not compromising rope functionality in one-year mussel production. The correlation between total mussel weight held per rope and the Load at Break results demonstrated that a 40% higher mussel weight held by B2 ropes had no significant effect on the variation of their mechanical properties.

Economic assessment: Currently, the raw materials used in biogears are economically more costly than the raw materials of fossil-based counterparts. Future trends envisage increasing biopolymer productions to meet market demand, which could in turn reduce their price and make biogears even more competitive than fossil-based ropes. Mussel productivity gains in biobased B2 ropes offset the over-cost of the biogears production, making mussel production more profitable with biogears than with the commercial fossil-based ropes. B2 prototype rope production and use should be encouraged, rather than biobased B1 and fossil-based ropes, due to their best eco-efficiency indicator (environmental impact and economic value of the ropes by kilogram of harvested mussel) (Figure 1).

(Continued on next page)
Environmental assessment: Biodegradability tests in marine conditions indicate that biogears will not biodegrade in sea water at 20-30 °C or below. Compostability tests simulated in laboratory conditions (58±2 ºC) concluded that industrial composting of biogears is technically feasible. However, it should be validated in industrial composting facilities. Composting, as EoL option for biobased ropes, would reduce by 10% the carbon footprint of their life cycle and the impact on the use of fossil resources, due to the benefits of avoided impacts and the use of the produced compost. So, actions for the collection, sorting and transport of biogears to industrial composting facilities are encouraged for a correct management at their EoL. Finally, considering rope aquaculture production (impact/kg mussels produced per rope linear meter), B2 rope shows the best environmental performance, reducing by 34% the carbon footprint of mussel productions compared to conventional fossil-based ropes.

It can be concluded that biogears, and specifically biobased B2 ropes, can be technical, economic and environmentally sustainable alternatives to currently used fossil-based ropes in mussel offshore productions promoting aquaculture decarbonization.

BIOGEARS is supported by funding from the EU European Maritime and Fisheries Fund (EMFF).
EVALUATION OF THE STRESS RESPONSE AT SLAUGHTER IN EUROPEAN SEABASS
(*Dicentrarchus labrax*)

Introduction

Fish welfare is a major component of sustainable fish farming and research to gain an in-depth understanding of the factors affecting the welfare of farmed fish is of high priority. Guidelines from the World Organisation for Animal Health and European Food Safety Authority of economically important aquaculture species are available, including harvest and slaughter, however, there is still a need to develop efficient humane slaughter methods (Hastein, 2007). Existing methods for European sea bass consider to be inhumane and not conclusive (de la Rosa *et al.*, 2021). Therefore, there is an urgent need to develop and evaluate stunning/slaughter methods that will ensure immediate loss of brain function, insensibility to pain and maintenance of flesh quality. The aim of the study was to evaluate the impact of different stunning methods prior to slaughter on the onset of rigor mortis, muscle pH and stress indicators in European sea bass.

Materials and Methods

European seabass (*Dicentrarchus labrax*) ranging in weight from 250 to 300 grams were used to evaluate the effect of three different stunning methods: chemical (Group Benzocaine), electronarcosis (Group E/A: electrical stunning, 1.5 V/cm), and thermonarcosis (Group Ice Slurry: immersion in ice-slurry without prior anaesthetization). Following crowding, all fish were captured by net and slaughtered by immersion in ice-slurry. Capture of fish by hook and line and immediate slaughter by pithing (ikijime), was used as control (Group Ikigun). Muscle pH and rigor mortis were performed at regular intervals between 0- and 4-hours post-mortem. Blood samples were taken to determine haematological (haematocrit), biochemical (glucose, lactate, osmolality) and hormonal indicators (cortisol). All data are expressed as means with the standard error of the means (SEM, n = 10 per group). Data analyses were based on ANOVA or Duncan’s multiple range test and significance ascribed to differences at the 0.05 level.

Results

(Continued on next page)
Discussion
Development of humane stunning/slaughter methods for farmed Mediterranean fish species is of high priority. E/A has shown a great potential as an alternative stunning method in European sea bass (Zampacavallo et al., 2015). Our results show that handling stress prior to stunning significantly enhances the stress response and has a negative impact on quality indicators (RI% and muscle pH). Electrical stunning delays the time needed to reach full rigor mortis and maintain muscle pH in comparable levels with those obtained in stunning/slaughter fish in ice-slurry. Chemical anaesthesia is also stressful for the fish and affects negatively flesh quality. Finally, the study confirmed that pithing, used by experienced staff, does not evoke an increase in stress indicators and ensures rapid insensibility.

Sustainable blue economy sets the ground for maritime investments in a number of sectors, among which falls also aquaculture, as a complementary dimension to the fishery sector. In fact, interest in aquaculture is nowadays steadily growing as a result of, among others, the: globally rising healthy dietary patterns and related demand; policy directions at the global and the European/national level, seeking to achieve a sustainable future of the sector that additionally contributes to the integrated coastal zone management and the protection of marine resources; radical technological advances that can abrogate adverse environmental repercussions of aquaculture; etc. The aforementioned developments frame, in a way, the future developments of the sector. Taking into consideration the dynamics of the broader decision-making environment, as well as the current spatial and developmental policy contexts in Greece, the present paper attempts to explore the key drivers of change that are decisive for shaping the future of aquaculture in the Greek marine environment; while keeping track with its multiple dimensions, i.e. spatial, developmental, social, economic, environmental, technological, etc. That said, a thorough exploration of the external decision environment is carried out that is grounded on: i) sector-related documentation, emanating by international organizations (e.g. FAO) and literature review, policy recommendations and institutional developments; and ii) developments that are taking place in related fields (blue economy, marine spatial planning, integrated coastal zone management, etc.) at the global, European and national level and have a direct or indirect impact on aquaculture development. Results identify key drivers that need to be taken into account for feeding the revision of the currently out-dated Special Framework for Spatial Planning and Sustainable Development of the Sector in Greece, in alignment with the radical developments occurring in the complex and uncertain era of multiple, sea-related, sectoral developments.
Dietary Supplementation with *Agaricus bisporus*, *Agaricus bisporus* Portobello and *Pleurotus* sp. on Growth Performance, Immunology and Histomorphology of Gilthead Seabream (*Sparus aurata*)

Introduction
Mushrooms contain several types of polysaccharides and other constituents that have proven antibacterial, antimicrobial, antioxidant and anti-inflammatory activities (Van Doan et al. 2019, Mohan et al. 2021). The genus *Agaricus* and *Pleurotus* are among the most popular and widely cultivated mushroom species for human consumption and recently have attracted the interest as potential natural prebiotics in aquafeeds having also immunostimulatory and growth-promoting effects (Van Doan et al. 2019). Despite the importance of gilthead seabream (*Sparus aurata*) in aquaculture, there is a lack of relevant information and thus this study aimed at evaluating the effects of dietary supplementation with mushrooms on growth, immunology and histomorphology of the species.

Materials and Methods
*S. aurata* juveniles of 3.36 g initial mean weight were stocked at 12 tanks (125L) in a closed seawater recirculation system. Fish in triplicate groups (22 fish/tank, 3 tanks/dietary group) were fed to satiety, twice a day for 75 days, each of the four isonitrogenous (50%), isoenergetic (21.5 MJ/Kg) and isolipidic (15%) diets that contained 0 (Control) or 2% dried powder of either *Agaricus bisporus* (AG), *Agaricus bisporus* Portobello (PO) and *Pleurotus* sp. (PL). At the end, fish were weighted to measure growth and feed utilization parameters. Blood samples from 18 fish per group were used for immunological analyses, while liver and foregut samples from 15 fish per group were used for histology.

Results and Discussion
The 2% supplementation with either mushroom species had not detrimental effects on growth performance and feed utilization, neither on feed palatability, but also had not any growth promoting effect in seabream (Table 1). A dietary supplementation with *A. bisporus* has been shown to promote growth in other fish species such as Nile tilapia (Dawood et al. 2020), common carp (Hoseinifar et al. 2019), koi carp (Safari & Sarkheil 2018) and sharptooth catfish (Harikrishnan et al. 2018), but not in rainbow trout (Amiri et al 2017). Also, *Pleurotus* sp. has promoted growth in Gibelion Catla (Sattanathan et al. 2018) and rainbow trout (Bilen et al. 2016), but not in cherry salmon (Oh et al. 2019). The histological analysis of seabream fed the experimental diets revealed a normal and similar histomorphological structure of liver and foregut among all dietary groups (results are not shown). Dietary supplementation with *P. ostreatus* significantly increased *E. coli* growth inhibition. On the one hand, the supplementation with both *Agaricus* species decreased (P<0.05) the bactericidal activity against *E. coli* and fish fed PO were significantly slower to assemble the complement complexe than control fish (Table 1). On the other hand, alkaline phosphatase was significantly increased in fish fed PO. Ceruloplasmin, nitric oxide concentration and trypsin inhibition were similar among the groups although the latter tended to be stronger in PO and PL fish. These results indicate that dietary supplementation with *Pleurotus* sp. significantly improved the antibacterial activity in fish serum through an increased complement. On the contrary, both *Agaricus* species had a detrimental effect on the antibacterial activity of the serum although the improved alkaline phosphatase activity by PO may show some positive effects on fish health. *Pleurotus* sp. has been shown to be an effective prebiotic for stimulating fish immunity by elevating either serum myeloperoxidase, phagocytic, lysozyme and bactericidal activities or developing immune resistance against infections in several fish species such as rainbow trout (Bilen et al. 2016), koi carp (Safari & Sarkheil 2018) and Gibelion Catla (Sattanathan et al. 2018). On the contrary to our results, *A. bisporus* has been proved to stimulate immune response in several fish species such as rainbow trout (Dawood et al. 2020) and sharptooth catfish (Harikrishnan et al. 2018). Future studies are required to enlighten the effectiveness of dietary supplementation with mushrooms on growth and immunology of *S. aurata.*

Introduction
When rainbow trout and the other salmonids become sexually mature, they experience reduced growth, poor carcass quality (external sex characters, reduced body fat and filet color), and high mortality if reared in seawater. Thus, early sexual maturity before the desired market size is a serious economic drawback for the producers. Limited number of estimates are available for genetic variation of this trait in rainbow trout, but evidence suggests the presence of significant genetic variation 1-4.

The aim of this study was to obtain reliable estimates of genetic variation for early sexual maturity at two years of age in rainbow trout, and to search for possible quantitative trait loci (QTL) for the trait that can be used for genomic (GS) and/or marker assisted selection (MAS).

Material and Methods
The population used in the current study originated from the breeding nucleus (year-class 2020) of Osland Genetics AS, comprising a total of 2054 fish, i.e., the offspring of 92 sires and 144 dams, with a median full-sib family size of 12 (ranging from 3-43). The fish were slaughtered at a mean body weight of 4.9 kg at about two years of age. The sexual maturity status (1=maturing; 0=immature) and the gender of each fish were recorded through the visual observation and palpation of gonads after the fish were killed and gutted. All the recorded individuals were genotyped using Illumina Infinium SNPs genotyping array carrying around ~22K SNPs.

Analyses: Estimates of genetic parameters were obtained using a linear mixed model(s) implemented in “ASREML, v4.2” with genomic and pedigree information. The GWAS analysis was performed with “GCTA, v1.94” program using the “--mlma-loco” function 5.

The fixed and the random effects in the applied statistical model are as follows:

where is the vector of the observed binary sexual maturity trait (0 immature and 1 maturing); is the overall mean; and are design matrices to relate the animal records to appropriate level of the fixed and the random genetic effects, respectively; is a vector of the fixed effect of gender, is the random animal genetic effect with , where is the genetic variance, is the genetic relationship matrix obtained using pedigree information, is a genomic relationship matrix computed using VanRaden’s method 1; and is the vector of random residuals with . Additionally, estimates of genetic variation for early sexual maturity trait were also obtained on the underlying liability scales using a threshold model(s).

Results and Discussion
The incidence of early sexual maturing fish at two years of age was very low (2%); with males showing significantly higher incidence (2.3%) than females (1.7%).

The estimated genetic parameters revealed low but significant genetic variation for early sexual maturity with estimates of heritability ranging from ~0.06 to ~0.16 (Table 1) which varied across model (LM vs. TM) and source of information (pedigree vs. genomic).

The genome-wide association analysis revealed a strong signal of a quantitative trait loci (QTL) at chromosome 28 with 27 SNPs surpassing chromosome and/or genome-wide Bonferroni corrected significant threshold (Figure 1). In spite of the low frequency of early sexually maturing fish in the current data, the highly significant SNP at chromosome 28 explained ~31% of the total genetic variance computed using (Falconer and Mackay, 1996 6). The display of a single clear QTL at chromosome 28 together with some minor indications from the SNPs located at other chromosomes (18 and 30) directs that the trait may be affected by a few gene(s) with large effect and multiple other genes with smaller effect size. The results show that the selection through GS and/or MAS can be used to further reduce incidences of undesired early sexual maturity in this population of rainbow trout.

(Continued on next page)
Similar parameter estimates will also be obtained based on data from a more recent year-class (2021). In addition, we will present estimates of accuracy of prediction using cross validation scheme(s) with different models (PBLUP, GBLUP, Bayesian, and MAS) to assess and compare the potential of genomic and/or marker assisted selection over classical pedigree information.

Introduction
Sea lice (L. salmonis) is an ecto-parasite that occurs naturally on wild and farmed Atlantic salmon. This parasite is one of the major threats for the farmed A. salmon industry in Norway, causing huge economic losses due to frequent treatment costs and increased mortality due to these treatments. The parasite load trait has shown low to moderate heritability with polygenic architecture of the trait reported in multiple studies1-4. There is a scarcity of studies showing significant signal(s) of quantitative trait loci (QTL) for lice count possibly due to lack of sufficient statistical power with low sample sizes and low lice counts.

The aim of the current study was to estimate genetic variation for lice counts obtained from three lice challenge tests belonging to the two year-classes, perform genome-wide association analyses of these data, and test the accuracy of genomic predictions from across and within population validation schemes.

Material and Methods
MOWI GENETICS routinely performs controlled challenge tests for lice on full- and half-sibs of breeding candidates and that smoltify at < one year (S0) and/or > one year (S1) of age. The recorded individuals were from two year-classes (YC); the parent YC-2018 (2825 “S1” individuals from 316 full-sib families) and the offspring YC-2022 (2329 “S0” and 2319 “S1” individuals representing 248 and 238 families, respectively) with family size ranging from 1 to 19. All 7473 individuals were genotyped using a custom developed Affymetrix axiom ~65K SNPs genotyping array. Moreover, tank (two or three per test), lice counter (3-6 for each of the three tests) and the body weight of the fish at the lice counting were also recorded. The phenotypic distribution of the lice count data was positively skewed and therefore the lice counts were log transformed to make them more normally distributed.

Analyses: The estimates of genetic parameters were obtained from the following linear mixed animal model(s) using genomic relationship matrix implemented in ASREML v4.2.

\[
\begin{align*}
\mathbf{y} &= \mathbf{\mu} + \mathbf{X}\mathbf{b} + \mathbf{Z}\mathbf{u} + \mathbf{e} \\
\end{align*}
\]

where \(\mathbf{y}\) is the vector of log transformed lice count values, \(\mathbf{X}\) is the overall mean; \(\mathbf{X}\) and \(\mathbf{Z}\) are a design matrix to relate the animal records to fixed effects and genetic values, respectively; \(\mathbf{b}\) is a vector of fixed effects of tank, lice counter and body weight of the fish as a covariate; \(\mathbf{u}\) is a vector of random additive genetic effects, where \(\mathbf{G}\) is the genetic variance, \(\mathbf{GG}\) is the genomic relationship matrix computed using VanRaden’s method 1; and \(\mathbf{e}\) is the vector of random residual effects with \(\mathbf{e} \sim N(0, \mathbf{I} \sigma^2_e)\). The three datasets (“S0” of YC-2018; “S0” of YC-2022, and the “S1” data of YC-2022) were analyzed separately, and as a single trait by combining datasets, and with a bivariate model considering the two year-class specific values as two different traits. Additional fixed effects of year-class and smolt type (“S0” and “S1”) were also added when both year classes were analyzed together.

Genomic breeding values (GEBVs) were computed using two different \(\mathbf{GG}\) matrices derived from two sets of SNPs; \(G1\) all SNPs regardless of linkage disequilibrium (LD) phase among parent and progeny year-classes, or \(G2\) a subset of the SNPs selected based on consistent LD phase among the two year-classes. A fivefold cross validation scheme was designed and used to evaluate the accuracy of predictions across the year-classes with multiple scenarios i.e., across and within year-class predictions.

(Continued on next page)
The GWAS analysis was performed with the $\log(LC)$ of each dataset separately and by combining datasets from both year-classes as the same trait with GCTA software using the "--mlma-loco" function.

**Results and Discussion**

The heritability estimates for $\log(LC)$ was $0.25\pm0.03$ (YC-2018) and $0.20\pm0.02$ (YC-2022). The genetic correlation for $\log(LC)$ recorded on “S0” and “S1” populations of YC-2022 was high with estimates of $0.88\pm0.07$ indicating possibility to analyze “S0” and “S1” of YC-2022 as a single trait. However, the genetic correlation of $\log(LC)$ for the two year-classes was medium ($0.69\pm0.06$). The GWAS analysis revealed consistent strong signals of multiple QTLs across the two year-classes located at chromosomes 2, 5, 11 and 25. There were also inconsistent signals of QTLs detected, e.g., single SNP at chromosome 14 crossing significant line (Figure 1). Overall, low proportions of the genetic variances were captured by the different QTLs (calculated as $\frac{\widehat{v^2}}{\sigma^2}$, Falconer and Mackay, 1996); e.g. the highest significant SNP at chromosome 2 explained 4.66% of the genetic variance.

The mean accuracy of the across year-class predictions of the GEBVs using either of the two types of G-matrices was generally low with magnitude of 0.22 and 0.42 using $G_1$ and $G_2$, respectively. The gain in accuracy for the across year-class prediction using $G_2$ was approximately doubled as compared to using $G_1$, possibly due to refining trait specific hidden relationship between the two year-classes. The mean accuracy of the within year-class prediction was 0.60 and 0.58 using $G_1$ and $G_2$ matrices, respectively. Hence, in the case of within year-class predictions the use of $G_2$ was not beneficial resulting in slightly lower accuracy of prediction as compared to the use of $G_1$.

In conclusion, lice count in A. salmon showed moderate heritability and a polygenic trait architecture, the accuracy of across-year class prediction was not advantageous compared to within year-class predictions (the latter of which is currently used in aquaculture breeding programs). GWAS revealed consistent signals of QTLs across the parent and the progeny year-classes.

SUSTAINABLE PACKAGING OF FISH FILLETS USING A NOVEL CROSSLINKED EDIBLE FILM

E. Athanasopoulou,*, G. Kalouda, T. Tsironi

Laboratory of Food Process Engineering
Department of Food Science and Human Nutrition
Agricultural University of Athens, Greece
efiatha@gmail.com

Introduction
Packaging materials represent the largest category of plastic waste, since almost 50% of global plastic waste comes from the packaging field. The compound annual growth rate (CARG) for global plastic waste is 5.4% from 2022 to 2030. Edible food packaging has been investigated as an alternative, environmentally friendly method to maintain food freshness and extend shelf-life (Galus et al., 2020).

However, packaging materials based on natural biopolymers often exhibit poor barriers and mechanical properties. For this reason, other components such as crosslinkers may be used to enhance barriers, and mechanical properties (Otoni et al., 2017). Crosslinking agents improve the mechanical and barrier properties of the films based on proteins and polysaccharides. When a crosslinking agent is added to the matrix of the polymer, a three-dimensional structure is synthesized by binding the polymer chains with covalent or non-covalent bonds, resulting in more hydrophobic films (Garavand et al., 2017).

Polysaccharides can be effectively used to synthesize biobased packaging materials, due to their biodegradability and biocompatibility. Among biopolymers, cellulose, and its derivates have been reported for their applicability in the packaging field, as cellulose-based films are odorless and tasteless. Carboxymethyl cellulose (CMC) is produced by adding carboxymethyl group (CH$_2$COONa) groups in cellulose molecules to obtain a water-soluble molecule. CMC-based films are biodegradable, but they exhibit poor barrier properties due to the hydrophilic nature of cellulose (Yildirim-Yalcin et al., 2022).

Plasma is an ionized gas containing electrons, photons, and atoms and it can be categorized as high temperature and low-temperature plasma. Cold Atmospheric Plasma (CAP) has been used in the packaging sector to improve the mechanical and barrier properties of polymers. Surface treatment of polysaccharide-based films using CAP may improve their functionality of the developed films (Zhu et al., 2021).

The objective of the study was the development of a novel polysaccharide-based and crosslinked, edible packaging film appropriate for fish and seafood. CAP was used as a surface modification method to enhance the barriers of the developed films. Fresh meagre fillets under refrigeration were selected as the case study.

Materials and methods
2% CMC-based films were produced according to the solvent casting method and glycerol was added as a plasticizer. Calcium cations (Ca$^{2+}$) were added as a crosslinking agent at the concentrations of 1% and 2%. The produced films were treated with CAP (kINPen® IND, neoplas GmbH, Germany) with continuous flow (argon, 4 L/min) for 5 and 10 min. Films without the crosslinking agent and plasma treatment were produced and tested as controls. Water Vapor Permeability (WVP) and Water Vapor Transmission Rate (WVTR) were evaluated according to ASTM E96/E96M. The hydrophilicity of the surface of the films characterized through contact angle with Theta Flow Optical Tensiometer (Biolin Scientific, Gothenburg, Sweden). The mechanical properties were measured according to ASTM D882 (ASTM, 2001), by Instron 3400 (Norwood, MA, USA) and load 50 N. The color changes of the films before and after plasma treatment were recorded. CMC-based films were applied on fresh meagre fillets (Argyrosomus regius) stored isothermally at 2°C for shelf-life evaluation, based on Total Viable Count (TVC) and Pseudomonas spp. growth and compared with the respective data obtained for conventional Polyvinyl chloride (PVC) films.

(Continued on next page)
Results
The results for the water barriers showed that by adding Ca$^{2+}$ to CMC film forming solution the produced films had lower WVTR and WVP. The WVTR for CMC-based films was 1206.73±66.24 g/day× m² and reduced to 973.98±82.81 g/day× m² and 869.88±282.10 g/day× m² for films with 1% and 2% Ca$^{2+}$, respectively. All the produced films had higher water barriers after CAP treatment. The WVTR for the CMC-based films was 1206.73±66.24 g/day× m². After 5 minutes CAP the WVTR was 1107.01±127.61 g/day× m² and after 10 minutes of CAP treatment the WVTR was 1080.25±157.08 g/day× m². Similar trend was observed after CAP treatment for the films with the crosslinking agent. The contact angle of CMC based films was 60.25±8.04° represented hydrophilic materials. CAP treatment resulted in reduced contact angle (44.28±2.63° and 37.06±4.31° for 5 minutes and 10 minutes CAP, respectively). The addition of 1% Ca$^{2+}$ led to increased contact angle of films (64.33±9.90°) but when 2% Ca$^{2+}$ was added the contact angle was lower (47.69±3.81°). Films with Ca$^{2+}$ had also lower contact angle after CAP treatment. The addition of Ca$^{2+}$ into the CMC film-forming solutions led to more brittle films at higher concentrations (1.5 and 2% Ca$^{2+}$). When 1% of Ca$^{2+}$ was added, the young’s modulus of the films reduced from 3120.51±672.76 MPa to 2505±516.56 MPa for CMC-based films and CMC/1% Ca$^{2+}$-based films, respectively. The tensile strength and the elongation at break were not statically different for the two types of the films. The color of the produced films did not change by adding the crosslinking agent or after CAP treatment. The replacement of conventional PVC films with the developed CMC-based films did not affect the microbial growth of meagre fillets during refrigerated storage, resulting at shelf-life of 10 days at 2°C (same for all the tested conventional and alternative packaging films).

Discussion and conclusion
The results of the study show the potential of CMC-based, edible packaging films for the effective preservation of chilled fish, without affecting quality and shelf-life. The appropriate design of polysaccharide-based films and surface modification for the enhancement of the barriers and mechanical properties of the developed packaging systems will contribute to the sustainability of the aquaculture sector towards a zero-waste future.

Introduction

Aquaponics combines recirculating aquaculture (RAS) with hydroponics, a soilless plant farming method. Plant choice in aquaponics may affect the growth and microbiome of fish because each plant has its specific microbiome, which may alter the microbes in aquaponics. Plant secrete root exudates, which may alter the microbes in the system. Mint is a plant known for its growth promoter effects on animals, and it may influence the fish growth when grown together with fish in aquaponics. On the other hand, fish in aquaponics excrete ammonia, which is toxic to fish and must be removed from circulating water. Ammonia is converted to nitrates and then to nitrates by microbial action during the process of nitrification. Nitrification is an essential process for the performance of RAS and maintains the water quality of aquaponics. The aims of this study were to investigate the growth of fish and fatty acids contents of rainbow trout (*Oncorhynchus mykiss*) in aquaponics when grown with mint. The other aims were to investigate microbial communities in the mucous and gut of the rainbow trout and to compare start-up of nitrification in aquaponics and RAS.

Materials and methods

Seven-week experiment was performed with three replicated RAS and aquaponic systems. Twenty rainbow trout (initial weight 55 ± 1.06 g) were stocked in each fish tank for RAS and aquaponic systems. Thirty mint seedlings were transplanted in each deep water culture rafts. Change in biomass for fish was recorded at the end of the experiment. Microbial communities in fish mucous and gut were analysed at the start and end of the experiment. The fatty acids were extracted from fish muscle from the start (fingerlings) and end samples. Concentrations of total ammonia nitrogen, nitrite, nitrate were recorded during the experiment.

Results

The weight gains (aquaponics = 324.33 ± 31.87 g, RAS = 295.13, ± 9.70 g , p = 0.24) and specific growth rates (aquaponics = 2.11 ± 0.11 g, RAS = 2.00, ± 0.06 g, p = 0.21) of rainbow trout were similar in RAS and in the aquaponics. Mint improved the fish growth through reduced feed conversion ratios (Figure 1). Mint reduced the feed consumption of the rainbow trout in aquaponics (Figure 1). However, fish in aquaponics maintained equal weight as fish reared in RAS despite of the lower feed consumption. The omega 3 fatty acids content of rainbow trout in aquaponics were slightly higher than the fish reared in RAS but without statistically significant difference. The retention of omega 3 fatty acids content was speculated in fish because fish maintained fatty acid composition similar to fish in RAS in spite of low feed consumption in aquaponics. Mint altered the microbial communities of rainbow trout in mucous and gut compared to fish reared in RAS. Nitrification start-up was faster in aquaponics than in RAS.

![Figure 1: Feed consumed and feed conversion ratios (FCR) of rainbow trout in RAS and aquaponics for 7-week experiment. Independent samples t test, n = 3. Different letters differ statistically significantly. For the aquaponics treatment mint (*Mentha spicata*) was grown in a coupled aquaponics system together with rainbow trout (*Oncorhynchus mykiss*).](image)

(Continued on next page)
Conclusions
Aquaponics with mint improved fish growth, water quality and initiated earlier start-up of nitrification as compared to RAS. Using mint in aquaponics may improve omega 3 fatty acids content of the fish. Growing fish together with mint in aquaponics may lower the feed consumption of fish compared to RAS which will reduce the cost related to fish feed and minimise the impact of aquaculture feed on aquatic environment.

Introduction

Despite the limited number of studies testing the effects of tryptophan on fish immune responses, data generally points out to immunosuppressive properties. Therefore, tryptophan poses as a potential regulator of an ongoing inflammatory process. This study main goal was to evaluate the effects of tryptophan dietary supplementation on immune and neuroendocrine responses of the European seabass, Dicentrarchus labrax, undergoing a chronic inflammatory response.

Materials & Methods

European seabass juveniles (34.55 ± 7.84 g) were distributed into twelve tanks of a recirculating seawater system. At first, fish were intraperitoneally injected with either Freund’s Incomplete Adjuvant (FIA, inflamed group), or Hanks’ Balanced Salt Solution (HBSS, control group). Within each group, fish were fed a control diet (CTRL) and a CTRL-based diet supplemented with tryptophan (0.3% DM basis; TRP) for 28 days. Samples of head-kidney were taken every week for neuroendocrine- and immune-related gene expression analysis.

Results & Discussion

The expression levels of gr1 at the end of 1 week were lower in FIA-injected fish than in HBSS-injected fish, irrespective of dietary treatment. When TRP was provided to FIA-injected fish, mcsfr increased from 1 to 2 weeks, and remained high until the end of the experiment. CTRL-fed fish mcsfr mRNA levels also increased, but later, from 3 to 4 weeks. Moreover, il34 expression at 1-week post FIA injection was higher in TRP-fed than in CTRL-fed fish. The canonical discriminant analysis clearly differentiated groups between those with the shortest inflammation period (one week) and those sampled later at four weeks (Fig. 1). Moreover, it showed how the feeding period seems to be critical in what tryptophan supplementation is concerned. Indeed, after one week, anti-inflammatory processes seemed to be favored in fish fed TRP (higher gr1, il34 and tgfβ; lower il1β). Later, at four weeks, the two dietary groups have more similar molecular patterns, both showing higher expression of T-cell and macrophages’ related markers than fish at earlier stages of the response.

Figure 1. Canonical discriminant analysis of gene expression in the head-kidney of European seabass sampled at one or four weeks following intra-peritoneal injection with FIA. A - Canonical discriminant scores of each group. Groups centroids are marked by a small diamond, whereas circles indicate data distribution per group; B - Correlation variables/factors (factor loads) for two main discriminant functions (F1 and F2).
Conclusion

Present results highlight tryptophan dietary supplementation potential in accelerating inflammation resolution, suggesting that its effects are mostly prominent at an early phase of the inflammatory response, dissipating towards the fourth week. It therefore provides important insights related to strategy of application.

Introduction
The current meat and fish production systems are not sustainable, and the protein content of animal feed plays a key role in this regard. This holds true also for trout, a fish reared specie characterized by a high feed conversion rate, where the consumption of fishmeal is responsible for serious environmental issues (e.g., overfishing, loss of biodiversity) and economic concerns due to the constantly increasing price of these commodities. Meanwhile, the agriculture and agro-food industry generate a considerable amount of organic waste and by-products whose management is often problematic and expensive.

Through the insects rearing, these substrates can be locally re-utilized and valorized to produce alternative protein for the rearing of monogastric animals, reducing the impact on the environment related to animal feeding, organic waste, and by-products management. More in details, the use of insect meal as an alternative aquafeed protein source is an opportunity to exploit the efficient bioconversion by insects of agricultural by-products and other organic waste into an animal feed resource. In a circular perspective, this allows to reduce the use of traditional high-impacting protein sources and, at the same time, the impact of conventional management these matrices. In Lombardy, a region with high population densities, and intense agricultural activities and agri-food industries, a large amount of organic waste is available. Valuing this biomass by reusing it as a resource for an alternative feed appears to be an important opportunity for several actors involved in the supply chain. Rice (Oryza sativa) is a major crop in the region in terms of area, value of production and, above all, quantity of by-products resulting from processing.

The newRIFF project
newRIFF project aims at testing the suitability for recovery and enhancement of paddy rice processing by-products, and to use them, together with other organic waste, as a substrate for the cultivation of insects to be used in turn for aquafeed formulations. The tests of the use of the feed thus produced will be carried out with the rainbow trout (Oncorhynchus mykiss) as a pilot species, due to the importance that this fish has in the Italian aquaculture sector, particularly in Northern Italy.

The project aims to fill the following knowledge gaps: (i) to test the productivity of insects, in particular black soldier fly (Hermetia illucens) and yellow mealworm (Tenebrio molitor), raised on a mix of different matrices consisting of by-products of paddy rice processing and other organic by-products and wastes; (ii) to evaluate, by in vivo trials, different diets having increasing levels of insect meals (mix of meals produced from the two species) in substitution of conventional protein sources in rainbow trout farming. Fish performance and diets digestibility will be used to evaluate the effectiveness of the insect meal mix inclusion; (iii) to evaluate consumer acceptance and economic, environmental and social performance of trout farming by replacing traditional proteins (e.g. soybean meal and fish meal) with insect meal produced using rice by-products and other organic waste as insect rearing substrate; (iv) to identify best practices regarding the use of insect meal as a source of protein water feed and summarize all the information gathered during the project in order to develop guidelines and policy recommendations.

newRIFF involves different activities: (i) identification of the best substrate mix and optimal growing conditions for insects, (ii) insect meal production by rearing the two selected insect species, (iii) feeding trials on trout considering 3+1 diets: a control diet (the one usually utilized in commercial livestock farms) and alternative ones with different level of insect meal (i.e. 25, 50 100% of fish meal replacement), (iv) the evaluation of the nutritional, sensorial and food safety features of the produced trout in order to assess if the quality trout filet is affected (and if yes, how) using insect meal, (v) the sustainability assessment with a Life Cycle Thinking approach. The main benefits arising from the implementation of the newRIFF are schematized in fig.2.

Introduction
The development of new technologies for decontamination in Recirculating Aquaculture Systems (RAS) is a challenging task. Devices generating ozone or UV radiation are commonly used to reduce the amount of pathogens, to ensure an appropriate water quality and to guarantee the welfare of fish (Stiller, Kolarevic et al. 2020). Though these technologies are well established and well known, they have disadvantages concerning costs (Engle, Kumar et al. 2020). Previous studies confirmed the antimicrobial efficacy of cold atmospheric plasma (CAP) and pulsed electric fields (PEF) in water treatments (Banaschik, Burchhardt et al. 2016, Schmidt, Hahn et al. 2019). Our aim was to develop and test system models operated for the treatment of larger volumes on the on-site use.

Materials and methods
Experiments with the developed plasma source and PEF device were carried out using model aquaculture water with the addition of *Vibrio cholerae* DSM 100200 as fish pathogen. To determine the inactivation of *Vibrio cholerae*, treatment parameters as flow rate and treatment time were varied for the total volume of 90 L. Next to the detection of the antibacterial efficacy, water analyses were carried out by ion chromatography and determination of pH, conductivity as well as temperature.

Results
For the experimental setting an initial concentration of 10^5 colony-forming units/mL of *Vibrio cholerae*, a flow rate of 150 L/h and a total treatment time of 480 minutes was adjusted. A 270 minutes continuous treatment resulted in an inactivation to the detection limit for plasma, whereas an inactivation of 1.9 orders of magnitude was achieved with PEF. Furthermore, the low resulting increase of conductivity (plasma: +200 µS/cm, PEF: + 80 µS/cm) and temperature (plasma/PEF: 22°C up to 30°C) confirm the suitability of the system model for utilization in RAS and will probably not affect the fish welfare.

Conclusion
The decontamination results of the treatments by using this system models are promising for further research and development, especially for larger scale experiments. The system models will further be optimized regarding to the antimicrobial efficacy and energy consumption to establish plasma and PEF treatments as a sustainable decontamination technology in aquaculture.

A HYDROXYTYROSOL-RICH EXTRACT FROM OLIVE JUICE POSITIVELY IMPACTS GROWTH POTENTIAL AND LIPID METABOLISM IN GILTHEAD SEA BREAM FED A HIGH-FAT DIET

S. Balbuena-Pecino1*, M. Montblanch1, I. García-Meilán1, E. Rosell-Moll1, R. Fontanillas2, Á. Gallardo1, J. Gutiérrez1, I. Navarro1 and E. Capilla1

Introduction

In the last years, there has been a wider use of high-fat diets (HFD) in many farmed fish species. These diets aim to partially substitute the protein source, resulting in economic benefits, while also meeting the increasing demand for fish consumption. It has been demonstrated that HFD can enhance growth performance by improving the use of dietary protein (protein-sparing effect) (Sargent et al., 2002). However, an excess of lipids in the diet can lead to adverse effects, such as impaired mitochondrial and peroxisomal fatty acid β-oxidation efficiency and, consequently, depressed lipid catabolism and increased fat deposition in the liver (or other tissues) (Turchini et al., 2022). In this context, the inclusion of dietary feed additives that could mitigate these negative consequences is considered a promising strategy within the aquaculture sector. Hydroxytyrosol (HT) is a phenolic compound found in the olive tree (Olea europea L.), in leaves, fruit, olive oil, juice and their by-products. In mammals, HT has shown antioxidant, anti-inflammatory and anti-obesogenic properties, among others (Karković Marković et al., 2019). Nevertheless, research on its potential benefits as an additive in aquafeeds is still very limited.

Materials and methods

After one month of acclimation in the animal facilities of the Faculty of Biology (University of Barcelona), gilthead sea bream (Sparus aurata) juveniles (obtained from Piscimar fish farm in Burriana, Castellón) were distributed into eight tanks of 200 L (n=15 fish per tank) and four of 400 L (n=30 fish per tank) for the experimental setup. One week before the start of the experiment, fish were fed a HFD ad libitum. The identified level of satiation was then used as the standard ration in the experimental trial. The initial weight of the animals was 80.81 ± 1.43 g. The diet consisted of a high-lipid formulation (24% of dry matter) with 23 MJ/kg of digestible energy, where 50% of the total oils were derived from rapeseed oil. Furthermore, this diet was formulated either in the absence (HF) or presence (HF+HT) of a HT-rich extract from olive juice (HIDROX®, 0.52 g HT/kg feed) provided by Oliphenol LLC. (Hayward, CA, USA). The diets were administered daily using the determined standard (ST) ration or a restricted (RE) one (40% reduction) over a period of 8 weeks. Each experimental group was represented by three tanks, one of 400 L and two of 200 L. The daily feeding ration was adjusted every two weeks based on the fish’s body weight. At the end of the trial, biometric data, plasma and tissue samples were collected. Plasma levels of insulin-like growth factor 1 (IGF-1) and metabolites were evaluated, while the expression of genes related to somatic growth and lipid metabolism was analyzed in the liver, white muscle, and/or bone. Additionally, lipid content and protein levels of the fatty acid transporter CD36 were measured in liver and white muscle.

| Table 1. IGF-1 (ng/ml) and FFA (mg/dl) plasma levels of gilthead sea bream juveniles fed with a high-fat diet in the absence (HF) or presence (HF+HT) of hydroxytyrosol (0.52 g HT/kg feed), at a standard (ST) (3% biomass/tank) or restricted ration (RE) (40% daily reduction) for 8 weeks.

Data are shown as Mean ± SEM (n=10). Statistical differences are indicated in 3 components: diet (D), ration (R) and interaction (D*R), using two-way ANOVA (p < 0.05, shown in bold). When the interaction between the two factors (D*R) was significant, comparisons among groups where analyzed by a Tukey’s post-hoc test and significant differences are indicated by different letters (p < 0.05).

(Continued on next page)
Results and Discussion

After 8 weeks of experimental trial, the inclusion of the HT-rich extract to the diet did not change body weight or any of the other biometric parameters evaluated (body length, condition factor, and hepatosomatic and mesenteric fat indices), regardless of the feeding ration. However, plasma levels of IGF-1 and free fatty acids (FFA) were affected by diet and the interaction between factors (i.e., diet and feeding regime). Specifically, the highest circulating IGF-1 levels, along with the lowest FFA levels, were observed in fish fed the diet containing the extract (HF+HT) at the standard feeding regime compared to the other three groups, suggesting potential anabolic and fat-lowering effects (Table 1). Moreover, in line with this, although it was not statistically significant, it is worth noting that the same group of fish exhibited the lowest hepatic lipid percentage. In terms of gene expression, those same animals exhibited, in white muscle, higher mRNA levels of members of the GH-IGF axis (igfbp-5b, ghr-1, and dock5), in parallel with lower mRNA levels of fatty acid uptake and transport markers (lpl, fatp1 and fabp1) in the liver, which agrees with an improved growth potential and a protective role under a lipid overload context by this polyphenol. Therefore, it could be hypothesized that a longer duration of the experimental treatment could have resulted in more pronounced effects. On the other hand, fish subjected to a 40% feed restriction showed a better feed conversion ratio and lower levels of HDL, LDL/VLDL, and triglycerides in their plasma than the ones that received the standard ration. Overall, HT appears to be a promising candidate for incorporation into functional diets for gilthead sea bream, as it shows the potential to positively impact lipid metabolism and enhance the growth capacity of the musculoskeletal system in this species.

Introduction
The European flat oyster (*Ostrea edulis* Linnaeus, 1758), one of the most valuable bivalve species, is traditionally cultured in the Adriatic sea. Since 1970s, overharvesting, habitat loss and parasitic diseases (bonamiosis, martelliosis) caused a rapid decrease in its production (Ezgeta-Balić et al., 2020; Šegvić-Bubić et al., 2016) under aquaculture conditions, feeding interactions between them were investigated in a highly productive environment of Lim Bay (Adriatic Sea. To compensate for the losses, the Pacific oyster (*Crassostrea gigas* Thunberg, 1793) was introduced to many European countries (Grize & Héra, 1991). The Pacific oyster has not been cultured in Croatia to date, but it has established self-sustaining wild populations with possible negative effects on the indigenous fauna (Diederich, 2005; Markert, Wehrmann, & Kröncke, 2010) southern German Bight. *C. gigas* settles predominantly on intertidal *Mytilus*-beds (*M. edulis* L.). The aim of this study was to find evidence of a putative hybridization between the two species in Croatia.

Materials and methods
European flat oyster samples were collected from three different locations in Croatia (Lim Channel n=36, Medulin Bay n=33, Savudrija n=35) and one from Ireland (n=12). Pacific oyster samples (n=12) were collected only from Ireland. Phenotypic and genotypic species identification was performed and the results were compared. Muscle tissue samples were collected and stored in 98% ethanol at -20 °C until DNA isolation, which was performed with an E.Z.N.A. Tissue DNA Kit following the manufacturer protocol. A multiplex PCR was used for the amplification of the 5S rDNA with four primers (ED1, ED2, CR1, CR2) published by Cross & Rebordinos (2006) using QIAGEN Multiplex PCR kit following the manufacturer protocol. The resulting PCR products were separated by agarose gel electrophoresis and the expected product size was 800bp and 400bp for *O. edulis* and *C. gigas*, respectively.

Results
We could not detect any deviations between the genotypic and phenotypic results. All *O. edulis* samples (n=116) amplified only one product with the expected size of 800bp and all *C. gigas* samples (n=12) amplified one product with the expected size of 400bp.

Discussion and conclusion
Our results do not support the hypothesis that hybridization took place between the two species in the Northern part of the Adriatic sea, near the Istrian peninsula, which might be explained by the differences in their reproductive cycle. We conclude that this novel multiplex PCR with the previously published primers might be suitable for DNA based species identification in oysters.

THE ADAPTABILITY OF ATLANTIC SALMON (Salmo salar) TO NOVEL TURBULENT ENVIRONMENTS

Emma Barbier*, Malthe Hvas, & Frode Oppedal
Animal Welfare Research Group
Institute of Marine Research
5984 Matre, Norway
E-mail: emmabarbiert811@gmail.com

Introduction

Atlantic salmon (Salmo salar) is the most important farmed species globally. In Norway for example, exports generated USD 11 billion in 2020. The government predicted a doubling of production by 2030, however this may be restricted due to the lack of suitable farming sites and limitations to the number of licenses issued. Consequently, alternative sites are increasingly being considered by industries in Norway and other countries. One popular alternative includes the attractive ‘offshore’ locations in areas further from the coastline, exposed to high current speeds and strong wave action.

Yet, the effect that heavy wave action will have on fish reared within cages in these novel environments remain unknown, raising questions about the Atlantic salmon’s coping ability and welfare.

The purpose of this original study was to investigate, in a fully controlled environment, the response of Atlantic salmon exposed to chronic water turbulence by measuring growth performance, behavioral conditioning, welfare scores, stress physiology, skeletal deformities, and swimming capability.

Materials and Methods

For 8 weeks, post-smolt Atlantic salmon were grown in three control and three treatment tanks at relevant farm stocking densities. Each treatment tank consisted of two tailor-made 100L buckets attached to a water pump, that when filled (approx. every 23s), tipped over back into the tank creating water turbulence. Appetite was monitored daily and various behavior traits were scored throughout the trial. At weeks 2, 5 and 8, a sub-sample of 48 fish were obtained to measure size, blood parameters and score welfare. At the completion of the trial, all fish were re-measured. Another sample of fish underwent a swim trial where the critical swimming speed (U_\text{crit}) was determined. A final sub-sample was analyzed with radiology to detect skeletal deformities.

Figure 1A. Left panel shows the average weight (g) of the Atlantic salmon. Figure 2B. Right panel shows the average of 5 daily recordings of feed intake (g of dry feed), averaged per group of three replicated tanks.

(Continued on next page)
Results

Atlantic salmon were able to cope and grow in constant turbulent conditions. A small 40g difference was observed between the groups (Fig.1A). The condition factor was similar; 1.27 in the turbulence treatment compared to 1.28 in the controls.

Appetite in the treatment tanks was 14% to 7% lower during the first 4 weeks of the trial, before reaching similar levels as the controls (Fig.2B). This variation coincides with a behavioral change observed. During the first 4 weeks of the trial, individuals in the treatment tanks swam less coherently (<90% standing in the current). However, after this period, the treatment and control groups were both swimming consistently (>90% standing in the current). No large difference in the total welfare score was observed.

Ongoing analysis of stress physiology, swimming performance and skeletal deformities will also be presented. These will provide further important insights into how well Atlantic salmon adapt, cope and develop in turbulent farm environments.

With the already analyzed data, both groups appear to have had similar coping, despite the slight differences observed during the first weeks of the trial. This suggests that Atlantic salmon have the capability to acclimatize to an environment with constant turbulence without compromising welfare or growth to a large extent. The difference in final size remains unexplained. It may have been caused by the difference in appetite at the start of the trial or by increased energy expenditure due to the efforts needed to swim in waves. Alternatively, if the trial had been running for longer, the weight differences might have disappeared due to compensatory growth.

This work is the first attempt to experimentally study the effect of chronic turbulent environments on a cultured fish species which provides valuable novel knowledge in the industry-wide efforts to establish responsible offshore aquaculture practices. However, as a land-based experiment, it does not fully mimic the true offshore conditions at a commercial production scale. Nevertheless, this work clearly demonstrate that Atlantic salmon are a robust species and have the capacity to adapt well in novel-high energy environments without suffering substantial reductions in welfare or long-term production performance.
MERCURY CONTENT IN EUROPEAN EEL (Anguilla anguilla Lineaus, 1758) FROM THE NERETVA RIVER DELTA

Oliver Barić1, Tena Radočaj1, Jurica Jug-Dujaković2, Ana Gavrilović1

1University of Zagreb Faculty of Agriculture, Svetosimunska cesta 25, Zagreb, Croatia
agavrilovic@agr.hr
2Sustainable Aquaculture Systems Inc., 715 Pittstown Road, Frenchtown, NJ 08825, SAD

Introduction
The European eel populations across Europe have been declining since the mid-20th century, and are now considered critically endangered (ICES, 2020). This species is a catadromous, migratory species and the success of migration largely depends on the physiological condition and sufficient reserves of fat that provide the energy for the journey (Righton and Metcalfe, 2011). One of the factors affecting the health of the migrating eels is the accumulation of contaminants such as mercury (Polak-Juszczak and Robak, 2015). Mercury is commonly used in household, industrial, and medical products (Ahmed et al., 2020). It can be transported into rivers where bacteria convert it into a soluble organomercury which enters the food web and accumulates in organisms over time (WHO, 2020). Since the eel has a long life cycle it can accumulate significant amount of mercury through feeding which lowers its physiological condition but also poses a health risk for human consumption (Polak-Juszczak and Robak, 2015). The aim of this research was to determine the mercury level in European eels caught in the Neretva river delta.

Materials and methods
The fish were sampled in the winter, spring, summer, and autumn of 2021 from Neretva river delta. Samples were weighed, total length was measured, and life stage was determined according to Acou et al. (2005). A portion of dorsal muscle without skin, was taken for the analysis of the mercury concentration that was determined using Direct Mercury Analyzer (DMO). Spearman’s correlation was used to test correlation between mercury concentrations and length or weight of the eels. The differences among groups for length, weight and mercury concentrations were tested using ANOVA. Post-hoc analysis with Tukey’s test was done to determine which groups statistically differ from each other.

Results
A total of 94 specimens of European eel were caught, 13 of which were silver and 81 yellow eels. Seasonal averages of weight and total length are given in Table 1. Seasonal length and weight differences among groups were determined to be statistically significant using ANOVA (F=2.98, p=0.023 and F=3.51, p=0.01). Using post-hoc test statistically significant differences for total length were found between yellow eels from the summer and silver eels (p=0.021), and yellow eels from the autumn and silver eels (p=0.040). Significant differences in weight were determined between yellow eels in the spring and silver eels (p=0.023), yellow eels in the summer and silver eels (p=0.015) and yellow eels in the autumn and silver eels (p=0.018).

The mean recorded mercury concentrations are given in Table 2. No statistically significant differences were found among groups using ANOVA test (F=2.126, p=0.085). No correlation was found between mercury concentrations and total length or weight of the eels.

Discussion and conclusion
Mercury in different forms (elementary, inorganic, and organic) can cause developmental and hormonal disorders such as lower growth rate and induced sex change (Crump and Trudeau, 2009). Polak-Juszczak and Robak (2015) stated that the negative effects of mercury in eels can be seen at concentrations above 0.5mg/l. In this research the highest concentration in a single specimen was 0.55mg/kg, while in the rest the concentrations was below 0.29mg/kg. No fish were found with the concentration above the maximal permitted level. Therefore, mercury was detected in only one specimen of eel in a concentration high enough to pose a danger for its health and all fish were safe for human consumption.

Introduction
Phytoplankton cultures are essential in mollusc cultures, as they constitute the completing the diet in the complete cycle, i.e., from broodstock to seed. Different types of cultures were maintained to produce enough quantities to sustain production.

The bacterial load in microalgal cultures is high, and they are directly and continuously supplied to the bivalves. Therefore, microbiological knowledge should be useful for hatchery management.

In previous work, we demonstrated that microalgal cultures carry vibrios, including potential marine aquaculture pathogens, with some species adjusted to seasonal patterns, mainly associated with temperature. We also stated that the vibrio load is highly variable during the year, but also over the course of a week.

By other hand, we have also established that active cultures of different microalgal species are able to reduce the load of pathogenic vibrios, until very low levels or even under the detection threshold.

We now present the preliminary results of the study of marine bacteria in phytoplankton, focusing on the spring-summer season, when temperatures rise and vibrio populations in the food supplied to cultures are high in quantity and diversity.

Materials and methods
Phytoplankton is developed in Centro de Cultivos Mariños-CIMA (Ribadeo. Xunta de Galicia), following the routine protocols of the installation for the two types of cultures.

a) Small volumes, 6 l. flaks, kept in the isothermal chamber (19±1ºC) under constant illumination and CO2-enriched aeration. Seawater is filtered and autoclaved, and enriched with Algal-1 medium.

b) The continuous culture system (“Sea Salter Continuous Algal Production Systems”), located in the greenhouse, consists of polyethylene bags with a volumetric capacity of 400 l. each. It is based on a constant supply of seawater with the nutrient medium (John Bayes Medium) and a constant harvest. The seawater is sterilized by pasteurization. The lighting is natural light supplemented with artificial light (leds), adjusted to a photoperiod of 18 h day:6 h night. There is continuous aeration in each of the bags and there is an addition of CO2 that is controlled by measuring the pH. The inoculation of the bags is done with cultures from the isothermal chamber.

The cultivated microalgae are Isochrysis, Diacronema, Tetraselmis and Chaetoceros.

Microbiological samples were taken and immediately processed on site, spread on plates of Marine Agar (MA), for marine heterotrophic bacteria, by a standardized method developed in the course of this sampling, to obtain enough information with a simple processing, easy to execute by the installation personnel.

Bacterial isolation, preservation and identification of isolates were carried out by USC, following the methodologies described in Prado et al. (2014).

Results and Discussion
In this first approach, randomly selected flasks/bags of each microalgal species were sampled in June-July, as this is when Vibrio episodes begin in the continuous culture, acting as “asymptomatic carrier” of larval pathogens.

(Continued on next page)
Preliminary results, obtained until the time of writing, are mainly for the cultures in isothermal chamber. They showed the frequent presence of γ-Proteobacteria, mainly *Alteromonadaceae*. α-Proteobacteria were also detected, belonging to different families: *Maricaulaceae*, *Ahrensiaecae*, *Devosiaceae*, *Roseobacteraceae* and *Rhodobacteraceae*. And *Flavobacteriaceae* (Bacteriodota) were other important component of the microbiota in these cultures.

The first results of bacterial isolates from continuous cultures showed similar taxa, with presence of Alteromonadales (γ-Proteobacteria), Rhodobacterales (α-Proteobacteria) and Flavobacterales (Bacteriodota).

These results are being completed, with isolates from both types of cultures, to obtain an overview of the marine bacteria present.

The microbiota of both systems will be compared to determine if there are differences that could explain the proliferation of vibrios in the CCS. In addition, the presence of potential algicide bacteria will also be studied.

BIOFILM FORMATION BY PATHOGENIC VIBRIOS ON HATCHERY SURFACES

Authors: J.L. Barja 1, S. Nóvoa, J. Ojea, Martínez-Patiño, D., S. Prado

1 Dpto. Microbiología y Parasitología. CIBUS-Instituto de Acuicultura. Universidade de Santiago de Compostela. 15782 Santiago de Compostela. Spain

Introduction

Episodes of mortalities caused by vibrios occur repeatedly in bivalve hatcheries, affecting all the cultured species. In our studies about the dynamic of these microorganisms in the installation, one important aspect is their persistence along the season and possible re-emergence. It is known that many microbes persist attached to surfaces with a structured biofilm ecosystem, where they function as an integral part of a population, obtaining ecological advantages.

In this work we demonstrated the ability of pathogenic vibrios of forming a biofilm in the surfaces of culture tanks.

Materials and methods

The assays were carried out at Centro de Cultivos Mariños-CIMA de Ribadeo (Consellería do Mar, Xunta de Galicia). The experiments were designed to optimize the obtaining of practical information in the hatchery, minimizing risks to the facility and enabling direct observation.

Pieces of used culture tanks were placed in containers with the seawater supplied to larval cultures and aeration. Each container was inoculated with a larval pathogen: P1 Vibrio neptunius 145.98, P2 V. ostreicida PP-203, P3 V. europaeus PP-638, P4 V. bivalvicida PP2-605 and P5 V. splendidus-like PP-58.

A protocol for scanning electron microscopy was developed and optimized. Samples were analyzed in FESEM Ultra Plus (ZEISS, Germany), at 3Kv, to obtain surface images using detectors SE/InLens (secondary electron detectors), depending on the information we needed. Samples were metallized with iridium to work in high vacuum.

Results and Discussion

All the pathogens formed biofilms on tanks surfaces under culture conditions.

Biofilms, assemblages of microorganisms attached to a surface, have ecological advantages versus individual cells (Davey and Toole, 2000): ability to acquire transmissible genetic elements at accelerated rates, acquisition of antibiotic resistance, virulence factors, and environmental survival capabilities. Biofilm-associated cells are more resistant to many toxic substances such as antibiotics, chlorine and detergents (Watnick and Kolter, 2000).

Therefore, biofilm formation should be taken into account as a pathogen resistance strategy in aquaculture facilities. In fact, Vibrio ostreicida PP-203 was isolated from tank surfaces in the nursery during recurrent mortality episodes when cultured bivalves reached post-larval stage (Prado, 2007), which could be explained by these structures and the re-emergence of the pathogen. The formation of vibrios biofilms has also demonstrated in phytoplankton tanks has also been demonstrated, recolonizing the microalgal mixture even after the source was eliminated (Prado et al., 2019). In the case of bivalve hatcheries, successive cultures of different species in tanks and the lack of specificity of larval pathogens, make the fact of persistence and re-emergence a high risk for production.

The ability of all the pathogens tested points out the need to consider these structures as a potential hazard in aquaculture production and, therefore, should be included as a target for cleaning protocols.

Introduction
Aquatic foods, increasingly recognized for their key role in food security and nutrition, have reached an all-time record of 214 million tonnes of production (EUMOFA, 2022). However, 30-35% of fish production is being wasted globally, mainly due to their perishability (FAO, 2002). There is a market demand for safe and healthy seafood products with longer shelf-life but also high sensory quality. Osmotic dehydration is a low-energy-consuming, mild treatment that has been proven to extend fish shelf-life (Tsironi et al., 2009; Alexi et al., 2020). The current study explored the effects of mild processing for shelf-life extension of gilthead seabream fillets stored at 2°C in two markets, Greece (GR) and Denmark (DK).

The study aims to evaluate consumer hedonic responses and associate those to the perceived sensory characteristics of the fillets from a consumer perspective to uncover country-specific hedonic drivers and barriers. Furthermore, it is being investigated whether consumers’ background characteristics, such as sociodemographic, fish consumption habits and attitudes affect liking and sensory perception.

Materials and methods
The study was conducted in GR and DK, with approximately 80 consumers per country. The samples were prepared and served under the same conditions. The fillets sampled for the consumer study were for the Control fillets D1 and D6, and for the Treated (via osmotic dehydration) fillets D1, D6 and D9 of commercial shelf life (corresponding to 1, 6 and 9 days of chilled storage, respectively). Liking was evaluated for each sample via the 9-point hedonic scale (anchored “Dislike extremely” to “Like extremely”, with a neutral middle point), subsequently the consumers were asked to provide quick profiling via the Check-All-That-Apply (CATA) sensory method. Besides the hedonic and sensory responses measured, at the end of the survey the consumers were also asked about sociodemographic as well as attitudinal and behavioural information regarding fish and shelf life. Additionally, the effect of mild processing on the fillet’s quality was determined by microbial enumeration including total viable counts, *Pseudomonas* spp. and *Enterobacteriaceae*.

Results
Examining the results combing the profiling via CATA and hedonic responses, the consumers in the two countries showed different hedonic drivers and barriers, which were specifically associated with sensory characteristics that they perceived on a country basis in the fish fillets. On a country level, the Greek consumers did not discriminate their hedonic responses based on the treatment but mainly on the level of freshness. On the other hand, the Danish consumers preferred the osmotically treated fillets. Besides the differential liking responses, the consumers in the two countries used different attributes to describe the sensory characteristics of the samples, especially for the Control fillets as well as Treated D9 fillets. In specific, for the Greek consumers the Control fillets were associated with marine flavour and juicy texture whereas for Danish ones with bitter and metallic taste; in their turn these can be perceived as positive and negative characteristics acting as hedonic drivers and barriers, respectively.

Discussion
A clear hedonic driver for Greek participants is marine flavour which is perceived in the Control fillets only in Greece, whereas for the Danish participants, hedonic driver is the umami taste that is perceived mainly in the osmotically treated fillets, and only in Denmark. The observed cross-cultural differences can be associated with familiarity with the species as well as culinary traditions and fish consumption patterns and indicate a high potential for the treatment in the Danish market.

Introduction
Seafood products, increasingly recognized for their key role in food security and nutrition, have reached an all-time record of 214 million tonnes of production (EUMOFA, 2022). However, high perishability of fish and seafood products calls for novel processing and packaging methods (Tsironi et al., 2018). As safety and freshness is considered a priority for fish production and consumer acceptability (Chun et al., 2014), the development of novel technologies and systems intended to ensure safety and continuously monitor quality and shelf life at (Kerry et al., 2006). Smart packaging consists of systems capable of providing consumers and stakeholders with information regarding food quality from production up to the consumption (Mohebi et al., 2015). In such a way, freshness of fish can be monitored during transportation, retail display, and domestic storage (Kerry, 2012). The development of smart materials would also contribute to the seafood waste reduction which accounts for 30-35% of total fish production (FAO, 2022). The aim of the study was to design a biodegradable smart packaging system for the evaluation of fish freshness via a pH-sensitive colour response. The application of the developed smart system on gilthead seabream (Sparus aurata) fillets during storage at refrigerated conditions was evaluated.

Materials and methods
The pH-sensitive indicator was prepared by the incorporation of methyl red dye in a starch-cellulose paper. In order to evaluate the sensitivity of the fabricated indicator to the ammonia vapor, ammonia sensitivity test was performed according to Zwang et al. (2019) using NH₃ solutions with concentrations varying from 0.002 -1 M. This test was acquired to show the potential of color response toward the volatile nitrogen components such as total volatile basic nitrogen (TVB-N), which are produced in different amounts during fish spoilage. Color response performance of pH-sensitive indicator was evaluated at different pH values at a range of pH from 2 to 9. L,a,b values were measured and ΔΕ (total color difference) was calculated. With ΔΕ>3, the color change was visually observed (Sailer et al., 2014). Application of the indicator into the fish packaging was performed by sticking the indicator inside the headspace of sterilized packaging sealed bags containing 50 g of gilthead seabream fillet. The bags were stored in 4°C for 10 days for shelf life evaluation. Chemical and microbiological attributes of fillets and ΔΕ values of the indicators assessment followed. pH, TVB-N content, packaging gas composition and total viable count (TVC) enumeration were performed in duplicate on each day of storage.

Results
Examining the results of the NH₃ sensitivity test, the sensitivity of the fabricated indicator increased progressively with time (0-24 min) and reached the highest sensitivity value of 35.2% at 24 minutes of exposure to ammonia solution 0.02 M. Regarding the color response test, the indicator appeared red-dark pink at pH values 2-4, turned light pink at pH values 5-6 and finally changed to light orange-yellow at pH values 7-9, exhibiting its capability to identify changes in pH (ΔΕ>3). The initial TVC of fish samples was 3.6 log₁₀ CFU/g (day 0) and the threshold TVC value of 7 log₁₀ CFU/g was exceeded at day 7 of storage. The color of the indicator changed during storage at 4°C from red-dark pink (day 0) to light pink-light orange (day 7). ΔΕ (total color difference) values of the indicator increased and reached the value of 17 (ΔΕ>3) at day 7. Nitrogen concentration within the sealed package increased from 79.25% at day 0 to 89.05% at day 7. pH of fish flesh exhibited a decrease from 6.73 (day 0) to 6.37 (day 3) and subsequently increased to 6.66 at day 7.

Discussion
Preliminary results indicate that the fabricated smart indicator based on methyl red dye and starch-cellulose paper showed satisfactory change of color in contact with various pH buffer solutions, ammonia vapor concentrations and spoilage of fish. Further experimental procedures (e.g., smart film stability, morphology analyses etc.) would lead to the development of an integrated smart packaging system for continuous monitoring of fish freshness in the actual supply chain.

Introduction
Insect meal (IM) has demonstrated an enormous potential as an alternative protein source to fishmeal (FM) in diets for European sea bass (Dicentrarchus labrax) (Basto et al., 2021 and 2022), one of the most important marine fish species in Mediterranean aquaculture. However, when IM is included at high levels to totally replace FM, alterations in the intermediary metabolism of sea bass are observed, which may compromise the health status of fish (Basto et al., 2023). In this connection, the impact of total FM replacement by an IM on the innate immune parameters and oxidative stress of European sea bass was assessed.

Material and methods
A FM-based diet with 47% of protein and 20% of fat was formulated and used as a control (CTRL). Two other isoproteic and isolipidic diets were formulated to replace 50 and 100% of FM by defatted Tenebrio molitor larvae meal (TM50 and TM100, respectively). Each diet was assigned to quadruplicate homogeneous groups of 15 fish (69 ± 5 g) that were fed until apparent satiation for 16 weeks. Fish were subjected to a 12-hour light/12-hour dark photoperiod regime and kept in a recirculating saltwater system (35‰, 22 ± 1 °C). By the end of the trial, 3 fish per tank (12 per dietary treatment) were sampled for analysis of health status-related parameters, and other 3 fish per tank were exposed to an acute stress episode consisting of 1 min air exposure followed by 1 h of recovery before sampling. Hematologic profile analysis (i.e., hemoglobin, hematocrit, and red and white blood cells), plasma metabolites (i.e., cortisol, lactate, and glucose) and immune parameters (i.e., total peroxidase, lysozyme, and alternative complement pathway activities), and hepatic oxidative stress (i.e., catalase, superoxide dismutase, and glutathione reductase, S-transferase and peroxidase) were evaluated in all fish sampled.

Results
A clear response to acute stress was observed, regardless of dietary treatment, by a significant decrease in hemoglobin, hematocrit and red blood cells, and a significant increase in almost all evaluated humoral parameters. On the other hand, the activity of total peroxidase and superoxide dismutase was significantly affected by the dietary treatments, being highest in fish fed TM100, but not affected by stress condition. Considering the canonical discriminant analysis, a clear separation between non-stressed and stressed fish was evidenced (Fig.1A). Based on the significant Mahalanobis distance of each group multivariate mean (centroid), it was possible to observe that both non-stressed and stressed fish fed TM100 were significantly different from those fed CTRL and TM50 (Fig. 1A). Non-stressed fish fed TM100 were positively loaded by hematocrit and red blood cells (Fig. 1B), whereas stressed fish fed the same dietary treatment were positively loaded by glucose and lactate levels, as well as by mean corpuscular volume (Fig. 1B).

Discussion and conclusions
The results of the present study demonstrated that the partial substitution of FM by IM did not affect innate immune parameters and oxidative stress of sea bass. Contrarily, total FM replacement by IM seems to compromise fish health status. The increased total peroxidase activity and superoxide dismutase, associated with a trend to higher glucose and lactate levels in fish fed TM100, indicate a counteraction to the excess of superoxide radicals and mobilization of fish energy reserves to overcome the stress condition. To better understand the impact of FM replacement by IM on fish immune response and oxidative stress it would be of high interest to deepen knowledge on their underlying mechanisms upon other challenging rearing conditions (e.g., pathogen exposure, chronic stress).

Introduction

The European project AQUA-FAANG (https://www.aqua-faang.eu/) has the primary goal of elucidating mechanisms of genomic regulation in the most commercially important fish species in European aquaculture. This includes two salmonids, Atlantic salmon (Salmo salar) and rainbow trout (Oncorhynchus mykiss). We generated extensive standardized functional genomic data in both species, specifically RNA-Seq, ATAC-Seq, and ChIP-Seq spanning 14 developmental stages and 8 tissue types. This data was used to construct genome-wide regulatory annotations for both species, allowing us to explore both conserved and divergent genomic regulatory features, including in relation to the salmonid-specific whole genome duplication (ssWGD) event that occurred ~100 million years ago (Lien et al. 2016; Gundappa et al. 2022). Our results provide novel insights into the expression and transcriptional regulation of duplicated genes, transcription factor binding site (TFBS) usage and Hox gene cluster evolution.

Methods

We used ChIP-seq to detect histone profiles (H3K27ac, H3K4me1, H3K4me3, H3K27me3) and ATAC-seq to measure chromatin accessibility. We integrated the data from these assays with ChromHMM (Ernst and Kellis, 2012) to characterize chromatin regulatory states across the genome. From this, we annotated twelve chromatin states common between Atlantic salmon and rainbow trout and for developmental stages (late blastulation, mid gastrulation, early, mid and late somitogenesis) and adult tissues (brain, liver, muscle). By using gene tree and synteny information, we identified ohnologs (duplicates resulting from the ssWGD) and ortholog relationships between Atlantic salmon and rainbow trout. Streamlining this information to a list of 2:2 ohnologs genes (Atlantic salmon/rainbow trout tetrad, where both genomic copies of the same gene is conserved in each species), we investigated gene expression differences by clustering the gene expression of each tetrad. GimmeMotif (van Heeringen & Veenstra, 2011) was used to reveal enrichment in TFBS usage and Hox gene cluster evolution.

(Continued on next page)
Results

After characterizing chromatin states of Atlantic salmon and rainbow trout, we focused on promoter and enhancer regulatory elements. Enrichment of TFBS in these regions revealed that active enhancer regions exhibited 141 common TFBS across species, and 46/53 species-specific TFBS. Conserved vertebrate TFBSs including POU5F1, Sox and Hox were identified for both species during developmental stages, alongside conserved TFBS specific to particular tissues, e.g. NRF1 for brain, PPARG for liver or MEF2B for muscle. These findings illustrate an overall conservation of TFBS usage for both salmonids. Clustering of expression of ohnolog-tetrads revealed five distinct categories of genes. A subset of genes fell into the category where both copies of the same species is expressed differentially compared to the copies of the other species. Moreover, a group of ohnolog-tetrads displayed similar expression patterns between both species, with either both copies being co-regulated or either only one copy in each species. We anticipate that gene expression differences are associated with differences in regulatory activity of chromatin. By exploring the gene expression profiles of the different Hox genes cluster in both Atlantic salmon and rainbow trout, we observed that despite the duplication of all the clusters, the transcription of each of the copies were maintained, with the exception of the HoxA-b copy, which appeared to be lost in rainbow trout, and is evidently on the path to pseudogenization in Atlantic salmon.
EDUCATION AND TRAINING IN AQUACULTURE: DEVELOPING SKILLS IN THE AUSTRIAN FISHERIES SECTOR

C. Bauer, D. Achleitner and F. Keil

Federal Agency for Water Management
Institute for Aquatic Ecology and Fisheries Management
5310 Mondsee, Scharfling 18, Austria
E-mail: office.igf@baw.at

Introduction
The aquaculture sector in Austria is relatively small compared to other sectors in Austrian agriculture, making it one of the smallest within the EU. In 2021, the total production of food fish in Austria reached 4,920 metric tons, as reported by Statistics Austria. This sector is primarily categorized into three major forms of production: salmonid farming, carp pond farming, and production in recirculating aquaculture systems (RAS). Despite its modest size, the Austrian aquaculture sector can rely on a fundamental basis of training and education, which is based on blended learning with a mix of face-to-face classes, practical lessons, and online and self-learning elements. The lectures are delivered by professionals from various fields, including economics, veterinary medicine, jurisprudence, and experienced practitioners. The vocational training in aquaculture primarily consists of three main components, offering comprehensive knowledge and skills to aspiring professionals in the field.

Skilled Worker in the Fishing Industries
The education is modular and can be completed within three years. The program covers topics such as salmonid aquaculture, carp pond farming and RAS, fish biology, lake management, freshwater ecology, fish health, and hydrology. The education in the special field of fisheries is conducted on behalf of the “Lehrlings- und Fachausbildungsstelle” of the Board of Agriculture for people throughout Austria. Subject-specific lessons take place at the institute in Scharfling, while general lessons and fish processing are conducted at the “abz Salzkammergut” in Altmünster. Similar to other professional guilds, the fisheries instruction follows a dual system, requiring apprentices to attend school in addition to their employment. The seven modules are conducted in rotation, allowing access to each module. The participants graduate after an exam by an examination board.

Master Craftsman – Master in Fisheries
On behalf of the Agricultural and Forestry Apprenticeship and Technical Training Center Upper Austria, fishery management master courses are centrally conducted for all of Austria at the Federal Office for Water Management. The 2.5-year training is modular, and entry is only possible for a complete module rotation. In addition to deepening fishing industry expertise, the training focuses on business and corporate management. Independent of the technical courses, the modules Instructor Course and Law & Agricultural Policy can be completed separately, with offerings available in all federal states of Austria. The individual modules are completed with an examination (written/oral). At the end of the training, there is a 5-hour written exam. A core element of the master craftsman training is the independent preparation of a master thesis in the specialist area of fisheries management, which is presented as part of a master craftsman examination before a commission.

Continuing Education and Basic Training
For individuals interested in aquaculture who do not wish to complete the skilled worker course, there is the option to join a basic training course. These courses consist of 40 hours and provide insights into the major concepts of fish production. The course is available for salmonid farming, carp pond farming, or RAS.

Further Information
For additional information on education and training in aquaculture in Austria, please visit https://www.baw.at/en/fish-and-water/education-and-training.html.
DEVELOPING A METHOD TO USE THE SETTLING VOLUME OF ZOOPLANKTON AS EASY CONDUCTIBLE MEASUREMENT FOR THE NATURAL FOOD AVAILABILITY FOR COMMON CARP (*Cyprinus carpio*) IN PONDS

C. Bauer, G. Gratzl, M. Fichtenbauer, K. Schlott, G. Schlott and E. Peham

Federal Agency for Water Management
Institute for Aquatic Ecology and Fisheries Management
Ecological Station Waldviertel
3943 Schrems, Gebharts 33
E-mail: oeko@baw.at

Introduction
Common carp (*Cyprinus carpio* L.) bred in extensive carp pond farming in Austria rely on the natural food (zooplankton and benthic invertebrates) occurring in the ponds. The natural food, especially the zooplankton, provides the fish essential fatty acids and proteins (Dabrowski & Rusiecki 1983; Tocher 2003; Steffens 2011). In good managed carp ponds, the zooplankton genera evolve coherent with the life-stages of the carp. Carp fry mainly feeds on ciliates and rotifers, while adult carps feed on larger zooplankton genera, such as *Daphnia sp.* (Šusta 1887; Wunder 1968; Adámek et al. 2023). For good water quality and economically management, it is advisable to use additional feed, such as grains, as needed instead of following feeding plans given in the literature. As it is very difficult for carp pond farmers to assess the amount of zooplankton in the pond, we have been working on an easy way for measuring the zooplankton in situ..

The Settling Volume
To determine the right amount of additional grain feed it is essential for the carp farmers to measure the given amount of zooplankton (Schlott-Idl 1991). Thus, they can adjust their feeding strategy in such a way as the carp get a balanced diet and both, insufficient utilization and overexploitation of zooplankton are avoided. It is commonly known that fish has a major impact on the zooplankton populations in the pond (Hrbaček 1962). By balancing the amount of grain feed, predation on the zooplankton can be regulated (Steffens 2011). The first experiments to use the settling volume (SV) of large zooplankton (>1 mm) as measurement technique for the natural food amount for carps have been conducted in Austria in 1984. *Daphnia* can be sampled relatively easy, by using a 500 µm net. As they are especially important for adult carp diet, it makes sense to sample only larger zooplankton and disregard smaller ones.

To assess the SV, 5 L water samples on four different places at 0.5 m depth are taken from the pond with a Schindler trap. As already mentioned, we use a plankton net with a patch of 500 µm net on the bottom to catch only daphnia. After flushing the smaller plankton out, the daphnia are concentrated in the cod end. The zooplankton is killed with 20% formaldehyde and flushed into a volumetric tube with distilled water. After a short settling time the SV can be easily read from the scale on the tube. Schlott & Schlott (2001) showed that an abundance between 20 and 40 daphnia per liter can be considered as good amount for a stable population. Our research showed, that this abundance of daphnia has a SV between 0.2 and 0.55 ml. According to the SV, carp pond farmers can adjust their feeding strategy, what enables reduction of costs and needles nutrient input into the pond.

In contrary to the longsome commonly used way of counting zooplankton under the microscope, this method of measuring the amount of daphnia is an easy and practical way for every carp farmer to assess the stability of the zooplankton population. As the zooplankton is the major source of essential fatty acids and proteins (Dabrowski & Rusiecki 1983; Tocher 2003; Steffens 2011) and the additional grain feed provides the fish carbohydrates, a well-balanced diet containing these food sources guarantees healthy fish and in the end a high quality product.

Introduction
Carp farming has been practiced in Austria since the 12th century, with a peak in the 16th century. Today it is concentrated in north-western Lower Austria (NUTS 3 region: Waldviertel) and southern and eastern Styria (NUTS 3 regions: Oststeiermark and Süd- und Weststeiermark). Ponds are important elements of the cultural landscape, but as the cultural landscape changes over the centuries, ponds disappear and reappear over time. Ponds play an important role in the landscape. They replace lost small water bodies, increase biodiversity and serve to retain and provide water in the landscape. With this in mind, it is worth looking back historically to explore the potential for restoring or revitalising old ponds.

Material and Methods
Digital georeferenced maps of the entire Austrian territory in WMTS format are available free of charge at www.basemap.de. Digital georeferenced historical maps in WMTS format (e.g. Franziszeischer Kataster 19th century) are partly available free of charge via the federal provinces (e.g. Styria) or for a fee via the map service www.mapire.eu. On the basis of this map material, selected areas in the three NUTS 3 regions mentioned above were investigated with regard to their current and historical stock of ponds. In addition, one area in the NUTS 3 region Weinviertel was included in the study. The data were processed with the free open source software QGIS (www.qgis.org).

Figure 1: Historical map of Eastern Styria from the 19th century, supplemented by the current situation of the ponds (outlined in red). Data of the current ponds: Umweltbundesamt GmbH, CC-BY 4.0; Map source: Franziszeischer Kataster, Steiermärkisches Landesarchiv, CC-BY 4.0; Map created with QGis, BAW-IGF, 2023

(Continued on next page)
Results and Discussion

The evolution of the number of ponds can vary considerably from region to region. While in some parts of the NUTS 3 region Waldviertel the number of ponds has not decreased dramatically since the 19th century (e.g. municipality Litschau -3 ponds), the losses are higher elsewhere (e.g. municipality Schrems -12 ponds). In the municipality of Seefeld-Kadolz in the NUTS 3 region Weinviertel, not only have ponds been lost since the 18th century, but the remaining ponds have only a fraction of their original area. In most cases, the reason for the disappearance of ponds is a change in land use. For example, sheep or arable farming have replaced fish farming. In the NUTS 3 region of Eastern Styria there is a good example of how a still existing carp pond farm has changed since the 19th century (Fig. 1). In the 19th century the pond economy consisted of 8 larger ponds, today 3 of them have completely disappeared, while originally 2 ponds became a total of 6 ponds due to the construction of dams. In addition to showing the changes in the cultural landscape, the analysis of historical maps and current geography also allows the identification of former ponds that could be reconstructed, especially in the light of efforts to increase aquaculture production. In the Waldviertel region there are indeed examples of planned or realized re-establishment of ponds that have been abandoned since the 19th century.
PROACTIVE AND NON-INVASIVE PATHOGEN DIAGNOSTICS TO PREVENT THE SPREAD OF *Bonamia ostreae*

Tim P. Bean¹*, Lavanya M. Vythalingam¹, William G. Sanderson², Nuala Hanley² and Tim Regan¹

² Institute of Life and Earth Sciences, School of Energy, Geoscience, Infrastructure and Society
Heriot-Watt University, Edinburgh, United Kingdom
E-mail: tim.bean@roslin.ed.ac.uk

The haplosporidian parasite *Bonamia ostreae* is one of the biggest issues facing European native oyster, *Ostrea edulis*, aquaculture and restoration. Measures to stop the spread of diseases in the United Kingdom have to date relied on the prevention of animal movement from disease positive to disease-free sites. However, these measures are not entirely successful and have seen recurrent failures in recent years, resulting in the gradual spread of *B. ostreae* across the UK. We tested the utility of protocols for pro-active pathogen diagnostics, combining a portable qPCR machine and field DNA extraction protocols with our experience detecting pathogens in disease challenge systems. We used a stepwise process of overnight incubation, sampling of substrates from the tank system, simplified DNA extraction and rapid diagnostic of the presence of DNA. Here we will present the concept of fully useable system that can be employed on the site of the shellfish farm. The process is now validated against a set of traditional diagnostic techniques including tissue qPCR and histopathology. This rapid, cheap and simple process allows native oyster farmers and restoration practitioners to make proactive decisions on whether to move animals, based on their up-to-date health status, and thus take full control of the risks associated with animal movement.

Figure 1. Schematic of protocol for non-invasive diagnostic process.
MariFish Inc: INCUBATOR AND LIVING LAB TO SUPPORT START-UPS IN SUSTAINABLE SEAFOOD PRODUCTION

S. Becaus1,* and M. Drouillon2

1 European Food Center, Noordzeestraat 201, 8380 Zeebrugge
2 BLUEGent, Ghent University, Coupure Links 653, 9000, Gent, Belgium
*E-mail: s.becaus@vlvis.be

MariFish Inc. is a newly established living lab and incubator for start-ups in the fields of aquaculture and innovative fishery located in Ostend, Belgium. More specifically, MariFish Inc. brings together entrepreneurial expertise with the commercial support of the Flemish fish auctions. In addition, it is backed by several scientific institutions with a strong track record in aquaculture (Ghent University) and innovative fisheries techniques (ILVO). It offers dedicated, flexible, food safety compliant growing space for aquafarmers and supplies large quantities of good quality sea water, ready to use. In addition, there is the option of extensive lab support for the tenants and participants of the incubator. As such, this new initiative aims at lowering the entrepreneurial risk for newly established aquaculture ventures.

Initially, the incubator and living lab target the incubation of start-ups active in sustainable seafood production, for example:
* Onshore farming of seaweed, fish, crustaceans and shellfish
* Onshore processing of mariculture production at sea, e.g. making ready to sell mussels/ oysters
* Watering of mariculture products
* Supporting technology to carry out the three previous activities
  (quality monitoring, big data, sensor technology, intelligent packing)

In the longer term, the activity domain will be extended to the biorefining of marine products such as e.g. products or molecules refined from marine raw materials or aquaculture products (e.g. from seaweed).
Introduction
The cardiac morphology of Atlantic salmon (Salmo salar L.) is known to exhibit phenotypic plasticity. Various factors, including environmental changes, production pressure, general health and life stage, contribute to altered morphology. The impact of such morphological changes on cardiac function, resulting from both biotic and abiotic factors, remains poorly understood.

Given the likely correlation between cardiac morphology and function, we investigated the impact of key morphological traits, such as ventricular shape and alignment of the bulbus arteriosus, on cardiac function.

Materials and methods
We employed in vivo echocardiography to assess cardiac function and utilized quantitative and qualitative morphological analyses to evaluate cardiac structures ex vivo. Cluster analyses and partial regression analyses were applied to examine the influence of distinct morphological traits on cardiac function.

Results
Initial qualitative assessment revealed large variability in the skewing of the bulbus relative to the long axis of the ventricle. Quantitative analysis indicated that a larger ventricular bulbus angle was linked to reduced systolic function, including lower cardiac output. Hearts with modest skewing of the bulbus presented with a lowered E/A ratio. Variable extension of the dorsal ventricular base was also noted and linked to systolic function. Indeed, greater extension of the ventricular base, measured as the angle of deviation from the heart’s transverse axis, was associated with lower cardiac output.

Conclusion
In conclusion, we believe that the morphological variability of the Atlantic salmon heart is a key determinant of cardiac function and performance.
**Introduction**

Broodstock nutritional programming improves the offspring utilization of plant-based diets in gilthead sea bream through changes in lipid metabolism. Attention was initially focused on fatty acid desaturase 2 (fads2) (the first and rate limiting step in the biosynthesis of n-3 long-chain polyunsaturated fatty acids, LC-PUFA), and selective breeding for enhanced fads2 expression in broodstock fish improved the offspring utilization of plant-based diets (Xu et al., 2021). Otherwise, de novo fatty acid biosynthesis of mono-unsaturated fatty acids offers the possibility to mitigate the signs of deficiencies in n-3 LC-PUFA, and the broodstock nutritional programming with a diet rich in α-linolenic acid served to maintain regulated the enhanced expression of scd1a (stearoyl-coenzyme A desaturase) in the gilthead sea bream offspring through changes in DNA-methylation (Perera et al., 2020). How such regulatory processes can be driven by a different genetic background is hardly underlined, and the present study aimed to assess how broodstock nutrition affects differentially the offspring transcriptome and genome-wide DNA methylome of reference and genetically selected fish for growth.

**Material and methods**

Gilthead sea bream brood fish belonging to reference (REF) or genetically selected (GS) fish within the PROGENSA® selection program received a diet with low fish oil content during the stimulus phase. Two 5-month old offspring subsets of each genetic background were fed either a control (15% fish meal and 5.7-7.6% fish oil) or a FUTURE (7.5% fish meal and completely devoid of fish oil) diet for about 6 months (challenge phase). At the end of the trial, 6 juvenile fish per each experimental condition were anaesthetized and liver samples were taken for wide-analyses of gene expression (RNA-seq) and DNA methylation, using methyl-CpG-binding domain sequencing (MBD-seq) for a large coverage of the CpG methylome.

**Results and discussion**

The offspring of GS fish shared a better performance than those of REF animals during the challenge phase, and differences due to diet (with improved values with the control diet) tended to be lower in GS lineage. Data highlighted a different hepatic transcriptome (RNA-seq) and genome-wide DNA methylation (MBD-seq) pattern depending on the genetic background, which agrees with previous studies in fish (Liu et al., 2022). The number of differentially expressed transcripts (comparing control and FUTURE diets) following the challenge phase varied from 323 in REF fish to 2,009 in GS fish. The number of transcripts of discriminant value by multivariate analysis, and associated enriched functions (Gene Ontology-Biological Process, GO-BP, terms), were also markedly higher in GS fish. Moreover, after selecting differentially methylated (DM) regions with an opposite trend for DNA methylation and gene expression, correlation analysis depicted a hyper-methylated and down-regulated gene expression state in GS fish challenged with the FUTURE diet, whereas the opposite pattern was found in REF fish (Figure 1A). Thus, the resulting epigenetic clock of the latter animals might represent an older phenotype (Piferrer and Anastasiadi, 2023). Moreover, after filtering for functions with a high representation in GS fish, 115 genes were retrieved as epigenetic markers nutritionally regulated in this group of fish (Figure 1B). Among them, genes within the GO-BP term Lipid metabolic process (23) were the most reactive following ordering by gene expression fold-change, which rendered a final list of 10 top markers with a key role on hepatic lipogenesis and fatty acid metabolism (cad36, ptpna, cidea, fasn, g6pd, lpl1, scd1a, acsb2, acsl14, acsb2g). These top 10 genes also showed a greater concentration of DM CpG sites in the promoter region. Down-regulation of most of those genes agrees with the initial statement that the epigenetic regulation of gene expression due to nutritional programming may preclude an over-expression of specific genes that might result counterproductive in a changing environment.

(Continued on next page)
Concluding remarks

Gene expression profiles and DNA methylation signatures following nutritional programming were clearly dependent on genetic background in our experimental model. Such assumption affected the magnitude, but also the type and direction of change. Accordingly, the resulting epigenetic clock of REF fish might depict an older phenotype with a lower DNA methylation for the epigenetically responsive genes with a negative methylation-expression pattern. That means that epigenetic markers will be specific of each genetic lineage, serving primarily the broodstock programming in our GS fish to prevent and mitigate later in life the risk of hepatic steatosis due to an exaggerated and/or poorly regulated hepatic lipogenesis when fish facing low fish oil diets.

Introduction

Aquaculture production is a promising way to provide seafood for the rapidly increasing human population. Catfish species are becoming more popular in the Central and Eastern European region, as their bone-free, high-quality, lightly colored fillets represent an improved quality for the carp-dominant (*Cyprinus carpio* L. 1758) production structure of the region. According to experts, the production volume of the European catfish (*Silurus glanis* L. 1758) can be increased by orders of magnitude using improved lines and technological innovations.

Materials and methods

Our program – is based on collaboration by several Hungarian research institutions - aims to select elite European catfish lines with increased robustness and higher tolerance towards poor water quality or infectious diseases. This work is supported by genetic and genomic platforms, including parent-sibling identification by polymorphic microsatellite markers and will include comparative analysis of transcriptomes using high throughput sequencing.

Results

Currently, the F2 generation of the selected lines are being analyzed and preparing for off-seasonal artificial propagation to produce the F3 generation. Our results show that the average mass performance and the specific growth rate (SGR) both increased by 91% and 11.4%, respectively, when compared to unselected controls. Moreover, the coefficient of variation (CV %) and the feed conversation ratio (FCR) dropped in F2 by 19.5% and 14%, respectively.

In parallel with the selection process, we are also testing culture technologies tailored to the needs of faster growing selected lines.

Funding

The work was supported by the European Regional and Development Fund and the Government of Hungary within the project GINOP-2.3.2-15-2016-00025; and by the National Research, Development and Innovation Office of Hungary through its Frontline Research Excellence Grant (KKP 140353).
RAPID, COST-EFFECTIVE SNP GENOTYPING USING STANDARD BIOTOOLS SNPTYPE ASSAYS AND X9 REAL-TIME PCR SYSTEM

Roberto Spada, Jordan Moore
Cecile.Freby@standardbio.com

The use of single nucleotide polymorphism (SNP) genotyping with non-model organisms—those whose genomes are yet to be sequenced—has increased in importance as it provides robust, comparative data sets that can be easily shared across organism communities for a variety of purposes. Non-model organisms have the added burden of low available genomic sequence information requiring custom SNP assay development. Until recently, SNP genotyping technologies have been prohibitive to these communities due to the high cost of developing and running quality SNP genotyping panels. Standard BioTools SNPTypeAssays and the X9 Real-Time PCR System have addressed these barriers with a custom assay design service, cost-effective and high quality SNP assays, and a high-throughput workflow minimizing hands-on time. The salmon research community has been specifically hampered by the cost barriers, and would benefit from the technology for conservation and management purposes. Using chum salmon (Oncorhynchus keta) as an example, we describe a simple workflow using Standard BioTools SNPTypeAssays, the X9 System, and 96.96 Dynamic Array™ Integrated Fluidic Circuits (IFCs) for Genotyping to achieve cost-effective and rapid development of a SNP genotyping panel. Moreover, SNPTypeAssays provide significant cost savings for high-throughput, routine testing post panel development.
COMPETITION FOR SPACE FOR OFFSHORE WIND AND AQUACULTURE WITH OTHER SECTORS AND MARINE PROTECTION IN THE NORWEGIAN ZONE

Introduction

The coming era for the blue economy will be shaped by humanity’s pressing need for sustainable energy and food, but any industrial expansion must take place in a safe, secure, and equitable manner. This requires careful study of the impact each industry has on its environment and on local communities, considering the cumulative effects from all industries combined. The MARine CO-existence scenario building (MARCO) toolbox will combine spatial and temporal analysis to capture this complexity, and the combined analysis address key uncertainties, barriers, and opportunities to deal with future spatial conflicts and to safeguard ocean health. The spatial analysis will utilise GIS (Geographic Information System) technology for mapping out plausible development trajectories in selected regions to link and explore implications to marine ecosystems and vice versa. The temporal analysis using system dynamics (SD) modelling links economic development with impact on nature through clearly devised causal relationships and feedback loops. To account for the lack of knowledge about key effects on ecosystems from e.g. offshore wind and/or offshore aquaculture development, consideration of uncertainty will be important and will contribute to a reduction of the trust gap among ocean stakeholders. Examples of scenario building and incorporation of ecosystem-wide and socio-economic information will be presented.

The Norwegian Government has recently opened two major areas in the Norwegian zone of the North Sea for offshore wind, Utsira Nord and Sørlige Nordsjø II. (Anon. 2023) Apart from providing more renewable energy, part of the rationale is to gain experience on the environmental impact and possible conflicts and synergies with other sectors. An auction for permits to establish offshore wind parks in this area is presently ongoing (Figure 1).

Even more recently, in April 2022, the Norwegian Water Resources and Energy Directorate has published a list of areas which could be suitable (Figure 1). However, in these areas, analysis of possible conflicts are probably still premature. The Government upholds a goal of installing 30 GW effect, equivalent to producing 100 TWh/year by 2040 from offshore wind in the Norwegian sector.

Furthermore, the Government has opened three areas for evaluation offshore aquaculture. Here, no auction has yet started, and the areas are to be further evaluated. There are still no plans for multi-use of areas in the Norwegian zone.

An extensive mapping of particularly vulnerable areas is presently ongoing (Eriksen et al. 2021). For instance, coral reefs and sponges has been mapped (Figure 2). Furthermore, data on spawning grounds and migration areas for juvenile fish has been mapped. These data, which are continuously updated, will contribute to the ongoing Marine Spatial Planning.

Introduction
The coming era for the blue and green economy will be shaped by humanity’s pressing need for sustainable energy and food, but any industrial expansion must take place in a safe, secure, and equitable manner. Offshore activities in aquaculture, offshore wind, and existing fisheries, transport and oil & gas activities are expected to increase competition for ocean space, but collaboration on for example environmental monitoring could mean synergies. We are developing a small-scale smart ocean experimental ocean observatory where real-time environmental monitoring by a range of sensors, could be combined with wireless underwater communication. By realization of “an underwater internet of things” dramatically improved environmental monitoring can be foreseen, aiming to improve synergies among sectors, as well as environmental protection.

Details of the project
SFI Smart Ocean is a center for research-based innovation to enhance the ability of industry innovation and value creation through a greater focus on long-term research. The center is hosted by the University of Bergen, and consists of 20 partners from industry, public management and research, partly founded by the Research Council of Norway, running from 2020 to 2028.

The two sensor rigs have been in place at the facility since May 2022. They were from the outset equipped with an Anderaa Seabird SBE 37 Microcat and an Anderaa Sea Guard ADPC, the latter functions as the hub in the rig. In the surface unit, there are batteries and a GDSM sender unit, ensuring real-time communication. A third rig will be placed at the facility, adjacent to the aquaculture experimental sea cage facility. By these instruments, a range of physical and bio-physical parameters are monitored real-time, and made available to all the Centre’s partners as well as collaborators at the research station.

Development of the project
Development now is focused on underwater wireless communication means, testing a range of different acoustic modems. It is the intention of the Centre to develop the rigs to be increasingly autonomous. Whereas sensors in close vicinity to an aquaculture facility may easily be based on GSM or even cables, this will not be possible in deep-water environments of fjords or the open sea, or in areas such as for instance under the polar ice.

The research station will be used to develop such a multipurpose local-scale network of modular autonomous sensors, for monitoring of oceanographic environmental parameters, with candidate measurement parameters such as O₂, CO₂, gravity, gas leakage, pH, pressure, temperature, salinity, turbidity etc.

Key factors are highly cross-disciplinary: measurement parameters, flexibility and adaptive sampling in time and space, point measurements vs. monitoring over large areas, distributed measurements, measurement uncertainty and reliability, time history as input to big data analysis, machine learning, prediction and emergency response, data format aggregation and safety, increased up-time with predictive maintenance, combined with low power consumption and local sensor intelligence. Standardized interfaces will enable integration of a diversity of sensor types and communication measures, in particular wireless communication.

HIGHLY DIGESTIBLE PROTEIN SOURCE FROM BLACK SOLDIER FLY LARVAE MEAL (HILUCIA™) IN EUROPEAN SEABASS (Dicentrarchus labrax)

H. Bergoug*, O. Konoval A. Diana

Innovafeed SA, Paris France
Email: hakim.bergoug@innovafeed.com

Introduction
Aquaculture production has experienced rapid growth and is projected to continue expanding to meet the increasing demand for safe and healthy seafood. Nevertheless, the animal feed industry, particularly the aquafeed sector, faces challenges due to a shortage of conventional high-quality feed ingredients. To address this issue and meet the rising demand, sustainable sources of proteins and oils are necessary. Over the past decade, the Black Soldier Fly has emerged as a promising candidate in this regard.

An experiment was conducted to explore the viability of using black soldier fly larvae meal as a sustainable nutrient and energy source for European seabass (Dicentrarchus labrax). By assessing its digestibility in the fish, the researchers gained valuable insights into its nutritional value and potential advantages.

Material and methods:
An experiment was conducted to assess the Apparent Digestibility Coefficient (ADC) of nutrients and energy in black soldier fly larvae meal “Hilucia™” in European seabass. The trial included two types of diets: a reference diet (REF) that contained 0.05% yttrium oxide (Reis et al. 2008) as an inert digestibility marker, a TEST diet with 70% of the same basal mixture as the reference diet, and 30% of Hilucia™. Quadruplicate groups of 12 fish with a mean weight of 89 ± 5 g were kept in 45 L sub-square tanks at a constant temperature of 21 ± 1°C, and their feces were collected by decantation using the Guelph system.

Results and discussion:
It was found that the protein in Hilucia™ was highly digestible, with an ADC of 92%. This is in line with what was found in other studies (Magalhães et al. 2017). It provides a sustainable source of protein that can meet the nutritional requirements of European seabass. The study revealed that the fat and energy in Hilucia™ were also easily digestible, with an ADC higher than 93% and 89%, respectively. This means that BSF meal could potentially be used as an energy source in aquaculture feeds, in addition to its role as a protein source. The study found that the apparent digestibility of essential amino acids in Hilucia™ was high, with values exceeding 90% in most cases. This indicates that the protein fraction in BSF meal was highly digestible, apart from cysteine with ADC of 72%.

Conclusion:
Overall, the study concluded that Hilucia™ was a highly digestible source of protein, essential amino acids, fat, phosphorus, and energy for European seabass. The study provides important insights into the potential of BSF meal as a sustainable protein and energy source for aquaculture feeds. The high digestibility of nutrients and energy in BSF meal suggests that it could be an effective alternative to traditional feed ingredients, and further research could help to identify ways to optimize its use in aquaculture feeds.

THE EFFECT OF TWO DIFFERENT EXPERIMENTAL REARING TEMPERATURES ON THE QUALITY AND THE LARGE-SCALE CRYOPRESERVATION OF EURASIAN PERCH (Perca fluviatilis) SPERM

G. Bernáth1*, S. Milla3, L. Várkonyi1, Y. Ledoré3, J. D. Griffitts2, P. Fontaine3, B. Urbányi1, Z. Bokor1

E-mail: Bernath.Gergely@uni-mate.hu

Introduction
Eurasian perch is an important fish species for European aquaculture diversification, but the quality of reproduction still remains one of the main limitations for further industry development. In particular, the optimal condition to obtain the best quality of sperm is poorly understood. Cryopreservation is an efficient technique for the long-term storage of fish sperm (Bernáth et al. 2017). The establishment of sperm banks can support aquaculture production and conservation programs (Cabrita et al. 2010, Martínez-Páramo et al. 2017). In Eurasian perch, the available techniques are usually limited by the small sperm capacity that can be preserved (0.5 mL straws). However, larger than 0.5 mL straws or cryotubes have not been tested for perch sperm.

Materials and methods
The aim of our study was to measure the possible effects of two experimental rearing temperatures (6 °C and the conventionally used 12 °C) and of hormonal stimulation, on the motility parameters (pMOT, VCL, VSL, LIN, ALH, BCF), osmolality and fertilizing capacity of Eurasian perch sperm at the end of the reproductive cycle. A prior untested, large-scale (5 mL cryotube and Polystyrene box) cryopreservation method was implemented using fresh sperm obtained from the two above mentioned temperature groups. Males were injected with 100 µg body weight kg−1 sGnRHa. For cryopreservation, an extender formerly adapted for perch sperm was applied (137 mM NaCl and 76.2 mM NaHCO3, Szabó et al. 2005) at a ratio 1:10 (Bernáth et al. 2015).

Results
No significant difference was recorded between the two rearing temperatures and between the saline control and sGnRHa treated groups on the different features of sperm quality. A similar fertilization rate was monitored in all sGnRHa treated (6 °C: 69±13%, 12 °C: 81±11%) and saline control groups (6 °C: 79±10%, 12 °C: 87±4%). Correspondingly, no significant difference in hatching rate was observed in the sGnRHa injected (6 °C: 27±9%, 12 °C: 40±20%) and saline control (6 °C: 35±18%, 12 °C: 36±7%) males. However, a notable negative effect of freezing process on sperm movement was observed following thawing in both temperature groups. No significant difference in the motility parameters was measured between the two temperature groups following large-scale cryopreservation. Furthermore, a similar result was observed in the fertilizing capacity (6 °C: 79±10%, 12 °C: 75±8) of thawed sperm as well as in the hatching rate (6 °C: 52±13%, 12 °C: 46±19%).

Discussion and conclusion
Our findings suggest that perch sperm quality and fertilizing capacity is not affected by the reduced rearing temperature (6 °C) following hormonal injection in Eurasian perch, using fresh or cryopreserved sperm. Despite a lower motility, sperm obtained from the reduced rearing temperature can be cryopreserved successfully using 5 mL cryotube. However, the freezing and thawing process needs to be improved using the adapted preservation method. Thawed perch sperm (cryopreserved in 5 mL cryotube) can be adapted for the fertilization of higher amounts of eggs in future experiments.

Introduction
Inclusions of fish meal (FM) and oil (FO) from trimmings by-products and oil-rich microalgae (MIC) into aquafeed formulations, can advance sustainability by valorising industry waste streams and reducing the utilisation of marine wild resources. However, these ingredients may present differences in long-chain polyunsaturated fatty acids (LC-PUFA) (Sprague et al., 2016) and contain higher levels of bones and ashes with a lower availability of nutrients (Albrektsen et al., 2022), compared to marine wild one. LC-PUFA such as eicosapentaenoic (EPA), docosahexaenoic (DHA) and arachidonic (ARA) are precursors of eicosanoids, which are key protagonists as a mediators of inflammation and in the immune response modulation. Marine fish have a limited capacity to synthesise LC-PUFA from C-18 precursors, thus it is important to understand how “free-catches” diets may affect eicosanoid production, particularly in relation to a stressful situation. In this trial, the effects of five diets, formulated with increasing inclusions of fish meal and oil from trimmings by-products and microalgae, were assessed on the European seabass (*Dicentrarchus labrax*) eicosanoids production by exploring both molecular markers and the eicosanoids metabolites found in anterior kidney samples.

Material and Methods
Five diets (FMFO100-MIC0, FMFO50-MIC0, FMFO50-MIC50, FMFO0-MIC50 and FMFO0-MIC100), formulated to totally replace marine wild ingredients with increasing inclusion of FM and FO from trimmings by-products and MIC, were tested on triplicate groups of 45 fish (initial weight: 46.66 ± 0.04 g) reared in a RAS over a period of 88 days. At the end of the trial fish were exposed to a confinement challenge by increasing stocking density to 70 kg/m³ for 2 hours. Samples of anterior kidney were collected from 2 fish per tank (n = 6) at 0, 2 and 24 hours after the challenge. The expression of the selected genes involved in eicosanoids metabolism (EP2, Alox5, Alox12, Alox15 and P450) were evaluated on anterior kidney samples by quantitative real-time polymerase chain reaction method, as described in (Betancor et al., 2021). Eicosanoids metabolites were detected in anterior kidney samples by using HPLC-MS technique. Statistical analysis were performed by means of two-ways ANOVA (*P* < 0.05) in order to evidence significant differences among dietary treatments, time and their interaction. Starting from metabolite responses, explorative multivariate PCA were considered in order to discriminate between treatments and the role of each metabolite and their relationship.

Results and discussion
At the end of the trial no significant diet effect were detected on the growth performances among the dietary treatments (data not shown). Regardless of some differences in the fatty acids proportions of the diets, the markers evaluated to assess European seabass eicosanoids metabolism appeared similar among dietary treatments. With regards to the molecular markers evaluated in this trial, only the expression of the gene P450 at time 0 was found significantly different among the treatments. This was found higher in fish fed diets with higher inclusion of microalgae. No other significant difference in gene expression was observed between the diets at the other sampling times (time 2 and 24). The two-way ANOVA model reveals a significant influence of time on the relative expression level of EP2, Alox5, Alox12 and Alox15. After HPLC-MS analysis, 23 eicosanoids metabolites were found in European seabass anterior kidney. Explorative PCA analysis has highlighted some relationship between the metabolites and the diets.

Overall, these results suggest the potential of using completely free catches aquafeed formulations in the diet of European seabass. Moreover, modelling the eicosanoids metabolites and their LC-PUFA precursors can contribute to the deep characterisation of the biological pathways involved in the eicosanoids production.

Introduction

*Holothuria* is a genus of marine invertebrates commonly called sea cucumbers, that belongs to the phylum Echinodermata. *Holothuria* species are deposit feeders, ingesting sediment with oral tentacles, extracting and digesting the organic matter with associated microorganisms, and voiding the sand through the anus. In this way they bioturbate significant areas of the seabed, playing a central role in the benthic habitats where these species live. The interest in sea cucumber aquaculture began in Asia, where many species are considered luxury seafood with a high market value, and soon reached the European market, making these species promising candidates to establish novel aquaculture production systems worldwide.

The genus counts more than 160 species, many of which are uncharacterised at the genome level. The only reference genomes so far available are those of the *H. leucospiota* (HL; Chen et al. 2023) assembled at a chromosome level and *H. glaberrima* (HG; Medina-Feliciano et al. 2021) and *H. scabra* (HS; Luo et al. 2022) assembled at a scaffold level.

In this study, we provided a preliminary comparative genome analysis among five sea cucumber species.

Material and methods

Whole genome sequencing samples of HG, HS (n=3) and HL were retrieved from the Sequence Read Archive of NCBI (https://www.ncbi.nlm.nih.gov/sra). Samples from the Mediterranean *H. tubulosa* (HT; n=4), *H. polii* (HP; n=3) were generated in-house with at least 20X of genome coverage and added to the dataset. These data were aligned to the three reference genomes (HG, HL and HS), with standard options using BWA mem (Li and Durbin, 2009). For each of the alignments, the genome coverage was evaluated. Variant calling was performed utilising the reference with the best output among the three references with bcftools (Danecek et al. 2021). A multidimensional scaling was performed to test the ability of the SNPs to discriminate the five species. Pairwise FST statistics were also performed for HS, HT and HP.

Results

The genome coverage using the three different reference genomes is reported in Table 1. The HG genome showed the best results, especially for the Mediterranean HP and HT and therefore was used for variant calling.

Variant calling performed utilising the HG-based alignment retrieved more than 2 million SNPs that showed a good power of discrimination among the five species (Figure 1), with HT and HP being close to each other as sympatric species. FST analyses was in line with the multidimensional scaling, showing a lower value (FST=0.25) between HP and HT and a higher value (FST=0.67) between HS with HP and HT.

Conclusion

HG reference genome provides the most suitable template for genomic analyses, especially for the Mediterranean HT and HP species. Nevertheless, there is the need to increase the efforts on expanding the genomic resources for holothurians.

Introduction

Triploids, which are individuals bearing three sets of chromosomes, are commonly used in fish breeding. Triploids are sterile which allow (1) higher growth after maturity, (2) better flesh quality and (3) lower risk of genetic introgression into wild populations. In rainbow trout where triploids account for a significant proportion of production, selective breeding programs are all performed on diploid lines expecting transfer of the genetic progress to their triploids progenies. However, evaluating only diploid performance is suboptimal as genetic correlations for the same trait between diploids and triploids may differ from unity. Hence, maximizing genetic gain in triploids requires the evaluation of breeding values on triploid sibs of the diploid candidates. In mixed-family designs of breeding programs, this implies correctly genotyping triploids and recovering their pedigree, which is not currently possible with open source tools. Here, we present a pipeline to genotype and assign triploids obtained by second polar body retention after fertilization (the technique applied in salmonids) to their diploid parents based on a newly developed R package, GenoTriplo and an adaptation of APIS (Griot et al., 2020).

Material and Methods

We genotyped 1,232 triploid offspring obtained from 190 diploid dams and 98 diploid sires of rainbow trout on a Thermo Fisher SNP chip array with 57,501 SNPs, from which we kept the 38,033 highest quality markers. Allele signals were obtained via Axiom Analysis Suite software as the luminescence of probesets A and B (\(S_A\) and \(S_B\)) for each marker and individual. GenoTriplo was designed in two steps, clustering and genotype calling. For the clustering, each individual was represented by a couple of coordinates (\(x\) the contrast and \(y\) the signal strength) for each marker. 

\[
x = \text{Contrast} = \log_2 \left( \frac{S_A}{S_B} \right)
\]

\[
y = \text{Signal Strength} = \frac{\log_2(S_A) + \log_2(S_B)}{2}
\]

\text{Rmixmod R package was used to find clusters of individuals sharing the same genotype for a given marker. In the iterative algorithm, the initial number of clusters was set to 8, i.e. twice to the maximum number of possible genotypes. Clusters with close contrast values were merged to keep only four or less clusters. Five iterations were realized and we kept the iteration with the highest likelihood value. For the genotype calling, we identified the more extreme cluster based on its contrast (\(x\)) mean value and set it as homozygous (AAA if mean(x)>0 or BBB if mean(x)<0). Then, the remaining clusters were ordered by contrasts. Three main criteria were involved to improve cluster precision and to discriminate low-quality markers. (1) Genotype was declared as missing if the probability of the individual to belong to the cluster was below 0.85. (2) Genotype was also set missing if the distance between the cluster center and the individual exceeds 2.8*SD\text{cluster}. (3) Genotypes of all individuals of the same cluster were all set missing if the standard deviation of the cluster exceed 0.28*(1+0.5*abs(Mean_{cluster})). There were three categories of markers: PolyHighRes markers with 3 alleles observed and 4 genotypes, NoMinorHom markers with one homozygous genotype missing and CRbelowThreshold markers with call rate below 90%. Finally, we adapted APIS to enable parentage assignment of triploids. To do so, we created three new likelihood tables, one for each possible offspring genotype (AAA, ABB, ABC – this latter being relevant only for microsatellite markers). Similar tables were performed to perform assignment by exclusion. To test whether this pipeline was efficient, we used APIS to assign the 1,232 triploid offspring genotyped with GenoTriplo. The assignment was done using the exclusion method with the 1,000 best markers selected on the highest values for minor allele frequency and call rate.

(Continued on next page)
Results
Thanks to the 8 clusters initially targeted, most of the rare genotypes were detected. This resulted in minimizing the proportion of CRbelowThreshold markers (4,734 markers ≈ 12.4%) and maximizing the proportion of informative NoMinorHom and PolyHighRes markers (27,948 markers ≈ 73.5%). Furthermore, all offspring were assigned to their parents. The best couple category had a maximum of 19 mismatches for 1,000 markers and a mean number of mismatches of 6.9 which is low (<1% of mismatch). The second-best couple had a minimum of 47 mismatches for a mean of 85.6 (Figure 1).

Discussion
Initially targeting eight clusters instead of four is a major difference between GenoTriplo and the method proposed by Grashei et al., (2020) for example, hexaploidy in wheat, octaploidy in strawberries, and diploidy, triploidy, tetraploidy, and pseudo-tetraploidy (partly tetraploid. It enabled the algorithm to identify clusters with few individuals that would have been included in a bigger cluster and which would have then been discarded due their distance to the cluster’s center. Consequently, GenoTriplo maximizes the number of informative PolyHighRes markers found. Meanwhile, we showed that the accuracy of GenoTriplo allowed to assign all our triploid offsprings to their diploids parents. Even though the true parents were unknown the difference in the numbers of mismatches between the best and the second-best couple was large enough to confirm the success of the assignment. Hence, this pipeline is a major breakthrough towards the selection of diploid lines to improve performances of their triploid sibs.

HEMP BY-PRODUCTS AS A PROTEIN SOURCE FOR ATLANTIC SALMON, *Salmo salar*

M.B. Betancor\(^1\)*, P. Wischhusen\(^1\), S. Shivaprasad\(^2\)

\(^1\)University of Stirling, Stirling, FK9 4LA, Scotland, UK

Introduction
Animal protein demand will double by 2050 with aquaculture expected to fill this gap given that it is the most efficient animal production system, with feed conversion ratios of approximately 1.1, lower than both poultry (1.7) and cattle (6.8). The rapid development of aquaculture will result in higher protein demands that cannot be fulfilled by soy protein (Gatlin et al., 2007), the main protein in aquafeeds as it leads to deforestation and carries a high CO\(_2\) footprint both from farming and international shipping. Alternatives of locally produced protein sources, or derived by-products, are required within the circular economy/zero waste concept. Hemp provides a competitive protein source to soy, being up to 5 times more effective than trees at sequestering CO\(_2\) (Madden et al., 2022). Rare Earth Global (REG) have developed a UK model for supplying locally produced and sustainable hemp protein, which avoids deforestation through fitting into UK farmers’ crop rotation schedules. This means that through full plant utilisation of stalks for primary uses (construction/energy), there can be a negative CO\(_2\) impact on the use of the seeds as a protein source. In contrast to other protein alternatives (e.g. microbial protein, insect meal), the scale needed for commercial use can be met through UK offtakes for the stalk (30K mT). The present study investigated the suitability of UK produced hemp seed by-product as a protein source for the Scottish Atlantic salmon industry. The first step to validate the use of hemp protein as an ingredient for aquafeeds is to characterize its nutritional attributes and assess its digestibility value.

Materials and Methods
Three different types of hempseed meal (HM) were nutritionally characterized (moisture, oil, protein ash, minerals and amino acid and fatty acid profiles) and antinutritional factors (phytic acid and glycosylates) analysed. The two HM with the highest protein content (HM1-42 and HM2-46%) were chosen for in vivo and in vitro digestibility studies. A trial with three experimental feeds, one control and two feeds including a 30% of either HM1 or HM2 was carried out (Fig. 1). A total of 360 Atlantic salmon smolts, with an average body weight of 802.0±15.9 g and 40.3±4.5 cm were distributed into 9 tanks (3 per treatment) and fed the experimental feeds for two weeks. At the end of the trial all fish in each tank were euthanized at ~6h after feeding and measured for weight, length and operational welfare indicators. Next, faecal samples were collected by stripping based on the methods reported by Glencross et al. (2005) for digestibility and short fatty acid analysis. Faeces were collected as two pools of 10 fish each per tank (total sample size n = 18). In addition, 4 fish per tank were dissected and anterior and posterior intestine as well as liver collected, fixed in 4 % buffered formalin for histopathological evaluation of the tissues. The bioaccessibility and the bioavailability of nutrients of the two HM selected based on nutritional characterization were evaluated on an artificial salmon gut (www.salmosim.co.uk) in order to complement the results obtained in vivo.

Results and Discussion
The protein content of the three analysed HM ranged from 35.6-46.0%, while the fat content oscillated between 8.6-10.5%. The two HM that were more protein and energy dense (HM1 and HM2) also displayed the lowest carbohydrate levels. The three HM included high levels of aspartic acid, glutamic acid, phenylalanine, histidine and arginine comparable to those of fish meal. Levels of methionine are approximately half to those present in fish meal, similar to soy protein concentrate. No glycosylates were detected and the phytic acid contents were 3.9%, similar to other terrestrial vegetable meals.

At the end of the feeding period, fish fed the diet containing HM2, displayed the highest weight gain. The protein digestibility of the test diets proved to be good at 84 and 87% for HM1 and HM2, respectively. The protein and amino acid digestibility of the two test ingredients was also generally high and in many cases was 100%. This proves that the digestibility of both HM was excellent and therefore may have the potential to be utilized as ingredient in hot extruded feeds for Atlantic salmon. These results were corroborated by the in vitro trial, indicating the potential high digestibility of this ingredient in cold extruded or compressed pellets. The histology assessment of liver showed the lowest degree of intracytoplasmic lipid vacuolization in fish from HM2 treatment, albeit not different to Control. The only morphological alteration found in intestine was a higher density of goblet cells in the posterior intestine of fish fed HM1, when compared to those fed the control feed, indicating greater mucus coverage. The results suggest that hempseed meal may be a good novel ingredient for Atlantic salmon aquafeeds. Long term trials are now needed to evaluate the impact that commercial inclusions of these ingredients can have of salmon performance and stress resistance.

E-mail: belikova.e.y@gmail.com

Introduction
The European grayling *Thymallus thymallus* (Linnaeus, 1758) is listed in the Red Book of Ukraine and has the status of a vulnerable species. Therefore, the protection and reproduction of this indigenous salmonid species for Ukraine is an important task. The work in this field was initiated by specialists of the Institute of Fisheries in 2006 at the farm of the Synevyr National Nature Park from individuals caught in the Chorna River (a tributary of the Tereblya River), and since 2014 the work continues at the Lopushno trout farm (Chernivtsi region, Ukraine) (Kucheruk et al., 2018). This fish farm participates in the program of the National Academy of Sciences of Ukraine, aimed at creating a brood stock of grayling with increased productivity and its further use for stocking the river network of the Western region of Ukraine to preserve the species diversity of local ichthyocenoses. Comprehensive work with this species includes both the classical assessment of morphological and productive parameters of the obtained generations of fish on the farm, monitoring of infectious and invasive fish diseases, and also genetic analyses. A set of molecular tools allows studying allelic diversity, assessing stock heterozygosity, and determining phylogenetic origin or relationships with other populations, and thus contributing to the effective management of the genetic resources of graylings on farms and their further use for the preservation of ichthyocenoses in rivers. This work aimed to analyze grayling generations from the Ukrainian fishery using microsatellites and mitochondrial DNA analysis.

Materials and methods
For molecular genetic studies, fish fin clips were collected from individuals of the first generation of grayling from 2017 and the second generation from 2021 of the Lopushno trout farm (Ukraine) with the aim to analyze and monitor changes in the genetic structure of the stock. The study of the genetic diversity was carried out using microsatellite loci (BFRO 005, BFRO 006, BFRO 010, BFRO011) with data processing in Genalex 6.5 software and related programs to obtain basic genetic parameters. Phylogenetic analysis of the existing stock was carried out using the gene of the control region of mitochondrial DNA. The obtained results of the analysis of mtDNA fragments were edited in Sequencher v5.1 and analysed together with reference sequences from the NCBI, BOLD databases in MEGA X, DNAasp and PopART.

Results
The number of alleles for all loci varied from 4 to 6, with values of the effective number of alleles per locus from 2.985 to 5.128. The average value of the allelic richness index (Ar) in the first generation was 4.7 ± 0.5 less than in the second generation 5.7 ± 0.5. Shannon’s diversity index ranged from 1.192 to 1.543 in the 2017 generation and 1.392 to 1.692 in the 2021 generation. In the first generation, the observed heterozygosity (Ho) = 0.600 ± 0.147 and the expected (He) = 0.729 ± 0.025, while in the second generation Ho = 0.767 ± 0.053 and He =0.778 ± 0.021. The average value of the fixation index (F) was lower in the second generation (0.014) than in the first (0.184). Phylogenetic analysis based on sequenced fragments of the control region suggested that the Ukrainian samples belong to the Mixed Central Europe clade defined by Weiss et al., 2002. This clade corresponds to lineage II of European graylings according to the separation proposed by Gum et al., 2009.

Discussion
In the comparative analysis of two grayling generations from the fish farm, it can be stated that the genetic diversity did not decrease in the second generation when taking into account indicators such as the number of alleles (Na), the effective number of alleles (Ne), allelic richness (Ar) and Shannon’s biodiversity index (I). However, further monitoring is needed to increase the number of monitoring points and to assess changes in effective population size. The predominance of expected heterozygosity (He) over observed heterozygosity (Ho) in both groups indicates the presence of inbreeding. However, the values of the fixation index (F) suggest, that the inbreeding decreased in the second generation.

(Continued on next page)
Based on the assessment and comparison of the morphological and productive parameters of generations at the stage of young-of-the-year (0 +), the most characteristic features observed were that the yield was at the level of 30% in the group of individuals of 2017 generation during the growing period from May to September, which is less than that obtained in the 2021 generation. However, the second generation was characterized by a lower average weight (4.6 g) than the first (9.73 g). Considering the principles of the identity of growing conditions, this fact may be related to technological shortcomings. To fully characterize the differences in the data of the two generations further studies of the 2021 generation are planned after the onset of puberty (for example, estimation of males and females, their fertility), as well as a comprehensive analysis of the variability of morphometric parameters. The study of the genetic features of the obtained generations of graylings is planned to be used in the future to preserve the species diversity of the ichthyocenoses of the river network. Phylogenetic studies of grayling allow establishing the belonging of the Ukrainian samples to the Mixed Central Europe clade and lineage II, which corresponds to previous generally presented schemes and, as indicated, is a mandatory step in the planning of conservation and stocking programs (Gum et al., 2009).

**Conclusions**
The results of the molecular genetic analysis will allow creating a basis for monitoring and controlling changes in the genetic structure and further selection work with these briding stock to maintain genetic biodiversity and rational economic management of them. Knowledge of the phylogenetic origin of the material will help avoid negative consequences during the stocking of rivers.

DEVELOPMENT OF A MODULAR AND SEMI-QUANTITATIVE SCORING SYSTEM TO ASSESS THE GILL HEALTH STATUS IN GILTHEAD SEABREAM (Sparus aurata) FED WITH FUNCTIONAL FEEDS FOR SPARICOTYLOSIS MITIGATION

Musmanno A.1, Quaglio F.2, Verin R.2, Kolega M.3, Colak S.4, Fioravanti M.L.1, Mejdandzic D.3, Baric R.3, Bignami G.1, Gustinelli A.1

4Department of Ecology, Agronomy and Aquaculture, University of Zadar, Croatia

Introduction
Sparicotyle chrysophrii is a gill hematophagous monogenean of gilthead sea bream (Sparus aurata) causing sparicotylosis, currently considered one of the most relevant health issues in sea bream farming in the Mediterranean mariculture. This parasite can be responsible for significant worsening in growth performance, serious gill pathologies even at moderate infection intensity up to mortality at massive infections in the most susceptible fish, i.e. juveniles. Since currently there are no effective, safe and environmentally friendly therapies authorized in European aquaculture, in recent years the implementation of mitigation strategies based on specific functional feeds has been pursued as an optimal option, being able to combine direct antiparasitic effects with positive effects on host immunity and growth, always when administered in the context of good health management practices. In previous studies, the parameters used to evaluate in vivo the efficacy of different functional feeds have been mainly related to the quantitative parasitology (prevalence, intensity and abundance), and biometric/growth and haematological indices of the host. In order to have an additional tool for the analysis of the results of feeding trials and the comparison between the experimental groups, a semi-quantitative histological scoring system with a modular structure - following the key principles suggested by Gibson-Corley et al. (2013) - has been developed to perform a more objective evaluation of the gill health status in caged sea bream fed with different functional feeds for Sparicotylosis mitigation.

Materials and methods
In the context of a 10-month trial based on the administration of two different functional feeds to prevent/mitigate sparicotylosis in cage-reared gilthead seabream (Musmanno et al., 2022), a histological study was performed in order to develop a semi-quantitative scoring system useful for assessing the gill health status during the whole trial but also in wider contexts. For this purpose, the four gill arches from the left side of 10 fish for each cage were monthly sampled (6 experimental cages×10 fish/cage/month×10 months=600 fish in total), fixed in 10% neutral buffered formalin, then processed following standard lab procedures. All the sections were 5µm thick and stained with Hematoxylin-Eosin (HE). The criteria of the system were identified and defined on the basis of a common consensus reached by three operators (fish pathologists) before the observation of the histological preparations.

Results and Discussion
Two modules were chosen for the development of the scoring system. In the first module, non-specific criteria were taken into consideration, chosen as independent stereotyped and generic reactions of the branchial tissue and grouped into 4 macro-categories: tissue adaptations, circulatory anomalies, tissue degeneration and inflammatory infiltration. In the second module, 5 specific criteria were taken into consideration, relating to the presence and intensity of pathogens such as primarily S. chrysophrii, associated or not with Furnestinia echeneis, Aporocotylidae eggs or other parasites, Epitheliocystis and the presence of bacterial aggregates linked to gill alterations. The score attributed to the overall evaluation was obtained from the sum of the scores obtained in the two modules. The range of the final score of the system, from 0 to 24, was divided into 4 levels of gill condition: excellent (0-6), good (6.001-12), poor (12.001-18), bad (18.001-24).

A good correspondence between the scores obtained in the different experimental groups and the quantitative parasitological parameters was highlighted by the first round of histological observations completed, although the accessibility and robustness of the system are being tested using Cohen’s kappa coefficient in a simple blind survey on 600 gilthead sea bream, aimed at assessing the concordance between the scores recorded by the pathologists, chosen so as to provide each one with a different level of competence (intermediate, advanced and expert). 

(Continued on next page)
Conclusion
The histological scoring system applied to the gills of gilthead sea breams examined during the feeding trial appears to be a suitable tool to characterize and support the promising results given by the quantitative analyses obtained so far. Strength of this scoring system would be the overall approach combining generic alterations of the gill environment and the presence of *S. chrysophrii* and other transmissible pathogens for characterising gill conditions and evaluating the pathology under study, providing fish pathologists and researchers with a standardised tool to interpret, monitor and compare gill disease trends and severity in various experimental and farming condition, even on a large scale. Furthermore, the modular nature of the system is suitable for any fish species, expanding the range of applications available compared to traditional systems, as the second module can be easily adapted to most aetiological agents responsible for gill pathology in aquaculture. The ongoing comparison of blind histological observations performed by three pathologists at different level of expertise will give further robustness to the scoring system.

Introduction

Freshwater Mud Eel (FME), Monopterus cuchia, is a highly nutritious and medicinally beneficial fish and it contributes to fulfill nutritional requirement and socioeconomic well-being in Bangladesh. Even in few years back, this eel fish was abundant in the natural bodies of Bangladesh, but now the abundance has declined drastically due to indiscriminate capture from natural habitat and insufficient knowledge of proper culture methods. FME population health is highly dependent on natural reproduction, and still no suitable method implies for its culture and feed development. Considering these issues, this study aims to develop appropriate aquaculture technique and suitable feed for mud eel.

Material and Methods

In order to identify suitable culture methods FME were stocked in three different habitat namely earthen ponds (T1), plastic tanks (T2) and cement tanks (T3) with three different stocking densities (2, 4, 6/m²) for each culture methods. Another experiment was designed with applying three different feed viz. trash fish (F1), live worms (F2), and commercial feed (F3) in order to identify suitable feed.

Results

After three months of culture period, highest eel body weight was observed in T1 with the stocking of 2/m² followed by T3 and T2. Although, higher fish body weight was observed at 2/m², but overall production found to be higher at the stocking of 4/m² which is more economical. On the other hand comparatively faster growth was observed in eel fish fed to trash fish (F1) followed by live worms (F2). Both the trash fish and live worm treated groups showed nearly identical growth patterns. In conclusion, the result suggested that, earthen pond system with 2-4 stocking density and both trash and live feed could be suitable for mud eel aquaculture. Although further field trial is necessary in order to disseminate this technology.

Introduction

Marine nematodes from the genus Anisakis are gaining more research spotlight as a result of an increase in the number of anisakiasis cases (i.e., the clinical condition in humans caused by Anisakis spp.) in Europe. In the natural environment, free-swimming second-stage larvae (L2) hatch from the eggs released in the seawater via the feces of the final hosts (marine mammals). The larvae are preyed upon by crustaceans (mainly euphausiids) and possibly small fish (intermediate hosts), moulting into third-stage larvae (L3). Intermediate hosts are consumed by larger fish (paratenic hosts) in which L3 migrate in the visceral cavity and remain in parathenesis until final hosts prey upon, and digest the infected paratenic host. In the final hosts, L3 moult through fourth (L4) and fifth (L5) juvenile stages into reproductively active adults of separate sex.

This research aimed to obtain in vivo the adult stage of Anisakis pegreffii from L3 isolated from fish, and to assess the production and hatchability of eggs over the lifetime of the adult specimens. The reproductive traits of this zoonotic nematode, such as fertility and life span will be helpful for the epidemiological modelling and risk assessment estimations.

Materials and Methods

Anisakis spp. type I larvae (identified as A. pegreffii following genotyping) were isolated from naturally infected blue whiting Micromesistius poutassou in the Adriatic Sea (Croatia). Isolated L3 larvae were cultured in Schneider’s Drosophila media supplemented by 10% chicken serum (n=30 in triplicate; B1, B2 and B3) to reach the adult stage using previously published protocol (Mladineo et al., 2023). The development of the adults from isolated L3 and the production of the eggs expelled in the medium was recorded every second day. Eggs collected were incubated in Sea Salt Solution at 19°C and the time of hatching was recorded. Anisakis fecundity was expressed as the daily expelled number of eggs according to Moratal et al. (2023). Additionally, the number, sex, and date of adults removed from the culture were recorded to calculate the sex ratio (expressed as a percentage of females) at each count. A graph was plotted depicting the number of eggs per day and per reproductive female.

Results and Discussion

Larvae begin to reach fourth-stage from 4th day in the medium, and another shedding of the cuticle marking the moulting into L5 was observed after 15 days. The adult stage, marked by the first shedding of eggs appeared after 17 days. However, the growth rate of the worms was asynchronous as some developed faster than others. The eggs were observed in the medium from 17 to 133 days post-incubation. The first hatching of eggs (i.e., first fertilisation) appeared 44 days post-incubation. For the following 51 days (i.e., 95 days post-incubation) eggs were fertilised and hatched into L2 larvae. Hatching occurred 5-7 days post-incubation of eggs. The average fecundity peaked on day 100 post-incubation, ranging from 80,000 to 266,000 eggs per day per female counted in triplicates. B1 encompassed 19 females, 9 males, 2 L5; B2 contained 22 females, 7 males, 1 L5; and B3 contained 19 females, 7 males, 4 L5 (L5 died before reaching the adult stage). Thus, a sex ratio of 1:2 was calculated for B1, and 1:3 for both B2 and B3. The number of dead worms was recorded throughout the experiment and the cumulative mortality is shown in the Figure 1.

At the end of the experiment, cumulative mortality was 59.99, 49.99, and 53.26% for B1, B2, and B3, respectively. Most of the dead worms recovered from the media were smaller in size compared to the others; indicative of underdevelopment and their inability to compete for nutrients with the others. Other biological factors could also contribute to their mortality.

(Continued on next page)
Conclusion

*Anisakis pegreffii* is able to survive, grow and reproduce in insect medium for as long as four months. However, the fertilisation of eggs and thus hatching of L2 for downstream experiments is feasible during a limited time (till 95 days post-incubation), similar to what has been reported by Moratal et al. (2023). Nonetheless, the observed cumulative mortality of adults, if maintained in enough replicates, guarantees the harvest of fertilised eggs satisfactory for robust downstream experiments.

EFFECT OF DIFFERENT DIETARY SUPPLEMENTS OF Nannochloropsis gaditana ON THE PRODUCTION TRAITS OF TWO-YEARS OLD COMMON CARP (Cyprinus carpio) STOCK

Introduction
Diets containing microalgae as an alternative protein source have a growing importance in the feeding of intensively reared fish species. Microalgae are characterized by high protein content of 30-55% (López et al., 2010) and a favourable essential amino acid content (Brown et al., 1997). Their lipid content ranges between 2-50% (López et al., 2010). Microalgae are rich in highly unsaturated fatty acids, carotenoids, vitamins and minerals (Idenyi et al., 2022). Microalgae positively affect the immune status of fish and have a beneficial effect on their growth and health (Ayala et al., 2023). The aim of the study was to determine how different amounts of Nannochloropsis gaditana supplementations affect the production traits of two-years old common carps (Cyprinus carpio) in a closed fish rearing system.

Materials and Methods
A six-week experiment was carried out at the Research Center of Aquaculture and Fisheries, Hungarian University of Agriculture and Life Sciences, using a recirculation aquaculture system (RAS). A total of 144 two-years old common carp individuals with an average initial weight of 720 ± 77 g were randomly distributed into 9 tanks in triplicate (16 fish per tank of volume 2 m³). A complete randomized design was used to set up the experiment. Experimental diets were formulated to contain Nannochloropsis gaditana supplementations in two different amounts. The control diet (Control) contained no algae, while the experimental diets contained 10 % (Algae 10) or 20 % (Algae 20) algae supplementation. Experimental feeds were fed at 2 % of biomass during the six weeks of the experiment. All diets were fed in triplicates. Fillet samples were collected from 9 individuals at the beginning of the experiment. At the end of the experiment fillet samples were taken from 45 individuals (5 fish/tank).

Results and conclusions
Growth rate of common carp fingerlings is shown in Figure 1. No significant differences were found in the mean weight between the groups at the two-weeks sampling times. Data of growth parameters and production traits determined at the end of the experiment are summarized in Table 1. After six weeks of feeding no significant differences were found between the groups either in terms of growth (weight gain, SGR) or feed conversation ratio, protein efficiency ratio, and fillet yield. At the same time some tendency can be seen towards a better performance of Algae10 group. Overall, it can be stated, that the fish utilized the Nannochloropsis gaditana containing feed well, without compromising the production and nutrient utilization parameters during the experimental period.

Introduction

Although fish meal (FM) has been considered the most preferred protein source in aquafeeds, intense focus has been given on the reduction and/or elimination of FM protein over the past several decades due to its high price and insufficient supply. Shark by-catch muscle meal (SM), which has been otherwise wasted away, was used to replace fishmeal (FM) in the diet of juvenile Japanese yellowtail, *Seriola quinqueradiata* to investigate its effect on growth and phosphorus (P) loading to the ecosystem.

Materials and methods

The control diet (C) was composed of FM as protein source, and 25%, 50%, 75% and 100% of FM protein from diet C was replaced by SM to formulate diets SM25, SM50, SM75 and SM100, respectively. A group of 25 fish (mean weight 18.01 ± 0.09 g) were stocked into each 500 L tank in triplicate for each treatment, fed two times daily until apparent satiation for 6 weeks. Feces collection trial was carried out by using chromic oxide as an inert marker after finishing the growth trial. The photoperiod was set to 12 h of light (07:00-19.00) and 12 h of dark during the whole rearing period. The UV-treated filtered seawater was supplied at 7 L/min per tank, and water temperature and dissolved oxygen levels during the test period were 26.1 ± 1.0°C and 6.4 ± 0.7 mg/l, respectively. During the test period, the bottom was cleaned with a siphon every day at 11:00, and dead fish were counted and weighed if mortalities were observed.

Results and conclusion

There were no significant differences in growth parameters among fish fed with diets C, SM25, SM50 and SM75 ($P < 0.05$, Tukey’s test), though SM100 produced significantly lower performance compared to all diets ($P > 0.05$). Moreover, there was a strong negative ($R^2 = 0.964$) and positive ($R^2 = 0.904$) linear correlation between daily feeding rate and SM, and between feed efficiency and SM levels in diets, respectively. Although there were no significant differences in protein and fat productive value among the treatments, P productive value was significantly increased with increasing levels of SM in diets, resulting in a significant lower P loading from SM-based diets ($P < 0.05$). There were no significant differences in plasma levels of total protein, glutamic oxaloacetic transaminase, glutamic pyruvic transaminase, and total cholesterol ($P > 0.05$); however, plasma levels of triglyceride, blood urea nitrogen and ammonia were significantly increased in fish fed with diet SM100 compared to the control group ($P < 0.05$). In conclusion, the results suggest that 75% of FM protein can be replaced by SM without compromising the growth performance and health condition, and that a significant ecological benefit can be achieved by reducing P loading from SM-based diet. From an economic standpoint of view, the application of SM would help to reduce dependency on high cost and scarce FM.
PHOTO-OXIDATION: A PROMISING SOLUTION FOR THE BIOSECURITY OF AQUACULTURE WATERS

The pollution of seawater by both biotic (bacteria, viruses, toxic algae etc.) and abiotic contaminants (toxin, pesticide, pharmaceutical residues, etc.) frequently leads to economic losses in aquaculture activities. The methods of water treatment commonly used in aquaculture (UVC, filtration...) do not allow to eliminate both biotic and abiotic contaminants. Advanced Oxidation Processes (AOPs) such as heterogeneous photocatalysis allow the removal of all organic contaminants present in water and therefore could reduce production losses in land-based farms (closed facilities). If this process has already been widely studied for the abiotic decontamination, its application for biotic disinfection is still overlooked (especially on viruses). Over the past decade the production of the Pacific oyster Crassostrea gigas has been regularly affected by massive mortalities due to the Pacific Oyster Mortality Syndrome (POMS). This syndrome is a complex and polymicrobial disease involving an initial viral infection by the Ostreid Herpes Virus 1 (OsHV-1 µVar) followed by multiple bacterial infections. In this context, we investigated seawater disinfection by the heterogeneous photocatalysis (UV/TiO2) method in the context of POMS by addressing both the impact of the treatment on a single opportunistic pathogenic bacterium (Vibrio harveyi) and on a complex microbial community reflecting a natural POMS event (OsHV-1 µVar virus and opportunistic pathogenic bacteria consortium). The viral inactivation has been monitored using experimental infections to see if viral particles were still infectious after UV/TiO2 treatment. Moreover, changes on the total seawater bacterial community have been investigated comparing UV/TiO2 treatment with UV-irradiated seawater and non-treated seawater. This study gave promising results for UV/TiO2 seawater disinfection. Both oyster’s pathogens tested were efficiently inactivated in a few hours of treatment. Even if treatment impacted transiently the total bacteria community, the seawater microbiota shift toward untreated seawater few days after the end of the treatment. Altogether, these results revealed that heterogeneous photocatalysis could be an interesting alternative process for the disinfection of land-based oyster farm seawater to prevent vibriosis and viral diseases.
UTILIZING ELECTROLYZED WATER TREATMENT TO MANAGE VIBRIOSIS CAUSED BY Vibrio harveyi IN AQUACULTURE SETTINGS

Introduction

Vibrio harveyi (Vh) is a Gram-negative halophilic bacterium widely distributed in marine environments that can cause disease in numerous aquatic animals, including cultured species. In fact, the bacterium has been recognized as one of the major causes of vibriosis (Amaro et al., 2020). Nowadays, epizootics and outbreaks caused by Vh are increasing due to its wider distribution because of global warming. Antibiotics have used to control Vh-vibriosis in aquaculture for years. However, resistant strains could pose a major threat to this industry, urging the need of developing alternative methods. Electrolyzed water (EW) is a powerful and environmentally friendly disinfectant. Its generation, through electrolysis, from a saltwater solution, results in the separation into two streams, alkaline and acidic. The acidic stream (anolyte) contains hypochlorous acid (HOCl) which is a potent bactericide, disrupting the cell membranes and leading to their fast destruction (Wang et al., 2020).

The objectives of this study were to determine the bactericidal effect of EW against Vh and assess its potential as a complementary method to antibiotic therapy for the control of Vh-vibriosis outbreaks in aquaculture settings.

Material and Methods

V. harveyi strains, isolated from diseased fish, were grown in Luria Bertani plus 5 g/L NaCl broth (LB-1) at 28 ºC for 24 h with shaking (100 rpm). Electrolyzed Water was generated from a saltwater solution at different pH (3.5, 5, 6.5 and 7.5), salinity (0.5, 1.5 and 3%) and available chlorine (from 5 to 125 ppm) conditions. EW samples were inoculated with Vh cultures (1:10 ratio) and incubated up to 15 min. Bacterial viability in EW samples was measured by drop plate onto Tryptic Soy Agar with 1% NaCl (TSA-1). All experiments were performed in triplicate.

Results and discussion

High concentrations of available chlorine (125 ppm) in EW had a strong effect against Vh strains, independently on the salinity and pH conditions. EW at 25ppm with salinity of 1.5 % and acidic pH (5) was highly bactericidal, leading to survival of less than 0.01% (Vh initial population: 10^6 cfu/ml) in 10 min, equivalent to more than 4 log unit reduction. This effect probably resides in the combined effect of free available chlorine concentration and all reactive oxygen species (ROS) generated in the electrochemical preparation. Under these conditions excepting for pH, EW was less efficient reducing the bacterial population (25% and 0.1% at pH 6.5 and 7.5, respectively).

At 25ppm and salinity of 3% (mimicking sea conditions), the effect of pH was clear: at pH 7.5 a reduction of three log units was observed in the bacterial concentration in less than 15 min (Fig. 1). The other test strains showed the same survival tendency under the same conditions (Fig. 2)

Conclusions

EW technology was highly effective reducing the Vh population, thus it could help to minimize the antibiotic treatments during vibriosis outbreaks. Moreover, implementation of EW in aquaculture facilities as a preventive strategy during stressing periods would probably contribute to reduce the load of pathogenic bacteria in farm seawater.

CONNECTIVITY BETWEEN AQUACULTURE SITES - RISK OF PARTICLE TRANSPORT AND ASSOCIATED SPREAD OF DISEASE

Nina Bloecher*, Ole Jacob Broch, Oliver Floerl
SINTEF Ocean, 7030 Trondheim, Norway
Nina.Bloecher@sintef.no

Introduction

Mortality in Norwegian salmon aquaculture averages at around 15% during time at sea, with gill disease being a major cause of mortality [1]. Gill health is impacted by many factors including pathogens, fish handling, and sea lice treatments, as well as waterborne particles such as harmful algae, jellyfish, and biofouling fragments [1, 2]. Biofouling assemblages occlude pen nets and are commonly removed via regular (up to weekly) in-situ net cleaning operations [3, 4]. During this process, cleaning waste is released into the water column and able to disperse within the pen and farm site. Contact with hydroid particles can cause gill injuries, lasting for up to 7 days [5]. In addition, hydroids and other biofouling organisms can harbour pathogens [6, 7], and dispersal of their fragments via currents may contribute to the spread of disease between pens or farm sites [8].

The study used a hydrodynamic particle tracking model to examine the spread of biofouling particles arising from in-situ net cleaning operations at a case-study farm located in mid-Norway. We determined in particular the potential transport of these particles to neighbouring farms.

Material and methods

The particle distribution model was set up for two similar sized farms in close vicinity (4 km apart) located off the coast of mid-Norway [9]. Input variables to the model were (i) hydroid particle abundance, (ii) hydroid particle size distribution and (iii) hydroid particle sinking rates. Abundance and particle size distribution were estimated based on an assessment of biofouling present before and after cleaning, and analysis of cleaning waste concentration and composition measured in situ. Particle sinking rates were measured in a laboratory study. Results are presented as particle concentrations per square meter accumulated for the upper 35 m of the water column (i.e. average depth of a sea cage) for individual pens, as well as for surrounding waters.

Figure 1: Model results showing maximum hydroid particle concentration after net cleaning on farm site A. Concentrations (particle m$^{-2}$) are shown accumulated for the upper 35 meters of the water column. Areas surround by blue contours have at least 10 particle m$^{-2}$, areas with red contours exceed concentrations of 100 particles m$^{-2}$ and concentrations in areas within black contours are above 1,000 particles m$^{-2}$.

(Continued on next page)
To put the dispersal of hydroid particles from our case-study model farms into a broader spatial context, we quantified the distance of 936 salmon farms along the Norwegian coast to the salmon farm nearest to it. We then determined the proportion of nearest-neighbour farm distances around Norway’s entire salmon aquaculture industry that was equal to or smaller than the dispersal distance of hydroid material quantified by our model.

Results and discussion

Hydroid particles released during simulated net cleaning at the two model farms resulted in a maximum concentration of 958,135 particles m\(^{-2}\) (integrated across the upper 35m of the water column) within individual pens. Particles released from one pen were transported into adjacent pens, leading to small ‘peaks’ in particle concentration even in pens that were not being cleaned. As a consequence, fish in individual pens were exposed to hydroid particles multiple times while they, or surrounding pens were being cleaned, increasing the risk for encountering harmful particles and gill injury. With recovery times after one-time exposure taking up to 1 week [5], repeated exposure may contribute to worsening gill conditions in salmon during time at sea.

Maximum dispersal of biofouling material released via cleaning occurred 48 hrs following onset of net cleaning operations (Figure 1). The largest unidirectional dispersal distance for hydroid particles was > 4.8 km. Of the 936 salmon farms along the Norwegian coast, 63% have at least one nearest neighbour farm within this distance. While our study was restricted to a case study location, these results suggest that inter-farm dispersal of biofouling material may also take place elsewhere.

Net cleaning may facilitate the dispersal of gill damage inducing particles between farm sites, including particles that are known to harbour pathogens. Novel cleaning tools that avoid the release of biofouling particles via containment or more regular cleaning (grooming) of nets [4] have the potential to reduce gill damage arising from biofouling maintenance operations.

Introduction

Nanoplastics (NPs), characterized as measuring below 1000 nm, represent a major part of plastic pollution, and are now considered ubiquitous in aquatic ecosystems (Sharma et al., 2021). NPs have been detected and quantified in most environmental and urbanised matrices, with polystyrene (PS) being a commonly detected polymer (Dong et al., 2021). Their nanoparticle properties translate into the ability to travel with blood through an organism, and to cross biological barriers, such as the blood/brain barrier (Ma et al., 2021). Although plastic contamination has been given increasing consideration over the past decades, little is still known on the effects of prolonged exposures to such pollutants in living organisms. The present study aimed to investigate the response of the commonly farmed gilthead seabream (*Sparus aurata*) to a waterborne exposure to PS-NPs of 42 nm diameter over a period of 28 days by investigating health and welfare parameters such as haematology and behaviour. In addition, accumulation of PS-NPs in different organs was investigated.

Material and methods

Juvenile seabream (9.15 ± 0.75 cm total length and 9.09 ± 1.73 g total weight) were randomly allocated into 9 experimental aquaria, each of which represented a replicate of either of 3 experimental conditions: Control (0 µg/L); low concentration of NPs (100 µg/L) and high concentration of NPs (1000 µg/L). Each aquarium contained 5 fish, and following an acclimation period in the experimental aquaria, the treatments were applied. Behaviour was recorded over a period of 10 minutes (2 minutes before feeding, while feeding and up to 8 minutes after feeding) on the first day of the challenge, and subsequently every 7 days. Following the 28-day exposure period, fish were randomly selected, and blood was extracted through caudal puncture using heparinized syringes. Samples were stored at 4 °C and analysed using the automated haematological analyser SYSMEX XN-1000V adjusted for fish blood. Following blood extraction, fish were euthanised by spinal rupture, and gills, liver, gut, muscle, and brain were excised and immediately snap-frozen in liquid nitrogen. The video recordings were analysed using ImageJ (Mattson et al., 2015), taking into consideration feeding time, distance travelled during swimming, and exploratory behaviour after feeding. Quantification of PS-NPs in tissue was performed by size exclusion chromatography (SEC) coupled to high-resolution mass spectrometry (HRMS), equipped with an atmospheric pressure photoionization (APPI) working under negative conditions.

Results and discussion

The haematological parameters considered were white blood cell count (WBC), red blood cell count (RBC), haematocrit (HCT), haemoglobin (HGB), mean corpuscular volume (MCV), mean corpuscular haemoglobin (MCH), and platelet count (PLT), amongst others. No significant differences were found in any of these parameters, which is in accordance with a previously published study investigating the effects of this polymer in the model organisms *Carassius auratus*. (Brandts et al., 2022). Gills, gut and liver were selected for PS-NPs quantification as they may represent a principal portal of entry for fish during waterborne exposure. Brain was also selected for this analysis, as NPs have been shown to cross the blood-brain barrier, and accumulation in this organ is likely to have strong deleterious effects on the health and welfare of fish, which will be potentially reflected by changes in behaviour. On the other hand, muscle was sampled for PS-NPs quantification as it represents a potential source of exposure to this contaminant for humans. Results will include both quantification of PS-NPs and behavioural analyses. At the overall functional level results reveal that variables are not initially affected by NPs, but at molecular and genetic level NP do induce alterations.

Introduction
European catfish (Silurus glanis L. 1758) is the largest predator in the freshwater bodies of Europe, located at the top of the food chain in most of the aquatic habitats. This species has remarkable somatic growth potential, robustness and high quality bone-less fillet positioning it as the next great candidate for recirculated aquaculture systems (RAS). The volume of aquaculture production is often reduced by infectious diseases. Among these, the European catfish-specific monogenean gill fluke (Thaparocleidus vistulensis, S. 1932) is a major pathological agent threatening farmed stocks, especially those kept in RAS facilities. Systematic studies on parasite-host interaction require regular access to diseased catfish. However, parasite loads could vary widely among hosts, which adversely affects the reliability of comparative studies. Furthermore, the daily management of gill parasite infected catfish stock on a laboratory scale is a challenge.

Materials and methods
We established a T. vistulensis parasite culture by cohabitating infected catfish individuals with healthy ones. Daily operation and maintenance over a prolonged period was achieved by regular water exchange (30%) combined with optimal water parameters (25±0.5 °C; pH of 7.13 ± 0.5; 80% O2) for catfish.

At Experimental Location 1 (EL1), catfish were anaesthetized, and a 3x3 mm biopsy was cut from both filaments of the first gill arch within the gill chamber. The total parasite load of the individual was estimated with the parasite count obtained from the biopsy. Hosts with similar loads could then be paired, and the two members of the pair were eventually divided between the two experimental populations to test whether using this method would result in a catfish population with a more homogeneous overall parasite burden at EL1 (Figure 1.).

Individual fish were collected randomly at Experimental Location 2 (EL2) to analyze the parasite burden differences among hosts (Figure 1.).

Results
Randomly assembled groups of catfish hosts were analyzed for parasitic load by counting the gill fluke under the microscope at EL2. The assumption of equal variances has been violated for total parasite numbers between EL2 experimental catfish groups (p=0.001) resulting in a high variance in total parasite numbers.

No preference of T. vistulensis was observed between the two sides of the gill (p=0.683) however, the first and second arches showed significantly (p=<0.05 for both) higher load of parasites of the hosts, compared to the others.

Minimally invasive gill biopsy is proven to be a reliable tool (correlation:  p<0.001; Spearman r=0.7913) to estimate the parasite load of a given individual in the size range of the examined catfish (48–84g). Biopsy-based pairing yielded reduced variation (equal population variances, p=0.350) in parasite counts within experimental groups (EL1) as compared to randomly assembled groups (EL2).

(Continued on next page)
Conclusions
We believe that our findings are novel and significant, and that our work will contribute to a better experimental grouping of catfish, infected with gill flukes. Furthermore, the method can be potentially adapted to other gill parasitizing monogeneans and other fish species as well.

CULTIVATION OF GIANT GROUPER (*Epinephelus lanceolatus*) IN RECIRCULATING AQUACULTURE SYSTEMS (RAS) IN EUROPE

Mirko Bögner*, Bert Wecker, Jaime Orellana, Svea Erichsen, Jörn Halfer, Kyra Böckmann, Matthew J. Slater

Alfred Wegener Institute, Helmholtz- Center for Polar- and Marine Research
Email: Mirko.Boegner@awi.de

Introduction:
Giant grouper, *Epinephelus lanceolatus*, a species already successfully farmed in aquaculture in the Pacific region, appears ideally suited for RAS aquaculture in Europe because of its good growth performance, known reproduction and market potential. However, for successful cultivation in RAS, reliable and site-adapted data must be available. Preliminary studies were carried out for future commercial cultivation in closed facilities and economic calculations for the species were performed for Germany. An important aspect is the identification of formulated feeds that meet the requirements of the species and can be purchased in Europe. In addition, it is necessary to determine an optimal rearing density at which the animals can grow in an economically viable manner while optimizing animal welfare.

Material and methods:
For the feed trial, commercially available feeds in Germany were tested. 3 basically suitable feeds with different protein/fat ratios were selected for the trial. Feed 1: 42/13, Feed 2: 54/14, Feed 3: 55/17. Juvenile grouper (61.5 ± 6.9 g) were fed ad libitum in replicate (4) four times daily for 35 days. At the end of the experiment, growth- and blood parameters and body composition were determined. In a second experiment, juvenile grouper (437.4 ± 40.3 g) were kept in quadruplicate tanks for 8 weeks at different stocking densities - low: 60 kg/m³, medium: 80 kg/m³, high: 100 kg/m³. Growth, stress parameters and external appearance were determined regularly.

Results and conclusion:
Results showed that 2 of the 3 tested diets, appear suitable in principle for giant grouper (table 1). Growth was comparable to previous studies using optimized diets Lin / Yeh (2022). However, insufficient protein content has a negative effect on the animals. In addition, it was shown that the tested rearing densities had no effect on growth, stress and external appearance in the trial. These data, together with production data of existing giant grouper aquacultures and site-specific financial and market data, confirm that the giant grouper appears suitable for cultivation in RAS in Europe.

Introduction
The world will be dependent on the development of novel feed ingredients from renewable sources to ensure sustainable growth of the aquaculture industry. A more balanced harvesting approach across the ecosystems can maintain ecological diversity in the oceans and make alternative marine resources available as future feed ingredients for aquaculture. Zooplankton like Calanus finmarchicus are viable raw material candidates, as they have optimal nutrient profiles for aquatic animals and may be sustainably harvested in large volumes. In this study, the aim was to investigate if a novel protein hydrolysate of C. finmarchicus could influence growth performance, oxidative stress, and intestinal health of European sea bass (Dicentrarchus labrax) juveniles in a feeding trial lasting 84 days.

Material and methods
The effect of dietary inclusion of hydrolysates was tested in a feeding trial with European sea bass juveniles, benchmarking calanus hydrolysate (CH) against other commercial hydrolysates of sardine, tuna, and salmon at 5 % inclusion. Fish were group weighed at day 0, 30, 67, and 84. Three fish per replicate tank were sampled for health assessments; the liver for analysis of oxidative stress (hepatic protein carbonyls and antioxidant enzymes), and faecal content for intestinal status (calprotectin and mucins). Data were subjected to a one-way analysis of variance (ANOVA), and means were compared with the Tukey method. Statistical significance was tested at a 0.05 probability level (n =3).

Results
CH improved growth performance of European sea bass juveniles, showing higher body weight and lower FCR compared to diets with other marine hydrolysates (Fig. 1).

The health assessment results at the end of the trial showed significantly lower oxidative stress (Fig.2A) and lower intestinal inflammation (Fig. 2B) in European sea bass juveniles fed diets with CH inclusion.

Conclusions
Dietary inclusion of CH at 5 % led to increased growth performance of European sea bass juveniles in the feeding trial. CH was also associated with significantly lower oxidative stress and less inflammation in the intestines, highlighting the potential of the hydrolysate as a functional feed ingredient for improved growth and health.

Introduction

The first commercial system using abalone effluent to cultivate the green seaweed *Ulva* was built on an abalone farm in South Africa in 2002. Over 1000 tonnes fresh weight of *Ulva* was produced in South Africa in 2007, grown predominantly in abalone effluent, and the main reasons for this seaweed production was as additional feed for the abalone, as well as to provide bioremediation of the effluent to enable partial water recirculation on a section of a single farm. Bolton et al. (2009) carried out a SWOT analysis of the use of these abalone/IMTA systems. After a further 15 years the aim of this contribution is to re-examine the findings of the analysis of Bolton et al. (2009) in the light of the subsequent development of the abalone/*Ulva* IMTA commercial operations in South Africa.

Progress and strengths

The strengths previously documented are largely still applicable, and so we could say that the development of the South African abalone aquaculture industry, and the role of IMTA, has developed as predicted with no major changes. The *Ulva* produced on abalone farms is not sold but is primarily utilised on-farm as feed addition. Thus, official government figures, the latest being 2718.10 tonnes in 2020, are an estimate. There are 5 farms (of the total of 14 commercial abalone farms in South Africa) which operate ca. 30m-long paddle raceways to cultivate *Ulva*. Four of these grow the *Ulva* in abalone effluent, and the other grows only in fertilised seawater. Thus production has increased by almost threefold in the last 15 years. Also in 2007 there was a newly built section of a single farm operating on partial recirculation using *Ulva*, and since 2014 two entire new farms are operating on this principle. The success of these integrated operations is evidenced by the continuous fully commercial operation in various forms for more than 20 years. The integrated system warms the water for abalone cultivation resulting in increased growth rates, and there are demonstrated improvements in the microbiome and other aspects of system and animal health.

Problems and weaknesses

Apart from the COVID-19 pandemic, the major setback has been a large and unusual dinoflagellate bloom (HAB) in January 2017 resulting in losses of >250 tonnes of abalone at three farms. At least one other farm successfully made use of the predicted potential of the IMTA system to switch to 100% recirculation. This can be done for at least 3 days without adverse effects on integrated farms. Lack of knowledge of the *Ulva* crop has been largely remedied, and most of the predicted weaknesses are well managed.

Opportunities

These systems have indeed assisted with the continued expansion of the local abalone industry, and integration is becoming widely acknowledged as a potential benefit both locally and internationally. Much work is being conducted on the benefits of *Ulva* as a component in formulated aquafeeds, as predicted. The stated benefits to sustainability of this system are becoming better recognised but are still far from being fully realised.

Threats

Diseases and grazers have thus far proved amenable to successful management. The predicted two major threats to IMTA expansion still exist. The cost of using space to grow *Ulva* rather than profitable abalone was borne out by a farm which was designed as an IMTA system but was changed to a pure abalone cultivation shortly before construction. A main reason cited was potential for biosecurity risks with recirculation of water and/or seaweed through the system. Nevertheless, area under IMTA has considerably increased although some producers are still reluctant to integrate their operations due to these thus far unsubstantiated risks.

(Continued on next page)
Conclusions

These South African abalone/\textit{Ulva} integrated aquaculture systems are slowly becoming recognised as a leading example of IMTA in action. The benefits to the system with respect to biosecurity, both in water integration and seaweed as feed component, are increasingly being demonstrated. Nevertheless there is still the perception of recirculation as a disease transmission threat, which could slow further development.

Aspects of these systems have been replicated in several other world regions, including in Europe and Australia. There are three main reasons for growing \textit{Ulva} in these land-based systems: 1: as a product (feed, feed component, biomaterial, human food etc.), 2: to enable partial recirculation saving pumping costs, 3: to bioremediate effluent for environmental benefits. In different regions/IMTA systems one or more of these benefits may dominate the reasons for integration. It seems very likely that the application of land-based, seaweed/invertebrate integrated aquaculture will continue to be developed as a successful example of marine IMTA in South Africa and around the world.

Sturgeons are the world’s most critically endangered group of species. One reason for this dramatic situation is the long-time unsustainable and often intransparent or even illegal sourcing and trading of the fish or its products, such as caviar. For sturgeon conservation, it is fundamentally important that products of poached sturgeons cannot infiltrate the legal market and that sturgeon aquaculture and trade are fully trustworthy. Furthermore, it is in the interest of caviar producers and traders to increase consumer confidence and to prove that their products and their business conduct are fully correct and conforming to the law at every stage of the supply chain.

The quantitative measurement of stable isotopes has the potential to determine the regional provenance of food commodities as it has been established for various agricultural and animal products, such as beef, dairy products, honey, and beverages. To increase transparency and traceability further, it is also necessary to track the origin of products back to farm level. That technology was already demonstrated in the BLE-funded Watermark project (2015, FKZ-28-1-91.024-13). It was shown that tracing pigs and cattle to the farm is possible within a probability context.

Traceability possibilities have not been tested for sturgeon yet. Therefore, a proof of concept has been launched to verify the potentials to generate individual signature patterns of sturgeon farms and their products (caviar, meat) based on stable isotope profiles.

The focus is to verify how robust the isotope signatures are at the sturgeon farm over a longer rearing period. As a rule, the animals’ tissue and tissue water reflect the isotopic signatures of the local water and feed. However, isotopic profiles of local water source and feed can change over time due to seasons. In addition, there is a risk that processing steps (extraneous water, salts) can also influence traceability.

Accordingly, in the Transparent-Sturgeon project, caviar, water, sturgeon and feed samples are taken from different European farms over a longer period of time and the robustness of the farm signature is tested. In a first step it could be shown that isotope signatures from 50 caviar samples across three different farm locations in Belgium, Germany and Italy were constant over a period of at least 3 to 6 months.

These results are promising to enhance the dataset with additional farms and extended sample periods. Thus, a standardized protocol could be established of tracking the origin of traded caviar back to the farm level which will help to increase transparency in the caviar market.
INTRODUCTION OF STRESS, SEX AND SEXUAL MATURITY ON SCALE CORTISOL AND DHEA CONCENTRATIONS IN RAINBOW TROUT (Oncorhynchus mykiss)

M. Bortoletti*, A. Meloni, E. Fonsatti, G. Gabai, G. Radaelli and D. Bertotto

Department of Comparative Biomedicine and Food Science
University of Padova, Italy
E-mail: martina.bortoletti@unipd.it

Introduction
Fish welfare is traditionally assessed by measuring cortisol levels, which is the quintessential stress hormone in these animals. However, the best practice to assess animal welfare is to utilize multiple indicators in order to provide a more comprehensive portrait of the animal condition, especially when assessing long-term stress. Among the physiological indicators, dehydroepiandrosterone (DHEA), a precursory androgen with anti-stress effects, seems to be promising in diagnosing mammalian chronic stress through the cortisol:DHEA ratio [1] besides DHEA has recently been demonstrated to increase in fish exposed to a chronic stress [2]. However, while DHEA in mammals has been shown to act in opposition to cortisol in many physiological pathways and to exhibit antioxidant, neuroprotective and immuno-protective characteristics [3], still very little is known about its physiological meaning and possible implication in the stress response in fish. For this reason, the present study aimed to investigate how the levels of this steroid are affected not only by a common stressful aquaculture practice, but also by sex and degree of sexual maturity in rainbow trout (Oncorhynchus mykiss) scales, a promising medium for multi-hormone stress analyses [4].

Materials and methods
The experiment was performed at a commercial farm where four groups of rainbow trout (n=96) were sampled: mature females (990 ± 28.5 g) and males (1005 ± 40.7 g), immature females (1350 ± 48.8 g) and males (1394 ± 33.3 g). Half fish of each group were subjected to 30 minutes confinement stress and the other half were controls. Prior to sampling, fish were sacrificed with an excess of anesthetic (MS222 Sigma-Aldrich) and subsequent cut of the spinal cord. Scales were collected after removing excess mucus by scraping the side of the fish with a small plastic rod and subsequently stored at -20°C until the analysis.

Cortisol and DHEA were quantified in the scales using a specific microtitre radioimmunoassay (RIA). Different washing protocols were tested and the RIA protocol was adapted and validated. All the data are expressed as mean ± standard error and were previously evaluated for normal distribution. Differences between treatments were analyzed using a general linear model (GLM) using sex, maturity and stress as main factors. The level of statistical significance was set at p < 0.05.

Results and discussion
Among the three factors studied, the degree of sexual maturity was the major factor influencing cortisol concentration, with mature fish having significantly higher cortisol levels than the immature (p<0.01). This result aligns with previous studies conducted on rainbow trout, in which mature individuals, both males and females, showed higher plasma cortisol levels than immature [5]. Differently, sex affected DHEA concentration, with males showing significantly higher levels than females (p<0.05). To our knowledge, DHEA has not been previously quantified in relation to sex in fish and thus there is currently no information available to compare our findings. However, there is evidence of higher DHEA concentrations in males than females both in humans and other mammals [6,7]. Results did not show stress-related difference in both cortisol and DHEA levels. This could be linked to the kind of stress applied in this study, i.e. acute, and to the bony nature of the scales, that slowly accumulate hormones. Nevertheless, the cortisol:DHEA ratio, resulted higher in the stressed fish compared to the controls, although not significantly (p=0.058). At present, knowledge about the involvement of DHEA in fish stress response is scarce. However, considering that it has been shown to counteract cortisol in mammals, this ratio might better describe an animal’s stress status than either hormone alone. Indeed, in humans and other vertebrates, high ratios of cortisol to DHEA have been considered indicative of chronic stress [8]. Finally, the meaning of the interactions between the three factors studied (sex, maturity and stress) is still under investigation.

(Continued on next page)
Conclusions
In the present study, both cortisol and DHEA levels were successfully quantified in the scales of rainbow trout. Furthermore, the obtained levels are perfectly in line with those reported in the only other study currently present on rainbow trout exposed to chronic stress [2], attesting the applicability of the RIA method developed in this study in quantifying these hormones in fish scales. To our knowledge, this is the first time DHEA has been evaluated with respect to sex and degree of sexual maturity in fish. Nevertheless, further investigation is required to better understand the role of this hormone in fish physiology. Moreover, these results need to be implemented by assessing a longer-term stress in order to test the suitability of DHEA as an alternative physiological indicator to be used alongside cortisol in the assessment of chronic stress in fish.

Introduction
The most apparent aquaculture benefit of the reproduction of external fertilizers, such as fish, is that their gametes which are naturally released into the environment where fertilization occurs, could be collected before fertilization and used in artificial breeding measures. Thus the gametes handling becomes almost an indispensable part of any artificial reproduction in most fish species. It allows optimization of fertilization rates, producing large numbers of healthy offspring, and applying selective breeding programs, increasing the quality and efficiency of artificial reproduction.

Compared to artificial reproduction programs in other species, including mammals, which generally focus on acquiring a relatively small number of individuals, fishes produce a huge quantity of gametes in both sexes and rely on a large number of offspring. In such a situation, preserving the high quality of maximal numbers of eggs and spermatozoa before fertilization is essential. At the same time, it is important to keep enough high genetic variability to avoid inbreeding and potential homogeneity of progeny.

In this report, we are summarising our recent results on sperm handling and suggesting the most promising steps for optimizing and improving sperm handling methods in the future.

Results
Sperm cryopreservation. Currently, cryopreservation protocols cover the vast majority of commercially important fish species with high preservation of sperm motility and fertilisability after thawing, using different cryoprotectants and freezing techniques. Moreover, sperm cryopreservation still requires the next steps in technology development, probably by cost-cutting and simplifying the methods, to become widely used in aquaculture.

In the past few years, we (1) optimized the protocols for sturgeon and carp sperm cryopreservation by adjustment of sperm concentration before freezing (Nascimento et al., 2021; Sotnikov et al., 2023); (2) tested using hypertonic cryopreservation media for cryopreservation of large volumes of carp and sterlet spermatozoa required for fisheries practice (unpublished data); (3) optimized two most common methods of uncontrolled sperm cooling by floating raft in Styrofoam box and dry shipper container (Horokhovats’kyi et al., 2017).

Short-term sperm storage. Similarly to cryopreservation, many protocols for short-term storage exist for fish spermatozoa. In contrast to cryopreservation, short-term storage accumulates damage in the spermatozoa slowly, and the last storage stages are commonly associated with increased bacterial growth, suggesting using antibacterial storage media. Therefore understanding the changes in the spermatozoa during storage is the critical element for further improvement of this handling method.

Recently we tested the effect of hypothermic storage: (1) on the epigenetics of sperm and the resulting embryos (Cheng et al., 2023); (2) on spermatozoa’s ability to tolerate temperature (Zhang et al., 2023) and osmotic shock (unpublished data); (3) on spermatozoa metabolome (unpublished data) and (4) bacterial contamination and apply polyphenolic extracts as an alternative to antibiotics (unpublished data).

Sperm separation. Unavoidable damage (due to ice crystals growing in cryopreservation or sperm aging during short-term storage) results in the appearance of a nonvaluable and semi-valuable population of spermatozoa (which still could be involved in fertilization). Thus, developing spermatozoa separation methods is the most promising next step for improving fertilization outcomes by eliminating damaged sperm populations. At the same time, these methods may allow us to study the separated populations more deeply to understand their specific physiological differences and possibly resistance to different types of damage.

(Continued on next page)
Currently, we are developing and testing methods for spermatozoa separation in different fish species by ultrasound (unpublished data) and Percoll gradient (Horokhovatskyi et al., 2018). At the same time, we are searching for the metabolic markers of individual sperm samples which can predict their storage and freezing capacity to maximize the outcomes.

**EX SITU BIODIVERSITY CONSERVATION: IMPORTANCE, ISSUES AND STRATEGIES**

E. Boscari and L. Congiu

University of Padova
Department of Biology (DiBio)
Via Ugo Bassi 58b, 35131 Padova (Italy)
Mail: elisa.boscari@unipd.it

**Introduction**

Sturgeon species and populations have experienced a dramatic collapse mainly due to a progressive disruption of habitat suitability in their distribution range and overexploitation for commercial purposes (He et al., 2017). This has pushed many of the species to the brink of extinction (Congiu et al., 2023). Consequently, massive efforts have been implemented in the past and others will be needed in the future, to rescue these threatened species.

In this context, *ex situ* conservation is a cornerstone of protection, maintenance and propagation of species outside their natural habitats and should guarantee needed conditions for secure life and optimal breeding so that releases can be put in place in the future (Overton et al., 2023). For sturgeons, *ex situ* conservation is entrusted, in a relevant part, to aquaculture facilities where they are farmed mainly for commercial interest, opening a heated debate about the use of aquaculture stocks for conservation purposes and about which features they should have to ensure their management success from establishment to propagation (Froehlich et al., 2017).

**Results and Discussion**

High long-term performances are achieved if the *ex situ* strategy aims at maintaining genetic diversity of the stocks in order to minimize adaptation to captivity and genetic erosion and maximise adaptive potential after release. This is complicated in sturgeons by their complex genomes, long life cycles, late sexual maturity and large size as well as by the ease interspecific hybridisation with production of fertile progeny.

Models, principles and *ex situ* strategies for an informed biodiversity conservation of aquaculture stocks are presented and discussed on the bases of case studies on different sturgeon species (Barca et al., 2022; Boscari et al. 2121; 2022). Important conservation topics that will be covered are: the role of the identification of conservation units or geographic structured populations, the importance of stocks’ pureness, the principles underlying the selection of target stocks for conservation such as the assessment of relatedness and the reconstruction of pedigree information, and useful strategies to set-up specie-specific breeding plan.

**Conclusion**

The aim of this presentation is to stimulate the discussion on the importance of a shared approach among different stakeholders. Recognition of this need will require adoption of a new paradigm for sturgeon *ex situ* conservation, in which on the one hand aquaculture makes an additional effort to preserve diversity while on the other hand conservation projects and competent authorities support the extra costs of farming-for-release. The protection of the most endangered group of animal species would certainly benefit from this change of perspective.

CULTIVATION OF HIGH-ADDED VALUE SEAWEED SPECIES IN A ON-LAND OYSTER-SEAWEED IMTA SYSTEM: THE CASES OF *Codium tomentosum* AND *Chondrus crispus*

S. Bouchemousse*, P.-A. Larsonneur, J. Grassien, O. Durif, L. Costes, and R. Michel

CEVA, Centre d’Etude et de Valorisation des Algues, Presqu’île de Pen Lan, 22610 Pleubian, France
Email: sarah.bouchemousse@ceva.fr

Introduction
Based on the association of different species connected by trophic interactions, the concept of Integrated Multi-Trophic Aquaculture (IMTA), performed in-land, aims to improve water quality of aquaculture systems and this diversification would ensure more stable incomes for producers. Oyster farmers usually perform mono-specific cultures, leading to a high vulnerability of economic spinoffs linked periodically to poor water quality and population declines, highlight a need for securing the sector’s future. Therefore, IMTA including seaweeds in oyster systems should be tested to evaluate potential of seaweeds 1) to improve water quality and 2) to add economic value to oysters’ farmers. In this context, we performed pilot IMTA experiments with Pacific cupped oysters and two high-added value seaweed species, *Codium tomentosum* and *Chondrus crispus*. In this study, we particularly explore:
- the impact of oysters’ effluents on growth and composition of both seaweeds
- the potential of seaweed nutrients uptakes

Materials and Methods
Specimens of *C. tomentosum* and *C. crispus* were collected in Brittany (France) from longlines on the CEVA concession and from mid-littoral tide pools at Pors Rand respectively. Half-raising oysters *Magallana gigas* were provided by a local oyster farmer. For each seaweed species, the experiment was designed with the following conditions:
- a seaweed monoculture in 340L tanks at a density of ca. 1.2 g/L, used as a control of the oyster-seaweed experiments
- a co-culture of seaweed in 340L tanks at a density of ca. 1.2 g/L, in a recirculating system with 340L tanks containing oysters at a density of ca. 5 g/L
- (Only for *C. crispus*), a seaweed monoculture in 340L tank at a density of ca. 1.2 g/L, enriched with F/2 culture medium, used as a positive control of “classical” on-land seaweed production.

Except the F/2 culture medium condition which was run in duplicate, all conditions were run in triplicate. Oysters were fed every 2 days with a Shellfish Diet following the manufacturer recommendations. Seawater of each tank was renewed weekly and was sampled before and after renewal to assess ammonium, nitrates, and phosphate contents. The whole biomass of each seaweed tank was weighed every two weeks to estimate the Specific Growth Rate (SGR). In addition, visual appearance of seaweeds and epiphyte development were qualitatively recorded during the experiment. At the end of each experiment, fresh biomass of each replicate was weighted and dried to evaluate the dry matter content and components of economic interests were quantified, i.e. glucuronic acid and sulphated polysaccharides for *C. tomentosum* and carrageenan for *C. crispus*.

Results & Discussion
Whatever the seaweed species, the recirculating system with oysters rearing showed a positive effect on SGR and fresh biomass of seaweeds. Indeed, SGR was significantly higher in the co-culture condition with SGR values between 1.5 and 4 times higher compared to the control. This difference was particularly marked during the first weeks of cultivation for *C. tomentosum* and after 4 weeks for *C. crispus*. However, due to the high nutrients input from oysters in the co-culture condition, a high development of epiphytic organisms has been reported some weeks after the beginning of the experiment pointing out the need of pure initial biomass. By opposite, a discoloration of specimens of both seaweed species in the control condition was observed which suggests a nutrients/minerals/vitamins deficiency (Fig. 1 for *C. crispus*). However, for both seaweed species, almost no significant differences have been observed between the co-culture and the control condition in the components analysed, suggesting that oyster-seaweed IMTA systems are likely to produced seaweed of valuable commercial interest. Interestingly, *C. crispus* cultivated in seawater enriched with F/2 medium displayed the highest values of SGR during the first weeks of the experiment and the highest final biomass. Moreover, *C. crispus* specimens showed a high-volume development compared to both other conditions (Fig. 1). Therefore, even if oysters provide enough nutrients to increase biomass gain of seaweeds, the F/2 medium remains more efficient.

(Continued on next page)
Despite high concentrations in renewal water, nitrates are almost completely consumed by both seaweed species in all conditions, suggesting that *C. tomentosum* and *C. crispus* are efficient to recycle nitrogen inputs from either natural environment or oysters’ excretion. For phosphate concentrations, higher values were reported in the co-culture condition compared to the control for *C. tomentosum* while similar values were observed for *C. crispus*, suggesting that *C. crispus* is more efficient than *C. tomentosum* in recycling phosphates from oyster effluents. No clear pattern has been highlighted for ammonium.

Altogether, this study provides first insights into the potential of IMTA with oysters to growth economic high-added value seaweed species. Beside the economic interest, the two seaweed species studied, but particularly *C. crispus*, could be considered as new biofilters to extract effluents from various on-land rearing such as fish or shrimp ponds.

Fig. 1. Visual appearance of *Chondrus crispus* after 12 weeks in recirculating system with three different culture media (a: seawater only, b: seawater with oysters, c: seawater with F/2 medium)
REUSE OF WATER FROM BFT SYSTEMS THROUGH DENITRIFICATION PROCESS FOR Penaeus vannamei FARMING

Introduction

Nitrification-dominated bioflocs are a common challenge in aquaculture systems, where nitrate production becomes constant and accumulates in the system. The build-up of nitrate over several cycles can harm farmed animals, causing reduced growth and survival. In order to overcome this production bottleneck and treat the water, strategies such as the biological denitrification process must be adopted to make the water suitable for culture or disposal. This study aimed to evaluate the performance of Penaeus vannamei and the water quality after being subjected to a biological anaerobic denitrification process using water from a biofloc technology (BFT) system. By assessing the effects of the denitrified water on the growth and survival of the shrimp, as well as on water quality parameters, this study provides valuable insights into the potential benefits of using denitrified water in BFT systems, ultimately contributing to the sustainable development of aquaculture.

Material and Methods

A 63-day experiment was carried out at the Marine Station of Aquaculture of the Federal University of Rio Grande. P. vannamei juveniles (1.30 ± 0.48 g) were stocked in 150-liter tanks at a density of 500 animals/m³. The experiment consisted of comparing denitrified water and natural seawater (never used for shrimp cultivation) under different biofloc formation strategies: with or without mature biofloc inoculum. Thus, the treatments were: DWI – denitrified water with inoculum; DWF – denitrified water without inoculum; SWI – sea water with inoculum; and SWF – seawater without inoculum, with three replicas each. In the treatments with biofloc inoculum, 15 L of water from a mature biofloc system was added to the tanks (10% of the working volume). In the treatments without inoculum, the bioflocs formation was stimulated from zero through the manipulation of the C/N ratio. Temperature, salinity, dissolved oxygen, pH, ammonia, nitrite, nitrate, alkalinity, and total suspended solids in the water were monitored. To assess growth and health conditions, 30 animals were randomly collected each week from each unit, weighed individually, and then returned to the tanks. At the end of the experiment, survival, final weight, weekly growth, and productivity were evaluated.

Table 1 - Water quality parameters of P. vannamei rearing in a biofloc system with water subjected to anaerobic denitrification. Different letters on the same line indicate a significant difference (p<0.05) between means.

Results

Animals exposed to denitrified water treatment without biofloc inoculum (DWF) died after one week of cultivation. The 100% mortality found in the treatment using denitrified water without biofloc inoculum could have been caused by various factors such as the colonization of opportunistic microorganisms in the environment, leading to diseases and ultimately death of the shrimps; the formation of nitrogenous disinfection by-products, which are known to be toxic to aquatic organisms; some unidentified metabolite or compound produced during the denitrification process, leading to adverse effects on the shrimps. Further investigation is necessary to identify the exact cause of the mortality and prevent future occurrences. Either way, no differences in survival (<89%) were found in the treatments using denitrified seawater with inoculum and natural seawater treatments, which indicates that the biofloc inoculum served as a biological treatment in denitrified seawater, readjusting the water for cultivation. Differences in the water quality parameters were found in ammonia, nitrite, nitrate concentrations, as well as in water exchange volume, organic carbon, and alkalizing agents between treatments. Total ammonia concentrations were highest in the treatment without biofloc inoculum, and nitrite concentrations were higher in the same treatment. Final nitrate concentrations were highest in the denitrified water treatment and lowest in the seawater treatment without inoculum. The treatment with denitrified water had higher pH values, and no significant difference was found in alkalinity concentrations between treatments. The treatments with inoculum had no water exchanges and organic carbon supplementation. The results indicate that it is possible to use denitrified seawater from a biofloc system for shrimp farming. However, alternatives for water treatment after the denitrification process need to be investigated.

Conclusion

The findings suggest that water from a biofloc system can be recycled by undergoing anaerobic biological denitrification. The denitrification process used is straightforward and can be performed in sedimentation basins or the same tanks used for cultivation once the animals are removed. This reduces the requirement for equipment and operational procedures. However, alternatives for further treatment of denitrified water are still necessary to ensure its suitability for cultivating P. vannamei, irrespective of the use of biofloc inoculum.
DO COMMON STUNNING METHODS RENDER AFRICAN SHARPTOOTH CATFISH (Clarias gariepinus) INSENSIBLE PRIOR TO SLAUGHTER?

J. Brijs*, T. Schwerte¹ and A. Gräns²

*E-mail: j brijs 84@gmail.com

Introduction

Farmed fish are a critical source of food worldwide, and aquaculture is expected to provide nearly two-thirds of the world’s fish supply by 2030. However, there is growing concern about the welfare of farmed fish, as many slaughter procedures have the potential to cause substantial suffering for prolonged periods of time. To address this issue, it is crucial to conduct comprehensive evaluations of potentially more humane slaughter procedures.

Humane slaughter requires that fish are stunned prior to killing (i.e., rendered insensible) and remain so until death without experiencing avoidable fear, anxiety, pain, suffering, or distress. To assess insensibility following stunning, behavioral indicators such as the ability to maintain equilibrium, reactions to painful stimuli, the vestibulo-ocular or ‘eye roll’ reflex, and ventilatory reflexes have traditionally been used. However, it has become increasingly clear that these indicators alone are insufficient, and that neurophysiological evidence of insensibility must be obtained to ascertain the effectiveness of stunning.

A relatively robust approach for gauging the state of sensibility in fish is by assessing the presence or absence of visually evoked responses (VERs) from electroencephalographic (EEG) measurements. VERs are measurable changes in brain electrical potential in response to a visual stimulus (i.e., a flashing light) that produce a distinct waveform in EEG recordings milliseconds after the stimulus. This makes it a powerful tool for evaluating the effectiveness of stunning procedures, as the abolition of VERs has been confirmed to be an objective and unequivocal indicator of insensibility in numerous species of mammals, birds and fish.

Thus, here we utilized a non-invasive electroencephalographic (EEG) method to monitor changes in the state of sensibility of African sharptooth catfish (Clarias gariepinus) to assess the effectiveness of various stunning procedures (Brijs et al., 2021).

Materials and methods

A custom-made suction cup fitted with electrodes was attached externally to the head of the catfish (Fig. 1A-B). The EEG of catfish was then continuously measured in response to 150 ms light flashes at 2 Hz from a strobe-light in a dark room. EEG signals were subsequently filtered and analysed for VERs for 10 min prior to stunning (Fig. 1C).

Figure 1: A schematic of the non-invasive EEG recording device (A) and its placement on an African sharptooth catfish (B). Representative examples of visually evoked responses (VERs) before stunning (C) and after an effective (black trace) or ineffective (grey trace) stun (D). Figure adapted from Brijs et al. 2020.

(Continued on next page)
Following the pre-stunning period, catfish were subjected to either ice chilling (i.e., immersion in an ice slurry for 30 min), electrical stunning (i.e., 2 s, 5 s or 10 s exposure to an electrical current of 1.69±0.09 A dm$^{-2}$), electrical stunning and exsanguination (i.e., 10 s exposure to an electrical current of 1.69±0.09 A dm$^{-2}$ followed by a throat cut), percussive stunning (i.e., a sharp cranial blow by a fish priest), or isoeugenol immersion (i.e., immersion in 10, 20, 30, 60 or 100 mg L$^{-1}$ isoeugenol). EEG signals were then continuously recorded in response to light flashes to evaluate if, and how long, it took for VERs to disappear and then reappear (Fig. 1D). Behavioural indicators (i.e., ventilatory/body movements and aversive behaviour) were also recorded throughout the stunning procedures.

**Results and discussion**

Based on the abolition of VERs:

**Ice chilling** induced insensibility between 2.6 and 7.6 min, during which catfish exhibited aversive behaviours (e.g., thrashing around and trying to escape vigorously). Once VERs were lost, they remained absent so long as catfish remained immersed in the ice slurry.

**Electrical stunning** induced insensibility immediately but not irreversibly. Depending on the duration of the stun, catfish regained VERs within 0.5 to 4.9 min after the completion of the electrical insult.

**Electrical stunning and exsanguination** induced insensibility immediately and irreversibly if fish were immersed in an ice slurry following the throat cut. However, if placed in warm water following the throat cut, fish regained sensibility prior to death.

**Percussive stunning** induced insensibility immediately and irreversibly when administered correctly. However, 36% of catfish regained sensibility, which is likely explained by the difficulty associated with administering an accurate manual percussive stun of sufficient force on a live and struggling catfish.

**Immersion in isoeugenol** at doses exceeding that recommended for euthanasia in salmonids did not induce insensibility in catfish, which indicates that this substance may not be suitable for stunning this species. However, the potential for using isoeugenol as a pre-stunning sedative for improving handleability and reducing handling stress of this species warrants further investigation.

**Conclusion and future directions**

This study clearly demonstrates that when singularly administered, none of the abovementioned stunning procedures could reliably induce insensibility immediately and/or irreversibly without compromising fish welfare. However, these shortcomings can be resolved by using a combination of methods, as a correctly administered electrical or percussive stun can immediately induce a state of insensibility, which can be maintained until death if fish are exsanguinated and immersed in an ice slurry directly after the stun.

To further improve the welfare of fish during slaughter, a promising future direction is to develop a portable, user-friendly, and cost-effective diagnostic tool based on our laboratory-based neurophysiological technique. This tool can be used by various stakeholders, including stunning equipment manufacturers, fish farmers, and regulators, to verify, test, and optimize stunning methods before commercial use. By implementing these measures, we can significantly enhance the welfare of fish during slaughter and ultimately achieve more sustainable and ethical practices in aquaculture.

Introduction
Aquaculture production is in continuous growth both for macroalgae species and fed fish species, like Atlantic salmon (*Salmo salar*) (FAO, 2020). The growth of fed fish species calls for novel feed resources to enable this growth, and in this regard, algae have been recognized as having promising potential relating to their nutritional value, sustainability in production, as well as their biologically active components (Naylor, 2009; Wan et al., 2019; Albreksten et al., 2022). However, the expected effects will depend on the species being fed, and the algae species in question.

The red seaweed species *Palmaria palmata* has been suggested as a feed additive candidate, mainly due to its high protein content and bioactive components that could have positive impacts on fish health (Florence, 1999; Holdt & Kraan, 2011; Grote et al., 2019). Wan et al. (2016) used different inclusions of *P. palmata* in feed for Atlantic salmon during the last feeding phase before slaughter, finding no difference in growth between algae-fed and control groups. This indicates the possibility of also using algae as a feed ingredient for carnivorous fish. However, the effects of such supplements in early feeding stages is yet to be determined. The fish are sensitive to environmental impact in the early phase (Lowe, 2021), suggesting that potential positive or negative effects from different factors like feed can be expected to be magnified. This study characterizes the effects of using a red algae (*Palmaria palmata*) as feed supplementation during the start feeding period of Atlantic salmon (*Salmo salar*) and discuss this potential use of this algae biomass.

Materials and methods
A 4-month start feeding trial was conducted by feeding tanks of Atlantic salmon fry up till an average weight of 10 grams. The algae used in the trial was sourced locally from the Trondheimsfjord shore (Storsteinan) during September. It was rinsed, freeze dried and ground into a powder for feed production.

Triplicate groups were fed with control and algae supplemented (5% dried *P. palmata*) diet from start feeding until an average weight of 5 grams, then a standard feed without supplementation until the end weight of 10 grams. This enabled a comparison of which effects relate to the algae diet, and whether these would be sustained after a diet change. Sampling of tissue from liver and intestines were performed at average individual fish weights of 0.4, 1, 5 and 10 grams, and samples were used to assess growth, intestinal development and health, and microbiological flora.

Results and discussion
Preliminary results indicate no negative effects on growth from the algae addition to the diet, with a higher average end weight for the algae fed group (10.4±3.1 gram±SD) but no significant difference from the control group (10.2±2.9 gram±SD). There was a non-significant higher survival rate in the *Palmaria*-fed group. These results give a preliminary indication that the red algae supplement does not have a harmful effect on the growth and survival of salmon fry.

Most samples, including tissue for histological and microbiological analysis, are still being processed. Results from this will be included in the amended abstract. Further discussions and results will be added to the amended abstract.

Conclusion
The study’s initial conclusion is that the use of red algae as a feed supplement can give equal growth as commercial feeds used today. Further conclusions will be included with the amended abstract.

Introduction
Buffeljags Abalone is a commercial abalone farm in South Africa that practices integrated multi-trophic aquaculture (IMTA) by growing the green seaweed *Ulva lacinulata* in D-shaped paddle-raceways receiving effluent water from adjacent *Haliotis midae* raceways. This practice allows for bioremediation of farm effluent, partial recirculation of water and the cultivated seaweed is often used as supplementary feed. Seaweeds cultivated in IMTA have also been reported to have a modulatory effect on the microbiome.

Microorganisms play vital roles in aquaculture systems, including DOM and POM decomposition, fermentation, nitrification, nutrient cycling and protection against pathogenic microorganisms. Host associated bacteria can synthesise essential amino acids, enhance digestion efficiency by supplying enzymes, produce essential micronutrients and metabolites (e.g., SCFAs), and enhance growth, health and development/morphology of the host. The microbiome of an IMTA and the associated species, is likely influenced by feeds and environmental factors but also by changing conditions during grow-out. Therefore, the aim of this study was to characterise the bacterial microbiome of hatchery-produced juvenile abalone (3 - 10 mm shell length (SL)) and the sources of bacterial introductions (feeds and seawater), and to compare this with the microbiome of adult abalone (± 70 mm SL), and their rearing environment, cultivated grown in an integrated abalone-*Ulva* IMTA system.

Materials and Methods
Hatchery-representative samples were collected from three tanks (L x W x D: 0.68 m x 0.50 m x 0.12 m) in the Buffeljags Abalone commercial hatchery, each stocked with 25 000 juvenile abalone. The juvenile abalone were fed a mixed diet of wild diatoms, formulated feed, *Ulva lacinulata* and *Gracilaria*. Samples (n = 36) for next-generation sequencing (NGS) included abalone intestines, abalone faeces, each feed, and bacterial cells in incoming seawater (500 mL) collected on 0.22 µm filters. Samples were collected in triplicate on the day that animals were moved from settlement plates to the rearing tanks and then once per month for two months. Grow-out representative samples (n = 60) were collected from three separate abalone-*Ulva* IMTA systems at Buffeljags over the course of a year. Samples included the abalone effluent water entering the *Ulva* paddle raceway, bioremediated water returning to abalone raceways after being mixed with 50% fresh seawater, and *Ulva* grown in the raceways. Simultaneously, the *Ulva* raceway that supplies the abalone hatchery with seawater was also sampled. *Ulva* in this system is not grown in abalone effluent and served as a non-IMTA control.

Intestinal samples (n = 30) from adult abalone fed diets supplemented with or without IMTA grown *Ulva* (or components of *Ulva*) were also included in this study to compare to that of juvenile abalone.

A 16S rDNA fragment was amplified to characterise bacterial communities and raw sequence data was processed using QIIME2. Bacterial 16S reads were mapped against the SILVA 16S rRNA reference database for taxonomic identification of amplicon sequence variants (ASVs). MicrobiomeAnalyst was used to assess within- and between sample bacterial diversity, as well as to quantify and visualise taxonomic abundance, perform differential abundance analyses and to identify putative functional capabilities of the taxa. Data from the respective sample sets (hatchery, grow-out and adult abalone) were treated in the same way to allow for comparisons between the datasets.

Results & Discussion
Juvenile abalone digestive tract bacteria were dominated by the genera *Formosa* (36%), *Psychrilyobacter* (11%), *Vibrio* (11%) and *Mycoplasma* (5%), all of which are known colonisers of adult abalone digestive systems and had high abundances in adult abalone digestive systems in the current study. Over time, abalone digestive tracts and their associated microbiome became more specialised, with a lower overall diversity in adult abalone guts when compared to juveniles.

(Continued on next page)
Faeces collected from juvenile abalone largely reflected their gut bacterial communities with the exception of *Tenacibaculum*, which increased in abundance from 3% in the intestines to 17% in the faeces. This could be the result of nutrient availability causing bacterial proliferation or as a result of the abalone digestive systems being a niche environment capable of selecting for/against specific bacteria. Similar observations were made for the genera *Rubidimonas* and *Lewinella*, which were present across all environmental and feed samples, but absent from juvenile and adult abalone gut samples. These results are further supported by the lower bacterial diversity observed for juvenile abalone digestive tracts (Chao1; ANOVA F-value 22.23, \( P < 0.05 \)) and adult abalone digestive tracts when compared to water and feed samples.

The gut bacterial communities of juvenile abalone were introduced by the incoming seawater, as well as the respective feeds, as a high abundance of *Vibrio* (19%), *Psychrilyobacter* (18%), *Tenacibaculum* (8%), *Formosa* (5%) and *Psychromonas* (4%) were observed in water and digestive tract samples. The *Ulva*-, *Gracilaria*- and diatom-associated microbiome also contributed to enteric bacteria of juvenile abalone, with the bacterial microbiome of *Gracilaria* and the diatoms showing a greater extent of similarity to that of juvenile abalone gut and faecal samples. Conversely, *Ulva* samples showed a distinct microbial profile, with a high abundance of *Granulosicoccus* (15%), Rhodobacteraceae (11%) and Saprospiraceae (9%), as well as other bacteria that are known for their involvement in *Ulva* morphogenesis and development. These results are similar to those obtained for samples from the grow-out IMTA system, where *Ulva* was also colonised by bacteria contributing to development of *Ulva* and nutrient cycling. In the abalone-*Ulva* IMTA, *Ulva* modulates its surface microbiome and that of the abalone effluent, reducing the abundance of certain genera, including known opportunistic pathogens, without causing a collapse in bacterial diversity of the bioremediated seawater, acting as a positive indicator for system health.

**Conclusion**

Incoming seawater and diet shapes the bacterial microbiome of the juvenile abalone gut, whereas inclusion (integration) of *Ulva* positively modulates the microbiome and contributes towards the functioning of IMTA on a commercial abalone farm. The complex interactions between microbial diversity, animal health and productivity has been observed in various aquaculture systems. This study contributes towards the understanding of the bacterial dynamics, their sources of introduction and their roles at different abalone production stages in an integrated abalone-*Ulva* system.

Introduction
More than 50% of the marine and coastal aquaculture products cultivated worldwide are macroalgae, with brown and red species dominating the sector and green algae contributing only to a small fraction (FAO 2022; Moreira et al. 2022) particularly in the last four decades, aquaculture is for the first time set to contribute half of the fish consumed by the human population worldwide. This reflects not only the vitality of the aquaculture sector but also global economic growth and continuing developments in fish processing and trade. Until a year or so ago, the production trends in aquaculture and capture fisheries were continuing without any drastic modification to those already in place at the start of this decade. The capture fisheries sector was regularly producing between 90 and 95 million tonnes per year, and aquaculture production was growing rapidly, albeit at a gradually declining rate. However, the substantial increases in energy and food prices, which started in 2007 and have continued into 2008, as well as the threat of climate change, mean that the conditions for capture fisheries and aquaculture are changing. That said, the combined effects of rising prices and climate change are complex, and they affect a very large number of fisheries and aquaculture operations in a mosaic of natural, social and economic contexts. Hence, it is too early to have a clear understanding of the cumulative impact worldwide on fisheries and aquaculture. Nonetheless, it is clear that there will be both winners and losers among fishers, aquaculturists and those employed in ancillary industries. On the one hand, rising prices for staple foods will also cause an increase in the price of many fish and fish products, and this will stimulate all in the sector to produce more. However, those who capture or culture fish, or other aquatic animals, using energy-intensive forms of production may find recent cost increases prohibitive. They may well face difficulties in continuing in their occupation, at least in the immediate future. On the other hand, low-intensity aquaculture and most small-scale and artisanal fisheries will attempt to expand production. This will increase the importance of improved governance in both aquaculture and low-energy-consuming fisheries (some near-shore fisheries, passive fishing gear, etc.). Among the green algae of economic interest is Caulerpa lentillifera, commonly known as “sea grapes” or “green caviar”. This edible seaweed is popular in the Indo-Pacific region for its unique texture and its high nutritional value (de Gaillande et al. 2017; Syakilla et al. 2022). In Viet Nam, the cultivation of C. lentillifera takes place mainly in earthen tidal ponds, where the algae are either planted directly into the sediment (sowing method) or grown on perforated plastic trays (tray method), depending on the characteristics of the pond’s substrate (Rabia 2016) www.m-hikari.com http://dx. Abstract Commercial cultivation of Caulerpa lentillifera is now gaining recognition because of the increasing demand in the domestic and international market. Studies on the different culture methods for large scale production of the species in the country are scarce. The present study evaluated the effects of two cultivation methods namely sowing and tray on the growth and biomass production of C. lentillifera cultured in brackishwater pond. For the tray method, propagules were clipped in two 0.75 m x 0.75 m tray and were hung in bamboo frame whereas for the sowing method, propagules were planted directly in the pond substrate with an interval of one meter. The weight gain using the sowing method was significantly higher and could be translated to an average of 1 kg every month of new or harvestable biomass. Specific growth rate of C. lentillifera grown in the substrate was at 3.85% day-1 during the first month and at 2.92% day-1 during the second month and was significantly higher compared to that of stocks grown in trays. High organic load of the soil (substrate. Also of economic interest in the region and used for human consumption is the spotted babylon snail Babyloba areolata. Co-cultivation of extractive species like seaweeds and fed species has been shown to effectively reduce negative impacts of aquaculture such as eutrophic wastewater (Chopin et al. 2001) especially where activities are highly geographically concentrated or located in suboptimal sites whose assimilative capacity is poorly understood and, consequently, prone to being exceeded. One of the main environmental issues is the direct discharge of significant nutrient

(Continued on next page)
loads into coastal waters from open-water systems and with the effluents from land-based systems. In its search for best management practices, the aquaculture industry should develop innovative and responsible practices that optimize its efficiency and create diversification, while ensuring the remediation of the consequences of its activities to maintain the health of coastal waters. To avoid pronounced shifts in coastal processes, conversion, not dilution, is a common-sense solution, used for centuries in Asian countries. By integrating fed aquaculture (finfish, shrimp. The objective of this study was to assess whether the integration of *Babylonia areolata* into existing sea grape ponds could potentially increase the economic profit of sea grape farmers without reducing the yield of *Caulerpa lentillifera*. The factors of (1) sea grape culture method (tray vs. sowing), (2) co-culture approach (spatially separated vs. common bottom space), and (3) *B. areolata* stocking density were investigated.

**Material and Methods**

The study consists of two experiments that were conducted at the Institute of Oceanography (IO) in Nha Trang, Khánh Hòa Province, Viet Nam: an outdoor terrace (six weeks) and an indoor laboratory experiment (four weeks). The outdoor experiment investigated how the culture method of *C. lentillifera* (in the following referred to as *Caulerpa*) and the co-culture approach with *B. areolata* (in the following referred to as *Babylonia*) affect the growth and physiology of *Caulerpa*. Three different treatments were assigned to nine 400L tanks (n=3): Only *Caulerpa*; *Caulerpa* and *Babylonia* together; *Caulerpa* and *Babylonia* spatially separated. Each tank contained *Caulerpa* in two different culture methods, on perforated plastic trays and directly in the sediment, respectively. The second experiment focused on different *Babylonia* stocking densities. Four different snail densities were set up in 10L aquaria: Control, low, medium, and high with 0, 2, 4, and 8 snails, respectively (n=5). The response parameters weight of both organisms, harvestable biomass, photosynthetic efficiency (maximum quantum yield of photosystem II, F_v/F_m), antioxidant activity (AOA, ABTS assay, following Re et al. 1999), and total phenolic content (TPC, Folin-Ciocalteu assay, following Gillespie and Ainsworth 2007) of the algae as well as NO\textsubscript{x} and PO\textsubscript{4} in the water were measured. AOA and TPC will not be considered further in the following (article in progress).

**Results and Discussion**

Overall, the presence of *Babylonia* had a positive effect on algal growth and physiology. The tray method resulted in higher weight gain and harvestable biomass of sea grapes compared to the sowing method over the course of the experiment, but only when co-cultured with *Babylonia* (Fig. 1A, B). Algae in the monocultures exhibited lowest growth rates and even decreased in weight. In the monocultures, the sowing method resulted in better growth of the sea grapes in the first weeks due to the availability of nutrients in the soil (Rabia 2016). Abstract Commercial cultivation of *Caulerpa lentillifera* is now gaining recognition because of the increasing demand in the domestic and international market. Studies on the different culture methods for large-scale production of the species in the country are scarce. The present study evaluated the effects of two cultivation methods namely sowing and tray on the growth and biomass production of *C. lentillifera* cultured in brackishwater pond. For the tray method, propagules were clipped in two 0.75 m x 0.75 m tray and were hung in bamboo frame whereas for the sowing method, propagules were planted directly in the pond substrate with an interval of one meter. The weight gain using the sowing method was significantly higher and could be translated

(Continued on next page)
to an average of 1 kg every month of new or harvestable biomass. Specific growth rate of C. lentillifera grown in the substrate was at 3.85% day\(^{-1}\) during the first month and at 2.92% day\(^{-1}\) during the second month and was significantly higher compared to that of stocks grown in trays. High organic load of the soil (substrate) was probably due to nutrient deficiency since NO\(_3\) and PO\(_4\) concentrations in the monocultures (0.06±0.08 µmol L\(^{-1}\) and 0.48±0.13 µmol L\(^{-1}\), respectively) were significantly lower than in the snail treatments (NO\(_3\): 7.7-33.68 µmol L\(^{-1}\); PO\(_4\): 0.9-2.53 µmol L\(^{-1}\)). Limitations of nutrients are known to inhibit metabolic activities of seaweeds, negatively affecting photosynthesis and growth (Roleda and Hurd 2019). Nitrogen and phosphorus are the main elements required by seaweeds for photosynthesis and growth. This review focusses mainly on nitrogen, but the roles of carbon and phosphorus, which may interactively affect seaweed physiological processes, are also explored. Fundamental concepts such as limiting nutrients, sources, and ratios, mechanisms of nutrient uptake, nutrient assimilation and storage, patterns of uptake and preferences for different nitrogen sources are discussed. The roles of abiotic (water motion, light, temperature, salinity and desiccation, which is why nutrient deficiency would also explain the decreased F\(_{v}/F_{m}\) values in the monocultures. Babyblonia growth and survival were not affected by spatial separation from Caulerpa. Babyblonia growth was consistent in both treatments and the snails nearly doubled in weight over the course of this study. Survival of the snails was 100% in both treatments. The indoor laboratory experiment showed that Caulerpa weight gain was positively correlated with snail density. The high increase in algal biomass in the high density-snail treatment indicates that snails can be implemented at high quantities without negative implications for the seaweed. The study showed the high potential of integrating Babyblonia into existing sea grape ponds. Co-culture of these two organisms could increase the economic profit of sea grape farmers without reducing the yield of Caulerpa.

Introduction

The influence of sound and noise on living organisms is widely recognized and well described. Most of the past research effort was dedicated to addressing the impacts of noise on humans and terrestrial life, mainly for practical reasons. Today’s evidence is pushing scientists to extends the impacts over several groups of marine life. Most of the existing literature about underwater noise is currently dedicated to marine mammals because of their well-known use of sounds for every aspect of their life cycle. Deadly effect of loud SONAR impulses on several marine mammal species has been clearly demonstrated. Currently there is an increased interest in the relevance of underwater sound in other marine animal groups both for ecological reasons (e.g. reef larval migrations following acoustic paths) and economic reasons (e.g. productivity of aquaculture farms carrying fish exposed to noise).

In this work we present results of a preliminary study, connecting these two aspects, thanks to the ongoing long-term investigation conducted on an offshore aquaculture farm in the Saudi Red Sea.

Area, materials and methods

The area lies in the Red Sea, in front of the Saudi Arabian coast, from 24.00°N to 18.50°N. In this large region, four locations were equipped with autonomous acoustic recorders. Two of these devices were in a fish farm t areas (Tharawat 1 and 17) while two were deployed in “pristine” sites (Yanbu, Al Lith,). Tharawat 1 was located at the centre of the fish farm, while Tharawat 17 was 1.3 km apart.

Within all stations, sea bottom is mostly sandy and ranges from -20m to -40m; coral reef spots and small islands are scattered around.

Two rounds of sampling were made in 2022 and 2023, obtaining about 600 hours (2022) and 1400 hours (2023) of wideband acoustic recordings in total. The analysis relied on skilled scientists displaying spectrograms (organized in chunks from 10 minutes to 24 hours) and through direct listening and in-deep spectrographic analysis when interesting slots were detected.

Results

Here we present a snapshot of results based on the analysis of the 2022 round of recordings (Yanbu, Tharawat 1 and 17, Al Lith).

Data were analyzed from the point of view of the differences between stations and depicting different soundscapes as shown in Fig. 1.

A 24h third octave spectrum (Fig. 2) and a SPL (Sound Pressure Level) in third octave (Fig. 3) for each station (as the one presented below, Tharawat 1 “farm” site) were also considered.

Discussion and perspectives

This screening shows a general uniformity of soundscapes among the areas, with the exception of Tharawat 1 where the soundscape is dominated by man-made sounds related to the fish-farming activity (recording station was in close proximity with the farm).

(Continued on next page)
In general, all stations seem not to be affected by intense man-made noise. RMS (Root Mean Square) cumulated for 24h showed Tharawat 1 as the station with the highest levels of acoustic energy, followed by Tharawat 17. The other two stations have lower acoustic levels that differ just by a few dB. Most of the energy is concentrated in the lower frequencies (below 20 kHz), as shown in figures 2 and 3, with some differences in the distribution of energy over frequencies between “farm” and “pristine” sites.

Current further analysis is targeted on describing fish farms related noise. Results will be used to address potential interaction between plants noise vs. farmed species as well as the natural environment. Vast area soundscape characterization will provide an additional decision parameter for future fish farm siting. This point is of major importance, given the expected offshore aquaculture development in the Saudi Arabian Red Sea.

Coupling offshore aquaculture farms with the use of Passive Acoustic Monitoring is a promising approach to increase knowledge about wild and anthropized environments, the understanding of the soundscapes related to aquaculture plants, the potential productivity of the farms themselves and the possible impacts of anthropogenic sounds on the marine environment.
IMPACT OF THE SUSTAINABLE BIOFLOC REARING SYSTEM ON THE COMPOSITION, FUNCTION, AND STABILITY OF THE INTESTINE BACTERIAL MICROBIOTA IN THE RIVER PRAWN *Cryphiops caementarius*

Introduction

Biofloc technology (BFT) has emerged as a sustainable aquaculture strategy because it does not require water exchange and supports heterotrophic bacterial growth, which increases nitrogen recovery by converting it into biomass that serves as a nutritional supplement. Juvenile river prawn *Cryphiops caementarius*, an endemic species of the arid regions of Chile and Peru, shows higher survival and growth in BTF than in the traditional clear water (CW) system. Thus, we aimed to compare the impact of these culture systems on the dynamics, stability, and functional potential of bacterial communities in the rearing environment and intestines of *C. caementarius*.

Materials and methods

The bacterial microbiota was characterized for the culture water (BF and CW) and in the intestines of juvenile prawns every 4-6 months for a total culture period of 14 months, using partial 16S rRNA gene sequencing. Additionally, after 8 months of rearing, prawns were subjected to an immune challenge using microbe-associated molecular patterns (MAMPs) to assess the stability of the intestinal microbiota. Taxonomic assignment was performed using the Genome Taxonomy Database GTDB Release 08-RS214 and the functional prediction was computed using FAPROTAX. The relative abundance of ASVs in each sample and community analysis (observed composition, alpha-diversity, and beta/diversity indexes) were calculated from subsampled datasets with the phyloseq package. The differential abundance of ASVs in each condition and of the functional potential was evaluated using the LEfSe method (linear discriminant analysis with size effect).

![Figure 1](image_url)

Figure 1. Relative abundances of the main bacterial groups present in the water (dashed line) and intestine (continuous line) microbiota in juvenile river prawns *Cryphiops caementarius* cultivated in Biofloc Technology (BF) and Clear Water (CW) systems for 14 months. Samples of water and intestines were analyzed each 4-6 months (T1-T2), and an additional sample of water (T0) was analyzed before the incorporation of the prawns in the systems.

(Continued on next page)
Results

Bacterial diversity was greater and more stable in the environment and Biofloc-cultivated prawns compared to the CW system. Planctomycetes (~40%) dominated and remained stable over the 14-month both in the environment and the intestines of prawns grown in BFT. Alphaproteobacteria (mainly Rhodobacterales) were initially abundant (30 to 15%) but gradually transitioned to Gammaproteobacteria (10 to 30%) (mainly Burkholderiales) (Fig. 1). In contrast, Alphaproteobacteria (mainly Rhodobacterales) initially prevailed (60 to 10%) in the environment and intestines in CW but were replaced by Gammaproteobacteria (10 to 60%) (mainly Enterobacterales) towards the end of the culture period. The intestines and water microbiota in the CW system show enhanced genomic potential for beneficial processes like aerobic denitrification and degradation of toxic substances. However, undesired side effects such as the proliferation of antimicrobial resistance genes and potential emergence of pathogens were observed. In contrast, the stable community in BFT is metabolically versatile, with genetic potential for fermentation, aerobic nitrification, and breakdown of complex organic compounds. Prawn intestines were significantly over-colonized by Gammaproteobacteria, particularly from the Aeromonadales, a well-known pathogen of aquatic animals, in both BFT and CW-cultivated prawns after 48 h immune challenge with MAMPs. Our results emphasize the microbial stability and higher diversity by BFT. Added to a bacterial composition that could foster improved exploitation of nutritional resources, together they could promote the productive performance of C. caementarius by BFT technology.
THE BIOFLOC TECHNOLOGY SUPPORTS HIGH STOCKING DENSITY FOR JUVENILE RIVER PRAWN *Chryphiops caementarius* FARMING IN ARID ZONES

Introduction

Biofloc technology (BFT) involves the cultivation of dense microbial communities within the water column, which serve as a natural food source for reared organisms. These microbial communities also help to maintain water quality by consuming excess nutrients and organic matter, reducing the need for water exchanges. This is particularly beneficial in areas with limited water resources like northern Chile, where the endemic river prawn *Chryphiops caementarius* is being cultivated. Increasing stocking density to an intensive or super-intensive level will help to support productive sustainability of this prawn. It has been shown that by using BFT, shrimp farmers can effectively increase the carrying capacity of their culture systems, allowing for higher stocking densities without compromising water quality. Therefore, in this study we evaluated whether BTF allows increasing the culture density of *C. caementarius*, comparing the physiological performance and productive parameters between individuals cultivated at different densities in the Biofloc or the traditional clear water (CW) systems.

Materials and methods

Juvenile prawns (0.44±0.07 g; 7.3±0.04 mm) were cultivated for 9 months in BFT and CW systems at initial stocking densities of 100, 200, and 400 individuals per m$^2$. At months 4 and 9, the components of the energy balance (energy intake allocated into the standard metabolic rate - SMR, and into energy losses by ammonia excretion and feces) and derived physiological index (scope for growth - SFG), and the status of chronic physiological stress state were determined under the different culture conditions. Physiological stress was measured through the transcriptional expression levels of the antioxidant enzyme superoxide dismutase (*SOD*) and the stress protein *HSP70*. In addition, the productive indices for each of the densities were determined via the growth and survival rates.

---

**Figure 1.** Survival rates of juvenile river prawns *Chryphiops caementarius* cultivated in Biofloc (BFT) and Clear Water (CW) systems for 9 months, at three densities (100, 200, and 400 individuals per m$^2$). Survival was measured each 2-3 months samples.

(Continued on next page)
Results

Juvenile prawns from BFT cultivated at 400 ind./m² showed higher SFG after 4 months of cultivation than CW-juveniles, which was associated with a higher energy intake and lower SMR in the formers. Energy balance and SFG were similar among juveniles cultivated in different densities and systems after 9 months, but superior in BFT considering that at this time the real densities in this system were two-fold the densities of CW due to higher mortality observed in the latter (Fig. 1). Chronic physiological stress was higher under CW than in BFT, as revealed by higher HSP70 transcriptional levels, which additionally increased directly with the stocking density. Survival was significantly higher in the BFT than in the CW-juveniles in each of the stocking densities assessed, with the highest survival observed in juveniles maintained at 200 ind./m² in BFT. However, growth was inversely associated with the stocking density and independently of the rearing system. However, given that at the end of the rearing period, the real density in BFT was approx. two-fold the CW density, it is suggested that BFT supported growth at higher densities than the CW system.

Overall, the results revealed BFT allows for higher stocking (to an intensive level) density than the traditional CW system. BFT would support an efficient energy balance and lower physiological stress, which could be the basis of the observed enhanced productive performance in terms of growth and survival of juvenile *C. caementarius*. Thus, this technology emerges as an effective tool for river prawn farmers looking to increase their stocking densities and improve the efficiency of their production systems in arid zones.
DIFERENT LEVELS OF FISH MEAL IN DIET TO *Mugil cephalus* REARED IN BIOFLOC SYSTEM: EFFECT ON GROWTH PERFORMANCE AND NUTRITIVE EFFICIENCY

Introduction

Biofloc technology (BFT) is an example of sustainable aquaculture due to its zero or minimal water exchange and its potentiality to reduce the input of artificial feed (fish meal) thanks to the establishing a nutritionally rich microbial biomass that can be used as natural food by the reared animals (Wasielesky et al. 2006). *Mugilidae* (especially *Mugil cephalus*) are excellent candidates for sustainable Mediterranean aquaculture due to its herbivorous/omnivorous feeding behavior. However, few information is currently available on the culture of this species in bioflocs combined with a reduction of fishmeal in the diet.

Therefore, the objective of the present study was to evaluate the growth and nutritional efficiency of *M. cephalus* reared in bioflocs and fed diets containing reduced levels of fishmeal.

Material and Methods

For the experiment, 600 animals with a mean weight of 80 grams obtained from the Institute of Agrifood Research and Technology (IRTA, Tarragona), were transported to the facilities of Universitat Politècnica de València. The animals were randomly distributed in 9 tanks of 3.3 m³. Three isolipidic feeds (10%; Table 1) were tested in tanks in triplicate with decreasing levels of fishmeal inclusion (15, 5 and 0% corresponding to treatments HP15, HP5 and HP0, respectively).

The ratio between essential amino acids (AAE) and non-essential amino acids (AAnE) was similar for the three feeds, being at 0.73 and 0.88. The animals were fed until apparent satiety three times per day (9:00, 13:00 and 17:00h). The water quality parameters were monitored during the whole experimental period, which had a duration of 27 days. Results were analyzed compared using one-way ANOVA and to significant differences between treatments were verified by applying the Newman-Keuls test (significance level of 5%). Additionally, at the end of the experiment, the effect of the diet on the intestinal microbiota was evaluated through the analysis of 16S ribosomal DNA.

Results and discussion

The mullets adapted quickly to BFT, and a total substitution of fish meal meant in lower survival with significant differences (Table 2). Additionally, HP0 showed the highest feed conversion ratio (FCR) and the lowest protein efficiency ratio (PER) and specific growth rate (SGR), but without significant differences. Nevertheless, HP5 did not reported differences with HP15 neither growth nor survival.

In relation to microbiote composition, the phylum with the highest representation was Proteobacteria (43.76 ± 6.74%), followed by Firmicutes (18.78 ± 5.38) and Spirochaetota (16.19 ± 5.47%). HPO reported an increase of Firmicutes (31.14 ± 10.71 vs 1.23 ± 0.19 %) and decrease of Planctomycetota (5.38 ± 2.62 vs 16.04 ± 0.83 %) presence respect to the initial point. No differences were observed independently of the diet respect diversity alpha (Shannon-index).

Therefore, low fish meal inclusion levels are possible in *M. cephalus* under BFT without affecting zootechnical performance and intestinal health. Similar results were observed by Nhi et. al (2018) in *Oreochromis niloticus*, also an herbivore/omnivore species, being able to reduce fish meal inclusion into the diets under BFT.

**Introduction**

The biofloc technology (BFT) and the clear water recirculation system (RAS) are two examples of closed aquaculture production systems that work with water recycling. In the case of the RAS system, the main difference to the biofloc system is its high structure and complexity of equipment for the filtration and treatment of the water, which is then returned to the rearing tanks (Badiola et al., 2018). On the other hand, the BFT mainly needs strong aeration to keep the bioflocs that are generated in the system active and in suspension, since there is zero or minimal water exchange in the system. Thus, there is the establishing a nutritionally rich microbial biomass that can be used as natural food by the reared animals (Wasielesky et al., 2006). Transcriptome analysis provides relevant information about gene expression, which can be influenced by the cultivation system. Thus, the objective of the present study was characterized and compare for the first time the intestinal transcriptome of *Mugil cephalus*, an excellent candidate for sustainable Mediterranean aquaculture due to its herbivorous/omnivorous feeding behavior, rearing in different systems, RAS and BFT.

**Material and Methods**

For the experiment, the animals were obtained from the Institute of Agrifood Research and Technology (IRTA, Tarragona) and transported to the facilities of Universitat Politècnica de València. The juveniles of *M. cephalus* were randomly distributed in 3 tanks of 3.3 m³ to the BFT experiment (± 82.68 g) and in 3 tanks of 0.4 m³ to RAS experiment (± 8.15 g). One isolipidic feeds (10%) were tested with 15% levels of fishmeal inclusion. The animals were fed until apparent satiety three times per day (9:00, 13:00 and 17:00h). The water quality parameters were monitored during the whole experimental period, which had a duration of 27 days. At the end of the experiment, the effect of the rearing conditions on intestinal transcriptome was analyzed using omic approach (FISABIO, Spain). The reads were mapped to the Mugil cephalus reference genome (GCF_022458985.1) using the bowtie2 software, and read counts were generated using htseq-count. For the analysis of differential expression, the DESEQ2 tool was employed. Subsequently, we focused on transcripts with a padj value of less than 0.05 and an absolute log2FoldChange greater than 1. Enrichment analysis of GO and KEGG terms was conducted using the Fisher Exact Test.

**Results and discussion**

A total of 7651 differential expressed transcripts (DETs) were obtained when we compared the intestinal gene expression between fish reared under RAS o BFT. From them, 3022 and 4649 genes were down and up-regulated, respectively. The representation of DETs shows a clear differentiated distribution of the samples corresponding to BFT and RAS experimental group (Figure 1).

After GO enrichment analysis, results showed that 18 biological processes (BP), 6 cellular components (CC) and 5 molecular functions (MF), mainly related to transcriptional regulation, were significantly affected by the rearing conditions. If we focused on the GO enrichment based on the genes that were up-regulated in BFT, we obtained 121 biological processes (BP), 8 cellular components (CC) and 19 molecular functions (MF), mainly related to immune system, metabolism/cellular transport and cellular proliferation (Figure 2). Besides, KEGG analyses revealed 24 disturbed pathways, related to cellular transport and metabolism, meanwhile in the fish reared under BFT the enrichment KEGGs were more focused on lipid metabolism. Therefore, a differential intestine expression was reported based on rearing conditions.

Sturgeon populations decline have dramatically increased throughout their range for the last 50 years due to anthropogenic impacts: overfishing, barriers to migrations and pollution have adversely impacted sturgeon species and populations worldwide. At about the same time sturgeon farming took hold in many countries in the range where sturgeons were native, and also in countries outside this range. The motivating cause of this farming, in addition to an initial interest in new species both for the market and for sport fishing, was the production of caviar from the nineties onwards. This product of great quality and of great economic value has stimulated many farmers to produce this good in their facilities, given the drastic reduction of natural resources and the maintenance of the product’s value to the final consumer. Thus, since the 2000s there has been a very rapid increase in the production of both meat and caviar which in 2022 probably exceeded 800 tons, with China as the first producer and exporter in the world. For over 30 years, meat and caviar production data have been collected by the WSCS, not only to provide an information service to farmers, traders and researchers, but also to have an overview of where and which species are farmed in the world, in foresight of the use of these banks of potential breeders for the production of suitable animals for wildlife recovery and repopulation projects. In fact, natural stocks are drastically rarefied, and the rules and regulations of almost all states prohibit fishing of these species, and resorting to farmed populations is often the only option left. The present work therefore aims to provide an overview of sturgeon and caviar production updated to 2022, despite all the difficulties in the collection of complete and reliable data by all farmers and/or all countries.
THE RISE AND FALL OF THE ZOOPLANKTON IN THE ARCTIC. UNRAVELLING THE CONTRIBUTION OF LIPOS TO COPEPOD DIAPAUSE WITHIN THE ARCTIC

Introduction

Copepods such as Calanus hyperboreus and Calanus finmarchicus, are a rich source of long chain omega 3 fatty acids, such as EPA and DHA, and are an integral part of the north Atlantic and Artic ecosystems. However, these fatty acids exist in the wax-ester form rather than as triacylglycerols, possibly owing to their role as a modulator of copepod buoyancy, allowing them to maintain a neutral buoyancy and hibernate below the thermocline during winter, in a process known as diapause. Changes in climate are predicted to have implications for both biodiversity, resulting in changes in the phytoplankton community, as well as physical ocean characteristics, which may impact the life cycle of Arctic copepods. The interplay between copepod diet, intact lipid composition, buoyancy and diapause is not well understood, with the substantial role of copepods to sequester carbon to the seafloor an integral part of the biological pump. Therefore, it is crucial to understand how intact lipids respond to dietary inputs, and whether different copepod species vary with regards to their wax-ester profiles. This additional knowledge will help improve our modelling of this vital trophic link and potential aquaculture resource, and the limits to which it can be exploited. To this end, copepods from several species, locations and depths were profiled, as were several diets, with regards to their intact wax-ester composition to ascertain initial trends relating to these parameters.

Material and Methods

Copepods were collected during the Nansen legacy cruise (Nansen and Amundsen basins) and the Meriam cruise (2022, West Greenland) from various locations and depths, with several species identified. Calanus finmarchicus (females) was also grown under controlled conditions from eggs to stages C4-C5, using two salinities and 3 diets (Thalassiosira weissflogii, Rhodopirellula baltica and Heterocapsa). All copepods were weighed into polypropylene bead beating tubes, with 10 µl of antioxidant solution added (0.2 mg/ml BHT and EDTA in 50:50 v/v methanol/water) followed by 350 µl of 90 % v/v methanol. Samples were then bead homogenised for 30 seconds, followed by the addition of 1 ml of MTBE. Following vortexing, samples were left at room temperature, followed by the addition of 250 µl of water. Samples were again vortexed, centrifuged, and the upper MTBE layer removed and placed into a new Eppendorf tube. A second MTBE extraction was carried out, which was pooled with the first, with the extracts dried under nitrogen. Samples were then resuspended in approximately 0.25-1 ml of 2:1 v/v MTBE/MeOH, with the volume dictated by the sample weight. A 1:80 dilution was then made, with 1.5 µl injected on to the SFC-MS/MS system for intact wax-ester analysis. An Acquity UPC2 connected to a Xevo G2-XS QTOF (Waters, Milford, MA) was used for the analysis, with data processed using Progenesis v3.0 (Waters). Further data processing was conducted in Excel, with hierarchical clustering conducted using the online Morpheus tool.

Results

Copepods showed a clear separation based upon species, as well as location for the Nansen legacy cruise. The two locations (Nansen and Amundsen basins) showed distinct copepod wax-ester profiles, with group 1 (Nansen basin) being more unsaturated, containing a greater proportion of wax-esters with 3-7 double bonds. Group 2 (Amundsen basin) however was found to be more saturated, enriched in wax-esters containing 1-2 double bonds, though found to be on average shorter, 36-38 carbons in length, compared to group 1, which were on average longer, 40-44 carbons in length. Regarding species, Pseudocalanus species were found to contain much shorter chain wax-esters, ranging from 30-38 carbons long, with C. glacialis and C. finmarchicus generally being less distinguishable from one another. However, these species were distinguished from C. hyperboreus in that they contained elevated levels of 36 carbon wax-esters whereas C. hyperboreus contained elevated levels of 42 and 44 carbon wax-esters. When comparing C. hyperboreus species across regions (West Greenland and the Nansen and Amundsen basins), copepods from different regions could be differentiated by the wax-ester composition, however, no overall defining trend emerged to describe the separation, as intra-species separation was also found within these regions. With regards to C. finmarchicus under different dietary and salinity regimes, diet had the greatest impact on the copepod lipids, with the intact wax-esters capable of clustering samples based on diet primarily, though separation based on salinity was also observable.
Discussion and conclusion
Overall, it was found that the intact wax-esters were able to discriminate Antarctic copepods based on species, as well as their trawl location. *C. hyperboreus* was generally found to be more distinct from the two other resident copepod species, *C. finnarchicus* and *C. glacialis*, though *C. hyperboreus* showed wax-ester discrimination based on location. Whilst there was not a strong location signal, *i.e.*, separation of *C. hyperboreus* populations between West Greenland and the northern basins, mainly due to intra-location groupings, this difference in wax-ester composition between populations may be due to age, sex and diet, as well as abiotic factors such as depth of isolation and sea temperature. It was found that diet does in fact play a large role in the copepod’s lipid storage composition, with climatic change postulated to change not only abiotic factors, such as sea temperature and salinity, owing to increased freshwater inputs from melting sea ice, but also species distribution, including algal food sources. These are all postulated to have an impact on the life cycle of copepods, including the spring feeding periods and winter diapause. Changes in copepod lipid compositions are likely to have an impact on multiple processes, such as copepod buoyancy, carbon sequestration and lipid profile for both human and aquaculture utilisation. Monitoring the impact of these alterations will be key in managing these marine resources, as they provide both an ecosystem service and a feedstock for long chain polyunsaturated fatty acids.

Introduction

Air breathing catfishes (clariids) are a group of stenohaline freshwater fish that can withstand various environmental conditions and farming practices. Therefore, considerable efforts are being made to increase and optimize industrial production of the African catfish (Clarias gariepinus).

However, there is tremendous lack of genomic resources indispensable to study genetic traits and variations, that are of high relevance in domestication and adaptation of clariids to aquaculture environments. In particular, there is a need of a high quality assembled and annotated draft genome as reference basis for addressing questions in catfish research in general, and specifically, to understand and enhance aquaculture production and performance traits of the catfish.

Here, we sequenced the genome of the African catfish Clarias gariepinus, one of the most commonly farmed clariids, and generated a gapless telomere-to-telomere (T2T) de novo chromosome-level assembly with high-resolution haplotypes, by integrating long-range sequencing (Hi-C) with PacBio single-molecule (HiFi), Oxford Nanopore, and Illumina sequencing data.

Results

The diploid genome assembly yielded 58 contigs with a total length of 969.72 Mb and a contig N50 of 33.71 Mb. We reported 25,655 predicted protein-coding genes and 49.94% repetitive elements in the Clarias gariepinus genome. Interspersed repeat are the most abundant class of repetitive elements (46%). Retroelements and DNA transposons accounted for only 12 and 6 percent of the repeatome, respectively. Approximately 99% of the assembled genome is spanned by the 28 chromosomes of the primary assembly, without gaps. The distribution of genes and repeats across the chromosomes followed the typical distribution in vertebrate genomes, with higher gene densities in GC-rich regions and lower gene densities in repeat-rich distal and pericentromeric regions.

We performed various assessments to support the high quality and completeness of our African catfish genome assembly. The BUSCO completeness was 97.5% with only 2% of the genes missing, showing that the gene space spanned by our genome assembly is nearly complete. Furthermore, approximately 92% of the Clarias gariepinus transcripts could map on our assemblies (>90% coverage and >90% identity), indicating their high functional completeness. We also mapped genomic reads to our assemblies to assess structural accuracy and found that more than 96.69% of raw PE reads were concordantly aligned. The alignment rate of ONT, HiFi, and Hi-C reads to the primary assembly was 99.91%, 99.95%, and 100%, respectively.

Furthermore, we annotated 6,403 full-length ribosomal RNA, 154 microRNA, and 13,536 transfer RNA throughout the African catfish genome. Remarkably, 96% (6150/6406) of the predicted 5S rRNA genes were all found in a single cluster on a 2-Mbp region on both chromosome 4 (n = 2455) and chromosome 13 (n = 3725). Similarly, 84% (21/25) of the predicted 18S rRNA genes were clustered within the first 500 kbp upstream in the terminal telomeric region of chromosome 27 (Figure 1).

(Continued on next page)
The comparative phylogenomic analyses performed with OrthoFinder assigned 336,681 (94%) of 390,198 genes to 27,587 orthogroups shared among catfishes and two outgroup species (common carp and goldfish). 16,281 genes in *C. gariepinus* were found to be orthologous between the 14 catfish species, with 378 of them being single-copy orthologs. According to our estimated phylogenetic tree using protein sequences of all homologous single-copy genes, air breathing catfishes (Claridae clade) split as a monophyletic group around 98 Mya, which is roughly comparable to the divergence time between rodents and humans (96 Mya) (Figure 2).

**Conclusion**

Our genome assembly provides the first comprehensive gene annotation and haplotype information, such as the male-specific haplotype, enabling us to identify critical genes and molecular mechanisms underlying amphibious traits and terrestrial adaptation of air breathing catfishes. We found that several gene families involved in ion transport, osmoregulation, oxidative stress response, and muscle metabolism were expanded or positively selected in *clariids*, suggesting a potential role in their transition to air breathing capabilities.

The reported findings expand our understanding of the genomic mechanisms underpinning the resilience and adaptive mechanisms of *C. gariepinus* to adverse ecological conditions. They will serve as a valuable resource for future studies in elucidating these unique biological traits in related teleost’s and leverage these insights for aquaculture improvement.
DETERMINATION OF NON-MYOFIBRILLAR AMINO ACIDS IN CAUDAL AND DORSAL MUSCLE FROM RAINBOW TROUT

Vander Bruno dos Santos*, Marcos Vinicius Bozzo Diório, Carolina Pereira de Morais Faria, Yara Aiko Tabata, Erna Elisabeth Bach
Fisheries Institute, São Paulo, SP Brazil
vbdsantos@sp.gov.br

Introduction

Amino acids perform different metabolic and physiological functions in animal organisms and, in fish, they are also associated with specific dynamic action with an important role in satellite cell activation and muscle growth. Fish muscles are extremely plastic and adaptable, being organized in compartmentalized structures containing different types of fibers (white, pink and red ones). Thus, the objective was to evaluate the profile of non-myofibrillar amino acids in the dorsal and caudal muscles of rainbow trout.

Material and methods

Five trout from the same batch and age (14 months after fertilization), 261.66±40.76 g and 23.00±1.06 cm were caught after 48 hours of fasting. The fish were stunned (benzocaine), slaughtered by the rupture of the cervical spine. Muscle tissue samples were removed from the middle portion of the body, below the dorsal fin (white fibers) and from the peduncle (red fibers more abundant) and they are frozen. About 200 mg of dorsal muscle sample was crushed in 0.6mL of Milliq water added with 0.2mL of 5% mercaptoethanol and 0.1mL of 5% perchloric acid, kept in the refrigerator for 30 minutes. For caudal muscle, 200mg of tissue was triturated with 0,2mL of water, 0,2mL of 5% mercaptoethanol, and 0.12mL of 8% perchloric acid. After 30 minutes in refrigerator, the solution was centrifuged at 10,000 rpm for 10 minutes at -10 °C. The pH of the supernatant was corrected to pH=4 with 0.1mol/l ammonium hydroxide for dorsal muscle. For the caudal muscle we used 60% ethanol for precipitation of compounds rather than pH correction. The samples were kept in a refrigerator for 12 hours, after which they were centrifuged again at 10,000 rpm for 10 minutes at -10 °C and filtered through 0.45um millipore. And it injected 20uL into the HPLC Y1 9300 using a Luna C18 column, acetonitrile solvent (ranging from 4-50%) and acetate buffer pH=4.7 (ranging from 50-96%) at a temperature of 35 °C. Amino acid readings were performed using the Clarity 8.8 software.

Results

The aminoacids detected from dorsal and caudal muscle are presented in Figure1 A and B, respectively. Dorsal muscle was characterized by high detection of Cys and Lys (666.46±191.20 and 1710.90±413.29 µM). Val and Leu were detected only in caudal muscle (583.08±64.47 and 82.08±6.21 µM, respectively) and it was observed higher concentration for Arg and Phe (375.43±34.83 and 5596.63±623.43 µM, repectively) when compared with dorsal muscle (33.04±4.79 and 576.30±115.80 µM, respectively). Pro and Ile were more abundant in dorsal muscle too (377.11±42.33 and 291.33±63.48 µM). Traces of Pro and Ile were detected in the caudal muscle and of Trp and Gly in both tissues.

The utilization or metabolism of AAs in fish is complex and compartmentalized and participate in biological oxidation, gluconeogenesis and lipogenesis in a cell- and tissue-specific manner (Li et al, 2021). Among the wide variety of functions, Arg and Phe are associated with energy storage and metabolism and regulation of basal energy metabolism, respectively (Wu et al, 2013). Val is associated with glucose metabolism action (Ahmad et al, 2021), indicating the important role of caudal muscle in this process if we considerer that fish were 48 hours fasting. Cys is associated with anti-oxidative process, Lys with long-chain fatty acid transport (Wu et al, 2013) and this find indicates that diferent role of dorsal and caudal muscle in the metabolism maintenance.

Non-myofibrillar amino acids profile was diferent in muscle dorsal and caudal in a 48h fasting, reflecting the different metabolic and physiological roles of these tissues.

EXPONENTIAL GROWTH MODEL OF RAINBOW TROUT STRAINS

Vander Bruno dos Santos*, Vinicius Vasconcelos Silva, Marcos Vinicius Bozzo Diário, Carolina Pereira de Morais Faria, Antonio Carlos Kida Filho, Erna Elisabeth Bach, Neuza Sumico Takahashi, Arno Juliano Butzge, Yara Aiko Tabata

Fisheries Institute
São Paulo, SP Brazil
vbdsantos@sp.gov.br

Introduction

In Brazil, the majority of trout farms are small-scale due to limited availability of cold water. Value addition and product diversification have been employed as alternatives to enhance the profitability of this activity. In this context, the establishment of different skin color strain has garnered attention, both in research as potential phenotypic markers, and commercially from fish farms involved in recreational fishing. Thus, the objective was to characterize the growth of trout strain, differentiated by their color pattern.

Material and Methods

Trout of four different colors (wild-type, blue, yellow-albino and white-albino) were obtained through the crossbreeding of white trout with wild-type trout. Obtaining eggs and semen involved the abdominal compression extrusion of sexually mature trout aged 2 to 3 years. Five white-albino males were suitable for reproduction and were paired with wild-type females. The semen from each male was mixed with a pool of eggs from females (N=80, average weight 1,327.67±79.35 g). The eggs were incubated under the same conditions, and the fry were cultivated in circular tanks of 2 m³ (in triplicate) in an open system with a constant water flow until reaching a commercial weight of 350 g. The minimum water temperature during the period was 13.55±1.89, and the maximum was 15.64±1.56. Dissolved oxygen was at 6.75±0.52 mg/l.

The fish were fed ad libitum with extruded feed specific to each phase, three times a day. As the fish grew, 30 trout from each tank were randomly sampled and individually weighed at 1, 60, 90, 150, 210, and 270 days of cultivation after a 24-hour fasting period.

All weight-to-age data were fitted to an exponential model represented by \( y = Ae^{Kx} \). In this model, \( y \) represents the observed weight of each fish; \( A \) represents the initial weight estimate; \( e \) is the base of the natural logarithm; \( K \) is the specific growth rate; and \( x \) is the age of each fish. 95% confidence intervals were used to compare the curve parameters for each strain. Equations and \( R^2 \) adjusted statistics were provided. The estimates were obtained using weighted least squares due to the lack of homoscedastic variance between days 1 and 270, and considering autoregressive errors (Draper and Smith, 1998; Santos et al., 2013).

Results

The screening was carried out by separating the color patterns, excluding undersized or oversized fingerlings, resulting in 2031 white-albino fingerlings, 1969 yellow-albino, 1971 blue, and 2306 wild-type ones. This quantity of the four colorations aligns with the color inheritance pattern from the crossbreeding of heterozygous white-albino trout with wild-type colored trout (25% wild-type aabb; 25% white-albino AaBb; 25% yellow-albino aaBb; and 25% blue Aabb) (Hattori et al., 2020).

The fingerlings started the experiment with a similar average weight of 3.07±0.14 g (P>0.05).

The estimates of initial weight “\( A \)” showed differences between trout strains (P<0.05). The estimate for the wild-type strain was higher than that for the white-albino strain (4.4983 and 3.4449 g, respectively), and they did not differ significantly from the blue and yellow-albino strains (3.6621 and 3.8656 g, respectively). The estimates of “\( K \)” indicated differences between strains (P<0.05). The white-albino strain exhibited the lowest growth rate (0.00159 g/day) when compared to the yellow-albino and blue strains (0.0174 and 0.0173 g/day). The growth rate of wild-type trout was 0.0163 g/day. The estimated final weight (at 270 days of cultivation) for the wild-type, blue, yellow-albino, and white-albino strain were 366.76 g, 391.13 g, 424.16 g, and 252.12 g, respectively.

(Continued on next page)
In the last few decades, the vast majority of fish farmers have been cultivating genetically improved lineages of certain species in their production systems (Gjedrem and Rye, 2018). Some traits that directly affect production costs are growth rate, fillet yield, and feed conversion. However, more recently, other traits such as body composition, nutrient content, well-being, and environmentally friendly production systems have gained prominence in consumer preferences. In this context, the establishment of lineages with different skin colors has garnered attention, especially among fish farms engaged in recreational fishing. Thus, the cultivation of lineages with lower performance but possessing consumer-attractive characteristics like coloration can translate into a competitive advantage, allowing for higher prices to be achieved.

INTRODUCTION

Post-mortem semen collection is a common approach in fisheries for breeding wild fish species prone to high post-capture mortality. Additionally, breeders are interested in utilizing milt from fish that have died during the spawning season. Following death of an organism, anaerobic metabolism leads to lactic acid build-up, causing post-mortem pH reduction. This lactic acid accumulation extends beyond blood and muscles. Previous studies have shown that lactate concentration under normal circumstances in epididymal semen collected from rats and dogs ranges from 0.6 to 0.9 mM, but this concentration surges nearly tenfold in samples taken two hours post-mortem [1].

Thereby, this study aimed to investigate: (1) the possibility of revitalising rainbow trout sperm with the use of short-term storage of undiluted and diluted semen samples collected posthumously; (2) the relationship between elevated lactate concentration, pH decrease, and the revitalisation process of sperm collected post-mortem from rainbow trout (Oncorhynchus mykiss) males.

MATERIALS AND METHODS

Semen samples were collected post-mortem from the sperm duct during mid-spawning from 3-year-old male rainbow trout with an average body weight of 0.44 kg, using a catheter (n=18). Sperm samples were collected at 2-hour intervals over 16 hours (n=6). The collected sperm were divided: one undiluted (50 µl) and the other diluted 1:10 (sperm:diluent) with artificial seminal plasma (ASP) composed of: 100 mM NaCl, 40 mM KCl, 3 mM CaCl₂, 1.5 mM MgCl₂, 20 mM Tris, and a pH of 8.2. Both samples were stored at +4°C in sealed 1.5 ml Eppendorf tubes on crushed ice. Immediate motility recording followed collection. Additional motility analyses occurred at 0.5, 1, 1.5, 2.5, 6, and 24 hours from the start of storage.

The significance of monitoring lactic acid and pH levels in seminal plasma was examined using an in vivo model. The concentrations of these parameters were measured in semen samples collected posthumously (n=18). Subsequently, semen samples from 6 males were diluted 1:10 with ASP at pH 8.5, 7.5, and 7.0. To study the effect of lactic acid concentration on sperm survival under in vitro conditions, we added 10, 20, and 50 mM of lactic acid to ASP solution with a pH of 7.5. Diluted sperm samples (50 µl) were stored in closed Eppendorf tubes at +4°C. Sperm motility was assessed immediately (time 0) and again after 24 hours. After 24 hours, some preserved samples were further diluted in a 1:4 ratio with ASP at pH 8.5, while the rest remained undiluted. Motility analyses were performed on all samples after another 24 hours. Motility analyses were carried out with the use of a computer-assisted sperm analysis system (CRISMAS, Image House Ltd., Denmark). For sperm motility activation 1µl of sperm was mixed with 100µl of a buffer containing 20 mM Tris, 154 mM NaCl, 1 mM CaCl₂, and 30 mM glycine supplemented with 0.5% bovine serum albumin (BSA, Sigma-Aldrich). L-lactate content in seminal plasma was measured using a colorimetric L-lactate Assay Kit (Abcam) at 450nm, following the provided instructions.

RESULTS

We observed that nearly immotile rainbow trout sperm retrieved from the fish body regained motility following short-term storage when collected 2, 4, 6, and 8 hours after death. We also observed that sperm collected 2 hours after fish death regained their motility potential as soon as 1 hour of storage. Regained motility in samples diluted with ASP was higher than in undiluted samples (i.e. 94 and 71% respectively for samples collected 2 hours posthumously). However, samples collected 10 hours after the fish’s demise showed considerably reduced sperm revitalisation compared to those obtained at earlier time points. Beyond this period, only samples diluted with ASP managed to recover around 20% motility.

(Continued on next page)
In collected post-mortem rainbow trout sperm samples, rising lactic acid levels were linked to lower seminal plasma pH. Within 24 hours, sperm motility in samples diluted with pH 7.0 ASP dropped significantly. However, samples diluted with pH 7.5 ASP showed no change in sperm motility during the same period. For samples diluted with lactic acid in pH 7.5 ASP, motility decreased from 80% to 30% within 24 hours. Meanwhile, samples diluted with pH 8.5 ASP showed higher motility than the initial level after 24 hours. Additional dilution with pH 8.5 ASP after 24 hours increased motility in all sperm samples. In undiluted samples, sperm motility gradually decreased, particularly in those diluted with pH 7.5 ASP compared to pH 8.5. Adding lactic acid at doses ranging from 10 to 50 mM led to a swift reduction in sperm motility within 24 hours of dilution. Subsequent additional dilution after 24 hours increased motility only in samples diluted with the lowest lactic acid dose (10 mM).

Discussion
While earlier studies indicated a decline in rainbow trout sperm quality during post-mortem storage [2], our research reveals the potential for a minimum 50% recovery in sperm motility within 8 hours after the fish’s demise. Furthermore, our observations demonstrate that sperm revitalisation occurred more rapidly when samples obtained from deceased fish were diluted with ASP. Notably, dilution with ASP proved effective in restoring sperm motility, particularly for samples collected 10 hours after fish death.

Chiba et al. [3] demonstrated a significant increase in lactic acid concentration in fish muscle and blood after death. In our study, we made a novel observation that lactate accumulates in the sperm duct following fish death and contributes to the decline in sperm motility. Through in vitro experiments, we discovered that this effect could be reversed, but only when the lactic acid concentration does not exceed 10 mM. We suspect that a combination of pH and lactic acid is responsible for the irreversible immobilisation of rainbow trout sperm after the fish’s death. However, it is evident that other factors, in addition to pH and lactic acid, play a pivotal role in fish sperm immobilisation or degradation after death, as the observed sperm decrease ratio in the dead fish body is much higher than in the in vitro experiments. Notably, the impact of lactic acid on sperm immobilisation has been previously confirmed in avians during sperm storage in tubules [4]. While the physiological implications might differ between fish and birds, the molecular mechanism of this action could be similar in both animal groups.

Introduction

Global food security, human health and well-being are at serious jeopardy, as marine resource production can no longer be sustained by ecosystems and natural fisheries production only. Broad evidence supports the potential of low trophic aquatic food to reduce food and nutrition insecurity (SDG 2) in a changing climate, while we hypothesize restorative impacts on natural ecosystem services by contributing to SDG 12, 13 and 14.

Expansion of low trophic aquaculture (LTA) for increasing seafood production are faced with opportunities in unexploited regions and environments and maximizing benefits of marine space by considering low impact multi-use (MU) of space such as combining offshore wind farm (OWF) areas and integrated multi-trophic aquaculture (IMTA).

Details of the project

In the following, the EU-funded OLAMUR (Offshore Low-trophic Aquaculture in Multi-Use Scenario Realisation) project will be presented. The main objective of OLAMUR is to bring together MU-LTA related key sectors, to demonstrate sustainable commercial solutions for both the North and the Baltic Sea. All data, information, products and standards for establishing, operating and evaluating will be monitored, simulated, stored and customized as an “OLAMUR digital MU-LTA farm service” (Fig. 1). This will provide a solid basis for MU-LTA upscaling. Through a transdisciplinary holistic approach, OLAMUR will ensure substantial contributions towards demonstrating and documenting the possibilities for low impact co-use of the marine space. Multi-disciplinary data will be collected and integrated from the demonstration sites via monitoring and modelling efforts. A databased service system will be developed for policymakers for knowledge-based decisions, and innovative governance/policy arrangements will be developed towards achieving a holistic, effective and sustainable solution for multiple uses. OLAMUR will focus on three pilots that will serve as testing and demonstration sites. Two of these pilot studies are located in the Baltic Sea (Denmark and Estonia) and one study is being conducted in the North Sea (Germany) (Fig. 2). Strategies are being developed for multi-use of OWF and seaweed as well as bivalve aquaculture, and the combination of existing fish farms and the multi-use with seaweed and mussels.

An important pathway towards impact in OLAMUR is the science-policy-industry-community interface. With that, OLAMUR ensures advancement in developing optimal and carbon-neutral use and enabling a quantum leap towards long-term sustainable, healthy and rich European marine spaces.

Funding Details
The OLAMUR project has 25 partners from eight nations, which deal with the topics of technical realization in the wind farms, as well as site selection, LTA performance, environmental monitoring, and much more. The OLAMUR project is funded by the European Union, grant no. 101094065.
Introduction

The terms “offshore” and “open ocean” have been used to describe aquaculture sites that are further from the coast and/or in higher energy environments. Neither term has been clearly defined in scientific literature or in a legal context and the terms are often used interchangeably. These and other related terms (e.g., “exposed”, “high-energy”), refer to specific aspects of a site, usually the geographic distance from shore or infrastructure, or the level of exposure to an extended fetch leading to large waves and strong currents. The term “offshore aquaculture” has hitherto encompassed various perspectives, including technology, geographical location, legal jurisdiction, and more. To resolve the ambiguity in this term and understand its implications for current and future aquaculture, “offshore” should be resolved into two separate metrics: (1) Distance from shore and (2) exposure. Consequently, “offshore is defined by the distance from the shore while exposure can be applied as additional character or aspect of any site”.

Details of the project

The ICES Working Group for Open Ocean Aquaculture (WGOOA) therefore established a need to define the terminology to reduce ambiguity for characterising these types of aquaculture sites or more precisely, to: 1) promote a common understanding and avoiding misuse for different classifications; 2) enable regulators to identify and designate the characteristics of a marine site; 3) allow farmers to be able to assess or quantitatively compare sites for development; 4) equip developers and producers to identify operational parameters in which the equipment and vessels will need to be operating; and 5) provide insurers and investors with better means to assess risk and premiums.

The United Nations Convention on the Law of the Sea (UNCLOS) delineates zones in which States are largely free to regulate aquaculture and other exploitation activities (e.g. inland and territorial waters, exclusive economic zones). Within this framework, different coastal states have developed policies and laws that specifically govern aquaculture. Neither UNCLOS nor national aquaculture laws, however, provide a precise definition of the term “offshore”. Such vague geographical concepts alone cannot aid in identifying, assessing, and geographically pinpointing suitable aquaculture sites.

(Continued on next page)
The metrics of distance from shore and exposure are seen as a range rather than a specific threshold, allowing for a continuum. Distance from shore is readily quantified as distance from the baseline. To rigorously quantify the exposure, six indices were generated, which covered various oceanic parameters (i.e., water depth, water currents, wave height and period). The influence and interaction of the oceanic parameters were all considered using the indices to determine site characteristics. Two indices were selected for utilization on the analysis of sites based on their ease of use and applicability.

Finally, we applied these indices to their use in aquaculture with different species, technologies and in O&M. We also considered the costs of expanding aquaculture from protected to more exposed sites. The influence of these definitions on socio-economic aspects is addressed. Negative public discourses on the expansion of nearshore aquaculture are one of the most prominent aspects driving public opinion against aquaculture. Expansion of offshore aquaculture out of sight from the coasts is a major advantage. Finally, we suggest necessary research areas to enable the expansion of aquaculture activities to “offshore” and “exposed” waters.

**Funding Details**
This research has been supported by the institutes of the scientists involved. The resulting 8 publications were compiled within the framework of the WGOOA (Working Group on Open Ocean Aquaculture) of the intergovernmental scientific organisation ICES (International Council for the Exploration of the Sea - Copenhagen/Denmark). Likewise, this project was supported by the OLAMUR project with 25 partners from eight nations dealing with the issues of technical implementation in the wind farms, as well as site selection, LTA performance, environmental monitoring and much more. The OLAMUR project is funded by the European Union under grant number 101094065.
SOCIETAL PERCEPTION OF AQUACULTURE: COMBINING SCOPING REVIEW AND MEDIA ANALYSIS

Introduction
Aquaculture has been recognised as a potential food industry to contribute to multiple United Nations Sustainable Development Goals; its growth and development depend on understanding societal perceptions in a broader context. However, to date, no comprehensive reviews have been conducted to understand whether scientific publications and newspaper outlets portray societal perceptions of aquaculture – in terms of sustainability – in positive, negative, or neutral terms. To fill this gap, this study syntheses articles on societal perceptions of aquaculture to understand whether scientific and newspaper articles mention multiple sustainable dimensions before portraying aquaculture as positive, negative, or neutral.

Methods and materials
Web of Science, Scopus, and Google Scholar were consulted to search research articles published from 1 January 2015 to 15 January 2023 with search terms: aquaculture, farmed fish, aquafarming, mariculture, polyculture, perception, belief, attitude, image, and opinion. Scientific articles following inclusion criteria were thematically clustered employing the visualisation of similarities (VOS) software. Further, 100 newspaper articles (n = 100) were selected from each of the following countries: UK, Denmark, France, Spain, Turkey and China; 79 were selected from Poland, while articles from Hungary (n = 29) and India (n = 70) were also selected for media content analysis.

Results
A scoping review identified 151 studies for inclusion in our five identified clusters of scientific publications: (1) social acceptability, (2) growth and development, (3) media coverage, (4) sustainable aquaculture, and (5) consumer perception. Further, with triangulation, the findings from this study suggest that scientific and newspaper articles mention one or more aspects of aquacultural sustainability in an abstract form to base their perception as positive, negative, or neutral.

Key stakeholder groups include the fish farming industry (fish farmers, aquaculture associations or groups), civil society groups (environmental NGOs, activists, community groups, media), governmental officials, scientists, and business leaders (retailers/wholesalers, technology industry, other industries such as fisheries, tourism), and the public (indigenous groups, residents, and consumers). The stakeholder groups perceive aquaculture differently, both between them and depending on the circumstances and context; their perception ranged from positive to negative. Multiple factors influence their perceptions, including aquaculture’s impact on multiple sustainability dimensions, knowledge, transparency, personal interests, types, and location of aquaculture practises, regulations, experience, food-related and dietary lifestyles, as well as sociodemographic characteristics such as age, gender, education, household size, occupation, and income.

Implications
We recommend that aquaculture practitioners focus on context-specific multifaceted strategies – prioritising transparency, communication, and accountability – and provide essential knowledge to ensure that societal perceptions of aquaculture are based on accurate, empirical information.
SUPPLEMENTATION OF THE PLANT Solanum glaucophyllum TO DIETS FOR ASIAN SEA BASS Latas calcarifer INCREASES GROWTH

Introduction
Although the vitamin D metabolism in fish is similar to the one described in other vertebrates, there are some marked distinctions. While the conversion of vitamin D to 25-hydroxyvitamin D (25(OH)) occurs in the liver, the main sites for the second conversion step from 25(OH) to the active metabolite 1,25-dihydroxyvitamin D (1,25(OH)2D3) are both the kidneys and the liver (Lock et al., 2010). In addition, 1,25(OH)2D3 seems to be the main circulating vitamin D metabolite in fish and not 25(OH) as in other species (Lock et al., 2010). Last but not least, the role of vitamin D on the calcium metabolism in fish is unclear (Lock et al., 2010).

Recently, additional effects of vitamin D and its metabolites on aquatic species have been examined. Observed effects were changes in lipid metabolism and thus growth (Lin et al., 2022) as well as effects on the immune system (Cheng et al., 2020).

As the conversion of vitamin D to 1,25(OH)2D3 might be impaired by other factors such as age or dietary mycotoxins (Abe et al., 1982; Sauvé et al., 2023), directly supplementing 1,25(OH)2D3 to the diet could be a way to close this gap. Solanum glaucophyllum (SG, waxy-leaf nightshade) is one of only a few plants naturally containing a high amount of 1,25(OH)2D3 in glycosidic form (G-1,25(OH)2D3). The aim of this study was to test the effect of different dosages of SG added to standard feed for Asian sea bass (Latas calcarifer) on performance.

Material and Methods
A total of 120 male and female Asian sea bass were distributed with a density of 15 fish/m3 in 24 300-liter tanks with a salinity of 15 ppt. Initial body weight was 44.5 ± 2.3 g. The fish received 3 times daily one of 6 experimental diets during 8 weeks: Control diet (CON), CON + 2.5 µg 1,25(OH)2D3 (T1), CON + 7.5 µg 1,25(OH)2D3 (T2), CON + 15.0 µg 1,25(OH)2D3 (T3), CON + 22.5 µg 1,25(OH)2D3 (T4), and CON + 30.0 µg 1,25(OH)2D3 (T5). The control diet was formulated according to standard recommendations and contained 39.5 % crude protein, 11.2 % crude lipids, 3.8 % crude fiber, 1.31 % Ca and 0.90 % total P. 1,25(OH)2D3 was added as G-1,25(OH)2D3 from SG (Panbonis®, Herbonis Animal Health GmbH, Switzerland). Performance (body weight (BW), daily weight gain (DWG), feed conversion ratio (FCR), and specific growth rate (SGR)) was measured from 0 to 4 and 4 to 8 weeks after the start of the experiment. Protein efficiency ratio (PER) was calculated for the whole experimental period.

Results
There was no mortality recorded in any of the tanks. All performance data were lowest in CON and highest in T2. Additionally, performance of T5 tended to be lower than performance of animals fed T2, T3 or T4. Effects were more pronounced at the end of the experiment than after 4 weeks. Final individual BW in CON was 87.2 ± 15.2 g and 146.0 ± 8.9 g in T2, respectively (p < 0.05). There were no differences among the treatments in SGR until week four with an overall mean of 1.68 ± 0.38 % per day. The value increased to 1.86 ± 0.38 % per day for the whole experimental period, showing a difference of 0.96 % per day between T2 and CON (p < 0.05). Similarly, the body weight SGR was lowest in CON and highest in T2 (p < 0.05). FCR for the whole experimental period was between 1.08 ± 0.04 (T2) and 1.78 ± 0.46 (CON), which was significantly lower than any other diet supplemented with SG. PER was 1.50 ± 0.38 for fish fed the CON diet and 2.36 ± 0.08 for fish supplemented with 7.5 µg G-1,25(OH)2D3 (p < 0.05).

Discussion
This trial showed that fish react in a dose dependent manner to the supplementation of SG. Interestingly, the dosages required to result in any changes are much higher than used in terrestrial animals. There, the standard dosage is 1.0 µg G-1,25(OH)2D3/kg feed. This might be related to differences in metabolism (ectotherms vs. endotherms) and digestive physiology. Further studies are planned to better understand the underlying mechanisms of the influence of 1,25(OH)2D3 on fish performance and to narrow down the optimal dosage for practical application.

LOW INCUBATION TEMPERATURE MAY INFLUENCE SURVIVAL AND DEVELOPMENTAL PLASTICITY OF INNATE IMMUNITY IN ATLANTIC SALMON LARVAE EXPOSED TO *Yersinia ruckeri*

Introduction
Norwegian aquaculture shares a large proportion (more than half) of global production, where Atlantic salmon (*Salmo salar*) is one of the most intensified farmed fish species. However, there is a significant number of fish mortality in the production line resulting in huge economic losses due to various infectious agents, selective breeding practice and high rearing temperature causing impaired immune functions. Moreover, higher temperature can be detrimental for fish health and can pose a threat for developing deformities during early life stages in Atlantic salmon. Continuous attempts have been undertaken to produce robust fish and rearing circumstances, particularly by adjusting water temperature during early life stages, which have been shown to be effective in regulating adult salmon phenotypes. In this study, we aim to assess if low rearing temperature during embryogenesis of Atlantic salmon can manipulate innate immunity which may improve disease resistance potential against potent pathogens in later life stages such as *Yersinia ruckeri* which is predominant in salmonids. *Y. ruckeri* causes enteric redmouth disease (ERM) and is more prevalent in rainbow trout in countries such as Scotland, Australia and Chile. However, the number of outbreaks in farmed Atlantic salmon has increased in Norway in recent years. *Y. ruckeri* is often a problem during the freshwater stage of production. Therefore, it is crucial to find sustainable options on how to improve disease resistance in Atlantic salmon. Manipulating embryonic rearing temperature may help producing robust phenotypes, as it is a strong regulator of immunity and changes occurring during early life stages may have a pervasive influence on the fish.

Materials and methods
Fertilized eggs of Atlantic salmon were reared under different temperature regimes of 4, 6 and 8°C until the eyed-egg stage (~320 day degrees), and thereafter reared under similar conditions as the 8°C group. Larvae (before start-feeding) were exposed for 2h to a *Y. ruckeri* bath challenge in a multi-well plate and followed for 72h. Bacterial localization was assessed by immunohistochemical (IHC) detection and followed up by histological examination in the gills and skin. Multi-gene expression analysis was performed on the BioMark HD platform to assess early immune competence (ImCom). Multiplex fluorescent in situ hybridization (FISH) was established, using RNAscope technology, to detect monocyte and lymphoid progenitor cells in whole larvae.

Results
Larvae from the 6°C group showed a better survival probability (up to 16.69%) than in the 8°C at 72h post challenge. IHC staining showed localization of the bacterial antigen mostly in the secondary lamellae of gills, and the epithelial and basal layers of skin. However, very mild histopathological changes such as sparse epithelial lifting of gills secondary lamellae and epithelial disruption of skin tissue were noticed after 24 and 72h. ImCom results showed that the larvae of the 4°C group had a significantly differential expression pattern of innate immune genes compared to the 8°C group. For example, *toll-like receptor 13 (tlr13)* involved in pathogen recognition and stress proteins such as *heat shock protein 70 (hsp1a1)* in the gills, whereas *gelsolin (gsn), collagen 1 (coll1a)* and *claudin 4 (cldn4)*, which are important extra cellular matrix (ECM) and tight junction proteins for their regulatory roles during inflammatory and antimicrobial response, were differentially expressed in the skin after 24 and 72h of challenge. However, *gsn, hsp1a1* and *cldn4* were also upregulated in 8°C, but immune response was overall more pronounced in the gills than in the skin. Moreover, 6°C group had a relatively suppressed immune genes expression in both gills and skin compared to 8°C group. Other pro-inflammatory genes also showed higher tendencies in the low temperature groups. The FISH method demonstrated the detection of monocyte lineage cell population in the head kidney region and lymphoid progenitor cells, which were more abundant in the thymus tissue in all temperature group. However, 4°C group larvae showed a relatively low number of these long living immune cells which could relate to thermal sensitivity of progenitor cell differentiation during embryogenesis.

Conclusion
Altogether, our results depict that low rearing temperature during early life stage may have an influence on developmental plasticity of innate immunity and better survival in later life.

INVESTIGATING SALMON BEHAVIOURAL CHANGES TO A STRESSOR FOR AUTOMATED FEEDING AND IMPROVED WELFARE IN AQUACULTURE FARMS

Meredith Burke*, Dragana Nikolic, Pieter Fabry, Hemang Rishi, Trevor Telfer, and Sonia Rey Planellas

Institute of Aquaculture
University of Stirling
Stirling, UK, FK9 4LA
meredith.burke@stir.ac.uk

Introduction
Aquaculture is expanding globally, valued at USD 281.5 billion in 2020, with Atlantic salmon dominating finfish production at 2.7 million tonnes annually (FAO, 2022). As the industry grows, more sophisticated technology is needed to monitor farms and ensure their sustainability. Using behaviour as a non-invasive form of monitoring, in combination with artificial intelligence and machine learning, can allow for higher control over farm management (Yang et al., 2020). The development of algorithms to analyse fish behaviour related to feeding may be used to fully automate the feeding process and reduce environmental and economical waste. The goal of this study is to identify changes to Atlantic salmon (Salmo salar) behaviour related to responses to stressors such as the well boat treatment for gill disease (freshwater) and sea lice (FLS).

Materials and Methods
For this study, 5 cameras were deployed at a Scottish Atlantic salmon farm consisting of 10 cages, each 100 m in circumference and ~15 meters in depth. The cameras were deployed in one cage in the following orientation: 3 down the centre (4 m, 9 m, 14 m), 2 at 9 m on the inner and outer areas of the cage, respectively. An algorithm was created by Observe Technologies to process video footage from these cameras and transform it into behavioural data useful for farmers (e.g., activity, speed, schooling, shoaling). For this project, daily internal validation occurs whereby experts compare the videos to the output from the algorithm. The analysis for this study used activity as a proxy for distribution, as an increase in activity corresponds to an increase in the number of fish observed in the videos. Activity was recorded for 5 days surrounding the mechanical treatment and statistical differences were determined with two-sided Kolmogorov-Smirnov tests. Additionally, latency to feed was documented as the time between when feeding was turned on to when activity increased at camera 2.

Figure 1. Activity (%) for each camera (blue: centre at 4 m; red: centre at 9 m; green: centre at 14 m; purple: left at 9 m, yellow: right at 9 m) during daylight hours for 5 days surrounding gill disease and sea lice treatment (T-2 to T+3). The grey bars indicate when feed was turned on.

(Continued on next page)
Results
The fish were distributed predominantly in two areas of the cage, at mid-depth towards the inner farm and at the bottom of the cage, which was observed 2 days prior to treatment (T-2; Fig. 1). The day prior to treatment (T-1), the fish were starved, and started to move towards the middle of the cage, indicated by the higher activity at cameras 2 and 4. On the day of treatment (T), the cameras were pulled from the water, so the day post-treatment (T+1) was used to analyse fish stress response. On T+1, there was significantly higher activity in cameras at mid-depth, cameras 2 (30.8% to 51.9%; D=0.96, p<0.001), 4 (25.2% to 46.3%; D=0.92, p<0.001), and 5 (43.9% to 51.3%; D=0.69, p<0.001), compared to on T-2. This coincided with a significant decrease in activity in the bottom of the cage (52.3% to 40.5%; D=0.90, p<0.001). Two days post-treatment (T+2), the fish moved back down to the bottom of the cage, however they appear to swim to the surface sporadically. Finally, three days post treatment (T+3), the fish resume the distribution observed at T-2. It should be noted that while the latency to feed was highest on T+1 (39.5 min), it was similar on days T-2, T+2, and T+3 (14.75, 12, 8.75 mins, respectively).

Discussion
Behaviour is a useful welfare indicator as it is the first change to occur after exposure to a stressor (Sadoul et al., 2014). The distribution of fish during this study period is largely governed by temperature. Temperatures ranged from 8 ºC at the surface to 9 ºC at the bottom of the cage. As salmon show a temperature preference between 16-18ºC, within the lower range of temperatures available they will congregate in the warmest depth, which was the bottom of the cage (Johansson et al., 2006). There appears to be a subsection of “shy” fish within the inner cage, which prefer to stay away from the bottom of the cage and the potential for predation. After treatment, the fish stress response was to move towards the centre of the cage, likely due to their innate defence behaviour mechanism of shoaling away from areas of higher potential for predation (Sadoul et al., 2014). On day T+2, while there were sporadic increases in activity at the surface, the latency to feed was not significantly different from days T-2 and T+3, indicating that changes to feeding behaviour only occurs 1-day post-treatment. Understanding these timelines can provide insight to the farmers on how to structure their feeding post-treatment to ultimately reduce feed waste.

Introduction

Recently, the gut microbiome has been at the focus of nutritional aquaculture research because it has been shown to regulate nutrient uptake (Semova et al., 2012) and changes in fish metabolism (Ni et al., 2014) immunity and health maintenance. The present study focused on factors affecting the gut microbiome of grass carp (Ctenopharyngodon idella). Such functional flexibility of the gut microbiota likely increases the adaptability of fish digestion, and studies of the gut microbiome are becoming a necessity for aquaculture nutrition research. In this study, the effects of experimental diets on the gut microbiome of juvenile and subadult European seabass were investigated after a 120- and 147-day feeding trial, respectively.

Material and methods

In both experiments, diets were formulated to be iso-proteic (45%), iso-lipidic (20%), isoenergetic (20.3 MJ kg⁻¹) and to meet the dietary requirements of juvenile and subadult European seabass. We used plant protein-based diet (CV), two plant-based diets in which graded amounts of plant protein mixtures were replaced with partially defatted Hermetia illucens pupae meal alone (VH10) or in combination with poultry byproduct meal (VH10P30), a fish meal diet (CF), and a fish meal diet supplemented with H. illucens (FH10).

Bacterial DNA was extracted from the whole intestine content of 15 juvenile and 20 subadult experimentally fed European seabass (3 juvenile replicates and 4 subadult replicates per treatment) using the Invitrogen PureLink Microbiome DNA Purification Kit (Carlsbad, CA, USA) following the manufacturer’s protocol. The commercial services of Microsynth AG (Balgach, Switzerland) were used for library preparation based on Nextera two-step PCR. Variable region V4 of the 16S rRNA gene was successfully amplified from 15 juvenile and 18 subadult DNA extracts using the MiSeq2000 Next Generation system (Illumina, San Diego, CA, USA). The USEARCH algorithm (Edgar, 2010) was applied to generate clusters (OTUs) and taxonomic assignment for the representative sequence of each OTU based on the RDP database (Cole et al., 2014). Downstream analysis was performed using the Phyloseq package (McMurdie and Holmes, 2013) for R (version 4.2.2).

Results and discussion

The results suggest that the gut microbiota of juvenile European seabass is more stable than that of subadult European seabass using the same experimental diet formulations, regardless of the diet tested. Although the majority of phyla detected were the same in juveniles and subadults (Actinobacteria, Bacteroidetes, Cyanobacteria/Chloroplast, Firmicutes, and Proteobacteria), the observed richness was lower in juveniles and there were no statistically significant differences between treatments for alpha and beta diversity. Interestingly, the overall growth performance of juvenile fish was worse on plant-based diets than on fish-based diets, whereas the opposite was observed in subadult fish. There is a possibility that changes in the gut microbiota of subadult fish increased their digestive adaptability and contributed to better performance on alternative plant-based diets containing poultry by-products and/or insect meal, while this effect was absent in juvenile European seabass. These results are important for the development of sustainable aquafeeds and the aquaculture industry.

Introduction
The increasing global need to find alternative and sustainable protein sources has promoted research in the field of non-conventional feed ingredients, such as single-cell proteins (SCPs). SCPs production is based on the fermentation of microorganisms such as yeast, bacteria, microalgae, and filamentous fungi. They have a high protein content with a suitable amino acid profile. Specifically, single-cell protein products obtained from fungi contain 30 to 50% of proteins, other nutrients including different vitamins mainly from vitamin B-complex, and a relatively high amount of nucleic acid. To date, various substrates have been utilized to cultivate microorganisms for SCPs production, such as agricultural wastes, fruit processing wastes, methane, and animal wastes. This study was undertaken to assess the effects of different inclusion levels of SCPs on growth, feed utilization, plasma biochemistry, and gut health of gilthead seabream reared under normal conditions and after a crowding stress period. The product utilized in this trial is a dried, inactive Paecilomyces variotii produced from sustainable industrial wood residual feedstocks to partly or fully replace traditional protein sources in fish feed.

Materials and methods
One trial with gilthead sea bream was conducted in a closed recirculation aquaculture system (RAS). Fish (initial weight: 120.3 ± 0.3 g), were fed over 104 days with four experimental diets containing different inclusion levels of SCPs meal (0% CTRL, 5% SCP5, 7.5% SCP7.5, and 10% SCP10) in substitution of fish meal (FM). After the end of the trial, fish were subjected to crowding stress for two hours (density 80 kg/m³). At the end of the growth trial, distal intestine content was collected for gut microbiota analysis and growth and feed efficiency parameters (specific growth rate, SGR, feed intake, FI, feed conversion rate, FCR), were assessed. Furthermore, blood and a portion of the distal intestine were collected at the end of the growth trial (T0), after the 2 hours (T2) and after 24 hours (T24) from the crowding stress in order to get information on the physiological status of the fish and to investigate on the expression of genes correlated to several gut functions, including immune regulation (interleukin 1β, IL-1β, interleukin 6, IL-6, interleukin 8, IL-8, interleukin 10, IL-10, tumour necrosis factorα, TNF-α, T-cell receptorβ, TCRβ, histocompatibility complex I, MHC I, Proliferating cell nuclear antigen, PCNA, Lysozyme, Lyz), stress response (glutathione reductase, GR, glucocorticoid receptor, GCR, Heat shock protein 70, Hsp70), nutrient absorption (peptide transporter 1, Pept 1, sodium-glucose transporter, SLC5A1, fatty acid binding protein 2, FABP2, Chemerin Chemokine-Like Receptor 1, cmklr1), and epithelial function (aquaporin8, Aquap8, Claudin15, Cldn15, Aminopeptidase N, AminopN). Data were analyzed by one-way, and a two-way ANOVA followed by Tukey’s multiple comparison test, using GraphPad Prism, version 9.1.1.

Figure 1. Relative expression of genes Pept1, SLC5A1, and Aquap8 at T0. Different superscript letters a, b and c denote significant differences (p < 0.05) among diets.

(Continued on next page)
Results
At T0, no significant differences ($p > 0.05$) due to the different treatments were observed in final body weight, FI, SGR, and FCR. Regarding gene expression analysis, genes related to immune regulation showed no differences among diets ($p > 0.05$). Regarding genes involved in nutrient absorption, Pept 1, showed higher values in SCP7.5 with respect to the control diet ($p < 0.05$), while SLC5A1 showed higher expression in SCP5 as compared to the control diet. Even if not significant ($p > 0.05$), the FABP2 showed a similar trend. Among genes with epithelial function, Aquap8 showed a dose-response effect ($p < 0.05$). In fact, its expression increased with the increasing inclusion of SCPs (Fig. 1). Considering T2 and T24, time effect, diet effect, and a significant interaction between diet and time were observed in the expression of several genes including interleukin 8, heat shock protein 70, glutathione reductase, glucocorticoid receptor, and FABP2.

Discussion and Conclusion
The results show that experimental diets containing different levels of SCPs inclusion from *Paecilomyces variotii* can replace 5%, 7.5% and 10% of FM without compromising the growth and feed utilization. Regarding the immune genes, there is no difference in immune response among treatments at T0, a result that matches growth performances. SCPs inclusion affected genes related to nutrient transport and water absorption indicating a probable higher capacity for nutrient and water uptake. Finally, both diet and time clearly affected gene expression.

Introduction

Fishmeal and fish oil are essential elements of diet of many species in aquaculture due to their excellent balance of nutrients however, the increase in its demand has generated shortages and increased prices (FAO, 2020). Recent research has focused on the development of replacement strategies for fishmeal and fish oil by alternative sources such as those of vegetable origin, among which those derived from cereals, legumes or vegetable oils stand out; however, other research areas that has emerged today is the search for industrial by-products that can be incorporated in diets for aquaculture species. Currently, the brewing industry generates large amounts of by-products such as spent grains and others (Mussatto et al., 2006). Spent rains from the brewing industry contain approximately 18 to 35.4% protein (Fărcaș et al., 2017), which does not make it the ideal candidate to replace fishmeal in a high percentage; however, have begun to be investigated with favorable results (Estévez et al., 2021). Besides, recently have been reported some methods to increase the protein of spent grain (He et al., 2019).

Although vegetable ingredients may present some deficiencies derived from anti-nutritional factors, one alternative to face these deficiencies are the biofloc cultures, since the bioflocs developed in these cultures can supplement part of the deficit of amino acids and essential fatty acids in diets with little or no inclusion of fishmeal. Roy et al. (2009) replaced fishmeal with alternative sources of animal and vegetable origin in shrimp diets and Bauer et al. (2012) verified that the complete replacement of fishmeal with alternative sources of vegetable origin (soybean meal) and biofloc meal does not affect the growth, FCA, or survival of *L. vannamei*, concluding that natural productivity acted as a source nutrient supplement. These studies suggest that bioflocs could play an important role in the diet when fishmeal and fish oil are substituted (Ekasari et al., 2010). That is why the objective of this work is to investigate the feasibility of using protein-rich spent grain from the brewery to partially replace fishmeal and its effect on growth parameters, chemical composition, meat quality and microbiota of Pacific white shrimp (*Litopenaeus vannamei*).

Materials and Methods

The spent grain from the brewery was processed according to the method published by He et al (2019). Subsequently, 4 experimental diets (37% protein and 10% lipid) were prepared. The Control Diet (DC) was formulated with fishmeal, soybean meal and poultry meal as protein sources, while in the experimental diets fishmeal was substituted by beer bagasse by 7.5% (D1-7.5), 15% (D2-15%) and 22.5% (D3-22.5). Subsequently, a batch of 2000 larvae (PL-7) of *Litopenaeus vannamei* shrimp was transported from the company Productos pesqueros del Evora, Sinaloa, Mexico to the aquatic organisms laboratory of the Veterinary Sciences Research Institute-UABC, where they were received in a tank of 1000 liters that is part of a recirculation system with seawater and were fed with a commercial diet until they reached the approximate weight of 0.5 grams. At that time, 300 juveniles (0.498 ± 0.01) were randomly stocked in 12 tanks of 100 liters each with biofloc culture (the density was 250 org x m3 at the time of stocking). The crop is developed with zero water changes and will last 45 days. The photoperiod is maintained in a scheme of 10 hours of darkness and 14 hours of light (6:00 a.m. and 8:00 p.m.). Dissolved oxygen (mg L-1) and temperature are monitored daily at 08:00 a.m. and 5:00 p.m. (YSI model 550A) and salinity is measured once a day (YSI30). Nitrogenous compounds (ammonium, nitrites and nitrates), alkalinity and dissolved solids are determined every four days using commercial reagents and Imhoff funnels, respectively. At the end of the experiment, samples of the biofloc and the digestive tract of the organisms will be taken for the identification of the bacterial flora. Likewise, biofloc and shrimp samples will be taken to determine their proximal composition, and shrimp to evaluate the performance and quality of the meat. Data for growth, proximal composition, and meat quality will be analyzed by linear regression using sigma stat 3.5 software.

(Continued on next page)
Conclusions
Through this project, valuable knowledge will be generated about the use of industrial by-products that are currently waste matter from the brewing industry in various parts of the world and that with the correct treatment can be used for inclusion in the diet of aquatic organisms; which, complemented with the nutritional contribution of the biofloc, could generate significant savings in food costs without affecting the health of the organisms or the quality of the meat.

Introduction

In recent decades, there have been ongoing efforts to replace marine proteins in fish diets with alternative and environmentally sustainable sources. The most used alternative proteins in aquaculture nowadays derive either from plants or from by-products from the land animal production sector, and these are usually deficient in taurine when compared to protein marine sources. Taurine is considered to be a conditionally essential amino acid for marine fish species and has been shown to have an important role in a wide variety of biological functions, such as control of endocrine tissues physiology, cellular osmoregulation, bile acid metabolism and immune response modulation, among others.

Aquaculture fish are usually submitted to several stress factors throughout their production cycle. Stressors in fish farming can arise from both anthropogenic factors, such as grading, vaccination, and fishing procedures, as well as natural factors, like sudden increases in water temperature. Changes in water temperature have been demonstrated to significantly affect the immune system of fish.

The aim of this study was to evaluate functional diets based on alternative proteins and supplemented with taurine, as a tool to increase resilience in European seabass (*Dicentrarchus labrax*) submitted to a thermal stress.

Materials and Methods

Four isonitrogenous and isolipidic diets (51% crude protein and 17% crude fat) were formulated with practical ingredients: a Marine, including 25% of marine ingredients (fishmeal and squid meal); a PAP, including 24% of animal by-products (poultry meal and poultry blood meal) and only 5% of fishmeal to increase pellet palatability; and two other diets based on the PAP formulation but containing two different levels of taurine supplementation, 0.5% (TAU0.5) and 1% (TAU1). The experiment was conducted at the Centre of Marine Sciences of Algarve (CCMAR, Faro, Portugal). Groups of 27 European seabass juveniles (12.9 ± 0.90 g) were distributed into 12 flat-bottom 100 L tanks under natural photoperiod conditions (Spring-Summer) at a density of 3.5 kg/m\(^3\). These tanks were part of a recirculating aquaculture system (RAS), and fish were reared following standard procedures with a controlled water temperature (18.0 ± 0.3 °C) and oxygen saturation (96.2 ± 1.9 %). Fish were hand-fed three times a day until apparent satiety for 33 days. At the end of this period, 10 fish per tank were anaesthetized, weighed and measured. Blood samples were collected from the caudal vein. Plasma, liver and intestine samples were collected and snap-frozen in liquid nitrogen for further analysis of physiological indicators, antioxidant status and immune parameters. All samples were collected after a 24 h period of fasting. After this sampling, the water temperature in the tanks was increased 5 °C, and fish were kept under the same dietary regime for 7 days. At the end of this period, a similar sampling procedure as described before was performed.

Results and Discussion

Preliminary results indicate that after 33 days, no significant differences were observed in the final biomass, weight gain, daily growth index, feed conversion ratio and protein efficiency ratio among the treatments.

No significant differences were observed in voluntary feed intake, indicating that the replacement of fishmeal with alternative ingredients did not influence the feeding behavior of fish, nor taurine acted as a feeding stimulant.

No significant differences were found in the hepatosomatic index and condition factor among treatments. Fish survival was high (>99.5%) and not significantly affected by the dietary treatments.

(Continued on next page)
Concerning the post-stress sampling, significant differences were found in fish size. Specifically, fish fed with the PAP diet ended the trial with a significantly greater total length compared to those fed with TAU0.5. However, no significant differences were observed in the condition factor nor in the hepatosomatic index. Fish survival during this period was high (>99.6%) and no differences were found among treatments.

Plasma, liver, and intestine samples are currently being analyzed. These findings will shed light on whether taurine supplementation enhances the fish’s readiness to respond to a thermal stress, providing valuable insights into its potential effects.

Introduction
Seabream (Sparus aurata) is usually slaughtered by asphyxia on ice or ice-slurry, a method that does not immediately stun the fish and cause notable suffering. With the goal of finding a slaughter method that do not compromise the welfare of seabream, in this study we evaluated the welfare of adult seabream during the slaughter process using different stunning methods followed by one of two killing methods.

Methods
We stunned the fish with either electronarcosis as an alternative method for the industry, an anaesthetic (2-phenoxyethanol) as a control, or not applying any stunning as the current practice. Following stunning, we started a killing phase of either ice-slurry or ikejime, a Japanese technique consisting of impairing the brain of the fish with a sharp tool followed by exsanguination. We evaluated the welfare of the fish by using behavioural indicators such as the latency to lose opercular movement, eye-roll reflex, equilibrium, and swimming activity. We also implanted heart-rate bio-loggers that measured the heart rate activity and internal temperature of the fish as an additional method to evaluate fish welfare.

Results
We found that electronarcosis stuns the fish immediately and 2-phenoxyethanol renders the fish unconscious within 100 s. No fish stunned with electronarcosis gained consciousness while they were in the ice-slurry, while only one fish stunned with anaesthesia gained consciousness after 18 min in ice-slurry. Ice-slurry did not stun the fish and the fish showed signs of distress within 55 s of being placed in ice-slurry and only losing consciousness within 15 min on average. Slaughtering with ice-slurry can take up to 40 min and it varies depending on the stunning method used and the individuals (Fig.1). Ikejime caused an immediate death, however performing the technique correctly required practice.

![Figure 1. Time to death during ice-slurry exposure of each individual subjected to either electrical stunning (dotted blue line), 2-phenoxyethanol (dashed orange line), or no stunning (grey line).](Continued on next page)
The bio-loggers showed that the internal temperature of the fish lowers at a very slow rate when exposed to ice-slurry, taking 24 minutes to go from 28 °C to 10 °C. The heart rate decreases over time, getting below 50 bpm within 2 min of exposure when no stunning method was applied beforehand, and increasing again after 23 min of exposure, showing some arrhythmias. Exposure to 2-phenoxyethanol reduced the heart rate from 90 to 70 bpm, and exposure to ice-slurry lowered it below 50 bpm within the first minute of exposure and maintained it low until the fish died. Electronarcosis lowered the heart rate from 83 to 65 bpm, and lowered it below 50 bpm within 1 min, also maintaining it low until the fish died.

Conclusions
Our results show that both anaesthesia with 2-phenoxyethanol and electronarcosis followed by ice-slurry are appropriate slaughtering method for seabream, and the slaughtering process can be even faster using the *ikejime* technique. Slaughtering only with ice-slurry induces suffering for 28 to 38 minutes and therefore should be avoided.
EFFECTS OF INTRAMUSCULAR INJECTION OF CARRAGEENIN, LIPOPOLYSACCHARIDE, AND POLYINOSINIC: POLYCYTIDYLIC ACID TO GILTHEAD SEABREAM (Sparus aurata) SPECIMENS ON SERUM AND SKIN MUCUS HUMORAL IMMUNITY

Introduction
Inflammation is a well-characterized process in mammals, but scarcely studied in fish (Esteban, 2012). In this regard, our studies focused on the development of a model of skin inflammation with carrageenin to study and reproduce inflammation in gilthead seabream (Sparus aurata) (Campos-Sánchez et al, 2021a). Carrageenin is a mucopolysaccharide derived from the cell wall of red algae (Rhodophyceae family), used for decades as a model of acute inflammation in rodents (Winter et al, 1962). However, other inflammation triggers frequently used in mammals such as the bacterial lipopolysaccharide (LPS) or the viral mimic Polynosinic:polycytidylic acid (poly I:C) have not been studied in depth in this context (Zhao et al, 2023). For this main reason, the present study aims to evaluate and compare the modulation of the humoral immune response in the serum and skin mucus of gilthead seabream after an intramuscular injection of either carrageenin, LPS, or Poly I:C.

Material and methods
In this study, 72 juveniles (59.94 ± 1.05 g, 15.26 ± 0.10 cm) of gilthead seabream (Sparus aurata) originated from broodstock of the aquaculture Research Station of Olhão (Portuguese Institute for the Ocean and Atmosphere) and maintained in the same facilities, were injected intramuscularly with 50 µL of phosphate buffered saline (PBS, as control), carrageenin (1%, Sigma), LPS (1%, Sigma), or Poly I:C (1%, Sigma) solutions. At 3, 6, and 24 hours post-injection, blood samples and skin mucus were collected by following the methods described by Guardiola et al (2016). The following parameters were analysed: peroxidase activity, esterase activity, lysozyme activity, bactericidal activity against Photobacterium damselae and total immunoglobulin levels in serum and skin mucus. Haemolytic complement activity was also studied in the serum (Guardiola et al, 2016). The results were expressed as mean ± standard error of the mean (SEM) and data were analysed by two-way ANOVA (followed by Tukey tests) to determine differences between experimental groups and each group in relation to time, respectively. The level of significance used was p < 0.05 for all statistical tests.

Results and discussion
Haemolytic complement activity increased in the serum of fish from the carrageenin group at 3 h post-injection, compared to fish from the control (injected with PBS) and LPS group. In addition, this activity also increased at 24 h in fish injected with carrageenin and LPS compared to fish injected with Poly I:C. The rest of the activities studied in the serum (peroxidase, esterase, lysozyme, bactericidal, and total immunoglobulin levels) were not altered by none of the inflammatory triggers at any experimental time. In skin mucus, peroxidase and esterase activities increased in fish injected with carrageenin and studied at 3h compared to fish in the control and LPS groups. Furthermore, peroxidase activity increased at 24h in the Poly I:C group compared to the carrageenin group, while esterase activity values increased at 24 h in the Poly I:C group compared to the control group. On the other hand, lysozyme and bactericidal activities increased at 3h post-injection in all three fish groups compared to the control group. However, at 6h post-injection, lysozyme activity only increased in the carrageenin-injected fish group compared to control fish. In addition, bactericidal activity decreased in the Poly I:C fish group compared to the LPS group. Thus, all three inflammatory triggers used in this study appeared to stimulate the release (Continued on next page)
of proinflammatory molecules into the cutaneous mucosa from cells neighbouring the injection site, exercising a very localised action (Campos-Sánchez et al., 2021b). Furthermore, while carrageenin and LPS seemed to activate the innate immune response of gilthead seabream, which is a shorter and non-specific response with granulocytes and macrophages involved, Poly I:C could activate the adaptive immune system with a later, but more specialised response developed mainly by lymphocytes.

Conclusion
The present results suggest that carrageenin, LPS, and Poly I:C are able to trigger inflammation in fish and may modulate the (innate or adaptive) immune response in gilthead seabream. These data not only could be used in further studies to elucidate inflammatory mechanisms, but also in the search for anti-inflammatory drugs of great relevance to the aquaculture sector.

Introduction

In recent years, the use of micro- and macroalgae as functional ingredients has been contemplated to improve the growth and general condition of cultured fish. The “health diets”, which include ingredients with functional properties on the organism, are a very promising option. In this context, nutraceuticals develop a fundamental role, providing numerous benefits for the health and physiological status of animals, including the prevention or treatment of diseases. LB-LIVERprotect is a compound formulated from microalgae that improves fish hepatic performance, contributes to cell structure maintenance, acts as a lipotropic agent that prevents the development of fatty liver and has a multibiotic effect. On the other hand, although starvation is a common situation in aquaculture, which can induce some damage to the metabolic status and welfare of cultured animals, it is still necessary to deepen the study on its negative effects and the way to prevent them. The present work aimed to evaluate the potential benefits on the metabolism concomitantly with hepatic and gut well-being of supplemented plant-based diets enriched with the nutraceutical LB-LIVERprotect for the gilthead seabream (Sparus aurata) in the face of a starving challenge.

Materials and methods

Three diets were formulated: i) control diet (C+) with a nutritional composition based on fish meal (FM) and fish oil (FO); ii) vegetalized diet with a high substitution (75%) of FM/FO by plant proteins and oils (C-); and iii) the C- diet supplemented with 1% of the LB-LIVERprotect compound (LP). Juveniles gilthead seabream (S. aurata) of 27-28 g initial mean weight were distributed in nine tanks (3 tanks per experimental diet) and fed ad libitum for 90 days. Subsequently, two tanks per treatment were starved for 14 days (St) and the rest of the animals were kept on continuous feeding (Cf) with the same diets. Sampling was carried out in which biometric parameters were measured and biological samples were collected. Somatic and zootechnical indices were calculated and histomorphological and histochemical analysis for the intestine and liver was carried out. Additionally, some metabolic parameters were also analyzed.

Results and discussion

C- experimental group (both fed and starved) showed the development of subepithelial spaces consequence of the separation of mucosa and submucosa layers in the anterior intestine. The ratio of the mucosa surface and width of the mucosa/submucosa layers did not present differences between treatments and/or experimental diets, but a significant increase of goblet cells was observed in starved fish from all experimental groups. In addition, starved fish presented alterations in the tunica muscularis of the intestine. This may be due to variations in the length and diameter of the intestine during the feeding/starving process (Liu et al., 2018). At the hepatic level, adipocytes number around the exocrine intrahepatic pancreas increased in C- group (both fed and starved), and a slight decrease was observed in the LP group (Fig. 1A, B, C). This agrees with the enhancement of hepatic triglyceride content and MSI index observed in LP group (Fig. 1D), suggesting that a metabolic orchestration could be taking place for the protection of the liver in specimens receiving this diet. In this way, the excess lipids generated by the plant-based diet and influenced by the nutraceutical compound may be stored fundamentally as perivisceral fat but not as hepatic fat. Starved fish from C+ and C- groups, showed significant atrophy of the hepatocytes, while in LP-starved group this atrophy was less evident. These results are related to those obtained for the HSI index which decreases in all starved groups, although this decrease was mitigated in LP group (Fig. 1E). So the diminishing of hepatocyte volume (cellular atrophy) contributes to the reduction of liver weight and thus, the

(Continued on next page)
HSI value. The decrease in the volume of the hepatocytes can be also due to the depletion of glycogen stores observed in starved groups (Karatas et al., 2021).

Our results indicated that administration of the nutraceutical compound has positive effects on the histology and metabolism of S. aurata, providing the fish with metabolic protection to prevent significant hepatic damage during the starving period.

Introduction

Diseases and infections caused by pathogenic agents in fish, as well as stress generated due to alterations in the homeostatic state of the specimens, are two of the critical points facing aquaculture. In recent years, the search for healthier and more environmentally sustainable alternatives for the feeding of farmed fish has increased. The concept of “functional feed” is an emerging paradigm in the aquaculture industry. It involves developing nutritionally balanced diets supplemented with food additives to improve health and disease resistance. In this context, microalgae are good candidates as a dietary supplement and ingredient because they possess immunostimulant properties, increase stress tolerance, and have an excellent nutritional profile. Likewise, nutraceutical compounds have acquired enormous potential in the aquaculture industry and are currently one of the main strategies to boost production in the sector. The present work aimed to evaluate, at metabolic and histological levels, the possible positive effects of the LB-IMMUNOboost nutraceutical compound in gilthead seabream (*Sparus aurata*) juveniles previously fed with a plant-based diet alone or supplemented with this compound and submitted to an inflammatory response induced by administration of IFA (Incomplete Freund’s Adjuvant) oleaginous solution.

Materials and methods

Three diets were formulated: i) control diet (C+) with a nutritional composition based on fish meal (FM) and fish oil (FO); ii) vegetalized diet with a high substitution (75 %) of FM/FO by plant proteins and oils (C-); and iii) C- diet supplemented with 1 % of the LB-IMMUNOboost compound (IB). Juvenile gilthead seabream (*S. aurata*) of 27-28 g initial mean weight were distributed in nine tanks (3 tanks per experimental diet) and fed ad libitum for 90 days. Subsequently, eight animals per experimental diet were injected intraperitoneally with two treatments: i) Saline (control injection) and ii) IFA (100 μL of IFA solution/100 g fresh weight, vaccine adjuvant that induces intestinal inflammation). At the end of experimental time and 72 hours post-injection, specimens were sampled for biometric parameters and biological samples. Histomorphological and histochemical analysis for the anterior intestine and liver was carried out. Plasma and hepatic parameters related to metabolism were also analyzed.

Results and discussion

At the metabolic level, mobilization of some metabolites seems to be taking place after IFA injection. In these animals, hepatic glycogen concentrations decreased, constituting a common strategy in some fish species to maintain circulating carbohydrate levels after an acute stress event. However, this carbohydrate mobilization was only significant in animals fed with C- diet since, in both C+ and IB groups, plasma and hepatic glucose levels remained constant between both treatments (Saline and IFA). Differences in plasmatic lactate values were only observed in the C+ group, increasing significantly in IFA-treated animals. TAG concentrations followed a similar pattern in plasma and liver, being higher (both, Saline and IFA) in animals fed with the two plant protein-based diets (C- and IB) concerning the control diet, so, in this case, it may be an effect of the diet itself and not of the treatment.

Fish of the Saline-C+ experimental group showed normal histological architecture in the intestine and liver. Mucosa/Submucosa surface Ratio (MSR), a measure of the absorption surface, was lower in all experimental groups injected with IFA (Fig. 1A). However, groups fed with IB diet enhanced this MSR. A significant increase in the thickness of mucosa/submucosa layers was observed in individuals injected with IFA and fed with C- diet. However, in fish fed with IB diet, this effect was not observed (Fig. 1B). Goblet cells increased in individuals treated with IFA in all experimental groups, especially in group C- where this enhancement was most significant (Fig. 1C). Hepatocyte area diminished in C- and IB groups (Fig. 1D); although the nutraceutical compound seems to have a partial protective impact on this parameter after IFA injection.

(Continued on next page)
Our results indicated that administration of the LB-IMMUNOboost nutraceutical compound has some positive effects on the metabolism and histology of *S. aurata*, providing the fish with metabolic and histological protection in the face of possible infection/inflammation challenges that can commonly occur in aquaculture practice.

Introduction
Fish meal is mainly derived from wild caught fish where landings have reached a maximum capacity and cannot expand further without detrimental effects on fish stocks. In contrast, the aquaculture industry is the fastest-growing animal food-producing sector worldwide [1,2]. Therefore, great efforts have been made to find sustainable, healthy and low-cost solutions for replacing fishmeal for carnivorous fish like Atlantic salmon [2]. Salmonids that are fed diets in which fish meal is completely replaced with plant-based proteins show reduced growth, lower FCR, altered gut microbiota, metabolic and intestinal dysfunctions [3,4]. Biodegradation processes such as fermentation have proven efficient in improving the nutritional quality of several plant-protein based diets [5]. Nevertheless, knowledge on this topic is still limited and the inclusion of fermented products is less than 0.5% in common Atlantic salmon feeds [6]. The aim of this study was to assess the efficacy of substituting fish meal for fermented products (rape seed, soy and seaweed) and map how these diets affect fish performance, welfare and gut microbiota in Atlantic salmon post-smolts.

 Materials and methods
This 12-week diet-trial was performed at the NIV A research station, Solbergstrand. PIT tagged Atlantic salmon (Salmo salar) were stocked in 9 tanks with full strength sea water in flow-through. Fish were allowed >14 days for acclimation before the trial started. At the start of the experiment, the mean fish weight was 250 ± 48 g. Two diets, EP199 (fermented rapeseed and soy, 15% inclusion), EP299 (fermented seaweed and soy 30% inclusion), were evaluated against a control diet (CTRL) (Table 1). Diets were produced by SPAROS R&D and all diets were tested in triplicate tanks. Fish were fed ad libitum with automatic feeders according to the daily feeding regime: 10:00, 12:00, 14:00, 00:00, 02:00 and 04:00. Water quality was monitored daily. Feed waste was continually collected in order to calculate feed conversion ratio (FCR) and feed intake. All fish were weighed at the start, middle and end of the experiment to assess condition factor and specific growth rate (SGR). 9 fish from each diet were sampled at the start, after 6 weeks and at the end of the trial (12 weeks). From these samples microbial composition and diversity in the gastro-intestinal tract was mapped using 16S rRNA amplicon sequencing of the V4-V5 region. Sequence reads were analyzed using DADA2 [7] and community composition and ordination analysis identified the most important drivers of observed diversity Blood plasma samples were analyzed for the immune health biomarkers (Lysozyme, protease, superoxide dismutase and peroxidase activity) using commercial kits. To assess if diet affected the fish’s ability to respond and recover after a stress event a standardized stress test was performed at the end of the trial according to [8].

Results and discussion
Preliminary results from this 12-week diet trial revealed that post-smolts fed with the EP199 diet had a higher condition factor compared to fish fed with CTRL and EP299 diets after both 6 and 12 weeks, and a better SGR and FCR compared EP299 fed fish at the end of the trial (Fig 1.). In contrast, fish fed EP299 besides having a lower condition factor also had a lower FCR and SGR compared to fish fed CTRL and EP199 diets after 12 weeks. Preliminary results from sequencing of the microbial community in the gut show no difference in microbial diversity (Richness and Shannon-diversity) between fish fed different diets, more data on the effects of diet on microbial composition will be presented. Post-smolts fed with EP199 also had increased levels of lysosome, peroxidase and protease activity in the plasma compared to fish fed a CTRL diet. Furthermore, EP199 fed fish had a higher stress responsiveness, measured as a larger increase in plasma levels of cortisol after a stress test. Overall, these results suggest that fish fed a diet with reduced fishmeal and a 15% inclusion of fermented rapeseed and soy perform as good or better than fish fed a CTRL diet. Furthermore, results suggest that the EP199 fed fish may have a better primed immune system and responsiveness to stress. Future studies are needed to assess and optimize inclusion of fermented seaweed products for Atlantic salmon feed.

In the present study, 5 diets were formulated, to fed *L. vannamei*, with organic raw materials (vegetal mixture, viscera Iberian pig, rainbow trout sub products, organic insect and a control diet with 30% fish meal), as an alternative to conventional fishmeal, studying its effects on growth and shrimp survival. No significant differences were found between the different treatments in terms of growth and neither in terms of survival. In summary, this study demonstrated that it is possible replace fishmeal with ecological alternative ingredients in shrimp diets without impairing its growth.

**Introduction**

Organic aquaculture consists in a aquatic production that is carried out respecting the certification codes that guarantee a production system that respects the environment and animal welfare in general and the sustainability of fisheries in particular (Regulation CE834/2007). In accordance with this context, the objective of this study is to replace the use of fishmeal in the feed of *L. vannamei* with completely organic ingredients for ecological and sustainable aquaculture. This was carried out by evaluating the different sources of protein in the replacement of fishmeal and studying their effects on growth.

Materials & Methods
5 experimental diets were formulated and manufactured with different raw materials of organic origin, substituting fishmeal. These ecological sources were: a mixture of vegetable flours, organic trout by-product flour, Iberian pig offal meal and insect meal (VEGETABLE, TROUT, IBERIAN, INSECT). A control feed whose main protein source was fishmeal (CONTROL with 30% fishmeal) was also used. The experiment took place within the facilities of the aquaculture laboratory of the Polytechnic University of Valencia, 15 shrimp were placed in each of the 30 experimental tanks within a RAS system. The duration of the experiment was 88 days.

Results & discussion
Figure 1 shows the growth of Litopenaeus vannamei fed with the different experimental diets. As shown in Table 1, no significant differences were found between the treatments in terms of relative weight gain or survival. The Iberian and trout diets were those that reached a higher final weight, without significant differences (21.2 and 21.6 grams, respectively). While the Iberian and Insect diets obtained the highest values in terms of survival level, again without significant differences with the rest.

Conclusions
Feeding white shrimp Litopenaeus vannamei organic protein ingredients can eliminate the use of fishmeal without adverse effects on growth and survival. The organic trout evisceration by-product meal, as well as the Iberian pig viscera meal, are especially promising in terms of growth and given their animal origin. However, they do not present significant differences between them.

Introduction

The aquaculture industry faces a significant challenge in obtaining affordable and sustainable feed raw materials. As a result, new potential ingredients have been researched in recent decades as replacements for traditional aquafeeds, which are already overexploited. To ensure long-term environmental sustainability, any potential replacements for the feed ingredients must have their environmental performance assessed, which is why many studies in the literature have emerged assessing the environmental impacts of alternative feed ingredients for the aquaculture sector using tools such as a life cycle assessment. However, the environmental dimension is not the only criterion to consider when looking for sustainable feed ingredients. The social and economic dimensions of sustainability are also relevant, as demonstrated by Elkington (1998) in the Triple-bottom-line approach, and are frequently overlooked in the case of fish feed ingredients. The use of alternative feed ingredients may have an economic impact on producers and other stakeholders of the industry because raw material prices vary, and any changes may affect the entire production supply chain. In addition, depending on the source of the raw material, the use of alternative ingredients may affect local employment positively or negatively, while consumers may change their purchasing decisions based on their willingness to pay for more sustainable fish feed ingredients.

Future challenges for alternative feed ingredients include developing oceans in a way that is economically and environmentally sustainable while reducing reliance on the human food chain for seafood production. The dependence on edible fish (such as anchoveta) and land-based feed ingredients (such as soy) for aquaculture feed will be reduced by using species unused for human consumption. There are many species in the ocean, especially in the lower trophic levels, which are either not harvested or are only marginally utilised. One of these species is Calanus (*Calanus finmarchicus*), a lipid-rich zooplankton that is present in large amounts in the North Atlantic Ocean. Calanus is mainly used for high-value n-3 fatty acid products for human consumption in Norway, while the protein fractions are used as attractants in starter/shrimp feed and as taste enhancers in pet food. Although the production volume is currently quite small, it has the potential to provide new and substantial quantities of marine raw materials to support the sustainable expansion of Norwegian aquaculture. With an estimated biomass of 290 million tonnes, *Calanus finmarchicus* is a resource with high opportunities for its harvest and use.

Following the previous, the objectives of this investigation are twofold: (1) Develop a framework for the sustainability assessment of fish feed ingredients encompassing environmental, economic and social impacts, and (2) apply the analysed framework in the sustainability assessment of Calanus-based feed production for Norwegian salmon aquaculture.

Materials and methods

The framework will consider methodologies such as life cycle assessment, cost-benefit analysis, and semi-structured interviews and questionnaires, to address the environmental, economic and social impacts of alternative feed ingredients. Life cycle assessment is a technique for assessing the environmental aspects associated with a product over its life cycle. Meanwhile, cost-benefit analysis and semi-structured interviews serve as a base for developing economic and social indicators.

Furthermore, because a comprehensive approach with environmental, economic, and social aspects is difficult due to the many different single results obtained and the use of both qualitative and quantitative information, the Multi-Criteria Decision Analysis (MCDA) method is used to address this issue. MCDA is well-known for its ease of use, transparency, and robustness in eliciting stakeholder preferences, as well as for determining the relevance and importance of each criterion used in sustainability assessments (Deshpande et al., 2020).

(Continued on next page)
Results and discussion
The framework developed consists of the following summarized steps:

1. Mapping the life cycle stages of the production of feed’s raw materials: to ensure a comprehensive assessment, the life cycle stages of the alternative raw material from harvest to the finished product are mapped. Additionally, the effect of incorporating the ingredient into a commercial diet could be examined. The Cradle-to-Gate system boundary can be used in conjunction with systems engineering methods to evaluate the environmental, economic, and social effects of the production method.

2. Data gathering and stakeholder involvement: Based on the stages of the life cycle, material, energy, and monetary flows are mapped with the participation of pertinent industrial stakeholders. As research techniques, questionnaires and semi-structured interviews are used to gather both qualitative and quantitative data relevant to the assessment.

3. Data processing and sustainability assessment: Processed data is fed into the framework for evaluating sustainability. The most pertinent environmental, social, and economic evaluation criteria are determined. For the chosen feed alternative, the life cycle assessment, cost-benefit analysis, and multi-criteria decision analysis research methods are used to evaluate the environmental, economic, and social aspects of sustainability.

4. Uncertainty analysis: Preliminary results are processed to estimate and reduce the uncertainty in the assessment to ensure a reliable analysis. In particular, to better understand the effects of emphasising one dimension (social, economic, and environmental) over another, a sensitivity analysis of the weights assigned to each of them is carried out.

In terms of the application of the framework to *Calanus finmarchicus* production, preliminary results indicate that harvesting and freezing on board presents the highest environmental impacts within the supply chain. Moreover, economic impacts are highly influenced by the production method and price of the feed material. Furthermore, it is expected that consumers are willing to pay more for salmon products in which local-based sources of feed such as Calanus are used. Also, there is a positive effect on local employment driven by a future scenario in which outsourced feed ingredients are partially replaced with local feed ingredients such as Calanus. More concrete and updated results will be presented at the conference.

Funding
This investigation is part of an industry-academic collaborative research project (CalaFeed - Enhancing the potential of Calanus as raw material for sustainable aquaculture feed ingredients) funded by the Norwegian Research Council (NRC). This investigation is part of WP4, which aims to perform a comparative sustainability assessment encompassing environmental footprints, economic feasibility and social impacts of Calanus-based feed production compared to traditional feed ingredients.

Introduction
Asian Seabass or Barramundi, *Lates calcarifer*, is one of the 15 species of finfish most produced in the world through aquaculture systems. In the last 20 years, the production of this species showed an increase of 80%, from 18.1 thousand tons in 2000 to 105.8 thousand tons in 2020 (FAO, The State of world fisheries and Aquaculture 2022).

Barramundi aquaculture industries are well-established in Thailand, Malaysia, Singapore, Indonesia, Hong Kong, Taiwan, the Philippines and Australia.

The feeding regime for larval rearing of Barramundi is similar to other marine species; the green water technique is used in the initial stage of larval development, together with rotifers, followed by co-feeding of *Artemia* and dry diets (Aquaculture of Asian Seabass or Barramundi, Global Aquaculture Advocate, 2020).

The present study, conducted on a research scale between BRINE research centre (Indonesia) and SFA marine aquaculture centre (Singapore), investigated the application of Natura pRo and ExL in warm water culture conditions in the backyard and advanced production systems.

The effect of rotifer replacement was also investigated by introducing dry feed from the first days of exogenous feeding. Moreover, the importance of live feed enrichment was shown by comparing different feeding regimes.

Materials and methods

*Asian Seabass experiments*

Experiment 1: Backyard system (Indonesia)
Hatched Asian Seabass larvae, originating from the same pool of eggs, were stocked at the density of around 15 larvae L⁻¹ in 4,000L larval rearing tanks. No pure oxygen and no continuous water renewal were used. The water temperature during the larval rearing was 28±1°C.

The effect of dry algae, live feed enrichment and early dry feed introduction was compared to the standard protocol (using fresh algae and not enriched live feed) from 0 to 25dph.

In both treatments, Control (Tr1) and RS (Tr2), algae were used from day 2 to 12ph. Enriched rotifers were fed from day 2 to 12ph in the Experimental treatment (reduced by 50% compared with the Control) and rotifers cultured by fresh algae were fed until 19dph in the Control. In Tr2 AF *Artemia* was fed from 10 to 13 dph, and enriched *Artemia* was fed from 13dph to 23dph. While in the Control group, non-enriched *Artemia* was provided from 13 to 23 dph. Different dry diets were used in the two groups: in the Control, Otohime was used from day 8 onwards and in the RS (Rotifer Substitution) group Natura was used from day 3 onwards.
The trial finished at 25 dph with the first grading.

A natural photoperiod was used (12L/12D), and the treatments were done in triplicate. During the larval rearing period, from 5dph, biometrics were carried out to compare growth rates, every 5 days. A salinity stress test was done to determine the stress resistance before the grading. At 25dph, growth, survival rate, final fish number per tank, fish size distribution and feed consumption were determined.

Experiment 2: Advanced system (Singapore)
Hatched Asian Sea bass larvae, originating from the same pool of eggs, were stocked at the density of around 30 larvae.l⁻¹ in 4,000l larval rearing tanks under controlled conditions: pure oxygen and continuous water renewal were used. The water temperature during the larval rearing was 30±0.1°C.

The effect of the rotifer substitution and early dry feed introduction was compared to the standard protocol from 0 to 21dph.

In both treatments, Control (Tr1) and RS (Tr2), fresh algae (Nanochloropsis) were used from day 1 to 14ph. Rotifers were enriched in both treatments and were fed from day 2 to 14 dph (Tr2 was fed with 50% less of rotifers compared with Tr1). Artemia AF was fed from day 10 to 14dph, and enriched Artemia was fed from 15dph to 21dph. Different dry diets were used in the two groups: in the Control, Otohime was used from day 14 onwards and in the RS group, Natura was used from day 2 onwards.

The trial finished at 21dph with the first grading.

A photoperiod of 12L/12 D was used, and the treatments were done in duplicate. During the larval rearing period, from 2dph, biometrics were carried out to compare growth rates, every 5-7 days.

At 21dph, deformity, survival rate, final fish number per tank and feed consumption were determined.

Results
The Asian Seabass larvae reared in a regime of reduced enriched rotifers and early use of dry diets showed similar growth, better performance and survival if compared with a standard feeding protocol. The adaptation of the protocols resulted in 42% rotifiers substitution in Singapore and 69% in Indonesia.

Conclusions
This study shows that Asian Sea bass larvae can be reared under a feeding regime with reduced offers of rotifers, obtaining a good survival rate and good fry quality when enrichment for the live feed and balanced diet is used from the first days of exogenous feeding. The importance of live feed enrichment, well known in European aquaculture, is a central theme that must be transmitted in the Asian aquaculture hatcheries.

A high-quality diet is fundamental to obtain optimal growth and quality in the larval rearing of Asian Seabass, showing that Natura pRo and ExL, developed for the European finfish species, demonstrated a high versability in tropical conditions.

Introduction
The North Adriatic lagoons host the important aquaculture activity represented by the rearing of Manila clams Ruditapes philippinarum. The filter-feeding habit of these animals enhances the association of several marine bacteria within their edible tissues and among them the genus Vibrio is one of the most recurrent. Several studies demonstrated the increase in spread and distribution of Vibrio and other pathogens as an effect of global warming (Froelich et al., 2020; Amato et al., 2022). In the aquaculture industry Vibrio infections are frequently the cause of great losses in stock and profits (Lafferty et al., 2015), but the identity of the pathogen is hard to determined and the dynamics of interaction within the animal microbiota could modulate the pathogenic effect. In the last few years, the improvement of the sequencing methods based on NGS allowed the detailed characterization of the microbial community dynamic and evolution. In this study, we apply shotgun metagenomics from clam homogenate and from colonies from Marine Agar (MA) and Thiosulfate Citrate Bile Salts Sucrose (TCBS) plates (enriched samples) to define and characterize the composition of the clam microbiota at species and strain level.

Material and methods
Manila clams of commercial size were collected in the Venice lagoon from the farming site of Chioggia and from Porto Marghera a polluted site in which the collection of clams is forbidden. For each site, the batches of clams were analyzed before and after the depuration treatment. A total of 12 batches were collected, 8 in summer (2018-2019) and 4 in winter (2019). After collection, depurated and non-depurated batches (25 gr) of clams were homogenized by adding 225 ml of Alcaline Peptone Water. The homogenate samples (HO) were diluted tenfold. Subsequently, 100 µl of each serial dilution was plated on MA medium (Marine Agar) and TCBS medium. MA medium was incubated at 22°C for 24 h and TCBS medium was incubated at 22 and 37°C for 24 h. The bacterial DNA was extracted from the homogenate and from pellet of bacterial cell scraped from -1 dilution plates of MA or TCBS incubated at 22°C and 37°C (enriched samples) for a total of 32 samples (8 homogenates, 8 enriched_MA, 8 enriched_TCBS22 and 8 enriched_TCBS37). The preparation of shotgun metagenomics libraries and the analysis of the resulting data were performed as described by Zampieri et al., 2020.

Results
The metagenomics analysis (after filtering the reads lower than 0.001%) reports a total of 145 bacterial species from HO samples including 21 different species of Vibrio (14.5 % of the total species). Regarding the enriched_medium samples that represent the cultivable part of the microbiota, 65,47, and 58 species were sequenced from the enriched MA, TBCS22 and TCBS37 respectively. As expected from enriched_TCBS samples most of the species belongs to the genus Vibrio (55% from TCBS22 and 91% from TCBS37). After Vibrio the most represented genera are Pseudoalteromonas with 17 species in TCBS22, 21 in MA and 19 in HO and Shewanella with 1 species in TCBS (22 and 37), 6 in MA and 7 in HO. Among the most represented species several pathogens were identified in the population of healthy clams: the human pathogenic Vibrio species (parahaemolyticus, vulnificus, colerae and alginolyticus), Vibrio crassostreae, Vibrio splendidus, Vibrio harvey, Vibrio corallilitycus, Vibrio tubiashii.

Discussion
The shotgun metagenomic approach allows the definition of the total community at strain level and evidences the presence of a very complex Vibrio community in clams. The human pathogenic Vibrio species were identified in the clam samples, in both depurated and non-depurated samples, demonstrating the inefficiency of the depuration treatment in the elimination of these bacteria. Several species reported as possible pathogens for marine organisms are part of the microbiota of healthy clams, both in winter and in summer season. This demonstrated the ubiquitous distribution of these species. Adverse conditions and environmental stress make the animals susceptible to the action of this community of potential pathogens (Green et al 2018).These data confirm the difficulty in the identification of the pathogenic agents causing the mortality events of farmed marine organisms (Manchanayake et al 2023). The shotgun metagenomic approach could provide a

(Continued on next page)
complete list of the virulence genes (if previously identified as virulence genes and reported in the database) associated to the samples and could help to elucidate the pathogenic action-interaction among the different bacterial species. The metagenomics of the fraction of cultivable bacteria (enriched samples), has the negative effect of the loss of the part of the community not able to grow in the medium. However, it reduce the host contamination (reads from the host could be over 90%) allowing a better definition of the most recurrent living part of the microbiota.

THE DIETARY ARACHIDONIC ACID CONTENT IMPACTS THE FATTY ACID METABOLISM, ENZYMATIC AND NON-ENZYMATIC METABOLITES OF LIPIDS AND THE RESPONSE TO ACUTE STRESSOR IN RAINBOW TROUT FRY

Introduction
The importance of arachidonic acid (20:4n-6, ARA) in fish nutrition is receiving increasing attention. Indeed, this fatty acid (FA) plays a crucial role in growth, survival, stress resistance, and immunity in fish (Bell and Sargent, 2003). Freshwater fish are capable of synthesizing ARA from linoleic acid (LA, 18:2n-6), unlike marine species, which have a reduced ability. The endogenous capacity of freshwater fish to synthesize polyunsaturated fatty acids (PUFAs) and thus ARA differs between species. The ARA requirements of rainbow trout have not yet been determined. Therefore, the objective of the present study was to evaluate the consequences of variable dietary ARA intake on survival, growth but also PUFAs biosynthetic capacity and stress response in rainbow trout fry.

Materials & methods
For this purpose, rainbow trout fry were fed diets containing different proportions of ARA (i.e. 0.6, 1.1 or 2.5% of total FA) for 8 weeks and survival and growth were monitored during the whole duration of the trial. At the end of the experiment, fish were exposed to acute confinement (10 min at 10 kg/m3) to evaluate stress response. Whole fish were collected to investigate the effects of diets on (1) endogenous biosynthesis of PUFAs, (2) production of FA oxidation-derived compounds, and (3) stress response through serotonin (5-HT) and dopamine (DA) pathways by monitoring 5-HT/5-HIAA ratios (target/one metabolite of 5-HT) and L-DOPA/HVA ratios (direct precursor of DA/one metabolite of DA).

Results & discussion
The ARA diet level did not affect the growth, but the lowest level of ARA significantly increased mortality, although the percentage of mortality was very low (1.6% for the ARA0.6 diet compared to 0.7% for the other diets, p-value=0.01). This ARA0.6 diet also showed a significantly higher level of expression of fatty acid elongase 5 (elovl5). This enzyme converts, in particular, LA to ARA, suggesting that rainbow trout can synthesize ARA from LA when dietary supply of ARA is low.

Oxylipins are bioactive lipids generated by the oxidation of PUFAs. Those derived from ARA, such as prostaglandin D2 and E2, are considered to be pro-inflammatory and may, in excess, harmful to fish (Bell and Tocher, 2009)ω3 (ω3 or n-3. When fingerlings were fed the diet containing the highest level of ARA (2.5% of total FA), the production of oxylipins derived from ARA significantly increased while that of oxylipins derived from other PUFAs, such as eicosapentaenoic acid (20:5n-3, EPA), docosahexaenoic acid (22:6n-3, DHA), LA, and α-linolenic acid (ALA 18:3n-3) were not altered.

The serotoninergic and dopaminergic activities resulting from stress revealed a more effective response when the ARA content of the diet was 1.1% of the total FA. This was evidenced by higher 5-HT/5-HIAA and L-DOPA/HVA ratios with the ARA1.1 diet than with the other two diets. These results indicated that the ARA content of the diet can modulate the response of the fish to an acute confinement stress.

(Continued on next page)
Conclusion
In conclusion, a dietary intake of ARA corresponding to 1.1% of total FA seems to be the most appropriate to promote the robustness of rainbow trout fry. Indeed, with an ARA intake of only 0.6% of the total FA, survival decreases even though the capacity to synthesize ARA from its precursor LA increases. With an ARA level of 2.5% of the total FAs, the production of ARA-derived oxylipins rises, which could ultimately have negative effects on the health of the fish.

OVERCOMING BOTTLENECKS IN SEAWEED CULTIVATION - NATURAL PROTOPLAST PRODUCTION IN *Ulva Lacinulata* AND ITS IMPLICATIONS FOR LARGE-SCALE CULTIVATION

Isabel Cardoso 1,2 *, Bela H. Buck 1,3, Laurie C. Hofmann 1,3

1Alfred Wegener Institute, Helmholtz Centre for Polar and Marine Research, Bremerhaven, Germany
2University of Bremen, Germany
3Bremerhaven University of Applied Sciences, Bremerhaven, Germany
Email: isabel.cardoso@awi.de

**Introduction**

The *Ulva* genus has proved to be a suitable candidate for large-scale cultivation and can serve multiple purposes in several industries (e.g., pharmacy, cosmetics, food, and feed) (Mantri et al. 2020; Leyva-Porras et al. 2021). However, to guarantee the success of its large-scale production, it is important to find solutions to the currently existing biological and technical limitations. Some *Ulva* species reproduce in predictable ways, and their reproduction can be induced by following established methodologies (see Mantri et al. 2020 for recent review). However, attempts at inducing the reproduction of the commonly cultivated species *Ulva lacinulata* (Kützing) have been unsuccessful, and large-scale cultivation of this species requires re-stocking from the wild or limiting the harvest to maintain a starting stock of biomass. While this species is often sought for cultivation because it grows well unattached and it does not sexually reproduce, which results in the loss of biomass, this species often degrades, which also contributes to a loss of biomass. The cause of this biomass degradation has until now not been understood. Here, we present evidence that tissue degradation in *U. lacinulata* occurs as a result of natural protoplast production and release. These protoplasts can then develop in several different directions. New blades can be formed, which either develop into adult thalli or undergo gametogenesis very early in their development, resulting in the release of gametes and the germination of new germlings. These results contribute to a new understanding of the life cycle of *U. lacinulata*, and provide the first evidence of natural protoplast production in this species. Because the induction of protoplasts in *Ulva* spp. is time-consuming and expensive, finding the trigger for this process will be an important step to accelerating the success of large-scale cultivation of this species.

**Methodology**

The biological material (previously molecularly identified as *Ulva lacinulata* by Cardoso et al. 2023) was collected in 2021 in a “green tide” area in Lagoa de Óbidos, Portugal (following the Nagoya Protocol) and then brought to the Alfred Wegener Institute, Germany where it has been cultivated in a closed system. Throughout its cultivation, it was kept in 5 L glass vessels at 15 °C (± 1 °C) and an irradiance of 70 μmol photons m−2 s−1 with a 16:8 h light:dark photoperiod (LD) in pasteurized artificial seawater (ASW) (30 PSU) supplemented with half-strength Provasoli in a concentration of 10 mL L−1. The medium was replaced once per week and an aeration system guaranteed the continuous tumbling of the material inside of the vessels.

Upon observation of the onset of biomass degradation, fresh biomass (0.72 g) was collected. The biomass was distributed equally into four 1 L beakers. The experiment ran for four weeks under the previously mentioned cultivation conditions. Every week, the water in each beaker was filtered and centrifuged to collect the protoplasts. After filtering the water, the debris and small pieces of the original biomass were collected, weighed, and placed back into the beaker with newly added culture media. Calcofluor white (CFW) was used to observe the presence/absence of cell walls and disposable hemacytometers were used to quantify the protoplasts yields obtained in each beaker each week. A defined amount of the collected protoplasts were isolated in individual Petri dishes and their development was observed under the microscope. The number of protoplasts that germinated into new blades were counted after five weeks.

![Development of the regenerated protoplasts from *U. lacinulata* obtained during a "degradation" event. a: single protoplast with no visible cell wall; b: first cell division; c: second cell division; d: *Ulva* discs originated from cell division of protoplasts; e: discs and germlings originated from protoplasts. A, b and c at a 400 x amplification, d at an amplification of 100 x, e taken with a binocular (each square = 1 x 1 mm).](image-url)
Results and Discussion
Our observations under the fluorescent microscope confirmed the absence of cell walls in the cells dyed with CFW, thus confirming that these cells are naturally occurring protoplasts. The total protoplast yield obtained in our first experiment was $3.21 \times 10^7$ cells per gram of fresh biomass, which is comparable to those reported in studies where the protoplast formation of different *Ulva* species was enzymatically induced (Reddy et al. 2018). Approximately half of the protoplasts regenerated (40-60 %) and grew into discs or germlings in a similar fashion to what has been described in the literature for induced protoplasts of *Ulva* spp (Reddy et al. 2018; Fig. 1). Moreover, sexual reproduction was found to occur during gametogenesis in protoplasts, rather than in adult blades.

Additionally, by measuring the weight of the initial biomass each week, we observed that the original tissue did not completely degrade after protoplast formation and release, and a final total fresh weight of 5.79 g resulted in a 7 % daily relative growth rate. Thus, revealing that degradation does not necessarily result in a total loss of the culture.

Conclusion
Our observations of natural protoplast production in *U. lacinulata* close an important knowledge gap in understanding this species’ reproductive cycle. This new knowledge can be beneficial when trying to understand the formation of “green tides” and the differences between “green tide” strains and non-“green-tide” strains. Additionally, the production of natural protoplasts can potentially be exploited to improve the efficiency of *Ulva* cultivation methods in the future and remove the bottlenecks existing today for safe and profitable large-scale production.

Introduction

Intensive aquaculture production has led to an increased occurrence of infectious diseases. In addition, co-infections in fish are natural events that should be considered when studying the biology of the pathogens for control measures, since infection with multiple pathogens may increase the severity of disease in fish. The SRS (Salmon Rickettsial Syndrome) produces a systemic disease in Atlantic salmon that was responsible for the mortality of 54.2% (of total infectious diseases) during first semester 2022 in Chile, resulting in annual economic losses of USD $700 million for this industry.

The biological agent of SRS, *Piscirickettsia salmonis* (a facultative intracellular bacterium) has been found in all the others important salmon farming countries like Norway, Canada, Scotland, and Ireland, where the disease can be considered as a potential emergent disease (Long, A, et al. 2021). *P. salmonis* evades the salmon immune system by replicating within cytoplasmic vacuoles of macrophages, avoiding the respiratory burst in these cells. That is why is hard to control by the host innate and adaptive immune responses and it could also be one of the reasons why vaccines still do not provide efficient protection over time (Rozas-Serri, 2022). There are currently two genogroups (LF-89 and EM-90) identified for *P. salmonis* with different virulence levels that cohabit in Chile (Saavedra, J, et al. 2017). Thus, our study focuses how this cohabitation can be related to high fish mortality, as the within-host competitive interactions are linked to virulence, changing the development and persistence of diseases. This, also modulate the population dynamics of pathogens by cooperative or competitive interactions with different antigenic epitopes triggering a cross-reactive immune response in the host, altering its efficiency and the health and welfare of fish (Kotob et al. 2016).

Materials and Methods

In this study, we evaluated the initial effect of co-infection in Atlantic salmon with the two different genogroups LF-89 and EM-90 in an intraperitoneal challenge model to compare pathogenicity and host immune response. Fish (average weight of 60.4 g) were smoltified at VESO Viken (Namsos, Norway) in brackish water (25‰ ± 2‰) at 15°C and continuous 24 h light exposure (24:0). Then, fish were starved for 48 h prior to challenge and divided into groups of 80 fish each (in three identical tanks with a stocking density of 40 kg m⁻³). To perform the challenge, fish were sedated and intraperitoneally (i.p.) injected with 0.1 mL of a 1.0 × 10⁷ cfu/fish (with one of the *P. salmonis* strain or in a ratio of 1:1 for co-infections). Fish were fed *ad libitum* and monitored daily. At day 0, 12 fish were sampled as negative control. Moreover, at 7, 14 and 21 days post challenge (dpc), 12 fish per tank were randomly selected for sampling of head kidney, liver and spleen for total RNA extraction and qPCR gene expression analyses of immune-related biomarkers. Serum samples were evaluated by ELISA after 14- and 21-dpc for total and specific IgM detection.

Results and discussion

The results revealed a variation in mortality between single- and co-infection. The LF-89 strain alone did not induce mortality, while the EM-90 strain produced 52.6% mortality at 22 dpc. However, during the co-infection challenge, mortality started earlier and reached 61.6% mortality after 22 dpc in a steeper curve. The gene expression of immune-related biomarkers at 14-dpc showed the up-regulation of *il-10* (anti-inflammatory cytokine) during the co-infection compared to EM-90 alone in spleen and in head-kidney. At the same time, *il-8* (chemokine) was significantly up-regulated in co-infection compared with EM-90 alone in spleen and liver, and *il-1b* in the liver. In EM-90 challenges this is already described (Rozas-Serri, 2022) but never with higher levels of expression in a co-infection study.

(Continued on next page)
ELISA analyses in serum showed an increase in the protein levels of total IgM (in EM-90 infections and in co-infections) at 14- and 21-dpc, being significative different to the control at day 0 and to LF-89 infection. Moreover, specific IgM against *P. salmonis* showed a peak production at 14-dpc for the three infected groups (EM-90, LF-89 and co-infection). Interestingly, serum from fish infected LF-89 had a higher cross-reaction using EM-90 as antigen than serum from fish infected EM-90 against LF-89.

**Conclusions**

Our study proposes that there is a synergistic interaction effect among the *P. salmonis* genogroups (LF-89 and EM-90) during the infection in Atlantic salmon that could modulate the host immune response, triggering higher mortality. This novel approach to SRS characterization as a multiple-genotype infection may offer better insights into the development and further control of the disease.

Introduction
Intensification of the aquaculture industry can lead to several production-related issues that may cause poor fish welfare and impact human health and the environment. One of these problems is the emergence of disease outbreaks that affect fish production and consequently induce economic losses. A common disease found in aquaculture farms worldwide is Tenacibaculosis, which is caused by the bacteria Tenacibaculum maritimum. This bacterium affects a wide range of species, however further knowledge about its impact on some of these species is necessary. Therefore, the current study aims to explore the impact of different methods of infection and concentrations of this bacterium on the survival of juvenile gilthead seabream (Sparus aurata), one of the most produced species in the Mediterranean.

Material and Methods
Gilthead seabream juveniles, bred in the Experimental Aquaculture Station of IPMA, Olhão, Portugal, were selected from stock populations reared under standard conditions (20 m³ fiberglass tank with a continuous flow of water at a 12:12 light-dark cycle). One-hundred and sixty-eight individuals with a mean weight of 19.5 ± 4 g were sorted and net chased for 1 min prior to the experiment. Five conditions were tested in triplicate in 40 L tanks, where eight fish per tank were injected subcutaneously with T. maritimum (CECT4276) at 1.6 x 10⁶, 1.6 x 10⁷ and 1.6 x 10⁸ or subjected to bath infection with 1.6 x 10⁴ or 1.6 x 10⁵ bacterial concentrations for 24 h. In the control groups, fish were injected or bathed with PBS, and this experiment lasted 5 days. Morphological welfare indicators and survival rate analysis were performed to evaluate the impact of the different infection methods and bacterial concentrations on the fish.

Results and conclusion
By the end of the experiment, no mortality was recorded for seabream injected with T. maritimum at a concentration of 10⁷ and a lower mortality rate of 4.2% and 8.3%, respectively, for infection with concentrations of 10⁶ and 10⁸. However, the mortality rate of the control group of injected fish was 4.2%. Seabream bathed with T. maritimum showed mortality rates of 41.7% and 83.3% in the groups infected with a concentration of 10⁴ and 10⁵, respectively. Fish in the bath groups exhibited clinical signs of infection such as hemorrhagic fins, tail rots, and skin lesions. Furthermore, no mortality was recorded in the control group. The presence of T. maritimum in the liver was confirmed by nested PCR. These results indicate that the bath challenge was more efficient than injection in recreating T. maritimum infection in juvenile seabream. However, the concentrations used in these methods were different and, consequently, could not be directly compared. Further studies to characterize T. maritimum infection in gilthead seabream are essential and are currently underway.
THERMAL PREFERENCE AS A WINDOW TO UNVEIL INFECTION SUSCEPTIBILITY IN SEABREAM UNDER DYNAMIC ENVIRONMENTAL CONDITIONS

Introduction
Strategies for stress management, including diseases, are pivotal for ensuring the well-being and longevity of fish populations in aquaculture settings and natural ecosystems. These approaches are essential for safeguarding fish health by reducing the negative effects of stressful situations and enhancing their ability to withstand disease outbreaks. One such strategy involves providing fish with a thermal gradient where they can choose their preferred temperature, which positively influences their coping ability and survival when facing stress, as it is known that fish can exhibit behavioral fever. The current study aims to explore whether gilthead seabream uses temperature gradients to enhance its fitness and survival when facing stressful challenges, which may provide valuable insights into improving their well-being and resilience to support sustainable aquaculture practices.

Methods
Gilthead seabream juveniles bred in the Experimental Aquaculture Station of IPMA, Olhão, Portugal, were selected from the stock populations reared under standard conditions (20 m³ fiberglass tank with a continuous flow of water at a 12:12 light-dark cycle). Six conditions were tested in triplicate, where unstressed, stressed, and infected fish with *Tenacibaculum maritimum* in groups of eight fish were subjected to either a constant temperature or a thermal gradient for 120h. The frequency distribution of the animals was recorded by video cameras in a custom-built multi-chamber tank under both constant temperature (21 °C) and a continuous thermal gradient profile (ranging from 18°C to 24°C), allowing the temperature preference of each group to be recorded over an 8h time period. Hematological, morphological welfare indicators and survival analysis were performed to evaluate the impact of thermal gradients on stress coping ability and fitness.

Results and conclusion
This experiment is ongoing, however some results can be described. The unstressed fish, exposed to a thermal gradient, preferred temperature was calculated as 21.06 ± 1.95 °C, while for stressed fish was 23.65 ± 0.25 °C. Additionally, the distribution within the first hour of acclimation was measured to assess differences in the acute stress response. Unstressed fish showed preference for 21.62 ± 0.90 °C and stressed fish for 21.11 ± 0.35 °C. Overall, these findings highlight the importance of considering thermal preferences and stress responses in fish when designing aquaculture or research environments. Understanding these thermal preferences could contribute to the development of more effective and fish-friendly aquaculture practices and management strategies.
A PROTOTYPE WITH SEDATIVE PROPERTIES BASED ON NATURAL COMPOUNDS TO UPGRADE WELFARE IN LIVE-FISH TRANSPORT: AMELIORATION OF STRESS RESPONSES IN SEABASS (*Dicentrarchus labrax*)

Introduction
In a context of global change and increased food demand, the growth of aquaculture production must guarantee animal welfare. Handling or transport operations activate the stress responses, which may compromise the integrity and general welfare status of fish. To improve these processes, the use of anaesthetics has been proved useful to reduce the possible adverse effects (Sneddon et al., 2016).

MS-222 or benzocaine are synthetic chemicals commonly employed as anaesthetics in aquaculture. However, their use is controversial due to human safety issues and the physiological side-effects that induce in fish (Zahl et al., 2012) there are several situations in which fish are subjected to handling and confinement. Netting, weighing, sorting, vaccination, transport and, at the end, slaughter are frequent events under farming conditions. As research subjects, fish may also undergo surgical procedures that range from tagging, sampling and small incisions to invasive procedures. In these situations, treatment with anaesthetic agents may be necessary in order to ensure the welfare of the fish. The main objective of this paper is to review our knowledge of the effects of anaesthetic agents in farmed fish and their possible implications for welfare. As wide variations in response to anaesthesia have been observed both between and within species, special attention has been paid to the importance of secondary factors such as body weight, water temperature and acute stress. In this review, we have limited ourselves to the anaesthetic agents such as benzocaine, metacaine (MS-222). Essential oils (EOs) derived from plants have been studied for this purpose, but its use might be problematic because of its compositional variability and effectiveness (De Freitas Souza et al., 2019) stressful events initiate a hormone cascade along the hypothalamus-pituitary-interrenal and hypothalamus-sympathetic-chromaffin (HSC. Therefore, the use of synthetic nature-identical compounds (such as eugenol, menthol or thymol), the bioactive molecules naturally present in those EOs, is a promising approach to develop new sedative strategies to improve operational processes in aquaculture.

For this purpose, this study assesses the effectiveness of a prototype with sedative properties (TecV2, developed by TecnoVit-FARMFaes Ltd.) in seabass (*Dicentrarchus labrax*) for a live transport of 3 and 6 hours.

Materials and methods
Seabass juveniles (*D. labrax*) (n = 72, weight = 48.9 ± 18.4 g) were placed into 15 L-tanks and distributed in four different experimental groups in triplicate: i) 3 h transport without sedation (CTRL-3H); ii) 3 h transport with 10 ppm of TecV2 prototype; iii) 6 h transport without sedation; and iv) 6 h transport with 10 ppm of TecV2 prototype. Prototype concentration was selected according to previous tests.

Transport simulations took 3 and 6 h respectively. At the end of stressing trials, half of the animals from each tank were euthanized and sampled (n = 9). The remaining fish were transferred into clean water tanks to determine their status after 24 h of recovery. Additionally, 9 fish were euthanized and sampled before any manipulation (basal conditions). Fish were euthanized with an overdose of 2-phenoxyethanol (1 ppt). Plasma samples were taken to determine changes on plasmatic secondary stress responses (cortisol, glucose, lactate, etc.). Liver was also excised to assess changes in the intermediary metabolism of amino acids, lipids and carbohydrates.

Tanks were well aerated every 90 min until oxygen full-saturation. Oxygen levels were monitored and remained above 5 ppm during the whole simulation periods. Temperature was also monitored and remained around 19 ± 1 ºC.

(Continued on next page)
Results

Our results showed that both live transport simulations for 3 and 6 h, were effective to activate stress responses in the seabass juveniles (*D. labrax*). Furthermore, these responses were modulated by the addition of the sedative prototype TecV2 to the water.

After 3 h transport an increase on plasmatic glucose was observed, a common secondary stress response triggered by cortisol elevation (Schreck et al., 2016). However, this response was ameliorated by the use of TecV2, together induced a reduction on lactate and protein levels.

The 6 h transport induced a greater disturbance on stress parameters. At this point, non-sedated fish had overcome stress situation, so plasma hyperglycaemia was not detected. However, this response was observed on sedated fish after 6 h of transport, probably because of TecV2 sedation effect was lowering. Protein and triglycerides (TAG) levels were lower in non-sedated fish, so TecV2 was useful to maintain these energetic sources in plasma. Alternatively, amino acids levels did not return to initial values after recovery and values were even lower than those observed during stress. However, the reduction after recovery on amino acids levels was lower when TecV2 was used. Hepatic carbohydrate and lipid metabolism was also altered and an increase on TAG levels after 24 h was observed. These results are in concordance with the results of enzymatic activity determined.

In conclusion, TecV2 has the potential to be used as sedative for the live transport of seabass juveniles, especially for a 3 h transport, since it reduces energy mobilization.

Introduction
The inclusion of natural additives in aquafeeds is one of the most promising research areas to improve production and animal welfare in aquaculture. The essential oils of plants (EOs) as feed additives have multiple beneficial effects, such as growth promotion, appetite stimulation, immunomodulatory and antioxidant effects, etc., due to the bioactive molecules that present (Sutili et al., 2018). Furthermore, the use of these supplemented diets might affect both the gut structure and its functionality, improving diet digestibility (Firmino et al., 2021). For this reason, the study of intestine enzymes activities, such as proteases, is recommended to assess the digestive and absorptive capacity of fish. Besides playing a key role in the digestive and absorptive processes, the intestinal mucosa, and the mucus produced by goblet cells, also acts as an immunological barrier against pathogenic microorganisms. Therefore, the histological study of the intestinal mucosa is also relevant to understand the influence of dietary treatments on fish welfare and growth (Alarcón et al., 1998; Galafat et al., 2020).

This study assesses the effect of the inclusion process in the diet (before the extrusion or during the coating of pellets) of a phytophagyic additive (PA), composed of garlic essential oil, thymol and carvacrol, on the digestive enzymatic activities and intestinal mucosa integrity of seabream (Sparus aurata).

Materials and methods
Seabream juveniles (Sparus aurata) (n=180; 57 ± 5 g) were randomly placed in 9 tanks of 300 L. Fish were fed for 78 days ad libitum using three different diets: i) Control diet (CTRL); ii) diet supplemented with PA during coating process of pellets (PA-Liq); and iii) diet supplemented with PA before extrusion process of the diet (PA-Sol). Growth performance was determined and intestine samples were collected to assess enzyme activity and histological parameters.

Total alkaline protease, L-Aminopeptidase, alkaline phosphatase, trypsin and chymotrypsin activity were determined spectrophotometrically. Intestine absorption rate was evaluated by a mucosal/submucosal surface ratio and the number of goblet cells was determined in order to verify whether the additive affected the gut health.

Results
Our results showed that the addition of PA to the diets did not have any negative effect on the growth parameters studied. Animals reached a final weight of 110 ± 10 g, with an average SGR of 3.3%. No differences were found on growth performance between both inclusion processes.

The inclusion of PA before the extrusion process increased the activity of L-aminopeptidase and alkaline phosphatase. These enzymes are located on the intestinal brush border and are often used as markers of intestinal integrity (Silva et al., 2010), consequently an increase of both activities might have contributed to improve the efficiency of digestive processes. However, a lower absorption ratio in the anterior portion of intestine was observed on fish fed with this treatment when compared to those fed with PA-Liq and the CTRL diets. The lower absorption ratio might indicate that the increased enzyme activity is due to compensatory mechanism. No differences were found among treatments on the posterior intestine segment. Additionally, the addition of PA-Sol reduced the goblet cells number, which corroborates that the extrusion process affects the properties of the additive and modulates gut health.

In conclusion, the inclusion of PA should be done during the coating of pellets to guarantee the beneficial effects of the natural additive.

Introduction

The illness with the biggest economic impact on Chile’s salmon farming sector is Salmonid Rickettsial Septicemia (SRS) caused by the bacterium *Piscirickettsia salmonis*, which results in significant mortality rates during the last phase of their productive cycle at sea (Rozas & Enriquez, 2014). Antimicrobials, most frequently florfenicol, remain the major treatment and control option for this infection because currently and commercially available vaccinations have not shown the expected efficacy levels (SERNAPESCA, 2016). Botanicals are frequently employed in zootechnical feed additives for terrestrial animals, and they are gaining popularity as an alternative to using antibiotics for their antimicrobial and immunostimulants properties (Beltran & Esteban, 2022; Kuralkar & Kuralkar, 2021; Rossi et al., 2020). To the best of our knowledge, there are not many research on aquaculture, and nothing is known about how they affect SRS control. The aim of this study was to evaluate the feasibility in using the active principles of Prototype α, a thymol-based blend of botanicals, as a mean to support the control of the seasonal outbreaks of SRS.

Materials and methods

In order to reach the aim of the study, Minimum Inhibitory Concentration (MIC) assays were performed. The antimicrobial activity of the compound was evaluated using the microdilution method in CASO broth (Vera et al., 2012), in which the active principles of the blend were dissolved ranging from 10 to 5000 ppm. Wells with no addition of products and with ethanol equivalent to the highest concentration were used as control and vehicle respectively while wells without bacterial inoculum served as negative controls. The trial was performed in quintuplicate. The Chilean *P. salmonis* isolate PS005 belonging to the EM genogroup was inoculated at a final concentration of 10⁷ CFU/mL, and the plates were incubated for 96 h at 18 °C. After incubation, bacterial growth was evaluated by absorbance measurement at 620 nm and the MIC was defined as the lowest concentration of the tested compounds that totally inhibited the growth of the bacterium. The data were analyzed with two-way ANOVA followed by the Dunnet’s post hoc test, and differences were considered significant at p ≤ 0.0001.
Results

The in-vitro effect of Prototype α’s active principles on P. salmonis were evaluated in a MIC assay providing bacterial growth inhibition to a statistically significant degree starting as early as 10 ppm until proving a complete inhibition of the pathogen from 200ppm upward. Results are provided below in Figure 1.

Conclusions

Aquaculture is one of the fastest expanding sectors, contributing worldwide to food provision (FAO, 2022). Due to the limitations and concerns on anti-microbial resistance coming from consumers and institutions alike (FAO, 2023), it is one of the challenges of feed additive to support the aquaculture production by regulating harmful bacteria, promote growth and stimulate the immune system. These in-vitro results, coupled with many studies proving the health boost and growth enhancement of botanicals additive, show a promising new opportunity for these compounds and their use in support to SRS control.

References

Introduction
According to the EU Blue Economy report (2023), The EU is the sixth largest producer of fishery and aquaculture products (behind China, Indonesia, India, Vietnam, Peru and the Russian Federation), covering around 2% of global production. However, overall production has been rather stable in the last few decades. The EU has slightly more than 56 100 active vessels landing about 3.9 million tons of seafood worth €5.8 billion; at the same time, the aquaculture sector reached a production of about 1.2 million tons worth €3.9 billion in 2020. Moreover, according to FAO, world production of aquatic animals was estimated at 178 million tons in 2020, a slight decrease from the all-time record of 179 million tons in 2018 and global consumption of aquatic foods increased at an average annual rate of 3.0 percent from 1961 to 2019, a rate almost twice that of annual world population growth (1.6 percent) for the same period. This aquaculture growth and intensive production causes a significant set of problems (i.e., creation of an anoxic zone, reduction in water quality, destruction of habitat, amongst others). In order to satisfy the demand, it is required to develop innovative, responsible and profitable cultivation methods to optimize the efficiency and mitigate negative environmental impacts. In this context, the Integrated Multi-Trophic Aquaculture (IMTA) farming is a promising concept to tackle some of these challenges, hence the EC has funded some projects on this subject to evaluate different aspects of the IMTA and its potential. Notably, the ASTRAL project focuses in IMTA farming as a possible alternative to develop a sustainable, profitable and resilient aquaculture, in this paper it will be presented a socio-economic assessment which highlights challenges and barriers of aquaculture and the IMTA possible solution approach.

Methodology
The methodology used was based on analysis involving ten countries: Norway, Spain, France, Portugal, Ireland, Scotland, Brazil, Argentina, South Africa and Nigeria. The two main sources of data were:
- the territory and regional knowledge (macro and meso economic approach) thanks to a strong bibliographic review per country,
- producers’ knowledge (meso and micro economic approach) thanks to a survey and preliminary results of producers’ one-to-one interviews; a total of 39 interviews were conducted, as follow:

(Continued on next page)
Collecting data faced two main obstacles:
• Most of the interviewees were not keen on providing economic data (confidentiality, lack of trust, no data available, etc.)
• IMTA development is quite recent in some countries. Most of IMTA projects are at experimental stage and don’t have economic data to share.

Factors analysis impacting aquaculture

Species' growth rate
• Growth rate is higher with IMTA systems because of the feeding process and the algal effects (mussel/scallop/seaweed or abalone/seaweed), depending on the value chain,
• But this is only true for certain species and combination of species (depending on the trophic links)
• However, Complexity of regulations, often fragmented and per species

IMTA products as selling argument
• IMTA allows product diversification and could enable price premium (+10%),
• But public awareness is very low, products are subject to price volatility and new markets/channels need to be created to be able to sell at price premium - "IMTA affects the production side, rather than sales" (verbatim from an IMTA producer)
• Diversification of products and, therefore, markets
• A « sustainable » systems (need to reduce consumption of resources such as space, food, etc.)
• The potential development of collaboration between players (between farmers and between farmers and academia)
• However, the social acceptance and public perception have been fully validated

Return on investment
• IMTA NPV is always higher than that for monocultures and ROI is estimated to be 4 years for a small/family farm,
• But ROI can be much higher for a larger farm, which will have more investment costs to start an IMTA farm - "Our ROI occurred after more than 10 years of production" (verbatim from an IMTA producer - 8 employees)
• An accelerated innovation potential
• However, complexity to implement and deploy (business, techniques, production methods, adaptation)
• Not enough government support and public funds
• Competition from other aquaculture segments (monoculture)

Production & HR costs
• IMTA systems tend to reduce the production and HR costs,
• But these effects can only be seen on small farms with specific characteristics
• Positive: Nutrient recycling
• Reduced demand for feed from pelagic marine fisheries and terrestrial crops
• Lack of know-how to find the right economic model(s)
• Greater structure costs with a potential lower profitability in the short term

Environmental services
• IMTA allows to reduce the environmental impacts of such production,
• But no actual data are available to see the long-term effects of this production, leading to a lack of understanding of environmental impacts
• The ecosystem services could improve revenue opportunities; they remain to be better identified and quantified

(Continued on next page)
**Recommendations**

The following section aims to draw up the main recommendations that arise from our analysis and the interviews conducted.

These recommendations have been drawn for producers, the aquaculture industry organizations and/or the policy makers. For each entry, a sticker helps understand to whom the recommendation is addressed to:

1. **Develop pilots and demos**
   - Economic demonstration is still premature and experimentation firms ongoing. More work is needed for IMTA systems to become a commercial reality, despite the large amount of research and field pilot work carried out to date. There is an urgent need to develop and optimize IMTA systems and to test new production methods. This implies that producers have time to dedicate to these projects, have been technically supported and benefits from public funding.

2. **Encourage an active policy to make a change**
   - IMTA implementation and growth will only be possible with the support of policy makers. There is a need to design an IMTA development plan that will help the industry to answer to current needs, to fund synergies between producers and to operate a two-way communication with policy makers, in order to help producers shifting to IMTA. This work should be done in close link with researchers, producers and professional organizations.

3. **Increase and organise the sharing of knowledge on IMTA**
   - Aquaculture and monoculture producers are generally open to this new approach but have not embarked on it due to the lack of knowledge and demonstration of the system’s effectiveness and viability. It is necessary to find the right way of dissemination and knowledge sharing on technical, economic and environmental aspects including experience exchange. Increasing links between researchers and aquaculture professional organizations is important to share with all producers. Innovation is a key factor of success and a great asset for IMTA systems.

4. **Improve and increase availability of trainings**
   - It is difficult for a manager with more than 50 employees to move from a standardised monoculture model to a multidisciplinary model. It is important that the workforce gets continuous training for the work to be done within the farms, especially regarding the complexity of the system. For the young generation and students, it is crucial to disseminate the approach and use IMTA.

5. **Estimate and monetise ecosystem services**
   - It is crucial that the values of ecosystem services are recognised, accounted for and used as financial and regulatory incentive tools, such as in the development of nutrient trading credits. However, no real system for recognising and rewarding ecosystem services is yet in widespread use and adoption. To create awareness of ecosystem services should be a priority at all levels of the aquaculture development.

6. **Adapt regulations and administrative processes**
   - A key aspect for IMTA growth will be to facilitate the implementation of experiments or diversifications on the concomitance of professions. A full map must be given to IMTA and its practices must not be blocked by the superposition of various regulations. Regulations must be made more readable, simpler and understandable by everyone.

7. **Make IMTA more visible**
   - Complementary to recommendation 9, it is important that IMTA is recognised among policy makers, general administrations and the general public. A strong communication and promotional strategy has to be launched in order to show the benefits of IMTA for the sector, for producers and for consumers. Producers will get information and knowledge on the advantages coming from IMTA and consumers will get more insights on product quality and environmental aspects.

8. **Better address the commercialization strategy of IMTA products**
   - The marketing of IMTA products by definition diversified. Argue of product corresponds to specific market and marketing channel. For IMTA to be an economic advantage for producers, one can imagine the creation of an association to highlight the environmental advantages of this type of production. Marketing through a local distribution channel is also to be preferred because it echoes the ecological philosophy of the IMTA. Producers need dedicated support on this aspect to reach new markets and sustainable growths.
THE IMPACT OF GENETIC SELECTION FOR FAST GROWTH ON THE EFFICIENCY OF GILTHEAD SEA BREAM (*Sparus aurata*) IN USING NOVEL DIETS

Introduction
High inclusions of fish meals (FM) and oils (FO) in aquaculture feeds are not considered indispensable ingredients anymore. To meet future the demand for aquaculture products and to reduce completely the dependence on FM and FO, it is necessary to find new profitable and more sustainable sources of protein and lipids. Insect meals and single-cell proteins from bacterial or microalgal sources have been recently investigated and pointed out as promising future feedstuffs for the aquaculture industry due to their high nutritional potential for fish, as well as their low ecological impact. Added to novel nutritional strategies, the implementation of genetic selection programs can also be a complementary tool to improve the robustness of farmed fish and their plasticity to deal with nutritional innovations and challenging feeds with low FM/FO. Some studies reported that fish that are selected for fast growing on FM/FO diets display also higher growth on plant-based diets (Palti et al., 2006), while some others, reported a significant diet x genotype interaction, which means that fish that are selected for their fast growth on FM diets may not be the ones that grow faster when facing a challenging diet (Geay et al., 2011). Therefore, the aim of the present study, as part of the AquaIMPACT project (Genomic and nutritional innovations for genetically superior farmed fish to improve efficiency in European aquaculture; EU Horizon 2020, 818367), is to determine the effectiveness of genetic selection for growth in gilthead sea bream, in response to a challenging low FM/FO diet that aimed to partially replace FM by two emergent ingredients: insect meal from black soldier fly or single-cell protein from *M. capsulatus*. These diets also aimed to totally replace FO by a blend of poultry oil with a novel microalgal oil. The response of selected sea bream to the novel dietary interventions was assessed on fish productive parameters, fish proximate and fatty acid composition, the apparent digestibility coefficients of the dietary nutrients, as well as on fillet quality properties at commercial size.

Materials and Methods
Three diets were formulated to be isoproteic and isoenergetic to meet the nutritional requirements of gilthead sea bream juveniles. Control diet (C) contained 15% of FM and 5.9% of fish oil to mimic the composition of a current commercial diet, as well as completed with some vegetable meals and rapeseed oil as protein and lipid sources, respectively. Insect meal diet (INS) was included at 5% of the diet to replace 33.3% of the dietary FM. Single-cell protein was included at 10% of the diet and replaced 66.7% of the dietary FM. Fish oil was also totally replaced in these diets by a blend of poultry oil and Veramaris algal oil. Yttrium premix was added at 0.1% to both diets to further determine the apparent digestibility coefficients (ADC) of nutrients. The nutritional trial was carried out at the experimental facilities of the ULPGC. Gilthead sea bream from each experimental group (HG genotype vs REF genotype) and with an initial body weight of 49.91 g (average body weight), were randomly distributed in 12 experimental tanks, at a density of 45 fish/tank (3 tanks/treatment). Fish were initially allocated in cylinder-conical tanks of 500 L. Fish were manually fed until apparent satiation with one of the two experimental diets for 12 weeks (4 times a day, 6 days a week). Fish growth performance was monitored every 4 weeks until the end of the feeding trial and fish whole-body, fillets and liver samples were collected at the end of the trial for biochemical composition. Furthermore, fish faeces were collected after a digestibility trial to calculate the apparent digestibility coefficients analysis of the dietary protein and amino acids. Texture properties at 1 and 4 days post-slaughter, as well as the sensorial attributes of fish fillets, scored by a human panel, was also assessed.

(Continued on next page)
Results
Diet showed an effect on fish growth performance sooner (after 4 weeks of feeding) than genotype. INS and SCP diets led to a poorer growth performance in terms of body weight, length and/or SGR and TGC than C diet from 4 weeks of feeding and this difference was maintained until the end of the feeding trial (12 weeks). INS and SCP diets also significantly decreased fish FI compared with C diet, irrespective of the genotype, but showed no effect on FCR. In contrast, selected genotype increased fish growth in terms of body weight, total length and productive parameters like SGR and TGC, as well as optimized FCR, irrespective of the diet. No significant interactions between g x d were observed in any productive parameter evaluated after the 12-week feeding trial. HG genotype significantly increased the ADC values of protein and individual and total amino acids, except for tyrosine, whereas diet showed no effect on ADC values.

Genotype did not affect fatty acid profile of fish tissues, but SCP and INS diets increased the n-3 LC-PUFA content of fish fillets.

As expected, time post-slaughter significantly affected many texture properties of fish fillets, irrespective of the diet or genotype, with the values for fracturability, hardness elasticity, gumminess, and resilience of fish fillets decreasing with time. However, no significant effect of genotype or diet were noted in the texture properties of fish fillets, neither at 1 nor 4 days post-slaughter. Concerning the sensory properties of sea bream fillets, scored by the evaluation panel, no significant effects of diet, genotype or an interaction between g x d were observed for any of the sensorial attributes of fish fillets.

Conclusions
Overall, the results reaffirm the positive effects of genetic selection in improving sea bream productive key indicators, as well as support the use of insect meal and microalgal oil as replacers of FM and FO, respectively, in diets for selected sea bream, especially microalgae oil to increase n-3 LC-PUFA of fish fillets and improving the nutritional value of fish final products for consumers. However, the use of feed attractants might be useful to achieve similar growth as when a Control diet with FM is used, since the inclusion of insect meal and single-cell protein at 5% and 10% of the diet, respectively, might compromise feed intake.

Introduction

The immunomodulatory role of certain amino acids is widely acknowledged. Apart from serving as building blocks in the synthesis of immune-related proteins, they also regulate crucial metabolic pathways associated with the immune response (Wu, 2013). Methionine is among the amino acids with recognized positive effects on immunity. Similar to the observed in other animals, dietary methionine supplementation has been shown to enhance the immune response and disease resistance in fish when faced with an inflammatory insult (Machado et al., 2015; Machado et al., 2018; Machado et al., 2021). However, its role in mucosal immune machinery and response to pathogens requires further investigation. Therefore, this study aimed to investigate the effects of dietary methionine supplementation on mucosal immunity and disease resistance against *Tenacibaculum maritimum* in European seabass (*Dicentrarchus labrax*).

Materials and methods

For 4 weeks, triplicated tanks of juvenile European seabass were given one of three experimental diets containing increasing levels of methionine supplementation: 0, 1 or 2% DL-methionine (referred to as CTRL, MET1 and MET2, respectively), resulting in methionine concentrations of 8.6, 18.5 and 29.2 mg/g dry matter, respectively. At the end of the feeding trial, blood, skin mucus, gut and head kidney were sampled and fish were bath-challenged with *T. maritimum*. The same tissues were collected at 48 hours post-infection, coinciding with the peak of mortality. The haematological profile was evaluated and blood smears were prepared for leucocyte counting and classification. Skin mucus samples were used to assess innate immune parameters, oxidative stress analysis was conducted on the gut and gene expression analysis was performed on the head kidney. The obtained results were subjected to canonical discriminant analysis (DA).

Results

A clear inflammatory response was observed in all experimental treatments, as evidenced by the separation between pre- and post-bacterial challenge points. While before infection fish fed different dietary treatments clustered together, inflamed fish fed experimental diets were significantly separated from one another. At 48h post-infection, the MET1 was the furthest group, whereas the CTRL and MET2 groups were relatively close to each other. The discrimination of the MET1 group was driven by the positive load of monocytes counts, IgM and total peroxidase in the skin mucus, as well as interleukin 8 (*il8*) and interleukin-1 beta (*il1β*) expression in the head-kidney. On the other hand, the variables that contributed the most to the separation of the MET2 and CTRL groups were haemoglobin and mean corpuscular haemoglobin concentration (MCHC).

Conclusion

While no significant differences were observed among dietary groups after the 4-week feeding trial, dietary methionine supplementation significantly influenced the immune response of the European seabass against *T. maritimum* infection. The great separation of MET1 from the other dietary groups suggests that there may exist an optimal or threshold level of methionine intake, beyond which the immune response may experience diminishing returns. These outcomes are consistent with previous literature findings (Shorter et al., 2015) and highlight the importance of carefully considering the dosage of methionine supplementation.

(Continued on next page)
Nevertheless, in relation to the aim of investigating the effects of dietary methionine supplementation on mucosal immunity, the MET1 treatment seemed to positively impact the skin mucus immune-related mechanisms studied. Therefore, further research is currently underway to comprehensively understand its potential role in boosting mucosal immune function.

SCREENING ANALYSIS OF THE PROBIOTIC BACTERIA Phaeobacter inhibens ON LARVAE OF MANILA CLAM (Ruditapes philippinarum), FROM GAMETE EMISSION TO METAMORPHOSIS

E. Casoni1*, L. Aguiari2, M. Mistri1, V. Gentili1, R. Rizzo1, C. Munari1

Introduction

Manila clam (Ruditapes philippinarum) is one of the most economically important farmed aquatic species in Italy (EUROSTAT, 2023). Since its introduction in 1983, this species became one of the most exploited resources of the lagoons of the Northern Adriatic Sea, forming large natural benches that satisfied the request of juveniles by local farmers (Brusà et al., 2013).

In the last few years, the natural recruitment of Manila clam juveniles decreases (Ponti et al., 2017), so the hatchery-reared seed emerged as a source of juveniles to support the clam industry.

Infectious diseases represent one of the bottlenecks for the mass production of seed in hatchery, due to mortality peaks caused by Vibrio bacteria (Dubert, 2017).

Currently, the prevention of diseases outbreaks is preferred to treatments with antibiotics, in order to avoid the emergence of antibiotic resistant bacterial strains, so the administration of probiotic microorganism represents a beneficial practice to fight vibriosis in shellfish hatchery (Prado et al., 2010).

The aim of this preliminary study is to verify the beneficial effects also on R. philippinarum larvae, starting from a test on survival of larvae treated with Phaeobacter inhibens DSM17395. Phaeobacter inhibens has been reported to produce antibacterial compounds and it has been verified to exerts a probiotic activity in other mollusk and fish larvae (Sohn et al., 2016; D’Alvise et al., 2012).

Materials and methods

The marine bacteria P. inhibens DSM17395, identified as potential probiotics (Ruiz-Ponte et al., 1998) was grown in marine broth, at 25°C, with gentle rocking.

Once fecundation was carried out, larvae were maintained in flasks containing 200 ml SSW (Sterile Sea Water) at 24±1°C, 28 psu and daily fed with microalgae of the species Isochrysis galbana (var. T-ISO) and Chaetoceros calcitrans, dosed with a total concentration of 100,000 cells/ml.

Selected concentrations of the probiotic were 10⁶, 10⁵ and 10⁴ CFU, referring to the most cited in similar work (Karim et al., 2013; Prado et al., 2009). Bacterial density was determined by measuring OD 600 through spectrophotometer. For each concentration, experiment was run in triplets, and in addition, a group of larvae were treated without the addition of probiotic, as control group.

SSW was periodically changed, together with the count of survived individuals, carried out through Sedgwick rafter cell counter. Then, survival rate has been calculated through the following formula (Prado et al., 2009):

\[ \text{Survival rate (\%)} = 100 \times \frac{\text{No. of live larvae}}{\text{Total no. of larvae}} \]

In the treated groups, the probiotic was dosed at the beginning of the test and in correspondence of water changes.

(Continued on next page)
Results

Preliminary results of the study are summarized in Fig. 1. Survival of larvae has been monitored from T0 (the day right after the emission) to T4 (ten days after the emission), when the metamorphosis event begins.

Among the three different treatments tested, the one involving the lower concentration of the probiotic, $10^4$ CFU, is the one showing result similar to the control. In addition, at T3 and T4, $10^4$ treatment results show a better survival rate.

Despite the decline in number of larvae through the time, this study shows that the survival rate of the treated groups is similar or improved when compared to the control ones (that should reflect the standard condition at which this species is farmed in the hatcheries).

Further results will be available for the oral presentation and will be focused on the effectiveness of the above-mentioned treatment.

![Fig. 1: Survival rate of larvae for each treatment. From T0, one day after the emission, to T4, ten days after the emission.](image)

Introduction
The fishery of the limpets *Patella aspera* and *Patella candei* (Patellogastropoda: Patellidae) in Madeira surpasses 100 annual tons and concerns about overexploitation of the stocks led to different legislative protective measures (Sousa et al. 2019). Recently, the research on the limpets' aquaculture achieved key methodological advances at hatchery level (Castejón et al. 2022a), being highlighted the potential role of the crustose coralline algae (acronym: CCA) to induce the limpet settlement (Castejón et al. 2022b). This study took a step further to explore the seawater conditioned with CCA as settlement inducer for *P. aspera* and *P. candei*.

Material and Methods
The adult limpets were captured during the breeding period (February to March 2022) and kept in captivity using an open system (20 ± 1 °C and 36 ± 1 psu). The production and culture of larvae used gametes obtained by dissection following the procedures described by Castejón et al. (2022a). The oocytes were matured artificially using a solution of NH₄OH at pH 9 during 20–30 min. Fertilization used 10⁵ sperm cells ml⁻¹. Incubation and larval culture were done in glass beakers and plastic jars at 16 ± 1 °C. Incubation used 50 oocytes ml⁻¹ and lasted 24h. Larval culture used 5 individuals ml⁻¹ and lasted 48h.

The CCA were obtained from adult limpet shells of which the soft body was removed and the aperture was cleaned thoroughly following Castejón et al. (2022b). Then, the shells were broken into pieces that were kept in small containers with filtered seawater treated with UV (acronym: FSS) during four days to obtain the conditioned seawater (acronym: CSW).

Two assays were done for each limpet species (*P. aspera* and *P. candei*): 1) different CSW concentrations (ca. 17, 5, 2 and 0.7 mm² CCA · ml⁻¹) and 2) influence of frozen CSW (-24 °C) obtained from three different CCA communities (*Pneophyllum* sp., *Neogoniolithon* sp. 1 and *Neogoniolithon* sp. 2). In *P. candei*, the influence of different treatments applied to the CSW was tested: raw and autoclaved kept at room temperature (0, 24 and 48h), raw kept in the fridge 2–4 °C (24 and 48h), raw frozen at -24 °C (48h) and filtered (0 h). All the assays used FSS as negative control and CCA as positive control. Settlers were identified by the loss of the velum (metamorphics) and the teleoconch development (post-larvae). The ratio of metamorphics and the ratio of settlers (metamorphics + post-larvae) were calculated.

Results and Discussion
The ratios of metamorphics and settlers decreased with lower concentration of CSW in both *P. aspera* and *P. candei*, but the values were markedly lower in the former (Fig. 1A–B). Regarding the frozen CSW, only *Neogoniolithon* sp. 2 induced the settlement in *P. aspera*, while all the frozen CSW treatments induced the settlement in *P. candei*. In *P. candei*, all the treatments applied to the CSW (raw kept at room or fridge temperature, autoclave and frozen) induced the settlement independently of the timing after obtaining the CSW (0 to 48h); being the single treatment without effect the filtered CSW (glass microfiber 2.7 μm) (Fig. 1C).

CSW promoted *P. candei* post larvae settlement in at a ratio positively related to its concentration with the potential to be preserved frozen. In *P. aspera* an efficient settlement response required the physical presence of CCA. Altogether, these results showed inter-specific differences in the sensitivity to the soluble cues released by the CCA, highlighting that limpet settlement requires to be studied at species level.

(Continued on next page)
261

**Figure 1.** Influence of the CSW concentration (five replicates per treatment) in the settlement of two limpet species (A–B): *Patella aspera* (A) and *Patella candei* (B). C. Influence of the combination of different CSW treatments and time (six replicates per combination) in the settlement of *Patella candei*. Different letters indicated significant differences (a–e: Tukey’s HSD, w–z: Games-Howell; p < 0.05).

**Introduction**

The limpet *Patella ordinaria* Mabille, 1888 is a marine gastropod of high commercial interest. The settlement of competent larvae is one of the factors limiting the development of the limpet aquaculture, although success has been recently achieved using encrusting coralline algae as substrate (Castejón et al. 2022b). This research focused on testing alternative methods for settlement using neuroactive compounds tested as settlement inducers in other mollusk species such as γ-aminobutyric acid (GABA), 3-isobutyl-1-methylxanthine (IBMX), acetylcholine (ACH) and potassium chloride (KCl) (Alfaro et al. 2014) (Table 1).

**Material and methods**

Broodstocks were collected between November 2021 and April 2022. Competent larvae were obtained following Castejón et al. (2022a). Fertilization was performed at a concentration of 100 oocytes ⋅ ml⁻¹ and 10⁵ sperm cells ⋅ ml⁻¹. Larval culture was performed in 500 ml beakers under static conditions and at a concentration of 4 ± 1 larvae ⋅ ml⁻¹. Three assays were performed using no-substrate as negative control, coralline algae (CCA) as positive control, diatom biofilms of *Navicula salinicola* and different concentrations of different settlement inducers (Table 1). The larval stages identified were: metamorphosed specimens presenting velum loss and post-larvae with teleoconch growth. Experiments lasted between 12 and 13 days.

**Results and discussion**

Crustose coralline algae showed the greatest settlement response in all the assays, validating its great potential as settlement substrate and positive control for settlement studies in limpets (Castejón et al. 2022b, b). The diatom *N. salinicola* showed a variable settlement response among different assays dismissing its utility as a positive control or utility as a reliable settlement substrate. Regarding the neuroactive compounds, GABA, IBMX and KCl did not successfully induced settlement at the concentrations tested. In contrast, acetylcholine (ACH) at concentrations ranging from 5 ⋅ 10⁻⁴ to 4 ⋅ 10⁻³ M showed an increasing settlement response with increasing concentrations (Fig. 1). Acetylcholine was also reported to influence the settlement of the marine gastropod *Haliotis iris* suggesting its potential to modulate the settlement behavior and velum loss in mollusks (Alfaro et al., 2014). However, additional studies are required to elucidate why the settlement response induced by the neuroactive compounds did not result in an

Introduction
Microplastics (size < 5 mm; MPs) have been found in almost every environment including oceans and represents a widely diffused pollutant for aquatic organisms. Several studies have demonstrated the presence of MPs in marine animals, from plankton to higher trophic levels. Furthermore, sea-farmed aquatic species have been shown similar rates of MPs accumulation as those evidenced by wild specimens. More recently, the problem of MPs contamination in farmed fish has been found to also affect the land aquaculture sector. In this context, the main MPs source is represented by aquafeeds since conventional marine-derived ingredients used for their formulation derived from caught fish. Particularly, it has been shown that the concentration of MPs in fish meal is higher than that found in the raw materials since the processing procedures of the ingredients and packaging methods significantly contribute to increase the final amount of MPs in the aquafeed (polyethylene is one of the most widely used materials to produce “storage bags” for fishmeal). Dietary MPs contamination can have negative effects on farmed fish during different life-cycle stages. The larval development is one of the most critical phases because of the fast morphological and behavioural changes that increase the risk of mortality. During this phase: (i) possible obstruction of the gastrointestinal tract; (ii) a reduced predatory activity caused by an apparent feeling of satiety; (iii) a decrease in growth and swimming capacity; (iv) the activation of inflammatory responses in gut and other organs because of potential translocation processes can occur. However, despite the large number of publications on the presence of MPs in fish, not much is known about the long-term MPs exposure and the effects on the different life cycle stages and developmental phases of fish. In this regard, the present study aims to compare the effects of dietary MPs exposure in zebrafish (Danio rerio) larval and juvenile stages, monitoring MPs translocation among organ and tissues and the effects on fish growth and welfare through a multidisciplinary laboratory approach.

Materials and Methods
Five experimental diets were used in this present study. A control diet was prepared according to a commercially available standard diet for zebrafish (Zebrafeed, Sparos ltd, Portugal). The four experimental diets containing MPs were prepared by adding during the preparation of Control diet the fluorescent polymers A and B at two different concentrations, as follows: (i) 50 mg/kg feed of polymer A (diet A50); (ii) 500 mg/kg feed of polymer A (diet A500); (iii) 50 mg/kg feed of polymer B (diet B50); (iv) 500 mg/kg feed of polymer A (diet B500). The microbeads were purchased from Cospheric LLC (Goleta, CA, USA) and their features were: (i) polymer A: amino formaldehyde polymer, 1-5 µm of dimensional range, peak of emission at 636 nm when excited at 584 nm; (ii) polymer B: polyethylene, 40-47 µm of dimensional range, peak of emission at 607 nm when excited at 584 nm; (iii) polymer B: polyethylene, 40-47 µm of dimensional range, peak of emission at 607 nm when excited at 575 nm. After hatching, zebrafish larvae were initially reared in fifteen 20 L tanks (3 tanks per experimental group; 500 larvae per tank). After 20 days post fertilization (dpf), fish of each tank were transferred in 100 L tanks (3 tanks per experimental group). Zebrafish were fed the experimental diets two times a day (daily dose corresponding to the 3% of the body weight) from 5 to 60 dpf. The required amount of fish were sampled at both 20 dpf (in which whole larvae were collected for each analyses) and at 60 dpf (in which samples of liver, intestine, and muscle were collected from juveniles). For both larvae and juveniles, the following parameters were evaluated: (i) survival and specific growth rate (SGR%); (ii) the absorption of the fluorescent MPs microbeads at intestinal level and their potential translocation to liver and muscle through a Nikon A1R confocal microscope (Nikon Corporation, Tokyo, Japan); (iii) the MPs microbeads quantification in whole larvae or in the target organs of juveniles through chemical digestion followed by a vacuum filtration on 0.7 µm pore-size fiber-glass filters and consequent analyses of the filters through a fluorescence microscope (Zeiss Axio Imager.A2; Zeiss, Oberkochen, Germany); (iv) possible structural alteration of the intestinal epithelium and the hepatic parenchyma through the application of a series of histopathological indexes and stains; (v) the relative expression of genes involved in immune (il1b, il10, and litaf) and oxidative stress response (sod1, sod2, and cat) starting from total RNA extraction from whole larvae or liver and intestine samples for juveniles.

(Continued on next page)
Results and Discussion
No significant differences in survival and specific growth rates were detected among the experimental groups for both zebrafish larvae and juveniles. The ingestion of the two polymers used in this study was confirmed both by confocal microscopy and MPs quantification in the zebrafish larvae and juveniles. However, only the polymer A (size 1-5 µm) was absorbed at intestinal level in both larvae and juveniles. The presence of polymer A microbeads was detected in liver and muscle samples only in juveniles suggesting a time-related translocation from the gastrointestinal tract. Furthermore, the MPs quantification in both whole larvae and in intestine and liver samples of juveniles highlighted a dose dependent accumulation of polymer A. Regarding polymer B (size 40-47 µm), no absorption was detected, but the transit through the intestinal tract caused a reduction of mucosal folds length and an increase in goblet cells relative abundance in B50 and B500 groups, suggesting a higher intestine lubrication.

The absorption or the simple transit of both MPs in groups A and B did not cause inflammatory events at intestinal level nor alteration in the expression of immune markers in both larvae and juveniles. However, the accumulation of polymer A microbeads in liver samples of juveniles caused the upregulation of the oxidative stress markers.

Results of the present study suggest the presence of biological barriers against the ingested MPs in zebrafish that are related to the polymer size, dietary concentration, and time of exposure, able to reduce the number of MPs reaching the muscle which is the edible part of a fish. This result is extremely interesting for the aquaculture sector and needs further studies performed on finfish species.

Introduction

Bivalves are usually cultured in land tanks connected directly to estuarine and coastal waters. This type of aquaculture exposes the cultured species to possible toxic blooms that often affect these natural ecosystems. The effects of toxic algae on humans have been the subject of many studies. However, information on the effects of these toxic species on bivalve species have been less explored.

Gymnodinium catenatum is a dinoflagellate which produces a saxitoxin like compound, being responsible for paralytic shellfish poisoning. It has been shown to cause an increase in antioxidant enzyme activities and oxidative stress in some bivalve species after exposures of 6-12 hours. However, the effect of such contaminants to short-time exposures has not been extensively studied. Shorter exposure times are important to evaluate possible effects into aquacultures, as these types of systems usually allow to close the connection with external water, thereby reducing the exposure of the cultured animals.

Besides toxic algae, other species can negatively affect the reared species. Algae like Skeletonema spp. Are known to damage the gills, leading to several health complications in marine animals (Esenkulova et al., 2022). In addition to physical damage, Skeletonema marinoi produces polyunsaturated aldehydes (PUA) when exposed to grazing (Vidoudez et al., 2011) which are toxic to many marine species (Romano et al., 2011; Tosti et al., 2003). Nevertheless, S. marinoi is commonly used to feed bivalves in aquacultures (Guéguen et al., 2008).

It has been observed that antioxidant enzymes respond to several contaminants (Cereja et al., 2018; Dias et al., 2019) including algae toxins (Cao et al., 2018) and thus can be used as a physiological stress indicator for toxic algae exposure.

The aim of this study was to assess the physiological effect of short-term exposure to G. catenatum and S. marinoi in cultured Magallana angulata.

Material and methods

Oysters were collected at an aquaculture farm in the Sado Estuary, Portugal and carried to MARE facilities where they were allowed to acclimate in 70L tanks. During the acclimatization period, all oysters were fed with ≈2*10⁹ cells L⁻¹ of a mixture of Tetraselmis sp. and Phaeodactylum sp. For the exposure treatments, both Gymnodinium catenatum and Skeletonema marinoi, were obtained from the algae culture collection of the Lisbon University (ALISU).

In the experiment, ≈2x10⁷ cells L⁻¹ of Tetraselmis sp. for the control group, ≈4x10⁷ cells L⁻¹ of S. marinoi and ≈1x10⁴ cells L⁻¹ of G. catenatum for the exposure treatments were added to three tanks, each containing 6 oysters, and allowed to filter for two hours. Afterwards, the six organisms of each treatment were opened by cutting the adductor muscle. The gills, the digestive gland and the adductor muscle were removed and stored at -80 °C.

(Continued on next page)
Subsequently, the samples were homogenized in PBS buffer saline solution, centrifuged (15 min, 10,000×g at 4°C) and the supernatants used to quantify superoxide dismutase (SOD), catalase (CAT), glutathione S-transferase (GST), acetylcholinesterase (AChE) and total ubiquitin (UBI) and the data was analysed using a PerMANOVA.

**Results:**
The results showed significant differences in both treatments: tissues and treatments. Gills were the tissue showing higher biomarkers while the adductor muscle had the lowest levels. Regarding the comparison between treatments, the control treatment presented higher levels of the analysed biomarkers. *S. marinoi* treatment presented higher CAT and GST than *G. catenatum* treatment.

**Discussion:**
The higher biomarker levels determined in the control treatment were hypothesized to be a consequence of reduced metabolic rates in the two other treatments, although such relation must be confirmed in future studies. The higher CAT and GST activities determined in the *G. catenatum* treatment in comparison to the *S. marinoi* treatment was hypothesized to result from detoxication process. These results suggest that *G. catenatum* may affect the physiology of *M. angulata* even in short-term exposures and that live *S. marinoi*, which is usually used as aquaculture feed, may also impact the *M. angulata* physiology, probably due to the production of PUA. Further studies must be performed to confirm this possibility and if such effect is also observed when using dead *S. marinoi* as PUA production may differ.

Introduction
From electronics to food containers and fashion accessories, plastics are indissociable from our daily lives. Designed to have high durability and resistance, the use of plastics in the food packaging industry has grown to unprecedented and unsustainable levels in the last decades. Despite they are usually meant to have a single use, to date, packaging plastics are not fully biodegradable and their complete elimination during waste treatment is a rather complex process (involving economical, societal, logistical, and territory planning), often resulting in their unintentional introduction in natural environments and landfills (Walker and Xanthos, 2018; Karbalaei et al., 2019). Hence, the presence of plastic polymers (e.g., polyethylene and polyethylene terephthalate, PET) derived from packages (and other materials) in the aquatic environment is a major ecological concern of our times. The ongoing inability to efficiently manage the huge amount of plastics generated and subsequent environmental introduction compromises water quality in coastal areas, as well as, the welfare and survival of organisms (e.g. fish) that accidentally ingested them.

Despite being usually associated with fishing activities, plastic pollution is a worldwide problem whose impacts also affect the aquaculture context, because: i) extensive and semi-intensive aquaculture facilities are often settled in areas subjected to high anthropogenic pressures and, thus, can present substantial levels of plastic pollution (Lusher et al., 2017); ii) recent studies have reported considerable levels of microplastics in fishmeal, due to the environmental contamination of wild small pelagic fish species that are used to prepare feed meals and oils; and iii) the aquaculture industry itself is also an important contributor to the global plastic usage and subsequent environmental pollution (Skiritun et al., 2022, Tian et al., 2022).

To respond to such issue, several research and technological innovation actions have recently attempted to create “eco-friendly” solutions, such as the development of materials/packages that are partly or entirely made from bio-based materials (e.g., sugar-based polymers, Ferreira et al., 2019, Li et al., 2023). Yet, they still present significant toxicity for aquatic environments and different biodegradability depending on the polymer, not representing a true ecological alternative (Babaremu et al., 2023, Zimmermann et al., 2020).

Within this context, NEWPACK is an innovative vertical project within the VIIAFOOD Agenda of the Recuperation and Resilience Plan in Portugal that aims to create a new generation of packaging materials - sustainable, from renewable raw materials, with functional preservation activity for packed food products and with the benefit of being an intelligent packaging, which allows providing information on product conservation. If such novel packaging material is unintentionally introduced into the marine environment and accidentally ingested by fish, it will not be dangerous but a nutritional asset upon metabolization.

Material and methods
Focusing on plastic reduction and technological innovation specifically within the vegetable oil packaging industry, the NEWPACK project encompasses 6 different and interconnected tasks, including the:
1. Revision of the state-of-the-art, with a special focus on the reported ecotoxicological impacts of conventional plastics and their additives, as well as, of recently developed and alternative bioplastics in aquatic biota;
2. Selection of suitable sugar-based candidate monomers (building blocks) to be used in the production of the new biopolymer, taking into account compound toxicological aspects, physical-chemical attributes (and related handling/synthesis easiness) and production costs;

(Continued on next page)
3. Conceptualization of a new recyclable and biodegradable biopolymer unharmful and nutritious to marine fish, that efficiently replaces the use of conventional plastics within the food packaging industry;

4. Optimisation and standardization of a multicompartment *in vitro* methodology that mimics, in a more realistic way, marine fish digestion process. The achievement of such milestone will constitute an important landmark in the field of “Live Animal Sciences” in general, and in Aquaculture Research in particular, as it will constitute a “Replacement” strategy, an alternative to *in vivo* studies that, in the future, will certainly reduce the number of animals used in nutrition studies, which are crucial to the expansion of the aquaculture sector;

5. Development and successful market implementation of cutting-edge smart labeling technology applied to the food packaging industry to assure products’ traceability throughout the whole production and value chain, preventing product quality deterioration, incorrect discard of food packages, and the subsequent plastic waste generated.

Dissemination of results among different stakeholders at national and international levels, to raise awareness regarding the impacts of plastic packages on the environment, the use of more sustainable alternatives already available to replace conventional packaging and validation of tools to improve traceability throughout the food chain, as well as, the disposal and treatment of plastic waste.

**Expected outcomes:**
NEWPACK project is aligned with the European Green Deal, aiming to provide a relevant contribution towards the end to wasteful packaging, by promoting the “reuse and recycle” policy and use of sustainably produced materials in one of the most plastic polluting industries, i.e., the food packaging industry. It is also expected to contribute to Goal 14 – Life below water - of the UN Sustainable Development Agenda, that aims at ensuring the conservation and sustainable use of the oceans and marine resources and has the specific target of preventing and significantly reducing marine pollution of all kinds from land-based activities, including marine debris, by 2025. The innovative concept and environmentally responsible nature of NEWPACK project will certainly have various tangible impacts at scientific, technological, ecological, economical and societal levels.

Introduction

Diet plays a crucial role in causing intestinal dysbiosis, leading to disruptions in the intestinal barrier and increased permeability. This condition facilitates the entry of harmful substances and microorganisms into the bloodstream, directly and indirectly contributing to the development of bacterial pathologies and physiological imbalances in the body. Consequently, the analysis and study of the intestinal microbiota have become significantly important for designing and implementing new diets or supplements in aquaculture. By studying the diet and gut microbiota at different life stages of Sparus aurata, this research has the potential to provide valuable information on how to promote a healthy digestive tract and improve aquaculture production in the future.

In this context, Nannochloropsis gaditana are microalgae rich in beneficial lipids, antioxidant compounds, and amino acids, which have shown to improve growth and product quality in Sparus aurata. The objective of this study is to investigate the changes in the microbiota during the transition from larval to juvenile S. aurata when fed a diet supplemented with microalgae in both raw and hydrolyzed forms for a period of 45 days.

Material and methods

N. gaditana was cultured in tubular photobioreactors at the pilot plant (EU-H2020 SABANA facilities) of the Universidad de Almería (Spain). Subsequently, enzymatic hydrolysis of raw algal biomass was carried out as reported in Ayala et al. (2020). An inclusion level (25 kg-1 w/w), and two microalgae formats (raw and enzymatically hydrolysed) were considered in 0.2 to 0.4 mm microdiets.

Therefore, diets were designed as R2.5 for raw microalgae, H2.5 for diet containing enzymatically hydrolysed biomass, and a microalgae-free diet was used as control (C). The feeding trial was carried out at randomly distributed in 15 tanks and fed daily at 5% of their biomass and sampled at 45 days of feeding trial.

Figure 1. Relative abundance (%) of dominant microbiota genera in larvae (L) and juvenile (J) Sparus aurata individuals fed control (C), 2.5% raw and (R), and 2.5% hydrolyzed N. gaditana (H) supplements

(Continued on next page)
A total of 80 intestinal content samples were subjected to DNA extraction using the precipitation saline protocol. Subsequently, the 16S rRNA gene of these samples was sequenced using the Illumina® MiSeq platform (Illumina, San Diego, CA, USA) with pairwise sequencing (2 × 300 bp) at the Ultrasequencing Service of the Bioinnovation Centre of the University of Malaga (Malaga, Spain). However, due to quality issues, only 35 larvae (L) and 19 juveniles (J) of Sparus aurata could be used for the microbiota analysis.

The bioinformatic data processing involved a workflow based on the DADA2 library of R, utilizing the SILVA 138 database with 99% clustering. The Shannon index was calculated to assess microbial diversity. Additionally, informative bar charts were generated to visualize the taxonomic distributions. The significance of the results was determined based on the Shannon index, using a t-student’s p-value of <0.05. Taxonomic comparison was conducted using the R package DESeq2 (p<0.05).

Results and discussion

All sequences exhibited Phred quality values higher than 20, indicating reliable results. The analysis of alpha diversity using the Shannon index revealed no significant differences across conditions or treatments.

In this study on S. aurata, the predominant phylum was Proteobacteria, followed by Firmicutes and Actinobacteria. However, in larval individuals, the percentage of Proteobacteria was lower, with a higher proportion of Firmicutes and Cyanobacteria. Furthermore, the presence of Bacteroidota was absent in treated larvae. On the other hand, in juveniles, the percentage of Proteobacteria was higher, especially in those fed with H2.5, where it reached around 90%. Notably, the phylum Bacteroidota was present in juveniles fed with the raw diet, but it was not observed in the other treatments studied.

Regarding genera (Figure 1), the presence of Acinetobacter in larvae (L_C and L.25) significantly differed from its occurrence in juvenile individuals. Similarly, Shewanella was more prominent in larvae compared to juveniles. Additionally, Shewanella and Pseudomonas exhibited significant differences in the R2.5 treatment in larval individuals. In the case of juveniles, there was a significantly higher abundance of Vibrio in the control group. Pseudomonas showed a significantly higher occurrence in the J_H2.5 group compared to L_H2.5, while Stenotrophomonas was more abundant in the J_R.5 group than in L_R2.5. Importantly, no significant differences at the genera level were observed in juveniles among the treatments.

The treatment of larval individuals fed the raw diet at 2.5 exhibited the most substantial changes, both compared to other treatments at their respective stages and, in comparison to juveniles, fed the same diet. These data suggest the larval stage is more sensitive to this treatment, leading to a more pronounced shift in the microbiota. However, the supplementation with N. gaditana at 2.5 did not affect the microbial composition in juvenile individuals. In summary, this study on S. aurata revealed significant differences in the microbial composition between larval and juvenile individuals and among different treatments.

Introduction
The present study was developed as a part of a currently developing research project “Potential use of wine and beer bagasse as sources of functional ingredients and nutrients in feeds for aquaculture” (UBAGALAC, P20-00923) jointly funded by the Junta de Andalucia and the EU. This project focus on the applications of wine by-products in fish fed and their benefits on health, and physiology of marine fish. Among by-products of interest in the project, like grape pomace, specific extracts like oligo-procyanidins from grape seeds, known for their strong antioxidant properties as well as their bioavailability, could be potentially benefic supplements to marine fish diets, and were investigated in this study.

Material & Methods
The objective of this preliminary study was to test different biological effects of a wine by-product concentrated extract specifically rich in oligo-procyanidines (Olpheel® Anti-Ox, OAO, Laboratoires Phodé, France) in feeds for juvenile European sea bass (*Dictenaruchs labrax*), on three different aspects: the oxidative status of fish, functionality of intestinal microbiota, and oxidation of fillets after fish sacrifice and one week storage. A total of 120 juvenile sea bass with average body mass of 46.35 ± 0.12 g were equally divided into 6 under controlled environmental conditions of salinity (37 ‰), temperature (19°C) and photoperiod (10L:14D). Experimental feeds (control diet and a diet supplemented with 80 ppm of OAO) were prepared using a lab-scale extrusion machine. Daily ration was offered till visual satiety distributed in 4 daily meals ensuring that the amount offered in each experimental unit was fully ingested. No mortality was recorded in any experimental group. The feeding-trial lasted 5 weeks. The normality of the data was performed using the Shapiro–Wilk test, and homoscedasticity analysis was conducted using the Brown–Forsythe test. Statistical analysis of the data was carried out by one-way or two-way ANOVA, followed by Fisher’s LSD test where appropriate. The significance level was established at p < 0.05.

Results
A significant effect of OAO on the microbial profile was evidenced as a reduced biodiversity (a lower number of functional groups) when compared to that of fish fed on the control diet, as well as by a higher functional richness (a higher intensity of the response that could be related to a higher number of specific OTUs (Operational Taxonomic Unit). Significantly higher levels of superoxide dismutase (SOD) were measured in the groups of fish receiving OAO compared to the control, with 7.38 ± 0.63 U SOD/mg SP in that treatment compared to 6.80 ± 0.34 in the control diet (Tab.1). The significantly higher levels of SOD can be the net result of an increased expression of genes coding such enzyme. Regarding oxidation in stored fillet of the fish, a protective effect against oxidation was evidenced in samples of fish fed on diet including OAO when compared to those fed on the control diet (Fig.1). At day 2, significant differences were observed as 457,47 pmol MDA/mg protein were found in muscles of the control fish, compared to 261,23 pmol MDA/mg protein for fish fed the OAO diet (Fig.1).

Those results together suggest that incorporating a wine by-product concentrated extract, Olpheel® Anti-Ox, to sea bass diets, could improve their antioxidant status and fillet quality. The low significancy of differences among different experiments in this preliminary study suggest that dosage of the product was potentially low and could be increased. Further studies should then be carried out with higher dosage, and to further understand the effect of such a product on diversity and functionality in microbiota and its consequences.

Introduction
The expansion of aquaculture fed species strengthens the need for sustainable fish nutrition and requires the development and testing of novel ingredients to be used in fish feeds. The Fish-AI consortium (H2020-FETOPEN project) is developing an artificial intestine platform based on Rainbow trout (Oncorhynchus mykiss) intestinal epithelial cells to evaluate the nutritional and health values of feed ingredients while reducing the use of animals in feeding trials. In this study, three test diets were digested in vitro and presented to rainbow trout (RT) intestinal epithelial cells and cell monolayers in order to evaluate the metabolic and health effects of feed ingredients on epithelial cells as well as their effects on the functional epithelial barrier.

Material and Methods
RT intestinal cells used in this work were derived from the proximal (RTpiMI) or distal (RTdiMI) region of the intestine (1). RT reference diet, a diet with high soymeal inclusion and a diet with high feather meal inclusion (Skretting) were digested in vitro by incubating the feed with RT crude enzymatic extracts from the stomach and the intestine in a static system and in a sequential manner (3). Protein hydrolysis was determined based on free amino groups and by protein electrophoresis. To assess the cell viability upon the exposure to the digested feeds, cells were seeded in 96-well plates (25,000 cells/cm²) and after 3 days in culture were exposed to various digestate concentrations (6%, 12%, 25% and 50%) for 24 h. After the treatment, cell viability was determined by Alamar blue fluorescence, an indicator of the metabolic status of the cells and by CFDA-AM, which also reveals the integrity of the plasma cell membrane. To study the effect of the digests on the intestinal epithelial monolayers, cells were seeded on ThinCert inserts (Greiner BioOne, 0.4 pore size) at a density of 250,000 cells/cm², maintained in culture until a functional monolayer was formed (2) and then incubated with different concentrations of the digests (6%, 12% and 25%) for 72 h. To evaluate the effect on the integrity of the cell barriers, transepithelial electrical resistance (TEER) was measured before and after the incubation with the digests. In addition, permeability assays were performed after the treatments by using three different fluorescent markers: β-Ala-Lys (AMCA) (BioTrend), BODIPY FL C-12 (Thermo Fisher) and Dextran-568 10 kDa (Thermo Fisher).

Results
The exposure of RTpiMI or RTdiMI cells to the three diets for 24 h induced a concentration-dependent detrimental effect (P<0.05.) on cell viability for all the tested feeds. However, no significant differences (P>0.05) were observed between diets, and both cell lines displayed similar responses. Interestingly, when cell monolayers were exposed to the different digested feeds for 72 h, the diets enriched with soy meal or feather meal induced a significant decrease (P<0.005) in TEER values at both, 12% and 25% concentrations. This was in contrast to the reference diet, which showed similar TEER values (P<0.05) to cell monolayers incubated with L15 medium. In accordance with these results, the permeability to β-Ala-Lys-AMCA, BODIPY FL C-12 and 10 kDa dextran was significantly increased (P<0.05) in a concentration- and diet-dependent manner. While 6% of the digests did not induce any alteration on the permeability to the markers analyzed, at 12%, diets enriched with either soy meal or feather meal induced a significant increase (P<0.05) in the permeability to all the fluorescent molecules, indicating a disruption of the integrity of the cell barrier. At 25% digesta, the negative effect of diets enriched with either soy meal or feather meal on the monolayer integrity was stronger, with the reference diet also demonstrating a significant adverse effect (P<0.05).

(Continued on next page)
Conclusion
High levels of feather meal or soy meal in a RT diet had no apparent effect on the metabolic status of RT intestinal cells, nor on the integrity of the plasma cell membrane, as compared to a reference RT feed. However, an epithelial cell membranal monolayer’s integrity was affected significantly following an exposure to digestates of both soymeal and feather meal rich diets. This study further demonstrates that both, TEER and the permeability to fluorescent molecules are efficient means to discriminate and rank different diet formulas using RT intestinal cell barriers. Thus, representing an important advancement in the development of the Fish-AI platform as an in vitro screening tool to predict the nutritional and health properties of novel fish diets.

Introduction

Nucleotides have a wide variety of functions beyond their most recognized role as the basic building blocks of RNA and DNA. They provide and mediate energy metabolism, are key components of cell signalling, and are key enzymatic cofactors (Cosgrove, 1998), to name a few. While organisms can produce nucleotides without dietary input (Cosgrove, 1998), this process is metabolically expensive and direct provision may allow fish systems to react faster to challenges (Ringø et al., 2012). Therefore, nucleotides are generally considered semi-essential nutrients (Li and Gatlin, 2006) and beneficial during periods of rapid growth or high metabolic demands, such as larval stages or disease (Li and Gatlin, 2006). Taking their lead from human nutrition (Cosgrove, 1998; Li and Gatlin, 2006), aquaculture research has begun to explore the potential of nucleotides to be used as feed additives (Li and Gatlin, 2006). A wide range of nucleotide-based products have been used for a variety of fish species and have been shown to optimise cell proliferation, promote growth (Hossain et al., 2016), enhance immune response (El-Nokrashy et al., 2021) as well as improve gut integrity and function (de Cruz et al., 2020). However, the mode of action of nucleotides on these various functions has in many cases yet to be fully elucidated. The deployment of ballan wrasse (*Labrus bergylta*) from the hatchery to the net pen is a period of high stress and mortality, with increased exposure to environmental stressors and disease. Working closely with industry partners, this study will explore the use of nucleotides as health additives in developing functional feeds to support ballan wrasse during this period.

Materials and Methods

Ballan wrasse (38.4 ± 9.4g) were randomly distributed into twelve 350 L flow-through tanks (100 fish per tank). Tanks were allocated to one of four experimental diets: A control diet following the current standard commercial formulation for this species with no added nucleotides (NT0) and three treatment diets with increasing levels of nucleotide supplementation (NT1, NT2 and NT3) using the commercial product Rovimax NX (DSM Animal Health and Nutrition). Each condition was conducted in triplicate with fish fed the experimental diets to satiation for 8 weeks. At the end of the trial, samples from different tissues were collected for histological, vertebral health, molecular biology analysis as well as plasma. In order to examine the robustness of the fish after feeding the supplemented feeds, the fish were subjected to an immune challenge by intraperitoneally (IP) injecting lipopolysaccharide (LPS) of *E. coli* as pathogen-associated molecular patterns (PAMP) at the end of the experiment. Fish were sampled 24 hours post-LPS injection, with plasma and head kidney collected. Operational welfare indicators (OWI) were also scored at the end of the nutritional challenge and after the challenge.

Results and Discussion

Fish performance was generally good, with fish increasing weight on average 1.6 times compared to the start of the trial. After 8 weeks of feeding the experimental feeds, fish fed the non-supplemented feed did not display significant different body weight compared to fish fed nucleotide-supplemented feeds. No difference was also found in terms of survival, being 99.2 ± 0.7 % on average. The fish showed good OWI scores, though not significantly different among the experimental fish. No significant difference was found in the fish haematocrit, the hepatosomatic index, and liver histology at the end of the nutritional trial.

The preliminary results seem to indicate that nucleotide available from the non-supplemented commercial formulation covered the nutritional requirements for the general performance of ballan wrasse. Further results will be presented, including molecular markers’ response to the immune challenge, to ascertain the benefits of nucleotide supplement for the ballan wrasse subjected to an immune stressor, in order to prepare them for the cage transfer.

(Continued on next page)
Fig 1. Mean weight (g) of the experimental fish at the beginning and after 4 and 8 weeks of feeding without nucleotide supplementation (NT0), and with nucleotide supplementation of 0.03% (NT1), 0.08% (NT2), and 0.15% (NT3). The error bars represent the standard deviation.

Introduction

Aquaculture is an essential activity contributing to food security, providing 88 million tonnes of aquatic food in 2020 (FAO 2022). Aquaculture continues growing rapidly, with an average annual growth rate of 6.7% between 1990-2020. Nevertheless, 92% of the global production is concentrated in only 20 countries, while 95 out of 170 countries with aquaculture activity produce less than 10,000 tons per year, as is the case of Argentina (Cai et al. 2022). 90% of aquaculture production in Argentina focuses on only two freshwater fish species (*Oncorhynchus mykiss* and *Piaractus mesopotamicus*), while marine aquaculture has been historically a marginal activity.

In this context, the aim of this work was to gather existing and generate new information relevant to promote and develop marine IMTA in Argentina and analyse the potential of low trophic native species to diversify the current production concentrated in fed aquaculture.

Material and Methods

We evaluated the potential of 12 native species of the Beagle Channel, located in the extreme south of Argentina (54°S), for IMTA production. The species were 2 fish, 2 crabs, 1 octopus, 2 sea urchins, 2 bivalves, 2 algae and 1 halophyte, covering the different roles in a theoretical IMTA: Fed aquaculture Organic Extractive Aquaculture (sedimented POM feeders), Organic Extractive Aquaculture (suspended POM feeders), and Organic Extractive Aquaculture (DIN feeders). Besides, several activities were carried out to design strategies to develop IMTA, including assessment of environmental conditions, regulations, markets, and social perception, among others.

Results and Discussion

We detected two groups with potential to be part of an IMTA system: 1) Red sea urchin (*Loxechinus albus*) reared in lantern integrated with blue mussel (*Mytilus chilensis*) reared in longlines. The other proposed system consists in whitebait (*Galaxias maculatus*) integrated with halophytes (*Salicornia magellanica*) in an open land-based system.

The market study showed that blue mussel is one of the most important species, while Salicornia (included in the algae category) is little offered. From the interviews with the restaurant managers, it was detected that there is interest in incorporating sea urchins, and they are still unaware of the gastronomic value of whitebait (Figure 2).

One of the strengths detected is that potential producers, decision-makers, and society, have an idea about the meaning of the IMTA concept.

Regarding the limitations found, it is worth mentioning the lack of aquaculture facilities to develop projects on a pilot scale, and a great distrust on the part of society towards aquaculture projects due to their potential environmental impacts and the lack of government capacity to monitor this activity.

Introduction

The market for seabass and gilthead seabream in Cyprus is considered to be saturated, with the wholesale market leaders dominating the market and utilizing their extensive retail networks to maintain their market share positions. In addition, local producers are facing competition from Greek aquaculture farms, which have been able to quickly and easily send fresh products to Cyprus at lower prices since last year. Furthermore, new local aquaculture farms will face significant increases in infrastructure costs, which potential government subsidies may not fully cover. As a result, it is advisable for prospective new aquaculture companies to develop business plans that prioritize exporting production overseas rather than relying on local consumption. To this end, a market research study was conducted to explore the possibility of exporting to neighboring countries such as Israel, Egypt, Jordan, and Lebanon. As fresh fish is favored by the consumers, the swift transportation and low freight costs create an ideal setting for potential new export markets. The market research analysis also explored the possibility of exporting two new species for Cyprus aquaculture, meagre and red porgy.

The primary objective of the study was to determine the market size per country, identify the dominant market leaders and key players, and understand the essential product category features according to consumer preferences such as fish species, size, quality, process level or product configuration, and distinctive characteristics. Additionally, the study outlines the sea transport procedures for importing fish into each country and documents any potential taxes, charges, and fees. Finally, the report presents business strategies for Cyprus aquaculture firms based on a comparative evaluation of the four countries included in the study.

Results

Israel, although a small country in terms of population, has a high per capita gross domestic product and a significant yearly fish consumption rate. These factors position Israel as a potentially attractive market for Cypriot fish farms to export seabass. However, the Israeli market for seabass is relatively small, with an annual consumption of approximately 6,500 tonnes. Additionally, the wholesale price of seabass is attractive for Cypriot fish farms. The wholesale price of seabream does not favor exports.

Egypt, on the other hand, is a significantly larger market for fish products, both as a producer and an importer. However, the country’s large-scale aquaculture projects have led to low wholesale prices for the species under study, making it a challenging market for Cypriot aquaculture farms to penetrate. In addition, Egypt plans to increase its exports and reach self-sufficiency in fish production, potentially becoming a strong competitor for Cypriot exports.

Jordan is a small market with a low but steadily increasing fish consumption rate. Local production is minimal due to the country’s very short coastline, and the low per capita gross domestic product has resulted in moderate wholesale prices for seabream and seabass. While this market may not be ideal for Cypriot fish farms at present, the increasing trend in fish consumption suggests a possible future market, especially if prices continue to rise.

Lebanon, too, is a small market with low yearly fish consumption. Political instability in the country has led to a constant drop in per capita gross domestic product and changing consumption preferences. While the wholesale retail price for seabass is high, demand is low. In contrast, Lebanon can import seabream at extremely low prices from Turkey, making it an unattractive market for Cypriot aquaculture farms.

According to the market research analysis, it has been revealed that neither meagre nor red porgy are feasible for export due to a number of factors.

Reducing feed-food competition in aquaculture and livestock is a way to decrease the environmental impacts of the food system and to free up large areas of arable lands to potentially produce more food. Previous studies showed that almost 50% of the feedstuff used in aquafeeds are causing feed-food competition in livestock and aquaculture production, focusing on feed use and the availability of by-products and residues. We then analysed the potential of replacing food-competing feedstuff—here cereals, whole fish, vegetable oils and pulses that account for 15% of total feed use—with food system by-products and residues. Considering the nutritional requirements of food-producing animals, including farmed aquatic species, this replacement could increase the current global food supply by up to 13% (10–16%). Indeed, fed aquaculture utilizes fish resources that could have been eaten directly by humans, but are used to grow more desirable species due to market demands. Furthermore, the quality of soybeans, maize, wheat, and other agricultural crops used in aquafeed, may or may not live up to food-grade qualities, but they are indirectly competing for land that could be used to produce food-grade crops. In general, food-competing feedstuffs have lower environmental footprints than farmed aquatic or terrestrial animals fed these resources, hence the interest to feed farm animals mainly with by-products that humans cannot or do not want to eat.

Tilapia is an aquaculture species of global importance, with a high contribution to food supply, especially in Asia and Africa. It can be cultured in various production systems (pond, cages, tank, raceway, RAS), with a varying need for external feed inputs and feed conversion efficiencies. Depending on the systems, and locations, the feed used may contain high-quality ingredients potentially competing with human food and/or non-food competing by-products. The total human-edible yield of tilapia can also be variable, as this fish can be consumed in various ways from the use of the fillet only, to the consumption of the whole fish, depending on fish size, processing technologies, and culture. All these factors may influence the food in / food out ratio of the tilapia farming systems leaving unclear which are net consumers of human edible nutrients, and which are net producers.

This study aims to quantify and compare the net contribution to human food production of contrasted tilapia farming systems from various world regions. To do so, we calculated the human-edible protein conversion ratio (HePCR) i.e., the quantity of human-edible protein in the feed divided by the quantity of human-edible proteins in the animal products, for different tilapia farming systems. These tilapia case studies were taken from peer-reviewed Life Cycle Assessment studies and covers the broad range of rearing systems that can be used in tilapia farming. Overall, this study discusses how the feed, the farming system and the valorization of fish by-products can influence feed-food competition in tilapia farming systems.

Introduction

Integrated Multitrophic Aquaculture (IMTA) has been suggested as an innovative method of aquaculture development (Mansour et al, 2022) that ensures sustainable development in agreement with the EU directions for Blue Growth and Blue Economy. Methodology of co-culture fishes, bivalves and holothurians have been developed in Mediterranean waters (Chatzivasileiou et al 2022). Although, studies on IMTA project have promising results in Mediterranean waters (Chatzivasileiou et al 2022), food safety of IMTA organisms has not been studied extensively. According to the Greek and European law it is not yet allowed to cultivate and commercialize organisms cultured in IMTA systems due to lack of specific IMTA food safety protocols. In the context of Innovated Development of Marine Aquaculture (IDMA) project after the co-cultivation of fishes, bivalves and holothurians, an investigation of food safety parameters was implemented. The results are expected to facilitate the European Food Safety Authority and the Greek Food Authority to compose safety protocols for IMTA products and consequently to permit the development of commercial IMTA systems.

Material and Methods

In this study, three Mediterranean species were co-cultured in three operating fish farms in the Aegean with different trophic conditions. It is defined as the cultivation of two or more aquatic species from different trophic levels in the same area in order to mimic the energy flow in natural ecosystems (Chapin T. et al 2004) The co-cultivated species were Mediterranean mussel (Mytilus galloprovincialis), rayed pearl oyster (Pinctada imbricata radiata), and sea cucumber (Holothuria polii) as described by Chatzivasileiou et al (2022). After a year of cultivation, edible tissue samples were collected for the co-culture species, in order to find out if the co-cultivated organisms are appropriate for consumption. The food safety analysis included the determination of antibiotics (oxytetracycline, florfenicol), metals (Hg, Pb), dioxins and related substances (PCBs, PCDDs, PCDFs, PBDEs, DDT, DDE, HCB, PFAs, and lastly biotoxins (DSP, PSP, ASP). All the analysis was conducted in samples of IMTA cultured sea cucumber, mussels and oysters as well as samples for a typical mussel farm and oyster and sea cucumber natural population.

Results

European committee has established limits on oxytetracycline and florfenicol concentrations for safe consumption of food products (100μg/kg for mussels and oysters, Regulation EU 37/2010). Our results showed that the concentrations of the two antibiotics were under the permitted limits for all samples regardless the type of mussel cultivation. Metals concentrations in this study were below the food safety limits defined by the European committee (0.5 mg/kg WW for Hg, and 1 mg/kg WW for Pb, Regulation EU 4661/2001). The permitted limits of dioxins and dioxins like substances is 3.5 pg/g for TEQ PCDD/PCDF, 6.5 pg/g TEQ PCBs, 75 ng/g for PCBs, 50 mg/kg for DDT, for HCB and for PBDEs (Regulation EU 1259/2011 and 2019/1021). In this study, the concentrations of organic pollutants were below the safety limits for IMTA mussels and oysters. Lastly, the permitted limits of marine biotoxins DSP, PSP and ASP are 160 mg/kg, 800 mg/kg and 200 mg/kg respectively (Regulation EU 853/2004). Our results showed that the biotoxins concentrations were very low and under the safety limits for all mussels and oysters’ samples.

(Continued on next page)
Conclusions

Until now the products of an IMTA aquaculture couldn’t commercialize, cause the lack of knowledge regarding the safe consumption of the IMTA organism. These results showed that bivalves and holothurians cultivated in a fish farm area are safe for human consumption, and IMTA aquaculture is a safe method to co-cultivate species from different trophic levels. Aquaculture wastes were not contaminating the co-culture species with antibiotics, toxins or metals. That fact makes IMTA aquaculture a promising method to cultivate more species in the same farm.

CIRCULARITY ASSESSMENT OF IMTA INFRASTRUCTURE IN THE CONTEXT OF ASTRAL PROJECT

Checa, D1; Michalek K2; Macleod A2; Sanchez, I1

1LEITAT Technological Centre C/ de la Innovació, 2 · 08225 Terrassa (Barcelona)
2Scottish Association for Marine Science (SAMS), PA37 1QA Oban, Scotland, UK
dcheca@leitat.org

Introduction

In the context of the Circular Economy Action Plan (European Commission, 2020) and as part of the growing economy sectors, aquaculture may play a relevant role within the circular and green transition.

Together with the transition to a circular economy, aquaculture of low-trophic species has been pointed out as an important industry for sourcing alternative proteins and facilitating the sustainability of food systems (Farm to Fork Strategy, 2020). Although these aquaculture systems are overall recognised by its lower environmental impact (Strategic guidelines, COM/2021/236 final), the infrastructure elements used are often composed of non-biodegradable fossil-based plastics. In this sense, there is an increasing interest on prospecting innovative sustainable solutions for the low-trophic –aquaculture sector to increase the circularity of infrastructure elements.

ASTRAL is a European project that aims at developing and providing innovative techniques and species combination to improve Integrated Multi-Trophic Aquaculture (IMTA). Within ASTRAL, a circularity assessment is being carried out to provide evidence-based metrics to evaluate how the new aquaculture systems performs in the context of the circular economy. Particularly, for the specific case study in Scotland, focused on the cultivation of seaweed and bivalves, we have identified the major drivers to increase the circularity in infrastructure.

Secondly, the assessment addresses the role of IMTA through the improved U when utility is defined as the total capacity to develop biomass.

Each infrastructure element is associated with an MCI parameter, which has been improved following the implementation of the IMTA differentiating between the three circularity principles (reduce, reuse, and recycle).

(Continued on next page)
The infrastructure elements have been assessed individually to quantify the circularity improvements of IMTA:

i. Anchor line: Increasing the biomass production due to the IMTA species, the utility of the element is increased.

ii. Seaweed Growing Line: Manual cleaning of remaining biomass and seeding twine before being reused for next deployment.

**Results**

The first approach has shown an increase of circularity by 20% related to the anchor line element, and by 68% for seaweed growing line element.

Secondly, the implementation of IMTA at SAMS site has increased the total biomass by 9%, reflected as a 6.7% increase in the Material Circularity Indicator.

**Conclusions**

When assessing the circularity individually for each infrastructure element and after the implementation of best practices, the circularity is increased based on the specific parameter that has been modified.

Positive results are shown as well if the circularity is assessed under a general approach, considering the higher amount of biomass produced, increasing the utility of infrastructure due to the shared purpose in IMTA.

Introduction
Ectoparasite infections represent a significant challenge in fish aquaculture, with the fish skin immune system serving as the frontline defense and comprising multiple mechanisms to protect against microbial invasion. Incorporating health-promoting additives as a preventive approach has enhanced skin mucus defense mechanisms and reduced parasite prevalence. This study aimed to examine the modulatory effects of a phytobiotic-based additive, APEX® BRANCHIA (Adisseo), on fish skin defense against ectoparasitic diseases- The Guppy-Gyrodactylus infection model and a shotgun proteomics approach were applied to evaluate the additive’s impact on fish skin.

Material and methods
Forty individually housed guppies (Poecilia reticulata) were initially provided with a diet containing the functional additive for 14 days. Subsequently, each guppy was inoculated with two Gyrodactylus turnbulli parasites, and the additive-supplemented feed was continued for an additional 17 days. Parasite numbers on each fish were assessed every 48 hours, and based on infection susceptibility, fish were classified into responsive, resistant, and susceptible groups. Skin samples were collected on days 13 and 17, corresponding with peak immune activities and the end of infections, respectively. Differentially expressed proteins in the skin tissue among the various susceptibility groups were identified using nano LC-MS/MS.

Results
This analysis elucidated the mode of action of APEX® BRANCHIA in relation to fish response to infection, revealing two primary strategies for combating parasite infection. The first strategy involved skin cornification in susceptible fish, wherein parasite burdens peaked on day 13 and subsequently declined sharply by day 17. Cornification is a programmed cell death process generating a dense barrier of dead cells, effectively impeding parasite entry. The second strategy was employed by resistant fish, which consistently displayed low parasite levels throughout the study. In these fish, the additive was found to activate the complement system, initiating a series of proteolytic events that facilitated the elimination of invading pathogens. In conclusion, the dual protection mechanism delivered by APEX® BRANCHIA is likely a key mechanism to reduce the severity of infection observed in field testing.
Introduction
Live transport has great potential to maintain the quality of cultured seafood (Fotedar & Evans, 2011). The live transport approach, however, involves different handling processes, which in mussels could cause stress and mortality (Nguyen et al., 2020). By inducing metabolic depression before transport, live mussels may be less sensitive to stress caused by handling processes associated with live transport. In this study, conditions that trigger metabolic depression were explored using a commercially important green-lipped mussel, *Perna canaliculus*, as a model species, by measurement of cardiac activity.

Materials and methods
Mussels were exposed to different treatments i.e., temperature (4°C, 6°C, 8°C and 14°C (control)), oxygen level (0.5mgO\(_2\)L\(^{-1}\), 1mgO\(_2\)L\(^{-1}\), 3mgO\(_2\)L\(^{-1}\) and 8mgO\(_2\)L\(^{-1}\) (control)) and anaesthetic concentration (MgCl\(_2\); 0gL\(^{-1}\) (control), 30gL\(^{-1}\), 40gL\(^{-1}\) and 50gL\(^{-1}\)) for two hours. During the exposure, eight mussels from each treatment were sampled at two time points (i.e., 30 minutes and 120 minutes after the exposure started) respectively for measurement of heartbeat (bpm) for 20 minutes.

Results
Linear mixed-effects models showed that temperature, oxygen level and MgCl\(_2\) concentration, and the exposure duration had an interactive effect (p < 0.05) on mussel HR (Figure 1). HR of mussels at low temperatures was depressed by 50–100%, whereas HRs of mussels exposed to MgCl\(_2\) decreased by 36–97%. Low oxygen levels only dropped mussels’ HRs by 1.5–51%.

Discussion
Depression of metabolic rate was most pronounced in the temperature and MgCl\(_2\) treatments. Reasons explaining this finding are body temperature of ectothermic organisms depends on the environmental temperature, which governs the biochemical reactions and, subsequently, metabolism and performance within thermal tolerance windows (Cheng et al., 2018). Decreased body temperature due to dropping environmental temperature could reduce ectotherms’ enzyme activity level and thus reduce metabolism, which could be indicated by depressed physiological rates such as respiration and heart rates (Schulte, 2015). Bivalves can also depress their metabolism by shifting from aerobic to anaerobic metabolism to tolerate prolonged hypoxic conditions (Stevens & Gobler, 2018), which was also demonstrated by depressed HRs of *P. canaliculus* at 0.5mgO\(_2\)L\(^{-1}\) over exposure time. Immersion in MgCl\(_2\) solution could relax the heart and adductor muscles of *P. canaliculus*, resulting in reduced HRs as Mg\(^{2+}\) blocks Ca\(^{2+}\) from entering the cell, which obstruct the release of acetylcholine to initiate muscle contraction (Azizan et al., 2021; Namba et al., 1995).

By comparison, low temperature and immersion in MgCl\(_2\) solution both successfully induced metabolic depression of mussel *P. canaliculus*. Studies on conditions in the combination of low temperature and MgCl\(_2\) should be explored to see if they will further suppress mussels’ metabolism.
Fig. 1 Heart rates of mussel, *Perna canaliculus*, sampled at different time points (i.e., T1 and T2) respectively exposed to various (a) temperatures, (b) dissolved oxygen levels and (c) MgCl₂ concentrations. The solid line and dark square represent the median and the mean respectively (Con = control, i.e., for temperature (14°C), dissolved oxygen (8mgO₂L⁻¹) and MgCl₂ (0gL⁻¹) treatments.

SEA-MONITOR: A GENOMIC DIAGNOSTIC SUITCASE BASED ON NANOPORE SEQUENCING

Germain Chevignon1*, Patrick Durand2, Pauline Auffret2, Aurélie Dotto-Maurel1, Maude Jacquot1

1 Ifremer, ASIM, La Tremblade, France
2 Ifremer, Sebimer, Plouzané, France
Email: germain.chevignon@ifremer.fr

With the development of high throughput sequencing techniques and dedicated bioinformatics tools, molecular epidemiology has experienced a spectacular boom in recent years and has demonstrated its usefulness in human health for the early detection of emergencies and the understanding of transmission and circulation dynamics of many infectious diseases. Aquaculture is a sector particularly sensitive to infections where flocks are regularly subjected to epizootics causing considerable ecological and economic damage. Currently, the sector lacks methods for early detection, prevention and control of diseases. To address this need, we have developed a tool and methodology to accurately and rapidly identify pathogens that could cause mortality in livestock. As a proof of concept, the SEA-MONITOR project has provided a concrete solution for real-time monitoring of marine mollusc pathogens to significantly improve their prevention and control. The concept is based on the development of a suitcase containing all the laboratory equipment necessary for genomic diagnosis. More precisely, this mini-laboratory is based on the use of Oxford Nanopore Technologies (ONT) portable sequencing technology, which allows to obtain high quality genomic sequences in near-real time. The solution proposed also includes the development of an analysis pipeline allowing the transfer of raw sequencing data to an adhoc calculation server and the automatic analysis of these data to quickly provide an accurate and complete diagnostic report to users. Tests performed in laboratory as well as in the field by our partners have enabled the identification and sequencing of viral and bacterial pathogen genomes within a few days. Results of the SEA-MONITOR project have demonstrated that genomic monitoring and diagnosis represent a promising opportunity for a better management of marine mollusc diseases.
THE EFFECTS OF ENVIRONMENTAL ENRICHMENT ON COGNITIVE FUNCTION AND STRESS RESPONSE OF JUVENILE ATLANTIC SALMON (Salmo salar)

Introduction

To achieve high standards of animal welfare, animals must be raised in healthy conditions in terms of pathogen presence and nutritional requirements, be free from discomfort or pain, free from distress or fear, and in conditions suitable for the development of natural behaviours (Mellor, 2016). In this regard, efforts are being made to not just avoid negative welfare states, but promote positive welfare, by providing environments that allow animals to fully develop their cognitive abilities and express natural behaviours. This can be achieved by providing environmental enrichment that can enhance positive welfare conditions. However, positive welfare is a complex concept, which depends on the biology of each species, the stage of development and even the individual's own personality (Mellor, 2016). It is therefore necessary to study in detail the behaviour of different organisms in relation to the application of protocols or techniques that result in the improvement of their quality of life. In the present study, we focus on the impact of structural environmental enrichment (SEE) on molecular parameters indicative of cognitive capacity, neuronal activity and stress response in juvenile Atlantic salmon (Salmo salar).

Material and methods

Groups of fish (1.59±0.41 g; 5.43±0.46 cm) were randomly distributed in 8 (700L) conical tanks (n=375 fish each) and kept in a Recirculating Aquaculture System (RAS) for 12 weeks, being fed ad libitum with a 24 h L photoperiod. Four of the eight tanks included structural environmental enrichment (SEE), through the addition of artificial plants attached to a PVC mesh. To assess the effects of SEE on the acute stress response, fish were exposed to a stress event at the end of the 12-week challenge period; a 5-minute net chase, a husbandry practice known to induce stress in fish, was used as a stressor.鱼 were sacrificed with an overdose of MS222 and the brains were immediately dissected and placed in a bath of RNA-PVC mesh. To assess the effects of SEE on the acute stress response, fish were exposed to a stress event at the end of the 12-week challenge period; a 5-minute net chase, a husbandry practice known to induce stress in fish, was used as a stressor. 鱼 was sacrificed with an overdose of MS222 and the brains were immediately dissected and placed in a bath of RNA.

Preliminary results indicate significant increase in bdnf and ndf1 in salmon with structural environmental enrichment (SEE), F(1,68) = 5.379, p = 0.0234 and F(1,68) = 4.250, p = 0.0431, respectively, meanwhile there was no significant effect of acute stress (p = 0.4163 and p = 0.2751), However, the acute stress events promote a significant increase in the expression of hsp90, F(1,68) = 4.556, p = 0.0364 and cfos (F(1,88) = 4.300, p = 0.0419), regardless of enrichment condition p = 0.4769, and p = 0.8767, respectively. Correlations analysis shown that there is high consistency between the levels of the same individuals, Pearson index = 0.708. Also between ndf1 and hsp90 p = 0.0293, Pearson index = 0.2570 and bdnf and hsp90 p = 0.085, Pearson index = 0.3078. In particular, in these last two pairs, there was a high correlation between fish with enrichment p < 0.0001, disappearing among fish that were not subjected to enrichment. p = 0.2704 and p = 0.1199, respectively.

(Continued on next page)
Discussion
There is a growing body of evidence indicating that bdnf and ndf1 are associated with neurogenesis, neuronal maintenance, neuronal survival, plasticity, and neurotransmitter regulation in fish (Lucini, 2018). In addition, previous studies in mammals point to a strong relationship between the transcription factor ndf1 and the stimulation of nerve growth via bdnf/trkb pathway (Lai et al., 2020). In our experimental conditions we observed that fish reared under a SEE displayed higher levels of bdnf and ndf1, suggesting an increase in neuron proliferation in those individuals. Moreover, the high correlation displayed between the expression of both genes support the interaction proposed before. Therefore, the results obtained demonstrate that SEE has a positive impact on the expression of genes related to neurogenic processes which translate onto higher cognition capacity (Lucon-Xiccato et al., 2022).

On the other hand, we observed that the acute stress event did not have a significant impact on the expression levels of genes related to cognitive function or stress axis, but we have detected an activation of the cellular response to stress, evidenced by higher levels of hsp90 and cfos, indicating a neuronal integration of stress event-related signals. There is considerable evidence indicating that a coordinated interaction between hsp70/hsp90 enhances the binding capacity of glucocorticoid receptors, increasing their sensitivity and affinity to stress related hormones (Kirschke et al., 2014), with cortisol (the main stress-related hormone) having been shown in teleost fish to promote the binding of hsp70 to the glucocorticoid receptor (Basu, et al., 2003). In this regard, we found a significant correlation between neurogenesis and cellular stress response-related genes in SEE-reared fish, suggesting that fish exhibiting higher cognitive abilities also develop a high level of hsp90. This finding may be indicative of higher sensitivity to stress events, thus indicating a superior competence of these fish to integrate stress-related stimuli as a stress coping mechanism.

SALINITY INDUCED CHANGES IN THE PROGRESSION OF WATER, ION AND NUTRIENT FLUXES ALONG THE GASTROINTESTINAL TRACT OF ATLANTIC SALMON SMOLT (Salmo salar)

Introduction
Anadromous fish species have a life cycle that begins in freshwater (FW), followed by smoltification as juveniles, which allows them to migrate to seawater (SW). Smoltification allows the FW fish to prepare for the SW environment (McCormick, 2012; McCormick et al., 2013; Prunet et al., 1989). Different organs are involved in osmoregulation during smoltification: intestine, gills, kidney and skin, but the main one responsible for water and ion fluxes is the intestine (Sundell and Sundh, 2012) to absorb ions to replace water lost by osmosis in SW. During smoltification, the drinking rate increases, in the intestine the ion and fluid transport increases and is further elevated after SW entry. In SW, the intestine absorbs ions to create an inwardly directed water flow which is accomplished by increased Na+,K+-ATPase (NKA. To maintain body homeostasis, water and ion flux occur in and out the gastrointestinal tract (GIT) (Larsen et al., 2014). Increasing water salinity is known to increase drinking rate in fish. Drinking behavior has been widely investigated in marine, euryhaline and freshwater teleost fish (Wood, 2019) and is a site of temporal and spatial variations in pH, HCO3−, and PCO2 (CO2 dynamics. However, only a minority of those studies have considered the interaction between drinking and feeding (Bucking et al., 2011; Eddy, 2007; Kristiansen and Rankin, 2001; Ruohonen et al., 1997; Usher et al., 1988; Wood and Bucking, 2010) 4-6 h after abrupt transfer from freshwater to seawater. In unfed fish the rate steadily increased to 6.46 ml kg-1 h-1 from 4 days post-transfer, apparently in response to increasing plasma ion concentrations. Drinking rate was independent of gut food content but was significantly higher in feeding fish (7.94 ml kg-1 h-1. Furthermore, it is unclear whether the increased drinking rate during feeding is intended to aid chyme liquefaction in the stomach or to maintain the osmotic homeostasis in the body. We hypothesized that the ingestion of seawater would decrease the dry matter in the stomach, especially at high salinities. Therefore, this study assessed the impact of water salinity on the progression of water, ion and nutrient fluxes along the gastrointestinal tract of Atlantic salmon smolt (Salmo salar) fed a commercial-like diet.

Materials and methods
The experiment was performed with a mixed sex population of Atlantic salmon (Salmo salar) smolts (n = 480) ready for seawater transfer. The fish were randomly allocated to 16 tanks with 30 fish per tank. Four different salinities, 0, 10, 20 and 35 ppt, were used in quadruplicate tanks for each salinity level. Fish were fed a commercial-like diet twice a day until apparent satiation for 8 weeks and feed intake was monitored through collection of feed spill. The final sampling was carried out during two days (days 56-57). Yttrium oxide (Y2O3) was used as an inert marker to measure digestion kinetic and water/ion fluxes in the gastrointestinal tract (GIT). Chyme was collected quantitatively from four segments of the GIT: proximal, middle and distal intestine, and was analysed for pH, osmolality and dry matter (DM). Furthermore, the kinetics of water, ion, crude protein, and protease activity were measured along the GIT. Blood was collected from the caudal vein to measure blood pH and plasma osmolality. All parameter were tested for the effect of salinity by regression analysis as well as one-way ANOVA.

Results
Drinking rate increased with salinity from 0.78 to 4.11 ml/kg/h between 10 and 35 ppt salinity. Between 0 and 35 ppt, chyme dry matter decreased by 1.7% and 4.8% in the stomach and proximal intestine, respectively. Chyme pH was not affected by water salinity in the stomach, but it increased linearly (p < 0.001) with salinity in all intestinal segments. Chyme osmolality increased linearly (p < 0.001) with salinity in the stomach and it decreased in all intestinal segments. Water fluxes were similar among salinities in the stomach, but they increased nearly fivefold (6.2 versus 27.3 ml g−1 ingested DM) in the proximal intestine between 0 ppt and 35 ppt. An efflux of monovalent ions (Na+ and K+) increased linearly (p < 0.001) with salinity in the proximal intestine. An efflux of divalent ions (Ca2+ and Mg2+) increased curvilinearly (p < 0.001) with salinity in the proximal intestine. Plasma osmolality and ion levels increased with salinity. Crude protein digestibility and protease activity decreased significantly with water salinity in the intestine.

(Continued on next page)
Discussion
In contrast to our hypothesis, the DM of the chyme in the stomach was stable across all salinities, slightly decreasing (1.6%) between 0 and 35 ppt. Furthermore, the drinking rate calculated and the osmolality of the chyme in the stomach increased with salinity without affecting the chyme DM. Therefore, our results show that drinking rate increased with water salinity but the influx of water in the stomach chyme was minimal compared to the chyme in the proximal intestine at higher salinities. Moreover, water influx in the proximal intestine was followed by a re-absorption of water in the middle intestine. As a result, ingested water had an effect on chyme characteristics and digestion kinetics in the intestinal segments rather than the stomach, where the ingested food appears to stay longer (higher chyme DM). At higher salinities, the majority of the ingested water is bypassing the stomach and moving to the proximal intestine more rapidly compared to the chyme in the stomach (Figure 1). In conclusion, our results suggest that the exogenous water entering the GIT does not really mix with the chyme in the stomach. Therefore, we propose that ingested water by the fish is primarily used for osmotic processes rather than chyme liquefaction in the stomach.

**Introduction**

Optimizing fish production in intensive aquaculture can lead to increased production with respect to fish welfare. The new technologies enable to development of the Precision Fish Farming (PFF) (Fore et al. 2017) concept, whose aim is to apply control-engineering principles to fish production, thereby improving the farmer’s ability to monitor, control and document biological processes in fish farms. Individual fish identification is one of the tasks necessary for precision fish farming.

The widespread and popular methods of fish identification are tagging and marking (PIT, RFID or VIE tags), which are invasive methods. It was shown that image-based fish individual identification could substitute fish tagging (Bekkozhayeva 2021, Schraml 2020, Bekkozhayeva 2022 and Cisar 2021). All the studies demonstrated long-term stability and high accuracy of image-based identification but only under controlled laboratory conditions. In this study, we implement image-based individual fish identification for real-time usage during the standard fish sampling procedure. The software used the ordinary web camera and was tested on rainbow trout identification with an accuracy of 100%.

**Materials and methods**

Rainbow trout Oncorhynchus mykiss (Fig.1 (right image)), a commercially important fish species, was used in our study. The size of the fish was around 13.7 ± 9.1 cm 32.8 ± 6.0 g. This species has a skin dot pattern on the body (juvenile pattern), which was used for the individual identification procedure. Those dots are different in size and location, which is expected to provide high discriminative power for individual identification within a close group of fish (tank). Fish were bought at the fish farm in Rybářství Litomyšl s.r.o., Czech Republic. Finally, 1602 individuals were used in the experiment. Three pictures of the lateral view of the fish were collected for each individual at different angles and positions. An image of the right side of the fish was captured for all fish. The average resolution belonging to the one fish was 820 x 180 pixels.
The fish detection is based on the CNN with YOLOv8 architecture. YOLOv8 is one step bounding box detector. The CNN was trained using 187 manually labelled images of the fish randomly selected from 1602 fish. The original implementation from Ultralytics was used. The CNN was trained using Google colab environment. The trained CNN was then used in C# .net software developed by the authors for fish identification. The example of detected fish is in Fig. 1.

The CNN performs the detection of the fish bounding box without the tail. The region of interest (ROI) used for identification is extracted from the central part of the fish. The area is defined by the percentage of fish width and height. The ROI is parametrized using a Histogram of oriented gradients descriptor to calculate the fish feature vector. The identification is implemented as nearest neighbour classification, where the distance of the unknown fish is measured to all images in the database. The unknown fish is identified as the fish with the smallest distance. Two images of each fish were used as reference database and one image for each fish was used to test the identification accuracy.

**Results**

The accuracy of fish detection using the CNN approach was 100%. The accuracy of individual identification using nearest neighbour classification was 100%. The time of fish individual detection using CPU only (no GPU acceleration is needed) was 500ms. The time of fish identification of one fish within 1602 individuals was 800ms.

**Conclusion**

Individual fish identification is one of the keystones of the emerging concept of Precision Fish Farming. It was already proved by several studies that individual fish identification based on the fish skin pattern could substitute invasive fish tagging. In this paper, we developed the software for real-time fish individual identification using an ordinary web camera to provide support for fish sampling. The software was tested on 1602 individuals of juvenile rainbow trout and reached an accuracy of 100%. The software can be used by researchers or by fish farmers to speed up non-invasive fish sampling. The adaptation for other species is simple and needs just training CNN detectors for the new species.

THE EFFECT OF BROODSTOCK DIETS AND FATTY ACID COMPOSITION ON THE REPRODUCTION OF BURBOT (Lota lota) IN REcirulating SYSTEMS

J. Claeyé *, T. Abeel, T. Lourenço De Abreu, H. Arnouts, W. Meeus
Aquaculture Education & Research Facility, Agro- and biotechnology, Odisee University of Applied Sciences
9100 Sint-Niklaas, Belgium
Email: joachim.claeye@odisee.be

Introduction
The burbot (Lota lota), a nocturnal and benthic gadoid freshwater fish commonly referred to as ‘the freshwater cod’, holds significant promise for the diversification of European inland aquaculture. Its delectable white flesh makes it an esteemed food fish among consumers.

Burbot exhibits a unique reproductive behavior, spawning only once a year when temperatures dip below 4°C. Current research efforts pertaining to burbot reproduction heavily rely on wild breeders captured shortly before the spawning season or those maintained in semi-natural conditions. Addressing the reproduction gap between hatchery and wild breeders is crucial to develop a well-informed strategy that ensures the consistent production of high-quality eggs and larvae within culture systems. This understanding is essential for the advancement of burbot aquaculture and the overall success of the industry.

For successful commercial production of burbot, it is imperative to establish a self-contained Recirculating Aquaculture System (RAS) for broodstock, as access to wild spawners is limited due to their scarcity and biosecurity concerns. An important step in the successful operation of a RAS for broodstock is to improve our knowledge of nutritional requirements, particularly fatty acid content, which has been poorly documented in burbot.

Material and methods
Burbot (Lota lota) used in this experiment were sourced from two commercial hatcheries (AquaLota, Belgium and LotAqua, Germany) during early fall 2020. The selected broodstock were originally reared from eggs obtained in January 2017 and were subsequently raised from larvae to sexually mature individuals under intensive RAS conditions. Fifty 5-year-old individually PIT tagged burbot broodstock with average bodyweight 1932.86 ± 756.51 gram were utilized in this study, comprising 30 females and 20 males. The broodstock were evenly distributed into two separate tanks (15 females and 10 males per tank), each with a capacity of 1800 liters.

These tanks were connected to an intensive RAS with photothermal manipulation to mimic natural conditions. At the time of the trial, the broodstock were second time spawners. The diets existed of a commercial compound dry feed specially formulated to enhance fish reproduction (Lansy breed Performance, Inve Aquaculture NV, diet A) and defrozen forage fish (diet B), commonly used in fish farms. Feeding quantity was corrected on dry matter basis at a level of 0.5% of biomass per tank per day.

At the start of the trial, fish were carefully examined to stage the oocytes. The oocyte staging process was performed by adapting the method as described for Perca fluviatilis (Zarski et al., 2017) which categorizes oocyte stages into stages I to VI. Females in stage VI were checked daily for ovulation. Fish, which were in stage I – IV, were injected with sGnRHa. The fish were subjected to strip spawning, and milt was collected from three randomly selected males to fertilize the oocytes of each female at a ratio of 1.5 mL of milt per 100 gram of eggs. To provide a uniform fertilizing ability for all egg batches, 0.5 mL of milt was collected from each of three males. The incubation process took place in a 96-well plate per female, each well containing one fertilized oocyte. The incubation temperature was maintained at 3.0 ± 0.2°C throughout the incubation period.

Various parameters were recorded during the study: fertilization rate, survival rates on 3, 6, and 20 days post-fertilization to assess developmental potential and hatching rate. Broodstock-related parameters such as body weight and length, condition factor, relative and absolute fecundity were also recorded. A sample of oocytes from each female was obtained and kept at -80°C to perform FAME analysis.

(Continued on next page)
**Results**

No significant effect of diets was found on the fertilization rate, survival at 3, 6 and 20 days post fertilization and hatching rate. In most cases, though not always, the fatty acid content of the feed is reflected in the oocytes. This is true, for example, for ARA and DHA, but not for LA. There were no differences in terms of relative fecundity or body condition factor. One interesting finding was that diet B led to a spawning period of only 4 days, whereas diet A required a total of 12 days. This indicates that the diet given to the broodstock influenced the speed and synchronization of the final oocyte maturation process.

**Conclusion**

This study was a first preliminary investigation on the impact of two diverse broodstock feeds on the reproductive performance of burbot. While interpreting these findings requires prudence, it is pertinent to note that both dry feed and forage fish-fed broodstock exhibited similar spawning qualities. However, the effect of the fatty acid composition of broodstock diet on larval performance has not yet been studied in burbot but needs to be done to distinguish the suitability of the feed. High fertilization rate of the oocytes and good embryonic development doesn’t necessarily imply good larval performance and qualitative fingerlings later on.

Further research should be performed to find a totally adequate feed for reproduction in burbot broodstock.
BUILDING ARMOUR FROM WATER: BICARBONATE UPTAKE FOR CALCFICATION DIRECTLY POST MOULT IN THE WHITELEG SHRIMP Penaeus vannamei

Katharine Clayton1, Trystan Sanders1, Rod Wilson1, Robert Ellis1

1University of Exeter, Streatham Campus, Faculty of Health and Life Sciences
E-mail of lead author: kc530@exeter.ac.uk

Introduction
Whiteleg Shrimp production is one of the most valuable and fastest growing sectors in aquaculture producing 5.5 million tonnes in 2019 (FishStatJ FAO, 2021). This industry is expanding across the world into indoor closed-system production where culture conditions can be carefully controlled. Moultimg is a key process for growth in crustacea, with their exoskeletons typically made up of chitin, calcium carbonate and other hardening elements. Immediately post moult shrimp cease feeding, and their soft shell leaves them vulnerable to predation, cannibalism and disease. To complete hardening sufficient quantities of these hardening elements are required in the culture environment, with their depletion being sub-optimal for exoskeleton hardening efficiency, potentially exacerbating vulnerability in closed aquaculture systems. Our hypotheses are two-fold, firstly that alkalinity in the production environment is a limiting factor for exoskeleton hardening rate immediately post-moult, and secondly, light cycle is a key factor influencing shrimp moult timing.

Materials and Methods
We exposed individual animals to one of three light regimes (12:12, 4:20 and 2:22 dark/light), whilst continually recording their behaviour, to identify moult time in relation to the light/dark conditions. Additionally, we measured post-moult calcification, measuring bicarbonate uptake rate in animals immediately after they had moulted, derived from a one-point titration for alkalinity as a proxy for bicarbonate concentration.

Results
Here we present data on moult timing in relation to light dark cycle, in addition to the uptake rate of bicarbonate and other calcification-related variables at 2, 22 and 24 hours post-moult from shrimp placed in alkalinities ranging from 100 to 2,000 µmol at 20 psu. From this we can report the maximum uptake rate of bicarbonate and the alkalinity at which uptake is most efficient. The data also enable us to identify cumulative uptake of bicarbonate for the hardening process. This provides a bicarbonate budget for Whiteleg Shrimp moulting, as well as evidence for bicarbonate concentration thresholds for successful post moult exoskeleton hardening, vital for improving the health and welfare of indoor intensive Whiteleg Shrimp farming.

Introduction

Turbot (Scophthalmus maximus) is a flatfish species farmed in Southern Europe. Production of high-quality turbot juveniles is paramount to have consistent and profitable aquaculture production. However, there are still some bottlenecks especially at early development stages that could improve hatchery phase cost-effectiveness and improve quality of juveniles: variable survival and growth rates, high dependence on live feeds and high malformations incidence in some batches. In the last decade turbot aquaculture has experienced very little R&D efforts while other flatfish species such as Senegalese sole experienced significant developments, including microdiet quality (Pinto et al., 2018). The knowledge transfer from such R&D developments is perceived as a good strategy to further develop early feeding and nutrition of turbot larvae. Therefore, this work presents two trials which were conducted to evaluate the effect of several microdiets with varying protein and lipid sources on the growth performance and survival of turbot early life stages, in order to create a tailored microdiet.

Material and methods

The first trial aimed at testing different dietary protein sources to investigate an eventual preference in turbot larvae. As such, three microdiets were produced by cold-extrusion and contained increased levels of a specific ingredient: Fish, Squid and Krill meals. Turbot larvae were reared according to standard procedures in triplicate tanks from 23 to 50 DAH (Days After Hatch). Microdiets were supplied using automatic feeders providing 5 meals per day with 1 hours stopping time in between meals, resulting in a 15-hour feeding period. The second trial, aimed at testing microdiets with different lipid sources on the growth performance of turbot larvae. Three diets were also produced by cold extrusion and contained a combination of specific ingredients: Diet 1 (fish oil and algal oil), Diet 2 (fish oil and algal meal), Diet 3 (algal meal). Turbot larvae were reared from 30 to 66 DAH, under the similar conditions as the first trial. Performance parameters evaluated at the end of both trials included wet weight, survival, relative growth rate (RGR) and feed conversion ratio (FCR).

Results

At the end of the first experiment, turbot fed on Squid meal -rich diet presented significantly lower wet weight when compared to turbot fed on the fish meal and Krill meal -rich diets (Figure 1). Furthermore, the Squid group also showed the lowest survival (53.8%) when compared to the other groups (>67.7%). No significant differences were found in RGR (11.9 to 12.3% day-1) and FCR (0.9-1.3). At the end of the second experiment, turbot fed on diet 3 showed significantly lower wet weight than turbot fed on diet 1 (Figure 1). No significant differences were found in RGR (9.0 to 9.5% day-1) and FCR (2.7-3.0).

Discussion and Conclusion

Overall, results clearly show that turbot has a preference for microdiets containing increased levels of Krill or fish meal, whilst squid meal rich diets can have an unfavourable effect on performance. The concept of testing the effect of different protein sources on growth performance was also object of study in other flatfish species including Senegalese sole and Atlantic halibut in this same project. Whilst sole did not show a preference between krill meal, squid meal, fish meal and vegetable protein rich diets (RGR varying from 6.3 to 8.6 % per day and survival from 67 to 83%, unpublished data), Atlantic halibut fed on the Squid meal rich diet showed significantly lower wet weight at the end of the trial (RGR 3.02-3.77% and survival >77%, unpublished data). Moreover, even the optimal diet for sole was giving sub-optimal results for turbot larvae.

(Continued on next page)
As for lipid sources, results of the present paper show that a mix of fish oil and algal oil relate to improved growth performance of turbot larvae, hence being preferable to the inclusion of algal meal alone in the diets. All the reported results ultimately show that turbot have improved growth performance when fed microdiets with specific ingredients and customized formulations. Furthermore, different flatfish have different feeding behaviours and distinct dietary preferences which supports the concept of tailoring microdiets to maximize fish performance and help to produce better quality juveniles.

Introduction
Algae are aquatic organisms that share some beneficial properties with those of land-based plants. They hold an interesting number of bioactive compounds known to have health-beneficial effects. When used in aquaculture feeds, these compounds will reach the gut mucosa and elicit a response that might support gut homeostasis and stability required for good fish performance. β-glucans and sulfated polysaccharides are carbohydrates that, due to their chemical structure, can elicit a defensive response coupled with a stronger regulation of epithelial permeability. These features are essential to support the response to insults in fish under culture conditions. In recent years, there has been a strong effort in obtaining these compounds from algae to access natural sustainable functional ingredients for fish health management. The aim of this work was to screen the functional effects of algae-derived β-glucans and sulfated polysaccharides as promoters of the intestinal mucosa defensive system and homeostasis, based on an Ex vivo model.

Material and Methods
β-glucans from *Euglena gracilis* and a mix of sulfated polysaccharides from macroalgae were tested in *Sparus aurata* intestinal explants. Each ingredient was tested in two dosages (low and high), and the responses were compared with the ones from β-glucans from other sources (e.g. yeast) and to insult-like compounds (e.g. LPS). Intestinal explants were processed following in-house standardized protocols, and after a 5-hour incubation with the ingredients, samples were collected and processed for response analysis. Here, the assessment was based on the molecular response triggered in the intestines following a panel that included genes related to immune (e.g. *cox2*, *IL8*) and antioxidant response (e.g. *cat*, *gpx*), but also related to epithelium integrity (e.g. *tjp*, *cldn12*, *ocl*). Relative gene expression was assessed and provided the basis for ranking the potential of algae-derived ingredients, comparing with responses after incubation with ingredients from other sources.

Results and Discussion
Algae-derived β-glucans promoted a stimulation of the intestinal mucosa comparable with others, and this was mostly highlighted through a differential expression of immune-related genes, and to less extent to epithelial integrity-related genes. A dose-response was not clear for these compounds, whereas, for the sulfated polysaccharides, a higher dosage prompted a stronger response. The latter induced an upregulation in genes related to epithelial integrity and permeability regulation (i.e. *tjp*, *cldn12*) and also in the acute phase response-related gene (i.e. *cox2*). Overall, these algae-derived ingredients have potential as intestinal mucosal health boosters, and further studies will be performed to further understand the beneficial outcomes of the triggered responses. This study highlighted the potential of these algae-derived ingredients as functional ingredients with specific applications in aquafeeds.

Introduction
This joint presentation aims at an intensified dialogue between farmers and conservationists about the shortcomings of the current labelling and enforcement approach for sturgeon products and best strategies to facilitate and improve the traceability of legal caviar.

As a result of the legal protection of wild sturgeons in trade, a massive increased production of sturgeon products from aquaculture was observed over the past 20 years, providing the only legal source for sturgeon products in trade. Nevertheless, wild sturgeons are still poached, and their meat and caviar enter the market illegally and mostly unnoticed. To safeguard the last surviving sturgeon stocks as well as to support the legally operating industry, effective and reliable traceability systems throughout the trade chain are essential. However, current CITES regulations are not sufficient or adequately enforced to detect and stop illegal trade.

An overview of the current gaps in the traceability chain (no marking of individuals, no documentation of transported fish, no labelling on domestic markets, labelling for international trade easy to falsify, no authenticity controls) will be presented.

To support enforcement activities, several experimental approaches are currently available and in continuous development, which include different methods of genetic analysis for the identification of species and interspecific hybrids, analysis of fatty acids for the distinction of animals from aquaculture or from natural environment and isotopic analysis for the geographical traceability of the samples. All these methods have considerable application potential but also have limits and margins of uncertainty which will be discussed in a very general way.

The adoption of strategies that allow efficient traceability and transparency of legal caviar would help limit illicit activities, by limiting the possibilities of using aquaculture to greenwash poaching products. In this perspective, we want to draw attention to two possible strategies that could be adopted to maximize traceability efficiency, facilitate commercial controls and reduce the associated costs.

Genetic references sample storage: As a possible way to minimize any kind of technical ambiguity we would like to explore the possibility of establishing tissue banks for temporary storage of tissue samples from each animal used for caviar production. These banks should be centralized at the national level and supervised by a public authority. Each tissue can be easily collected during caviar processing and would be identified by a code also reported on the boxes of caviar along any repackaging. This would allow the genetic analysis upon request, only of those tissues with the code corresponding to the caviar to be checked. The analyzes would be very simple as it would be a matter of confirming the genetic identity. The approach, however, could be subject to various fraudulent circumvention possibilities which should be the subject of collective discussion to identify the most effective control solutions.

Blockchain database approach through genetic characterization: The second approach is also based upon the genetic analysis of individual profiles of fish based upon SNPs panels, allowing individual assignment of fish to a lineage of broodstock maintained at a farm. The difference to the previous approach is the fact that the test is performed upon identification of sex of an individual, when the fish is marked with an individual code (PIT) that is stored in a blockchain database and that is used to document movements of the fish between farms, providing a record of the performance/location of the fish and is passed on to the products that derive from the individual. The blockchain database is stored centrally, can be used on three different levels of detail: by the farmers to follow up on the stock development, as a documentation for CITES purposes, as well as and for consumer information upon rearing conditions.

The applicability of the methods, along with improved approaches for labelling as a prerequisite for increased consumer safety and enforcement agency information are to be discussed and the advantages for the caviar trade are to be identified in a discussion round, aiming at the identification of preferences and concerns by the industry.
A NEW SET OF FEED ADDITIVES TO PROMOTE FISH FEED INTAKE AND WELFARE IN AQUACULTURE: A COMPARATIVE STUDY ON ZEBRAFISH (Danio rerio) LARVAL AND JUVENILE STAGE

Introduction
One of the main goals of modern aquaculture is the formulation of sustainable aquafeeds, mainly based on alternative protein sources respect to the conventional marine-derived ones. The first widely used alternative was represented by vegetable ingredients which, however, have led to negative side-effects on fish growth and welfare, especially considering many carnivorous species. However, the improvement of processing methods for vegetable meals production as well as the introduction of new and more sustainable alternatives (e.g., processed animal proteins, insect meal, and single-cell proteins derived from cultures of different microbial sources), have partially solved these drawbacks. Nevertheless, the use of alternative ingredients often results in lower diet palatability that can consequently impair fish zootechnical performance, water quality, and the farm’s economy. In fact, not ingested feed remains in wastewater outflows and thus can contribute to the eutrophication of aquatic ecosystems, affecting the company’s economy as well. To improve aquafeed palatability, marine-derived feed attractants are regularly included in aquafeeds. Particularly, meals derived from shrimp, anchovy, and squid are well-recognized feed attractants, but their use on large-scale is still limited by different factors. In fact, they still rely on fisheries activity that poses sustainability concerns and fluctuations in the product availability. Furthermore, their attractive effect is highly variable depending on raw material composition, freshness, and processing methods. The current alternative solution is represented by a limited number of molecules, such as a mixture of free amino acids, nucleosides, and nucleotides, or substances such as betaine and taurine, that can be used as feed attractants. Particularly, amino acids have been widely studied for their attractive properties, although the limitations and disadvantages of their use as feed attractants are well-known. Therefore, a novel, standardized, and sustainable alternative to marine-derived feed attractants is represented by synthetic ones, obtained through standardized processes. Existing literature indicates that few specific studies exist on this topic, which instead represents a great opportunity for the aquaculture sector.

The aim of this study was to identify new different synthetic feed additives, widely used in other industrial sectors, testing them on zebrafish (Danio rerio; ZF) to assess their potential role as feed attractants. ZF represents a well-validated model for aquaculture nutritional studies and allows to investigate possible dietary effects on all its life cycle stages, in a relatively short time.

Materials and Methods
A behavioural screening test was conducted on ZF larvae to select three positive and a negative commercial feed additives (To Be Pharma S.r.l., Stant’Egidio alla Vibrata, Teramo (TE), Italy) within a plethora of 40 ones. The selected feed attractants (positive: B, C, D; negative: E) were then included in a commercial diet for ZF (Zebrafeed, Sparos ltd, Portugal) to be tested from the larval to the juvenile stage. Particularly, the commercially available standard diet for ZF was used as Control, while five experimental diets were obtained by adding the previously selected feed additives to the Control diet (diets B, C, D, and E). All feed additives were added at 1% (w/w) concentration using a micropipette, coating the pellet by mixing homogeneously. ZF larvae obtained from broodstock AB strain were divided to set up seven experimental groups: Control, group A (Control diet + feed additive basic solvent), group B (Control diet + feed additive B), group C (Control diet + feed additive C), group D (Control diet + feed additive D), group E (Control diet + feed additive E), and group F. This last group was fed the three attractive diets (B, C, and D), each administered singularly in a weekly rotation scheme since it has been demonstrated that teleost, in response to a repeated stimulation, develop olfactory receptors habituation to the same stimulus. ZF were daily fed the experimental diets (3% of the body weight) from 5 to 60 days post fertilization (dpf). The required number of fish per tank were sampled at 21 dpf to evaluate dietary effect of feed additives administration during larval development. The remaining fish from each tank were gently transferred to bigger tanks, fed on the same diets and, at 60 dpf, were euthanized to evaluate the long-term dietary effect of feed additive administration on juvenile stage. For both

(Continued on next page)
larvae and juveniles the following analysis were performed: (i) growth performances calculating the specific growth rate (SGR%); (ii) histological analyses to evaluate eventual alterations or the occurrence of inflammatory conditions in both the intestinal tract and the hepatic parenchyma; (iii) molecular analyses to evaluate the relative expression of genes involved in fish growth (igf1, mstnb), appetite regulation (ghrl, npy, lepa), stress response (gr), immune response (il1b, il10, tnfα), and brain reward system (drd1b, drd2a, drd3).

Results and Discussion
Fish welfare was not affected by all the feed additives tested, while considering SGR%, significant differences (p < 0.05) were detected among groups, supporting the fact that the positive feed additives here tested stimulated fish feed intake and thus growth. All these results are well supported by both histological and molecular analysis on fish welfare (immune-response, stress response, gut/liver anatomical architecture) and appetite regulation and showed some interesting analogies or differences between the larval and juvenile stages which will be presented during the research discussion. As regards the analysis on gene expression involved in reward analysed in brain, results evidenced a different activity among groups of the dopamine receptors, the main neurotransmitter involved in the pleasure sensation, suggesting a pivotal role of the tested feed additives in their activation/inactivation. In conclusion, the positive feed additives administration promoted higher feed intake, acting on the fish brain reward system without impairing welfare and represents a very promising result for the aquaculture industry since a faster and complete feed intake by the fish has both ecological and economic benefits for the sector.
Introduction

The ability to coordinate internal biological processes and behavioural response with cyclical environmental variations is crucial for health and survival and has been widely demonstrated from the simple form of bacteria to more complex organization of vertebrate (Bell-Pedersen et al., 2005). As a result, the evolution has selected the existence of endogenous circadian clocks which are an important adaptation to life on a rhythmic planet. Daily cycles of light and temperature are powerful environmental cues and they strongly influence ectotherms’ behaviour, physiology, and habitat distribution (Chapman et al., 2020). Moreover, the light-dark cycles and the daily variations in temperature are directly linked: highest temperature during the day (thermophase) and lowest temperatures during night (cryophase).

Fish, being ectothermic animals, display a thermal preference because water temperature affect and modify their performance by influencing their growth and survival rate.

This study sought to verify that the presence of daily rhythms of thermal preference using an automated system that maintain a horizontal temperature gradient. In fact, in nature, fish experience gradients in water temperature on a variety of spatial scales, e.g., in relation to depth and horizontal position. The species of interest of this study was the black bullhead catfish *Ameiurus melas* which is nocturnal and may have commercial interest.

Materials and methods

According to previous studies (Rey et al., 2015a; Vera et al., 2023), we built 3 multi-chamber tanks in which fish are freely to move across the chambers. An automated system based on Arduino microcontroller (Elegoo Mega R3) recorded the temperature in each compartment and regulated the activation of water heaters in order to maintain a horizontal thermal gradient (from 18 ºC to 26 ºC).

The fish (n=8/system) were subjected to 14:10 h light-dark cycle (LD) which was subsequently reversed to a 10:14 h dark-light cycle (DL), concluding with the constant dark condition (DD) to ascertain whether rhythms are controlled by an endogenous circadian clock (Herrero et al., 2003). The experiment lasted a total of 27 days.

Animals were randomly fed once a day during the night phase and the food was evenly distributed in all chambers. During the DD period the fish were fasted. The light-on time was designated Zeitgeber Time 0 h (ZT 0 h). All experimental phases lasted 10 days except the DD phase which lasted 7 days. Daily temperature preference was established by video analysis of animal behaviour using Ethovision XT software (Noldus, the Netherlands). The videos were recorded by 3 different camera modules connected each to Raspberry Pi (Raspberry Pi 4 model B), remotely controlled for avoiding disturbance to fish during the experiment. Behavioural observation was videorecorded by a custom written Python script based on picamera package (ver 1.13) created for this purpose (RTS-Fish).

Results

We are still analysing the videos and afterwards we plan to analyse the rhythmicity using the El Temps chronobiology software (v.1.291, Prof. Diez Noguera, University of Barcelona, Spain). In agreement with previous works (Vera et al., 2023), we expect to find a daily rhythmicity in thermal preference. The thermal preference could be related to daily changes of environmental temperature that fish experience in the wild, higher temperatures during the day and lower temperatures at night. However, being a nocturnal species, we would expected a reversal scenario in which *A. melas* may select higher temperatures during the night when it is most active and cooler temperatures during the day when it is in its resting phase.

The results may suggest an important cue to design husbandry protocols where fish are kept in captivity (e.g., fish farms). (Continued on next page)

Introduction
Common practices in aquaculture production often include procedures as fish manipulation for triages and transportation, which can act as stressors. Stressed fish are more susceptible to infection, potentially leading to massive losses for aquaculture produces. Hence, stress mitigation strategies, including the development of new functional feeds are on demand. Due to its high protein content and biochemical composition, polychaeta meal (PM) is emerging as a viable alternative to fishmeal and potential functional ingredient to modulate fish immunological system and/or stress response.

The overall aim of this study was to evaluate the potential of PM as a functional ingredient in European seabass diets by assessing its impact on intestinal health, metabolic and immune status, and hepatic oxidative response towards a stress challenge.

Materials and Methods
A growth trial with European sea bass (Dicentrarchus labrax) juveniles (14.5 g) was performed using four isoenergetic (22% dry matter, DM), isoproteic (51% DM), and isolipidic (17% DM) diets. A fish meal-based diet (FM, control) was compared with three experimental diets including 2.5% (PM2.5), 5% (PM5) and 10% (PM10) of spray dried PM (Alitta virens), to replace 10%, 20% and 40% of FM, respectively. All experimental diets were extruded (Nofima, Norway). Homogeneous groups of fish (initial body weight: 14.5g) were distributed by twelve 160 L fiberglass tanks and fed the experimental diets to satiety, three times a day (9h, 12h, and 16h), for 93 days. Triplicate groups were established per diet. The fish were subjected to a 12-h light/12-h dark photoperiod regime and kept in a recirculating saltwater system (salinity 35‰, 22 ± 1 ºC). Upon trial conclusion, fish were weighted and measured and a small part of the posterior intestine was fixed in phosphate-buffered 4% formalin, for histologic evaluation. The remaining fish underwent an acute stress challenge: 1-minute air exposure followed by 5-minute overcrowding. After 1 hour of recovery, plasma and liver samples were collected. Plasma metabolite levels, immune parameters and liver oxidative status of stressed fish were compared to those of non-stressed fish (n = 18).

**Figure 1.** Plasma glucose and lactate of stressed and non-stressed European seabass juveniles fed the experimental diets.

(Continued on next page)
Results
All diets equally promoted growth and ensured high feed efficiency. Posterior intestine health status was assessed by histologic analysis. No statistically significant differences were found among dietary groups concerning submucosa lymphocytes and granulocytes presence and lamina propria granulocytes. However, lamina propria lymphocytes presence was reduced in fish fed PM2.5 and PM10. PM impacted plasmatic metabolic status. Plasma glucose levels were significantly higher in fish fed PM10 compared to fish fed FM, independently of stress (Figure 1). Both the diet and stress condition affected the hepatic redox status. In non-stressed fish the basal GST activity was significantly higher in fish fed PM diets compared to those fed the CTRL, but no differences were observed in stresses fish. Likewise, the glutathione content was highest in fish fed PM2.5 and PM5 before stress.

Upon stress, a significant increase was observed in all biomarkers analyzed, regardless of the dietary treatment. Cortisol, lysozyme and peroxidase levels were not affected by diet. Although basal plasma lactate levels were similar between diets, levels after stress were significantly higher in fish fed PM2.5 compared to fish fed FM (Figure 1). On the other hand, no differences were observed in the hepatic redox status among dietary treatments.

Discussion and Conclusion
Our results suggest that dietary replacement of fishmeal with PM can modulate European seabass intestinal health and acute stress response, although dietary impact appears to be limited to metabolic (glucose and lactate alterations. In the present work, PM10 fed fish exhibited higher glucose levels, independently of stress. Plasma glucose is commonly used as a sensitive indicator of stress in fish. However, the observed increase in this parameter, particularly in fish fed PM10 diets, may be attributed to an increase in gluconeogenesis to provide energy to meet the higher metabolic demands of these fish, independently of stress condition. Cortisol and lactate did not follow glucose increasing trend, supporting the idea that increased glucose in fish-fed PM may be linked to metabolic alterations not related to stress. Furthermore, the metabolic alterations triggered by PM in the hepatic redox status before experiencing stress, including increased activity of glutathione and GST, remain to be explored.

Introduction

Implementing biofloc technology (BFT) has allowed an increase in shrimp culture densities, but at the cost of raising the requirements for dissolved oxygen (DO) in the water of production units, becoming one of the biggest risk factors in aquaculture production. Because BFT systems rely on technologies such as blowers and hydraulic pumps to generate and replenish oxygen in the culture water, the risk of energy outbreaks, generator, or pump failures could lead to a potential drop in oxygen levels, with resulting mortalities in the cultured organisms. The high oxygen consumption in BFT systems depends on several factors such as the density of cultured organisms like shrimp, salinity, and water temperature. Temperature, for example, acts directly on the solubility of gases in water and regulates the metabolism of the animal by increasing or decreasing its consumption over time. Salinity also directly affects the oxygen solubility in water, when salinity increases the dispersion decreases, and when it decreases the portion of DO in water increases. Due to several factors, the oxygen concentration in the water can be depleted, which requires emergency strategies to overpass a lack of aeration, affecting shrimp survival. For this reason, we ran several experiments to test the factors affecting oxygen consumption in biofloc systems and the effect of different re-oxygenation strategies on *P. vannamei* survival.

Material and Methods

The experiments were performed in 20L plastic tanks with individual aeration supplies, placed in thermostatic baths for temperature maintenance throughout the experiment, using total suspended solids (TSS) at 500mg/L, all treatments with three replicates. Dissolved oxygen levels were initially measured in all tanks, and then the air supply was cut off and again measured at 20-min intervals until levels reached hypoxia. Then the survival was evaluated by counting the number of dead animals after exposure to stresses. First, we tested high (30º and 36° C) and low (16º and 22°C) temperatures at different densities (150 and 600 cam/m³), using individuals with an average weight of 15g, to determine the consumption time and survival. Then, we determined the DO consumption time in a *P. vannamei* culture and survival using different salinities (5 and 30‰) and different stocking densities (150 and 600 cam/m³). Finally, we determined the effect of different re-oxygenation methods (hydrogen peroxide and manual aeration) on the survival of *P. vannamei* shrimp in BFT systems. The re-oxygenation was performed in 4 different ways: Abrupt (RA - total reinsertion of DO up to 5 mg/L in less than 20 min), Gradual (RG - DO rising 1 mg/L every 20 min), with hydrogen peroxide (RPH - 7ml/m³) and with hydrogen peroxide powder (RPP) in the amounts indicated by the manufacturer (SwBio). Survival was observed for 3 days after reoxygenation.

Results

The experimental units at a density of 600 reached critical levels faster than those at 150. There was also an increase in the time required for the system to reach the hypoxia scenario considering the temperature of the experimental units. The temperature directly affected survival, which reduced the animal’s metabolism, directly influencing energy output and productivity.

In the salinity trials, the stocking density was the most significant factor in DO consumption. The densities of 600 cam/m³ took about 1h40min at 30‰ and 2h at 5‰ to reach hypoxia, consuming about three times faster the DO than the treatments with a density of 150 cam/m³ that took 4h20min at 30‰ and 5‰. At low salinity, outside its isosmotic point, osmoregulatory stress combined with hypoxia leads *P. vannamei* to a high mortality rate, at a salinity of 5‰ and density of 600 cam/m³, survival was only 29.1%, thus demonstrating that this combination of stress factors is highly detrimental to production.

(Continued on next page)
In the re-oxygenation trials, survival was largely affected by critical oxygen depletion, showing significant differences between treatments. The animals can maintain themselves in the basal state to prevent mortality as long as there is no other problem associated with DO deprivation. The lack of oxygen combined with re-oxygenation is a stressful factor for the animals and may affect their ability to maintain homeostasis and metabolism, directly affecting survival and may have caused mortality when these organisms were exposed to combined hypoxia/re-oxygenation stress.

### Conclusion

Based on our results, we recommend determining a strict protocol for dissolved oxygen management in shrimp biofloc culture systems. Monitoring and maintaining adequate TSS concentrations, animal culture density, and water temperature is also critical. We also emphasize the importance of not letting dissolved oxygen levels go under the value of 2 mg/L. Our data and observations from both experiments showed that the density of the cultured animals and the biofloc in the BFT system can directly influence the consumption of dissolved oxygen in the water, and consequently affect the production performance of the shrimp.

Introduction

The rapid growth of aquaculture requires an increase in aquafeed production, and consequently in raw materials availability. Currently, a change in dietary ingredient basis is already taking place and future aquafeed formulations will rely on novel ingredients, including insects (Glencross et al., 2023), allowing a reduced and strategic use of fishmeal (FM). Over the last years, research on the impact of the dietary inclusion of black soldier fly (BSF, Hermetia illucens) and yellow mealworm (YM, Tenebrio molitor) larvae meals on the growth performance and feed efficiency of European seabass (Dicentrarchus labrax) has increased significantly, but little is known about the inclusion of a mixture of processed BSF and YM protein in diets for this fish species that include low FM levels (Maulu et al., 2022). Thus, this study aimed to evaluate the potential of a processed mixture of BSF and YM protein to partially replace FM in practical diets for European seabass, focusing on the effects on fish growth and feed efficiency.

Materials and Methods

A practical diet (15% FM, 9% processed animal protein sources, and 55% vegetable protein sources) with 46% protein and 19% lipids on a dry matter (DM) basis was formulated and used as a control diet (CTRL). Three other isoproteic, isolipidic, and isoenergetic (23 kJ/g DM) diets were formulated to include 0.5%, 4.3%, and 8.4% of an insect-based protein mixture (50% processed protein from BSF larvae and 50% processed protein from YM larvae), replacing 3% (IM3), 25% (IM25) and 50% (IM50) of FM, respectively. Homogeneous groups of 75 fish (12.9 ± 1.3 g) were distributed among 12 fiberglass tanks of 250 L within a saltwater recirculation system (22 °C, 35‰ salinity, 16 L min⁻¹ flow rate, 12 h light/12 h dark photoperiod), and each diet was randomly assigned to triplicate groups of fish, which were fed until apparent satiety three times daily, for 75 days. By the end of the trial, all fish were individually weighed (g) and measured (total length, cm), and the amount of feed (g) eaten per group was registered. Then, growth performance and feed efficiency parameters, as well as body somatic indexes, were calculated.

![Graph](image)

Figure 1 – (A) Final body weight (FBW) and (B) feed conversion ratio (FCR) of European seabass juveniles after 75 days of feeding with the experimental diets.

(Continued on next page)
Results
After 75 days of feeding, no statistically significant differences were observed among the dietary groups concerning the final body weight (57.5-58.2 g – Figure 1A), weight gain (44.6-45.3 g), daily growth index (2.0 g day⁻¹), feed conversion ratio (1.0-1.1 – Figure 1B), and voluntary feed intake (1.8-1.9% day⁻¹). Fish hepatosomatic and viscerosomatic indexes also remained identical among the dietary groups (1.6-1.7% and 7.5-8.2%, respectively).

Discussion and Conclusion
The results of the present study indicate that a mixture of processed protein from BSF and YM larvae can replace, at least, up to 50% of the FM in practical diets for European seabass, without compromising fish growth, feed efficiency, and somatic indexes. Altogether, these results evidence the great potential of this insect-based processed protein mixture as a FM substitute. Future work will focus on the impact of this mixture on diet digestibility and seabass metabolic status. The functional potential of this ingredient will also be explored.

As seafood demand increases globally, aquaculture production is growing fast and becoming the main source of seafood, but not without facing some sustainability issues. Most challenges in the aquaculture sector today are related to the sustainable use of resources, such as space, water, energy and feed, with the latest probably being the most important resource used in the aquaculture industry.

Feed will directly influence production performance and efficiency but can also indirectly affect water quality if there’s a high feed loss or increased production of faeces, resulting in an excessive organic load in Recirculating Aquaculture Systems (RAS).

SPAROS has been developing nutritional IT tools based on mathematical modelling (FEEDNETICS™ and FiT feeding tables™) to support feeding management. These tools are already being commercialized for gilthead seabream, European seabass, rainbow trout, Atlantic salmon and Nile tilapia, and one of the objectives of the current study is to extend them to corvina. For this, data collected from the scientific literature were processed and used to calibrate the models for corvina. The models were tested with independent datasets and will be further validated for SEAentia’s pilot RAS using data that are being generated in the context of the present study.

Based on the previous knowledge gathered from other fish species, this study set out to gather ground-truth measurements (feed intake and growth) of corvina in real operational conditions, for the purpose of generating data to validate the models. To achieve this, a trial is being carried out at SEAentia’s pilot RAS, with 2 batches being grown with IBW of 0.03g and 50g and fed ad libitum to apparent satiety. All parameters that may affect the factors of interest (e.g., dissolved oxygen, temperature, salinity, pH, photoperiod) and other variables that may correlate with the responses of interest (e.g., behavioural patterns) are being measured and recorded.

This trial is currently ongoing, and we only have preliminary observations, although we expect to have all the data from the trial collected and analysed on time to be presented at the workshop and the updated abstract included in the book of abstracts.

bcp@oceanfoods.org

RAS are in the planning, investment, and development stages throughout the World. RAS have tremendous potential to play a pivotal role in the radical transformation of aquaculture to become a major global food source. However, there are identifiable risks arising. Aquaculture’s modern industrial history is repeating itself in many countries as RAS developments are being denied or delayed due to adverse decisions by less-than-fully informed government agencies and well-funded public interest groups. Both use less than comprehensive, updated, science-based information to deny permits. Both accelerate community opposition to RAS. The GESAMP (2008) Risk Analysis and FAO (2010) Ecosystem Approach to Aquaculture (EAA) are valuable frameworks for use worldwide to move RAS developments forward. These frameworks integrate aquaculture developments into the wider, interlinked, community and bioregional social-ecological systems to promote greater equity and resilience. They account for the full range of stakeholders, spheres of influences, community and educational development contexts, and their interlinkages. Using GESAMP and the EAA, RAS companies can proactively engage communities to identify win-win situations. However, companies need to accelerate their investments to build the expertise and capabilities of grass-roots, aquaculture community organizations to ensure their long-term stability to address the known social-ecological concerns of communities considering incorporating RAS into their futures:

Accelerated non-product investments in these approaches would advance RAS developments in rural communities worldwide so that these high potential systems can contribute more significantly to the urgent needs for the global transformation of food systems as envisioned in the United Nations Sustainable Development Goals (SDGs).

Capture fisheries and aquaculture are researched, planned, and managed throughout the world as if they are independent entities. This ignores their complex and evolving interdependencies. Global attention on “blue foods” is focused on restoration of capture fisheries and sustainable expansion of aquaculture. Such a binary approach does not fit the current realities, opportunities, and innovations in ocean food systems (OFS), and does not integrate knowledge across the professions. Three OFS typologies of American and spiny lobsters as fed fisheries, salmon aquaculture as aquaculture-enhanced fisheries, and eel aquaculture as a capture-based aquaculture.

Typologies illustrate productive, valuable, and evolving OFS which have great potential for accelerating innovations greater than those of capture fisheries and aquaculture alone. OFS increase production and social benefits of blue bioeconomies but are disruptive as they require radically changed science, education, management, and development policies.
INFLUENCE OF GENISTEIN & GENISTIN CONTENT FOUND IN SOYBEAN MEAL AND SOY PROTEIN CONCENTRATE ON GROWTH PERFORMANCE AND ANTIOXIDANT & LIPOGENIC BIOMARKERS IN GILTHEAD SEABREAM Sparus aurata

Introduction
Nowadays, soybean meal (SBM) or soy protein concentrate (SPC) are the most used plant-based protein source ingredients in commercial fish feeds as alternative to partially replacement of fish meal-based diets in carnivorous fish such as the gilthead seabream S. aurata. Both SBM and SPC components contain phytoestrogens such as isoflavones the most abundant of which are the aglycone genistein and its β-glycoside conjugate genistin. The glycoside (genistin) is in greater amounts than the aglycone genistein in SBM and SPC. Literature evidence suggests that the biological activity of soy phytoestrogens does not depend upon the glycoside form. In mammals, for example, hydrolysis of the glycoside is necessary for their absorption and activity in the organism [1, 2]. Studies in fish with exogenous (synthetic) genistein-enriched diets have shown variable metabolic effects on fish depending on the genistein dose administered [3,4]. Besides, there is good evidence that exogenous supplemented genistein in the diet affects lipids metabolism as well as fish overall growth rate, produces estrogenic effects and alters fish antioxidant ability [3,4,5]. This study aims to estimate the impact of genistein and genistin on the growth performance and on the antioxidant and lipogenic mechanisms (enzymes activities) of gilthead seabream S. aurata via feeding on SBM-based and SPC-based diets and applying specific and indicative biomarkers.

Materials and Methods
Genistein (GE) & genistin (GIN) were quantitatively determined in the methanolic extracts of SBM and SPC ingredients by a spectrophotometric method [6]. Three isoproteinic (49.75% ± 0.44%) and isolipidic (17% ± 0.13%) diets were formulated and produced at the IMBBC-HCMR (Anavyssos). The diets were designated as: a soy-free diet (Control), a 20% soybean meal diet (D-SBM) and a 20% soy protein concentrate diet (D-SPC). Three groups of S. aurata with an average initial weight of 27 g were fed on the diets in triplicate groups for two months. The amount of food consumed was calculated during the whole experimental period. At the end, all fish were weighted. Livers were excised, placed in liquid N2 and stored at -80°C till analysis. The specific activities of the antioxidant enzymes [catalase (CAT), superoxide dismutase (SOD), selenium-dependent glutathione peroxidase (Se-GPx)] and the lipogenic enzymes [fatty acid synthase (FAS), malic enzyme (MA), glucose 6-phosphate dehydrogenase (G6PDH)] were determined. All the enzymes activities were expressed in nmoles/min/mg protein. Statistical analysis was performed with the SPSS 13.1.

Results and Discussion
GEN and GIN content was significantly higher in SBC (~621μg/g) than in SPC (~1.6 μg/g). The lower content in SPC could be attributed either to lower content or to the extraction method that was with methanol. Growth indicators are shown in table 1. The antioxidant and lipogenic biomarkers are indicated in figures 1 & 2, respectively.

Conclusions
Findings suggest that soy-based diets with elevated dietary genistein & genistin content such as SBM-based diet could significantly increase weight gain and enhance lipogenesis in S. aurata. Contrary, SBC-based diet could lead to noticeably dysfunction in eliminating ROS production, while SPC-diet could improve antioxidant capability.

Introduction

In shrimp farms, salinity drop in the water due to excessive rainfall has been mentioned to be a risk factor for WSSV outbreaks (Thuong et al., 2016a). It was hypothesized that when WSSV is introduced into the rearing water and a sudden lowering of the salinity occurs, this could lead to an uptake of water through the nephropores into the antennal gland, as shrimp attempt to regulate their haemolymph osmolarity and urinary ion excretion. Once the cells of the antennal gland become infected, the virus infection can spread further into the body. An experimental WSSV immersion challenge mimics a natural water-borne WSSV transmission. Thuong et al. (2016a), performed an experiment in which shrimp were immersed in sea water containing $10^{5.5}$ SID$_{50}$ mL$^{-1}$ of WSSV. Subsequently, these shrimp were subjected to a salinity change from 35 to 5 g l$^{-1}$. After 5 hours, the salinity was restored to 35 g l$^{-1}$. The mortality due to WSSV infection was 53%. There was no mortality in the control group without a salinity drop. This suggested an important role of a salinity drop in the WSSV infectivity during an immersion challenge. However, WSSV is also reported to be transmitted through consumption of infected tissues (Wang et al., 1999). In the current study, we examined the effect of a salinity change on infection and mortality during a per os WSSV challenge, because it simulates natural WSSV infections through cannibalism. By testing these conditions, we aim to investigate if salinity change is also a risk factor for WSSV infection during an oral WSSV challenge in *L. vannamei*. These results could then be used in future work to further elucidate WSSV transmission dynamics.

Materials and Methods

Virus stock production: specific pathogen free (SPF) *Litopenaeus vannamei* were imported as postlarvae (PLs) from the United States of America (USA). Shrimp were housed in artificial seawater at 20 ppt salinity and 27°C ± 1°C. They were injected intramuscularly with the WSSV Thai-1 strain (Escobedo-Bonilla et al., 2005). WSSV positive solid inoculum was prepared from the resulting infected carcasses.

WSSV challenge and salinity drop: The inoculum was used to infect PL76 shrimp through oral route. Briefly, during the experiment, shrimp were randomly divided into three challenge groups (A, B, C) consisting of three replicates of 10 shrimp. Ten shrimp were assigned to a first negative control (Mock1- 15 ppt drop). Another group of ten shrimp served as the second negative control (Mock2 – 30 ppt drop). Shrimp were housed individually in 10L tanks. Shrimp from groups A, B, and Mock1 were acclimatised to 20 ppt salinity, while shrimp from groups C and Mock2 were acclimatised to 35 ppt salinity. The oral infection trial followed a procedure adapted from Van Thuong, et al. (2016b). Group A remained at a salinity of 20ppt during and after the oral WSSV challenge. Individual shrimp from groups B, C, Mock1, and Mock2, were transferred into seawater with a 5ppt salinity. Groups A, B, and C received WSSV positive inoculum, while Mock1 and Mock 2 received negative solid inoculum. After a period of 5 hours, the salinity in the individual tanks from groups B, and Mock1 was restored to 20ppt, while the salinity in the tanks of groups C and Mock2 was restored to 35ppt. The animals were observed in the following days and the experiment ended when no mortality was observed for 48hours. WSSV infection presence or absence in the tissues of collected shrimp was confirmed by qPCR. The survival/mortality data were analysed statistically using the Log-rank (Mantel-Cox) test.
Results
At the end of the challenge trial, cumulative mortality rates in the WSSV-challenged groups A, B, and C were respectively 21%, 33% and 40%. The differences in mortality rates showed a trend between group A, that was not subjected to a drop in salinity, and group C, that was subjected to a 30ppt drop (from 35 to 5 ppt) (p-value = 0.0952). In the two control groups, Mock1 and Mock2, that were subjected to a salinity drop of respectively 15 and 30ppt, all shrimp survived. WSSV infection was confirmed by qPCR in a sample of the dead shrimp. WSSV was absent in sampled survivors and negative controls.

Discussion and conclusion
The results of the experiment showed that the probability or risk of infection in the population increased when the animals were subjected to a salinity drop during an oral WSSV challenge. This result was similar to the results obtained by Thuong et al. (2016a) during their WSSV immersion experiments with the same change in salinity. It suggests that salinity change could indeed be a risk factor for WSSV infection in the field, where natural WSSV transmission occurs both by water-borne or cannibalism routes. De Gryse et al. (2020) argued that this could be explained, because sudden salinity drop during, e.g., heavy monsoon rains, aggression, establishment of social dominance, and feed intake (cannibalism) are conditions where frequent urination, and thus frequent opening of the nephropore, takes place. Subsequently, this could create a window of opportunity for WSSV invasion, making entry via the antennal gland possible (de Gryse et al., 2020).

INTRODUCTION

With global warming, the surface temperature of the Mediterranean Sea has increased by 0.4 °C per decade from 1985 to 2006 (Nykjaer, 2009) and is projected to continue increasing by 2.2 to 3.4 °C until 2080 (IPCC, 2021). Therefore, it is crucial to understand the impacts of this warming on the larval growth of the European sea bass, *Dicentrarchus labrax*, which is very important for both fisheries and aquaculture. In this study, we investigated the larval growth and differential survival of three natural populations: Atlantic (AT), Western Mediterranean (WM) and Eastern Mediterranean (EM) in different temperature conditions.

MATERIALS AND METHODS

The production of the three populations was achieved using three different full factorial design with 30 sires per population and 6, 14 and 13 dams for AT, WM and EM populations, respectively. Until 19 days post-hatching (dph), the populations were reared separately in 2 tanks per population at 13 °C. From 19 dph, the populations were mixed in equal proportions and placed in four thermal environments that mimic the temperatures encountered in the Atlantic (*eAT*, annual average = 13.8 °C, min = 10.4 °C, max = 18 °C), the western Mediterranean Sea (*eWM*, annual average = 16.6 °C, min = 12.6 °C, max = 22.5 °C), the eastern Mediterranean Sea (*eEM*, annual average = 21.7 °C, min = 16.8 °C, max = 27.6 °C) and a temperature generally applied in aquaculture (*eAQUA*, 16 °C until 70 dph, 23 °C from 70 to 120 dph and then an eastern Mediterranean temperature regime). Each thermal regime was replicated in 4 tanks. Twenty larvae per tank were sampled in each regime at six time points corresponding to equivalent developmental stage from an average notochord length of 8.8 mm to an average fork length of 53.5 mm. Larvae were photographed, weighed, and their photos were analyzed with ImageJ to measure the notochord length (until the fourth sampling) and then, the fork length. The population of origin of each larva was recovered by parentage assignment using 96 SNPs with the APIS software (Griot et al., 2020). At around 10 grams, 2000 fish per regime were genotyped and assigned to their parents to evaluate the survival of each population in each thermal regime.

![Graph](image1.png)

Figure 1 – A) Total length (mm) of larval European sea bass populations (AT = Atlantic, WM = Western Mediterranean and EM = Eastern Mediterranean) as a function of age in four thermal regimes (*eAT* = Atlantic regime, *eWM* = Western Mediterranean regime, *eEM* = Eastern Mediterranean regime and *eAQUA* = Aquaculture regime). *** = P < 0.001; ** = P < 0.01; * = P < 0.05; B) Number of fish per population and thermal regime at tagging (~10 g mean weight).
Results

From the fourth sampling (~27.8 mm fork length), the AT fish showed a tendency to be longer than WM and EM fish. This difference became significant (P < 0.01, AT > WM ≈ EM) from the fifth samplings (~40.2 mm fork length) in all thermal regimes. Furthermore, the size advantage of AT was larger in the coldest thermal regimes (eAT and eWM, Figure 1.A). Regarding survival, there was a strong interaction between population and thermal regime (P < 2.2e-16, Figure 1.B), and within each regime, there was a significant effect of population on survival (P < 2.2e-16 in eAT, eWM and eEM regimes). The AT population had the best survival rate in the eAT and eWM regimes while the EM population survived best in the eEM regime. The WM population had the worst survival rate in all thermal regimes. We identified three main periods of time where population-specific mortality may occur through linear regressions of survival on temperature at different stages: between 19 dph and the first sampling (6.6-8.8 mm), between the fourth and the fifth samplings (27.8-40.2 mm), and between the fifth and sixth samplings (40.2-53.5 mm).

Discussion

The results demonstrate the growth of European sea bass is strongly influenced by thermal regimes. However, in terms of growth, we did not observe evidence of adaptation of a population to a specific regime. A local adaptation to low temperatures could explain the better growth potential of AT population than WM and EM populations under the coldest regimes (eAT and eWM). The largest size of AT population in the warmest regimes (eEM and eAQUA) could be explained by the countergradient variation phenomenon, where cold-adapted population may express better growth rates when warmer temperatures occur (Conover and Present, 1990).

The study of survival rate revealed that populations are adapted to their thermal regimes of origin. Specifically, the AT population was the better suited to the coldest regimes in terms of both growth and survival. However, for survival, there was also an adaptation of the EM population to the eEM regime. The WM population had the worst survival rate in all regimes, although it survived better in warm than in cold regimes. These results are consistent with previous research that suggested nonadaptive introgression and maladaptation of the WM population (Guinand et al., 2017).

ATLANTICLAM – BRING EURO-NATIVE CLAM SPECIES FROM ‘FARM TO FORK’

A. Cruz*, E. Guévélou

Oceano Fresco S.A.
Porto de Nazaré
2450-075 Nazaré, Portugal
*Email: andreia.cruz@oceano-fresco.pt

Introduction

As the world population grows, demand for food increases just as much, both in quality and in quantity. Within this context, bivalves which filter-feed on phytoplankton, are the most sustainable source of animal protein. However, few gaps along the value-chain exists that needs to be overcome to increase the shellfish industry standards and to support the production, packaging, and supply of European autochthonous species such as *Ruditapes decussatus* and *Venerupis corrugata*.

The ATLANTICLAM project aims to bring Euro-native clam species from “farm to fork”, in an integrated, differentiated and consumer-oriented perspective, fostering the consumption of sustainable, healthy and tasty food, contributing to tackling climate change and providing a new income source for the blue economy.

The project intends to solve the main obstacles to a wide dissemination and consumption of Euro-native clam species: availability all-year round; difficulty to match production with market demand; lack of trust on the source/origin of the clams; lack of trust on the quality and freshness of the clams; lack of solutions to increase the in-house consumption of clams.

It will be developed by Oceano Fresco and its partners: INL - International Iberian Nanotechnology Laboratory, Faculty of Biotechnology of Catholic University of Portugal,

Nofima

This project has an investment of 1.394.411 EUR and is funded under the Blue Growth Program of the Financial Mechanism of the European Economic Area (EEA) 2014-2021. The EEA (EEA Grants Portugal) financial mechanism aims to reduce social and economic disparities in Europe and strengthen bilateral relations between Iceland, Liechtenstein and Norway and the beneficiary countries.

Material and methods

At ATLANTICLAM project different tasks will be performed in order to impact the clam value chain from “farm to fork”, such as (i) the development of a meticulous and highly scientific selective breeding program, in order to produce more resilient and high-value clam elite stocks (“farm”), (ii) the development of an operations model to ensure efficiency, integration and digitalization of the supply chain (“smart operations”), (iii) the development of a QR-code consumer interface allowing product traceability along the value chain, about the quality, nutritional value and environmental impact of the European clams (“traceability & source”), (iv) the development of new products (chilled clam) and sustainable packaging (“new products”) and (v) the development of new recipes and commercial concepts (“fork”).

Results

At the end of the EUROCLAM project, it is expected to have: 1) an improved breeding program and production optimization of clam elite stocks; 2) a smart model to predict demand and plan the harvesting and supply chain of European clams; 3) a new QR-code consumer interface, with data about all the product chain and source; 4) new chilled clam line up and new sustainable and innovative packaging; 5) new recipes and commercial concepts.

(Continued on next page)
Conclusion

With a consortium between Oceano Fresco, Nofima, INL and ESB-UCP, ATLANTICLAM will strengthen both bilateral relations and international cooperation between Portugal and Norway, sharing know-how and disseminating knowledge across borders.

Acknowledgements

ATLANTICLAM project is funded under the Blue Growth Program of the Financial Mechanism of the European Economic Area (EEA) 2014-2021 (PT-INNOVATION-0097). The EEA (EEA Grants Portugal) financial mechanism aims to reduce social and economic disparities in Europe and strengthen bilateral relations between Iceland, Liechtenstein and Norway and the beneficiary countries.
IS SAND IMPROVING *Ruditapes decussatus* BROODSTOCK CONDITIONING?

T. Nunes¹, C. Tchobanov², D. Pires², A. Cruz³*, E. Guévélou¹, T. Baptista¹²

Introduction

In Europe, in recent years, capture production of clams has decreased due to numerous factors such as overfishing, abiotic stress, diseases, and failure in recruitment. Seed production in hatcheries has become essential to ensure the sustainability of clams production. Thus, artificial broodstock conditioning allows hatcheries to extend their production season, reducing their reliance on the period of the year when wild beds become naturally mature. Also aims to achieve maximum fecundity whilst maintaining the quality and viability of the gametes. Most clam species have been demonstrated artificially conditioned without the need for substrate. However, in nature, clams tend to live buried in the substrate. This study aimed to evaluate the impact of the sand substrate on clams under artificial conditioning.

Material and methods

Adult specimens of *R. decussatus* (39.2 mm ±3.50 mm) were conditioned with and without sand at 19 ± 1°C in flow-through systems and fed with a diet of 3% meat dry weight per dry weight of algae. During conditioning, samples were collected at the beginning (T0) at after 41 days (T1) and after 73 days (T2 - end of the conditioning). To provide information regarding gonad development, condition index, histological analysis, and biochemical composition (glycogen, protein, and lipids) were performed at each sampling time.

Results

Results showed that the use of sand as a substrate did not have any effect on gonadal maturity evolution. Mortality was 56% for the sandless treatment and 59% for the sand treatment. Regarding biochemical composition parameters, it was observed an increase during the conditioning period. Between the conditions (sand/no sand) significant differences (*p*-value < 0.05) were observed in biochemical composition in the end of the conditioning period for the without sand.

Conclusion

The conditioning of *R. decussatus* broodstock did not showed to be improved when sand was used, in comparison with using only water as a substrate.

This work constitutes an important step in the improvement of broodstock conditioning in the hatchery.

Introduction

Fish oil is currently the primary source of omega-3-polyunsaturated fatty acids (ω-3-PUFAs) for the increasingly growing aquaculture feed market, and the Docosahexaenoic acid (DHA) and Eicosapentaenoic acid (EPA) global consumer markets [1]. The total amount of aquatic resources grown or harvested for human consumption (excluding algae) has now set a record of 157 million tonnes [2]. About 1/3 of wild fish stocks are currently overfished, and the remainder of the wild fish stocks are already exploited at maximal sustainable levels [2]. This alarming decrease in wild fish stocks caused by unregulated fishing and its deleterious effect on the marine ecosystem has recently promoted research on alternative sources of these valuable fatty acids [1]. Microalgae are thought to be the primary producers of ω-3-PUFAs in the marine food chain and could therefore serve as a direct source of these nutrients which would help to satisfy the increasing demand for sustainable seafood [3].

Marine protists used in this study can accumulate lipids in the cell as a defense mechanism against various stress factors, and can produce biomass with more than 50% of their cell dry weight as lipids, in which ω-3-PUFAs account for more than 40% [4]. What makes them advantageous over other oleaginous unicellular microorganisms is, besides accumulation of a high PUFA content, their competency for the industrial scale fermentations due to their fast heterotrophic growth and their production of toxins-free oils [5]. Considering the lack of genomic insights and detailed studies on lipid biosynthesis in thraustochytrids, as well as the complexity of stress adaptation, rational genetic engineering of these microorganisms is limited. Also, oils with high PUFA content and other valuable metabolites produced by genetically modified microalgae are still not accepted by the food and pharmaceutical industries in many countries. Therefore, Adaptive Laboratory Evolution (ALE) serves as an effective tool to study the molecular-level response of microorganisms to stress and adaptation and can aid in designing genetic engineering strategies for optimizing microbial production systems and constructing new microalgal strains [6]. In this study, a combined two-stage ALE approach is proposed to obtain a non-transgenic mutant with a potentially higher cell growth/biomass production and stable lipid production (Figure 1).

Aim

To enhance the phenotype of a thraustochytrid strain using ALE, and to identify the possible molecular mechanisms underlying such an adaptation.

Methodology

Adaptive Laboratory Evolution

A two-stage Adaptive Evolution approach was designed and first Evolution experiment was conducted using a high oxygenation stress in the culture medium. UV C mutation was applied to the starting culture at logarithmic phase to increase genotypic diversity of strain. Mutant screening was conducted by analysing cell growth and cell dry weight, as well as by analysing the fatty acid content using Gas Chromatography. Resulting mutant strain will be used in the second ALE experiment.

De novo whole Genome assembly and Transcriptome sequencing

Long-read Nanopore MinION sequencing was used for the whole genome sequencing in conjunction with Illumina NovaSeq 2x150 bp sequencing. Final de novo genome assembly was conducted using a hybrid approach combining high depth Illumina short reads with Nanopore long reads. Additional Illumina NovaSeq 2x150 bp sequencing was used for the RNA sequencing of the reference strain at the three separate growth stages.

(Continued on next page)
Results and Discussion
A two-stage ALE approach was designed and the first Evolution experiment using high oxygenation as a stress parameter showed significant difference in fatty acid content between final mutated cultures compared to control. Resulting mutants will be used for the second evolution experiment. The Nanopore MinION sequencing run produced around 20.3 Gb of data, altogether generating an approximate 450x coverage of the genome. Around 2.5 M reads were generated with an N50 value of up to 11.7 kb. An additional 6.8 Gb of paired-end 2x150 bp Illumina reads were generated, representing approximate genome coverage of 150x. The final Illumina-polished assembly generated with Flye showed improved quality and completeness with >95% sequence identity, 91.09% of complete BUSCO genes and greatly reduced indels to 26.10 per 100 kbp. Additional RNA sequencing of the reference strain in three separate growth stages generated around 130 Million reads. This high-quality data will be used to generate a complete de novo Transcriptome assembly that will be used to for analysing genetic changes in final ALE mutant strains. This will also help to identify the key-genes involved and molecular mechanisms underlying evolution adaptation, and provide novel biomarkers for targeted genetic engineering for metabolic products and pathways of interest.

Conclusions
A high-quality genome assembly and transcriptomic sequencing was generated that will serve as a reference for the subsequent mutant analysis. ALE experiments coupled with further omics-based analysis including transcriptomics, proteomics and metabolomics will allow for deciphering the connection between genotype and phenotype in the evolved strain compared to the original strain.

Introduction
Intensity, frequency and geographic distribution of harmful algae blooms have increased also in areas previously unharmed (Dubois et al., 2010) like the Northern part of the Mediterranean Sea. The toxins produced by these microorganisms can contaminate seafood and represent a potential threat to human health. One of those threats is the Paralytic Shellfish Poisoning (PSP) due to non-proteinaceous paralytic neurotoxins (Tetrodotoxins TTXs), that selectively bind to voltage-gated sodium (Na+) channels interfering with or completely inhibiting the neural transmission in nerve and muscle tissues (Denac et al., 2000; Magarlamov et al., 2017). TTX is commonly present in Tetraodontidae Teleosts, anyway it has been recently reported in several shellfish species. The European Food Safety Authority (EFSA) has specified a concentrations of 44 μg of TTX or TTX analogues equivalents per kg of shellfish meat as maximum threshold for food safety (Knutsen et al., 2017). The elective methods for TTX detections are based on chromatography separations mainly in tandem with MS like LC/MS(/MS) with hydrophilic interaction liquid chromatography (HILIC) or MS/MS and the method of extraction is optimized (Turner et al., 2023) with high sensitivity and low concentrations of TTX (from µg/ml to ng/ml). Anyway the need to expand monitoring plans are requiring analytical efforts to perform an early diagnosis, with a minimal approach also for sample preparation. To meet such requirement for a rapid preliminary screening, an immunsensor assay, based on fluorescence detection, coupled with PocOrEl (Orel d.o.o, SI) analytical devices for the detection of TTX in mussel meat is presented.

Material and Methods
A calibration curve was prepared with TTX (Creative Diagnostic Inc., USA) in buffer acetate and diluted with PBS at a ratio of 1:10 to obtain samples with 80, 60, 40, 20 and 0 µg/L of TTX; data were compared with mussels’ meat spiked with the same amount of TTX to obtain the same absolute TTX concentration. The effect of the matrix in the assay that retrace an indirect ELISA test was evaluated on mussel extract after or without a filtration step through 20µm filters. A black plastic cartridge with a reaction chamber of 35μl volume has been used (Daniso et al., 2020) for immunosensor implementation. The bottom of the reaction chamber is a polyethylene (PE) transparent substrate subjected to a coating with selected organosilane (GPTES) for better adhesion of the TTX-BSA molecule (Daniso et al., 2021). The TTX-BSA (Creative Diagnostic Inc., USA) mix was deposited in the reaction chamber and let to react overnight at room temperature. Subsequently, a blocking step with defatted milk 2% was performed. Then, sample mix, composed of sample and MonoclonalAntibody-TTX (1.5 mg/ml) diluted 1:250 in PBS, was loaded in the well and was incubate at 37°C per 15 min. Afterward, the slides were washed twice to eliminate unbound MAb-TTX to the substrate and 40µl of conjugated PolyclonalAntibody with the florophore Atto 430LS (2 ml/ml) diluted 1:50 was added to the well and incubated as above. After washing twice, the cartridge was left to dry before measurements with PocOrEl (Orel d.o.o, SI) analytical devices. Data were validated with an ELISA assay using a Sunrise (Tecan USA).

Results
The trend of the obtained results for the two sets of samples follows the expectation of a decrease in the signal with the increase of the toxin concentration of sample, and the signals in the two situations are almost equivalent. The analysis carried out with the TTX in PBS provided similar signals in comparison with the data obtained for the spiked mussels samples that contain equal amount of target toxin. The filtration step with a 20 µm filter of spiked homogenized mussels and the dilution of 1:10 of the Acetate buffer used for the extraction resulted a key step. A reduction of the Mab-TTX activity was observed when the raw homogenized mussel meat was used while the filtration step at 20µm reduce the interference of the matrix with the Mab-TTX. The cut-off value of 44 µg/kg of the analysis is marked on the graph with the red arrow; samples that exhibit a number of counts close to the corresponding cut-off figure should be considered as positive.

In conclusion, the presented implemented assay for the Poc-OrEl system (OrEl d.o.o, SI) shows a good discrimination between positive and negative sample even if must be refined, at the moment is limited at the detection of TTX and should be implemented for the analogues compound in order to meet the requirements of extensive monitoring applications.

Introduction
Skeletal deformities affects approximately 40% of the farmed fish produced in Europe, resulting in considerable losses for the aquaculture industry. Microalgae are rich in compounds with innovative bioactivities, in particular osteoactive molecules that hold a great potential toward bone health improvement. The manipulation of nutrients in microalgae culture medium can modulate the production of bioactives of interest. Copper plays a vital role as an essential nutrient for aquatic life, participating in various biological processes such as energy metabolism, antioxidative defense, iron metabolism, and bone growth and development (Cavalletti et al., 2022; Creaser, 1934; Mikulski et al., 2009). Manipulating the copper content in algal cultures leads to changes in the algal biomass (Levy et al., 2007), which, in turn, affects mineralization. This study aims at investigating the effect on the production of osteoactive compounds by manipulation of copper contents in the growth medium for Phaeodactylum tricornutum.

Materials and methods
Ethanolic extracts of P. tricornutum were prepared from cultures grown in increasing concentrations of copper (250-1500 µM), then lyophilized and resuspended in DMSO. The mineralogic activity of the extracts was assessed in VSa13 cells exposed for 3 weeks to culture medium supplemented with 31.6 mg/mL of each extract and in 3-pdf zebrafish larvae exposed for 3 days to system water supplement with the same extracts. Extracellular matrix and operculum mineralization were evaluated after alizarin red S staining and quantification according to Laizé et al., 2022, Tarasco et al., 2017 and Tarasco et al., 2020.

Results
Only ethanolic extracts prepared from microalgae cultured with 1250 µM of copper showed an increase in the mineralization of the operculum (~ 20%), while all extracts increased extracellular matrix mineralization from 26% (Copper 1250) to 69% (Copper control-2.0*10^7 nmol/L), when compared to the vehicle (DMSO). This mineralization increased from the supplementation with 500 nmol to the supplementation with 1000 nmol and then decreases.

Figure 1. Effect of copper manipulated Phaeodactylum tricornutum extracts on (A) operculum mineralization in vivo, n=45 and (B) extracellular matrix mineralization in vitro, n=6. Statistical analysis: one-way ANOVA (**p<0.01; ***p<0.005, ****p<0.001).

(Continued on next page)
Discussion
By testing the ethanolic extracts in two different systems in vivo developing bone and in vitro cell system to evaluate ossification and ECM mineralization respectively. Both approaches have their advantages and limitations. The use of cells provides greater experimental control and the ability to explore specific molecular mechanisms involved in mineralization. However, it requires cell culture techniques and may not fully reflect the complexity of the in vivo environment.

On the other hand, the operculum system allows for studies that closely mimic the natural conditions of zebrafish, but the analysis is limited to this specific structure. These differences can explain the distinct effects observed. The larval operculum mineralization only increased with a copper supplementation of 1250 nmol/L. While, in the VSa13 cells, the control condition exhibited the highest mineralization. This observation suggests a potential correlation with the role of copper in biological responses in mesenchymal stem cells (Burghardt et al., 2015). Nonetheless, further studies are necessary to better comprehend the relationship between the concentration of supplementation and mineralization. In conclusion, the supplementation of 1250 nmol/L showed the most promising results for enhancing mineralization in vivo and potentially for addressing skeletal development and mineralization problems in fish production, such as skeletal deformities.

Introduction

Production of white leg shrimp (Litopenaeus vannamei) experienced decades of spectacular growth. Global production was estimated at around 5.2 million MT in 2021, with a forecasted volume of 6 million MT in 2023. White leg shrimp is an interesting species for the aquaculture industry, due to its high growth rate, with excellent yields. Additionally, shrimp market demand is high, making it interesting for fish farmers to produce and export globally. White leg shrimp are known to have a relatively low feed conversion ratio and environmental impact. Nevertheless, the industry is increasingly faced with challenges, such as increased pressure of diseases. One of the most severe diseases in shrimp industry is early mortality syndrome (EMS). EMS, also known as Acute Hepatopancreatic Necrosis Disease (AHPND) is characterized by high mortalities, in many cases reaching 100 percent within 30-35 days of stocking of grow-out ponds, leading to huge financial losses for farmers. EMS is caused by the toxins produced by Vibrio parahaemolyticus, a bacterium that colonizes the gastrointestinal tract and damages digestive organs such as the intestine and hepatopancreas. Since mortalities are high and bacteria can spread over different farms quite fast, the economic losses are huge. Shrimp-producing countries in South East Asia, such as Thailand, India and Vietnam have experienced significant drops in volumes and export. In Thailand, for example, it is estimated that in the period between 2010 and 2016, EMS has caused financial losses of just under 12 billion dollars and the associated loss of tens of thousands jobs. Recovery from this period is still ongoing, and volumes in some countries in South East Asia are still below that of before the EMS era. Since it is difficult to completely prevent bacterial presence in the water, the focus of the industry is on increasing shrimp resilience through nutrition. One possible solution is the right application of selenium (Se) in the diet. Se plays an important role in preventing oxidative stress in humans and animals, as it is part of the selenoenzyme glutathione peroxidase. Deficiencies in Se are often followed by decreased growth performance, and an increased susceptibility to diseases. In the battle against diseases like EMS, Se addition can be an important strategy to increase shrimp resilience, with decreased mortalities as result. For the addition of Se to the diet, various forms can be used. In general, it is accepted that organic Se in the form of L-selenomethionine is the only form of Se that can be stored into animal protein. All other forms of Se, such as inorganic sodium selenite or selenocysteine present as part of the organic Se in selenized yeast, cannot be stored into animal protein. Therefore, L-selenomethionine seems the preferred source to provide a safe deposit of Se inside the animal, ensuring an optimal Se status also during disease challenge. The goal of this experiment was to compare the effects of adding organic Se, in the form of L-selenomethionine to the diet and inorganic selenium, in the form of sodium selenite, on the antioxidant capacity, immune status and resistance against a Vibrio parahaemolyticus challenge.

Material and Methods

The animal experiment was conducted at Kasetsart University, Bangkok, Thailand. To investigate the effect of different sources of Se on white leg shrimp, three diets were created and fed in 6 replicates with 25 shrimp per repetition: 1) Control diet, a basal diet without added selenium; 2) Diet SS, control diet + 0.5 ppm Se from sodium selenite; 3) diet SM, control diet with + 0.5 ppm Se from L-selenomethionine (Excential Selenium 4000, Orfà Additives B.V.). Shrimp were fed one of the three experimental diets for 8 weeks, after which 30 shrimp were randomly selected from each treatment and immune and antioxidant parameters were measured. After the feeding trial, a challenge with Vibrio parahaemolyticus was conducted. Over the following period of 15 days, mortality was measured and, after the challenge period, immune and antioxidant parameters were once again measured. All generated data were analyzed using one-way ANOVAs.

(Continued on next page)
Results and Discussion

Immunity and antioxidant capacity at the end of the 8 weeks feeding trial, showed improved health status of the shrimp for both treatments where Se was added to the diet. L-selenomethionine, compared to sodium selenite addition, showed a higher improvement in immune and antioxidant status of the shrimp. Superoxide dismutase (SOD), lysozyme activity and hemolymph protein levels were all shown to be significantly highest in animals fed the diet with L-selenomethionine ($P<0.05$). Besides, phenoloxidase activity showed a numerical improvement after addition of L-selenomethionine. On the other hand, hemocyte count and glutathione peroxidase (GPx) were unaffected by addition of Se, regardless of the source. Bacterial count before the challenge was shown to be the lowest in the shrimp fed diet SM, indicating shrimp on this diet have a better defense against the bacteria in an unchallenged environment (Table 1; $P<0.05$). Consequently, increased survival in unchallenged shrimp was observed for diet SM, showing the highest survival after 8 weeks (85.33%), followed by diet SS (83.33%) and control (77.33%) ($P<0.05$). After the *Vibrio parahaemolyticus* challenge, changes were visible in the health status of the animals, lysozyme activity and SOD were significantly improved by addition of L-selenomethionine. Other immune parameters were numerically improved by the addition of L-selenomethionine. Se addition significantly decreased the *Vibrio* count in the shrimp, with L-selenomethionine being significantly more effective compared to sodium selenite (Table 1; $P<0.05$).

After 15 days the survival of shrimp fed the diet with L-selenomethionine was significantly higher compared to the shrimp fed the diet with sodium selenite or without added Se (Figure 1; $P<0.05$). The results of survival after challenge demonstrate the increased defense capability of shrimp by addition of L-selenomethionine.

Conclusion

Addition of Se in shrimp diets seems to be of vital importance to maintain productivity in a global sector with increased disease pressure. Se is seen to improve the overall health status of animals by improving immunity, antioxidant capacity and survival of challenged and unchallenged shrimp. L-selenomethionine was shown to be highly effective in increasing shrimp health and disease resilience, compared to sodium selenite, indicating that L-selenomethionine, is a better solution for the shrimp feed sector.
MUSSEL (*Mytilus galloprovincialis*) BIOMETRIC AND BYSSUS PERFORMANCES AFFECTED BY PROLONGED HEAT WAVES

Introduction

According to the predictive models, in the near future, the heat waves (HWs) will increase their duration up to 30 days, with negative consequences for the shellfish farming sector. Nowadays the farmers are facing the loss of mussels which come off the socks when the water temperature increases. In order to figure out the physiological mechanism behind these events and what to expect in the future, this study simulated an exposition of mussels to a prolonged HW. Morphometric indices, byssus quantity and quality through analysis of the fiber morphology were assessed.

Materials and Methods

260 specimens of farmed *M. galloprovincialis* reared into 12 aquaria were divided in two groups: the control one at temperature of 20±0,5°C and the heat wave exposed group at 28±0,5°C. Mussels destined to byssus mechanical analysis, will be placed on square of polypropylene (PP) film in order to simulate the attach to PP socks used in farming.

At 3, 5, 10, 30 days exposure, mussels were sampled in both groups to determine the biometric indices of animal weight, wet and dry soft body and shell weight, the condition index (CI), meat yield (MY) and hepatosomatic index (HSI), clearance rate (CR), survival at air exposure. At final sampling time (30 days), byssus quantity and quality of the animals attached to PP, was evaluated by analysis under SEM observation.

Results and Discussion

About biometric indices, significant differences were found for hepatosomatic index, clearance rate and survival at air exposure where the lowest values were reported by the exposed group at the end of trial. For the HSI, the exposed group at 30 days of exposure showed a significant reduction in the digestive gland energy reserve, compared to other time points. Although, the heat wave reduced the energy reserve of the stressed group but only in long-term and did not alter the pulp yield. Moreover, the exposed group, after 5 days, started to filter at a rate significantly lower than the beginning and the control group, a sign of metabolic activity decrease. Concerning the survival at air exposure, the exposed group, at the end

![Fig. 1](image-url)  

Fig. 1: Mussel HSI (A), CR (B), survival at air exposure (C), quantity of byssus filaments produced on PP plates at 30 days (D). The uppercase letters (A,B) represent significant differences in two-way ANOVA (P < 0.05) between the groups. Lowercase letters (a,b) stand for significant differences between times for the same group.

(Continued on next page)
of thermic stress period, revealed a significant reduction in the capacity to survive compared to the other samplings and group. It proves that the prolonged heat wave has made these animals more susceptible to additional stress input (Fig. 1). Counting the byssus filaments, at 30 days of experiment, produced by the animals attached on the PP plate, it was found that exposed specimens made significantly fewer filaments, less than half of the other group. Probably, stressed mussels did not have enough energy to spend for the byssus formation (Fig 1D).

**Conclusion**

Prolonged heat waves cause a reduction in the quality of the mussel as a food product, not in terms of loss in pulp yield, but animal energy reserve and the shelflife of a product that has to be sold alive: in fact, this thermic stress reduces the survival duration outside the sea. Moreover, with the reduction in byssus filaments, stressed animals are able to detach more easily from the socks under the force of the currents, with the risk for the farmers to lose a great quantity of product.

COMPARISON OF FARMING TECHNOLOGIES FOR MANILA CLAM SPAT PRE- FATTENING

A. De Marco*, L. Aguiari†, E. Scarpa†, R. Urbini‡, S. Natale*, A. Bonaldo*

*Department of Veterinary Medical Sciences, University of Bologna, Bologna, Italy

Introduction
In the Italian production systems of Manila clam there are no standard management guidelines. It is essential to define which system is more efficient and productive, especially for the pre-fattening phase of clam spat. For this purpose, different supports were tested, evaluating which allows a greater growth of the seed.

Materials and Methods
Three different pre-fattening systems for the Manila clam spat were tested at the NaturEdulis company from April to July 2023.

Spat (4.68±0.53 mm length) was placed in 1) net lanterns suspended in superficial sea water of Goro lagoon (FE, Italy), with a mesh size of 1.5mm; 2) poches suspended in less superficial sea water, with a mesh size of 1.9mm; 3) land upwelling tanks in the company hatchery. During four sampling points, one per month, growth/performance parameters were monitored. 30 clams were sacrificed, in the aquaculture laboratory of the University of Bologna, to evaluate the length, width, height, individual total weight, wet and dry flesh and shell weight, condition index (CI), the specific growth rate (SGR) (ln weight 1-ln weight 0/interval time*100) and the daily shell increment (DSI) (shell length1 –shell length0 / duration of the experiment*100). At the beginning and the end of the trial, clearance rate also was assessed for each support (CR).

Moreover 3L of sea water from the different pre-fattening sites were collected in bottles in order to analyze the concentration of the A chlorophyll (Chl).

Results and Discussion
The most interesting results can be found in the length and total weight. In fact the clams increased the length significantly during the time in each support, following the chlorophyll trend (Fig. 1A). During May and June (2-3 time sampling) the A chlorophyll concentration do not show significant difference between the supports. However, a significant increase can be found during all the months for each support collocation. Finally the high Chl values in lantern can have contributed to the best performance of clam grew in this support, on the contrary for the upwelling tank system. Despite the clearance rate capacity by clams was no different between the support (Fig. 1B), it is possible to notice the difference in the animal growth. Making a comparison between the supports at the same time, in the second sampling clams from poche support had the shorter length and at the third time this situation appeared for the clams from upwelling. At the end, poche and upwelling supports showed the same length, different from the longer clams from lanterns (Fig. 1C). There is not the same significant trend for the weight values. It is possible observe that the weight in the poche. Comparing the supports, in the end, the clams in the lanterns had the greatest weight (different from upwelling and the smallest poche) (Fig. 1D). The condition index results indicate that the clams in the poche did not increase the CI during the months. At the end, this support maintained the same initial CI value, that is the smallest between the supports (no significance for lantern and upwelling) (Fig. 1E).

Conclusion
Observing the different growth parameters, the lantern seems to be the best support that can provide a faster growth and good performance of the Manila spat. On the contrary, the poche was not an efficient system, maybe due to the massive biofilm that was forming around the mesh, avoiding a sufficient water flow.

Introduction
Live food consumptions in the feeding regimes of marine fish larvae have been decreased considerably during the last decades, making the producers less reliant on the success of rotifer cultures and reducing the amounts of Artemia that are being used. A lot of progress has been made in diet formulations and production techniques, proving that early starter feeds are accepted well by marine larvae as soon as mouth opening occurs. In the meantime, quantities of live feed consumed during larval rearing have been reduced considerably. Despite these improvements, excluding completely the live preys from the menu does not result in successful larval production for any of the commercially most important marine species.

As nutrition has a large impact on fish gut mucosal health status, larval mucosal architecture and microstructure, larvae were examined through histology to evaluate diet-induced alterations. Additionally, transcriptome analysis by 3’ end RNA-sequencing of pools of larvae was conducted to perform an in-depth analysis of the impact of live food deprivation on the fish larval health status. Fish growth and survival were evaluated as ultimate outcomes.

Materials and methods
Test set-up
Nearly hatched seabream larvae, originating from the same pool of eggs, were stocked at a density of 100 larvae per liter in 390L tanks. Seawater was provided through a semi-closed water renewal system at a temperature of 18±1°C. Dissolved oxygen levels were kept around 100% saturation. Larvae were reared under green water conditions. A standard live food regime (LFC) was compared to a treatment where no live food (No LF) was introduced, providing a special early start-feeding diet from the onset of exogenous feeding.

Weekly biometrics
20 Larvae per tank were sampled every week and controlled for Standard Length (SL).

Histology
6 Larvae per group were sampled at 20 and 35dph for histological analyses of the posterior intestine (PI). Whole larvae were fixed in Bouin’s fixative and stained with May-Grünwald/Giemsa. PI folds height, width and enterocyte height were measured.

3’ end RNA-sequencing
270 Larvae were sampled from the 2 experimental groups (LFC and No LF) at 20dph. Larvae were washed with PBS, proceeding with RNA extraction with Genezol. RNA concentration, purity and integrity were checked before proceeding with the RNA sequencing. A bioinformatic pipeline was applied to statistically analyze differentially expressed genes (DEGs) and assess enrichment of Gene Ontology (GO).

Results
The weekly length measurements showed very early significant differences between the No LF and LFC groups and the last survivor in the No LF group died at 36dph, indicating the poor biological performance of the latter.

Histomorphometric analyses of distal intestine from larvae at 20 and 35 dph revealed significantly shorter and narrower villi, and shorter enterocytes in the No LF compared to LFC treatment. Nevertheless, no coarse histological damages were visible in the gut mucosa in the No LF group.

(Continued on next page)
RNA sequencing performed on pools of larvae at 20 dph highlighted 486 Differentially Expressed Genes (DEGs) between both groups: 260 and 226 were down- and up-regulated, respectively, in the No LF treatment compared to LFC. Based on statistical significance and extent of gene expression change, the absence of live food resulted in the disturbance of many Gene Ontology biological processes such as lipid transport, proteolysis, immune response, glycolysis and cartilage development.

**Conclusions**

This study indicates the types of biological processes that are highly influenced when the live food is removed from the standard larval feeding protocol. Live food remains fundamental, ensuring proper development and growth of gilthead seabream larvae and assesses its efficacy as a naturally derived functional feed.

Introduction
The life cycle of most teleost fishes embraces a crucial phase known as larval period, during which larvae undergo many evolutionary events (e.g., start of the exogenous feeding, the yolk-sac reduction and the inflation of the swim bladder) that chiefly affect their morphological, behavioral and physiological status (Urho, 2002). Those changes appear to have a different impact on the performance (often referred to as quality) of fish larvae (Kjørsvik et al., 2003). Among others, growth-related traits have been commonly used as parameters to assess larval quality and were reported to significantly vary between the specimens even of the same cohort (Mun et al., 2019; Wang et al., 2021). Despite that, mechanisms and factors leading to different performances during the early life history of fish are largely unknown. Therefore, using a family-based experimental approach, we intended to thoroughly investigate the relation between zootechnical and transcriptomic profile of Eurasian perch (Perca fluviatilis) larvae in order to gain deeper insight into the developmental processes influencing larval quality.

Material and methods
Sixteen unique families of Eurasian perch were created by controlled reproduction. Eggs were fertilized in vitro using cryopreserved semen (Judycka et al., 2022), and then incubated in a recirculating aquaculture system (RAS). The hatched larvae were reared for 30 days following the standardized procedure described by Palińska-Żarska et al. (2020) and during the larvicultural period several zootechnical data were collected (e.i., length, weight, swim bladder inflation rate, cannibalism rate, mortality). In addition, larvae at mouth opening stage (right after hatching) were sampled for transcriptomic analysis. Obtained RNA-sequencing data were mapped to the reference genome P. fluviatilis and later processed with Weighted Gene Coexpression Network Analysis (WGCNA) using a R package (Langfelder & Horvath, 2008). Gene ontology (GO) enrichment analysis was carried out using ShinyGO (Ge et al., 2020).

Results
The analysis revealed statistically significant differences (p < 0.05) between families for length and weight at hatching and throughout the rearing period (first feeding, oil droplet reduction, weaning and at the end of the larval period), cannibalism rate, mortality and specific growth rate (SGR). There was no significant difference for the swim bladder inflation effectiveness (SBIE).

WGCNA of RNA-seq data showed interactions between genes (grouped in different modules according to their Pearson correlation) and the zootechnical data collected. There were significant modules related to weight at mouth opening, cannibalism and mortality but mostly to the length at mouth opening. Specifically 5 modules were positively correlated to length at mouth opening and 3 modules were negatively associated to it. We found that in positively length-related modules, ribosome biogenesis, translation processes, rRNA processing were most enriched biological processes. On the contrary, in modules negatively correlated to length, the most enriched processes included neurogenesis, neuron projection development, cell-cell signalling, cell projection and cytoskeleton organization.

(Continued on next page)
Discussion
Here, for the first time, we attempted to explore differences in larval performances by comparing 16 different families in Eurasian perch. WGCNA highlighted the importance of length data at hatching and the results indicate candidate genes and biological processes providing ground basis for understanding mechanisms leading to length heterogeneity in fish. Ribosomal proteins (RP), such as rps19 and rps6, being positively correlated with the length of newly hatched larvae, are suggested as potential biomarkers in controlling larval development. Furthermore, the analysis outlines a negative link between genes related to cytoskeleton, nervous system and the length trait. During the early life stages, larvae are still evolving and genes involved in the formation of the cytoskeleton and axon growth could play a crucial role in larval performance. In this context, IQ motif containing GTPase activating protein 2 (iqgap 2) gene could largely influence the early developmental stages of larvae (Fang et al., 2015).

The outcomes of our study provide new insights into the processes involved in the determination of larval quality and propose WGCNA as a robust approach to investigate the transcriptomic profile of Eurasian perch larvae.

Introduction
The mineral zinc (Zn) plays an important role in several physiological functions of shrimp and therefore it is important to know the minimal dietary Zn requirement for shrimp. The bioavailability of Zn, and therefore the requirement, may depend on the Zn source used in feed supplementation (i.e. organic Zn vs inorganic Zn). To date, more than 17 studies reported Zn requirements of 4 shrimp species, of which more than 10 focussed on *Litopenaeus vannamei*. Despite, an overall consensus is lacking on dietary Zn requirement of *L. vannamei* as these study results were highly variable and recommendations range from 15 to 261 mg Zn/kg diet (Bharadwaj et al., 2016; NRC, 2011; Pan et al., 2022; Shi et al., 2020). This study thus attempt to determine the minimal dietary Zn requirement of *L. vannamei* using a meta-analytical approach.

Methodology
Data from published and unpublished studies including a Zn dose-response experiment with *L. vannamei* and at least three dietary Zn levels were collected. Ten studies were selected based on these criteria. Two data sets were created depending on the Zn source (organic vs inorganic). Selected data were standardized prior to the meta-analysis to eliminate inter-study differences due to initial shrimp sizes, magnitudes of growth, and trial duration. For example, weight gain (WG) data were normalized using the following equation; relative weight gain (%) = actual weight gain of the group/maximum weight gain in the given study × 100. Meta-analysis was done using the linear plateau (LP) model (Prabhu et al., 2013). In case the LP model did not fit, a linear regression model was applied. The analyses were done on different response criteria; WG, whole body and hepatopancreas Zn, and Zn deposition (%).

Results
The meta-analysis showed that minimal dietary organic- and inorganic-Zn requirements were 72 and 104 mg/kg diet, respectively, to attain maximum WG (Fig. 1).

Among 10 studies, 5 studies reported whole body Zn (wet weight) and there was a positive linear correlation with dietary Zn levels (R² = 0.49, P < 0.001). Only 3 studies reported Zn deposition (%) and a negative correlation was observed (R² = 0.89, P < 0.001). Three studies reported hepatopancreas Zn, but no specific relation was observed (R² = 0.02, P > 0.1).

![Graphs showing weight gain vs Zn levels](image)

Fig 1. Minimal dietary Zn for *Litopenaeus vannamei* (organic Zn source left graph and inorganic Zn source right graph) estimated using a linear plateau model based on weight gain. Different colors in the graphs indicate different studies.

(Continued on next page)
Discussion
All studies used WG as a response criteria to estimate minimal dietary Zn requirement of shrimp. The meta-analysis showed that the estimated minimal dietary organic- and inorganic-Zn were respectively 32% and 60% lower than the maximum values reported in literature. The large differences in WG as well as Zn requirements among studies could be a results of different factors like differences in environmental and dietary factors. Diet composition may have an impact on Zn requirement; for example, presence of phytate may increase Zn requirement of shrimp (Davis et al., 1993). Due to a low number of studies it was however not possible to test this in the current meta-analysis.

Apart from WG as response criteria, some studies also looked at whole body and hepatopancreas Zn, or Zn deposition (%). However, estimation of minimal dietary Zn using these criteria was not possible in the current meta-analysis due to the low number of studies.

This meta-analysis showed dietary organic- and inorganic-Zn requirements of 72 and 104 mg/kg respectively for L. vannamei. The number of studies used in this meta-analysis was less to draw an absolute conclusions. Further studies determining the minimal dietary Zn requirements of L. vannamei are therefore suggested.

RECORDING DISEASES AND BIODIVERSITY OF EUROPEAN FLAT OYSTER
(Ostrea edulis) IN THE BELGIAN PART OF THE NORTH SEA: OPPORTUNITIES AND
CHALLENGES FOR RESTORATION AND SUSTAINABLE AQUACULTURE

Introduction
The European flat oyster Ostrea edulis is one of the most appreciated mollusks due to its gastronomic, cultural and environmental value, and plays an important role in the marine ecosystem through, e.g., its reef-forming capacity. Despite its historical and ecological importance, flat oyster reefs have completely disappeared from the Belgian part of the North Sea (BPNS). Next to overexploitation and habitat destruction by bottom fisheries, diseases caused by Bonamia and Marteilia parasites contributed to the demise of oyster populations. To evaluate the feasibility of restoring and cultivating flat oysters, within the H2020 UNITED project we started a demonstration project inside a Belgian offshore wind farm. The goal of this study was two-fold: On the one hand to determine the status of flat oysters introduced in the BPNS and their offspring regarding bonamiosis and marteiliosis, and on the other hand to characterize the fouling biodiversity associated with flat oysters.

Methodology
Flat oysters implemented were initially certified Bonamia and Marteilia free and originated from Norway (adult oysters) or from England (oyster spat). After six months to two years, these oysters, and their offspring, were sampled (N = 356) during late spring (May – June) or autumn (September – October) from both nearshore and offshore sites within the BPNS. The associated fouling biodiversity was also sampled and taxonomically identified in situ and in the lab.

Each oyster sample was split in two, one for histology analysis and the other for Real-Time PCR analysis. Only in case oysters tested positive for the detection of Bonamia sp. or Marteilia refringens parasites through qPCR, the histologic slides were further analyzed.

Results & Discussion
In none of the tested flat oyster samples, Bonamia or Marteilia parasites were detected, while the control samples were positive. This is the first time these oyster diseases have been monitored in the BPNS, allowing to demonstrate disease-free status, which is a promising result for oyster restoration and cultivation projects envisaged in the BPNS. Nonetheless, other diseases might be present or emerge in this new oyster population. Thus, it is crucial to continue monitoring by checking health status via histology and qPCR, especially if mortality occurs.

A high species diversity was associated with flat oyster habitat, including other reef-forming species such as the Ross worm Sabellaria spinulosa. However, also high densities of tube-dwelling amphipods such as Jassa spp. and Monocorophium spp. were recorded, posing challenges to offshore aquaculture.

Conclusion
This research is a first, but necessary, step to pave the way for the restoration and sustainable aquaculture of the once abundant flat oyster in Belgium. When situated inside an offshore wind farm, the combination of restoration and aquaculture can be a prime example of sustainable marine multi-use. Furthermore, the restoration of flat oyster reefs brings back a lost habitat with its associated biodiversity and ecosystem services and helps to appreciate again the cultural, ecological and economic value of this once so-important species.
INDOLE SIGNALING, A PROMISING TARGET TO CONTROL VIBRIOSIS IN AQUACULTURE

Tom Defoirdt*, Shanshan Zhang, Xuan Li, Qian Yang

Center for Microbial Ecology and Technology
Department of Biotechnology
Ghent University
E-mail: Tom.Defoirdt@UGent.be

Introduction
Diseases caused by pathogenic vibrios cause major losses in aquaculture. The use of antibiotics in order to control these infections has led to the development and spread of antibiotic-resistant pathogens, rendering antibiotic treatments ineffective and causing problems for food safety (Defoirdt et al., 2011). Therefore, novel methods to control vibriosis are needed. A promising alternative is the interference with quorum sensing, bacterial cell-to-cell communication (Defoirdt, 2018). Recent research has shown that indole controls virulence-related phenotypes in pathogenic bacteria and indole is one of the cell-to-cell signaling molecules produced by vibrios. Consequently, we aimed at investigating the interference with indole signaling in order to control vibriosis in aquaculture.

Results and Discussion
We found that indole controls several virulence-related phenotypes in vibrios, most notably biofilm formation and motility. Further, we found that the addition of 100-200 µM indole decreases the virulence to aquatic organisms in all marine vibrios studied thus far, including V. anguillarum (in sea bass), V. campbellii (in brine shrimp and giant river prawn), V. crassostreae (in blue mussel), V. parahaemolyticus (in brine shrimp) and V. tasmaniensis (in blue mussel) (Li et al., 2014; Yang et al., 2017; Zhang et al., 2022c; Zhang et al., 2022d). At these concentrations, indole did not affect the growth of the vibrios. This is important because it indicates that there will be a lower risk for the spread of resistance against the virulence-decreasing effect of indole signaling when compared to antibiotics.

Given the fact that indole signaling controls the virulence of Vibrio species, we have been searching for more potent indole analogues to control vibriosis. Indole analogues are widely present in nature (Lee et al., 2015). Most notably are the auxin plant hormone indole-3-acetic acid and its precursors such as indole-3-acetamide and indole-3-acetonitrile (Zhao, 2010). Indole-3-acetic acid has been shown to decrease biofilm formation and motility of V. campbellii, V. harveyi and V. parahaemolyticus strains at 200 µM and to protect brine shrimp larvae from these pathogens when added at 400 µM to the rearing water (Zhang et al., 2023). The auxin precursors indole-3-acetamide and indole-3-acetonitrile were shown to have a similar effect as indole-3-acetic acid, with indole-3-acetonitrile being active at a relatively low concentration of 10 µM (Yang et al., 2017; Zhang et al., 2022b). Interestingly, auxins are not only produced by terrestrial plants, but also by algae and seaweeds (Stirk et al., 2004; Lin et al., 2022). Hence, micro-algae and seaweeds could be interesting sources of auxins to control vibriosis in aquaculture.

In addition to natural indole analogues, we have also studied synthetic derivatives. A first group of derivatives are indene, 2,3-benzofuran and thianaphthene, in which the N atom of indole is replaced by C, O and S, respectively. All three of these compounds were found to increase the survival of brine shrimp larvae challenged with V. campbellii to around 80% or more when added to the rearing water at 200 µM. Further, they significantly decreased swimming motility, but had no effect on biofilm formation. A second interesting group of indole analogues are halogenated indoles. We investigated the impact of 31 halogenated indoles on V. campbellii (Zhang et al., 2022a). None of the compounds affected growth of V. campbellii for concentrations up to 200 µM, whereas 10 compounds increased the survival of brine shrimp challenged with V. campbellii to over 80% when added to the rearing water at 20 µM, and 5 compounds (6-bromoindole, 7-bromoindole, 4-fluorindole, 5-iodoindole and 7-iodoindole) did so when added at 10 µM. All of these compounds decreased swimming motility of V. campbellii at 10 µM and most of them inhibited biofilm formation at 100 µM.

In conclusion, we found that indole signaling controls the virulence of all vibrios we have tested thus far in different host organisms (fish, bivalves and crustaceans) and we identified several indole analogues that are highly effective in blocking the virulence of vibrios. These results indicate that indole signaling is an interesting target for the control of vibriosis in aquaculture.

Introduction

The sustainable development of European seabass aquaculture strongly depends on the ability to control the epidemics that can impact farms. For open ocean farms, one of the main threats is viral nervous necrosis (VNN) caused by the NNV virus which can cause up to 90% mortality. A bacterial pathogen, *Vibrio harveyi* is also considered a highly problematic pathogen across species, including seabass. The mortality caused by *Vibrio harveyi* can reach 50% in case of an outbreak. The French seabass breeding and hatchery industry is now leading the application of new selection methods, notably by being the first in Europe to have implemented genomic selection in this species.

In this study, we obtained whole-genome sequences (WGS; NovaSeq sequencer, Illumina) of sires and/or dams from several selection cohorts which enabled us to perform fine-mapping of QTL regions for VNN and *Vibrio* resistance. GWAS was performed for each population and each resistance phenotype separately, using a Bayesian sparse linear mixed model (BSLMM) with GEMMA software. The most interesting SNPs from each QTL identified by these models were integrated into a panel of SNPs genotyped with the Agriseq technology, in order to evaluate to identify to the effect of these candidate variants in the next generation of fish, for the two diseases studied.

Materials and methods

A total of 5799 European sea bass (*Dicentrarchus labrax*) from two French breeding companies, EMGi and FMDS, were used in a first study (S1), to analyze VNN resistance. In a second study (S2), 3498 European sea bass (*Dicentrarchus labrax*) from the French breeding companies EMGi was used to analyse resistance to *Vibrio harveyi*. To study survival, all offspring were experimentally challenged to VNN in S1 and to *Vibrio harveyi* in S2. Both challenges were performed at the SYSAAF-ANSES Fortior Genetics platform (ANSES, Plouzané, France) to assess resistance by enumerating dead or surviving individuals. All challenged individuals were genotyped on the ThermoFisher 57K DlabCHIP SNP chip (Griot et al., 2021). The whole-genome of the sires and/or dams used in the crosses of the commercial populations were sequenced, on a NovaSeq sequencer (Illumina), in order to identify all genetic variants characterizing both populations. Variant calling was processed according to the DeepVariant best practice and after classical filtering steps we identified nearly 1 million SNPs shared by the two commercial populations for S1, and 2.5 million SNPs for S2. Second, FLimpute v2.2 software was used to obtain an imputed genotype for these million SNPs for all S1 and S2 offspring, using their known 57K genotype.

GWAS was performed for each population separately, using a Bayesian sparse linear mixed model (BSLMM) on a dataset of these imputed SNPs for all challenged individuals, using GEMMA software. Several QTL regions were identified on the European sea bass genome, 18 QTL in the S1 analysis (Delpuech et al., 2023) and 14 QTL in the S2 analysis with a Bayesian factor higher than 10. From these QTL, 282 candidate variants for NNV resistance were selected, as well as 82 candidate variants for *Vibrio harveyi* resistance.

A validation approach for these candidate variants was performed. For this purpose, two groups of European sea bass offspring were created: the first group consisted of 2,772 individuals challenged for resistance to *Vibrio harveyi*, and the second group consisted of 3,401 individuals challenged for resistance to NNV. Genetic data from the tested individuals were obtained by targeted genotyping using AgriSeq sequencing (Thermofisher). A total of 563 markers were genotyped and these markers can be divided into three groups, 199 markers to perform parentage assignment, 282 markers to detect NNV resistance, and 82 markers to detect *Vibrio harveyi* resistance. These disease resistance specific markers were genotyped in order to validate in the offspring generation a single nucleotide polymorphism identified by GWAS in the parental generation.

(Continued on next page)
Results
Challenges for individuals of the offspring generation were conducted over approximately 40 days. Survival rates were 59% for VNN challenges and 37% for Vibrio challenges. Peak mortality was at 17 days post-infection for VNN challenges and at 2 days post-infection for Vibrio challenges (Figure 1).

Survival rates were close to 50% as expected in both challenges. We studied the effect on survival of the highest-effect QTLs identified in the parental generation, on LG12 for VNN (Figure 2a), and on LG22-25 for Vibrio harveyi (Figure 2b). For each of the candidate markers presented, better survival was confirmed for resistant genotypes compared to susceptible genotypes, identified from previous generations via GWAS analyses.

Further analyses on validation of models for estimation of breeding values will be performed on the same data and presented at the conference.

The *Genypterus* genus include relevant native species with economic relevance and high potential to Chilean aquaculture diversification. Has been observed that increase in temperature could generate stress in these species. However, still the knowledge on how thermal stress affect at brain and reproductive level is limited. The objective of this work was compare the effect of heat stress in brain and gonads in two *Genypterus* species, the red cusk-eel (*G. chilensis*) and black cusk-eel (*G. maculatus*).

Red and black cusk-eel juveniles were collected and separated into control and stress groups. The stress group was subjected to high-temperature stress (19°C) for five days and then fish were euthanized, sampling brain and gonads for RNA purification and reverse transcription for posterior qPCR. Relative gene expression evaluation through RT-qPCR in each species was performed, normalizing with the geometric mean between two reference genes (actb and taf12). Multiple t-test was performed to identify significant differences.

High temperature produces a significant increase in heat shock protein on brain on the stress group on red cusk-eel (hsp70, hsp60 and hsp90, Fig. 1A, B and C) and black cusk-eel (hsp70 and 90, Fig. 1D and E), join with an oxidative stress response in red cusk-eel and black cusk-eel (sod1 and gpx1, Fig.1F, G, H and I). In the case of gonads thermal stress increases hsp60 on black cusk-eel, but no in red cusk-eel (Fig. 1J), with an oxidative stress response in red cusk-eel (gpx1 and cat, Fig. 1K and L) and black cusk-eel (cat, Fig. 1M). This study showed how thermal stress can affect *Genypterus* species, determining the differences and similitudes in brain and gonad response to thermal stress, information is relevant to the understanding of species response to thermal stress. philip.dettleff@uc.cl

The Chilean teleost fish includes several economically important relevant species for Chilean marine industry. Several of these species have aquaculture potential as red cusk-eel (*Genypterus chilensis*), pink cusk-eel (*Genypterus blacodes*) and black cusk-eel (*Genypterus maculatus*) or are relevant for Chilean fisheries as the Chilean hake (*Merluccius gayi*). However, these species remain in marine ecosystems, therefore, are exposed to different environmental stressors and pollutants. One of these pollutants is microplastics, which are abundant in marine environments. These fish species could be exposed to microplastic presence; however, little is known about the microplastic pollution in the population of these species. This study aimed to evaluate the prevalence of microplastic in *Genypterus* and *Merluccius* species across the Chilean coast.

These species of teleost fish were sampled in different locations of the Chilean coast registering length, weight, and the tissue of the animals. The tissue was digested in KOH and then filtered using Whatman glass microfiber and analyzed using a high-resolution optical microscope. We found microplastic presence in all the *Genypterus* species, showing that this genus is affected by microplastic pollution. In the case of *Merluccius gayi*, we found important contamination with microplastics in the intestine, with more than 20% of prevalence, which presents higher levels compared to previous reports for this species in other locations. In this sense, the condition factor K in this population of Chilean hake was not influenced by the microplastic presence, presenting a low R² between microplastic number and K. This information is evidence that microplastic pollution level is a relevant issue for species of *Genypterus* and *Merluccius* genus, evidencing that microplastic pollution is dependent of the species and geographical location, requiring more studies to determine its effect at the physiological level on these species. EPIGENETIC CHANGES IN PYLORIC INTESTINE OF ATLANTIC SALMON FED DIETS WITH INCREASING LEVELS OF LIPIDS AND CHOLINE

Anusha K.S. Dhanasiri*, Daphne Siciliani1, Trond M. Kortner1, Åshild Krogdahl1

Introduction
Substantial replacement of fishmeal and fish oil with plant ingredients in the diets has caused certain challenges in health and welfare of the Atlantic salmon. Excessive lipid accumulation or steatosis in the pyloric caeca and mid intestine is such a gut health challenge predominant in farmed salmon. Severe steatosis can cause lipid malabsorption resulting floating faeces in surrounding waters also called lipid malabsorption syndrome (LMS). Through a series of studies, it has been recently established that supplementation of choline, which is deficient in plant-based diets, can prevent the steatosis in Atlantic salmon (Hansen et al., 2020a; Hansen et al., 2020b; Krogdahl et al., 2020). Choline is an essential nutrient and a precursor to produce phosphatidylcholine, the major phospholipid in the lipoproteins that facilitates the transport of lipids from the enterocytes. Moreover, choline can influence epigenetic regulation by being the key methyl donor for DNA or histone methylation.

Epigenetic mechanisms, such as histone modifications, DNA methylation, noncoding RNA and chromatin structure rearrangements can produce heritable changes in gene expression without changing actual genomic sequence. Alterations in DNA methylation in different genomic regions differentially influence gene activities producing diverse physiological and phenotypic changes. Considering the role of choline as methyl donor in DNA methylation, this study was conducted to evaluate the epigenetic changes in pyloric intestine of Atlantic salmon fed diets containing increasing levels of lipid and choline.

Materials and Methods
Four diets were formulated to have lipid levels of 16% (L16), 21% (L21), 26% (L26) and 31% (L31). The first 3 diets were choline deficient and had levels of 1542-1619 mg/kg while the L31 diet had somewhat higher, but still suboptimal choline level of 2310 mg/kg. A feeding trial was conducted with Atlantic salmon parr with initial weight of 25g in duplicate tanks per diet group, at 8℃, for 8 weeks.

A genome-wide analysis of DNA methylation patterns was performed by reduced representation bisulfite sequencing (RRBS) to examine the global epigenetic alterations in the pyloric intestine. Library preparation for RRBS was performed with the NuGen ovation RRBS methyl-seq system (Tecan Genomics). Briefly, DNA from 6 replicate samples per diet group were digested with MspI followed by adapter ligation, final repair, bisulfite conversion, amplification and subsequently sequenced on the NextSeq 500. Bisulfite-specific DNA mapping to Atlantic salmon genome and methylation information was extracted using Bismark aligner. Differentially methylated cytosines (DMCs, q value ≤0.1 and methylation differences ≥10%) in CpG context between the genomes of Atlantic salmon fed different diets were analyzed using methylKit package. Genomic feature annotation of DMCs was performed using the HOMER package. Functional annotation of the genes associated with DMCs was performed using g:Profiler online tool and manually inspecting the Ensembl and NCBI data bases.

Results and Discussion
This study revealed that increasing levels of lipid and choline in the diet induced genome-wide epigenetic changes in the pyloric intestine of Atlantic salmon. The highest number of differential methylations were observed between the fish fed diets with largest choline differences (L31 vs L21) and the lowest number of differential methylations were observed between the fish fed diets with similarly low choline levels and highest lipid differences (L26 vs L16). The observations indicated that choline and/or high lipid levels epigenetically modulated several genes of membrane components and transporters, adipose lipolysis and lipogenesis, and microRNAs important for lipid homeostasis. Our observations support the vital role of choline in epigenetic regulation also in Atlantic salmon similar to that reported in higher vertebrates (Zeisel, 2017; Korsmo et al., 2019). The knowledge could be valuable for further optimization of the feed formulations for Atlantic salmon.

SERUM REDUCTION DOES NOT AFFECT PROLIFERATION IN ATLANTIC STURGEON STEM CELLS

V. Di Leonardo1,2*, B. Grunow1

1 Fish Growth Physiology, Research Institute for Farm Animal Biology, Dummerstorf, Germany
2 Università Ca' Foscari Venezia, Italy
Email: di-leonardo@fbn-dummerstorf.de

Introduction
Stem cells are characterized by the unique abilities of self-renewal and differentiation, making them a powerful field of research for many applications (Hong et al., 2011). Fish stem cells are gaining popularity in the last few years thanks to the increasing interest in cellular aquaculture as an alternative and potentially more sustainable protein source to fishing. Currently, two of the main challenges, in developing cell-based seafood, are the lack of available fish cell lines and the poor knowledge about fetal bovine serum (FBS) substitutes for cell cultivation (Goswami et al., 2022). Here, we evaluate the effects of serum reduction on the proliferation of an Atlantic sturgeon cell line (AOXlar7y) derived from larval tissue (Grunow et al., 2011).

Materials and methods

Cell culture
For these experiments, Atlantic sturgeon stem cells from passages 43 to 47 and 78 to 83 were cultured in L-15 medium (Gibco) with 10% of fetal bovine serum (PAN Biotech) at a temperature of 25 and 28°C for proliferation analysis. All experiments were performed within six replicates using different passages.

Real-time cell electronic sensing
To evaluate the effect of lower serum concentration on cell growth, the impedance of the sturgeon stem cells was determined at 2%, 5%, and 10% serum concentration for 7 days. Cells were incubated at 25°C and 28°C in a 96-well plate and cell behaviour was measured via Cell impedance (Cl) using the xCELLigence RTCA SP instrument (Roche Diagnostics GmbH). The Cl is influenced by three cell parameters: cell number, cell adhesion, and cell size/morphology and can be seen as an indicator of proliferation.

Cell confluence
Cells were seeded in two 12-well plates (TPP) at a concentration of 70,000 cells per well and with three different serum concentrations (2%, 5%, 10%) and incubated for 2 days at 25 and 28°C. Cell confluence was evaluated using the Cell and Gene Therapy Catapult Cell Confluency Tool (https://ct.catapult.org.uk/resources/confluency-tool). Data were obtained from six microscope pictures per well which were taken on the third day of cultivation. Mean ± SD was analysed from each experimental trial.

Actin Filament staining
The morphology of AOXlar7y cells was evaluated by immunofluorescence labelling staining against β-actin. Cells were seeded on 3-chamber slides (Ibidi) at a concentration of 70,000 cells per chamber and cultured for 2 days at 25 and 28°C at 2%, 5% and 10% FBS concentration. For staining, fixed and permeabilised cells were stained with Phalloidin-iFluor 594 (Abcam) and DAPI (Carl Roth GmbH + Co. KG).

Results and Discussion
In this study, we evaluated the effect of serum reduction from 10% to 5% and 2% via real-time cell impedance measurement. The results show that a concentration of 5% FBS does not affect AOXlar7y cell proliferation. The curve from 5% is comparable to that of cells cultured with 10% of FBS, which is the standard amount of serum commonly added in most cell cultures. The proliferation curve of cells cultivated with 2% of FBS is instead markedly lower, confirming the direct correlation between serum quantity and cell proliferation capacity. The effect of the three FBS concentrations was further confirmed by comparing the cell confluence of each condition, which indicated an increase in proliferation for cells cultured at the higher temperature (28°C). The actin filament staining has been used to visualize the cytoskeleton to detect signs of stress or differentiation due to temperature increase and/or serum reduction. In particular, an abrupt serum starvation can be a stimulus for the stem cells differentiation (Messmer et al., 2022), making it more difficult to reduce serum during common stem cell maintenance. The results showed no evidence of differentiation, and cytoskeleton structures remained largely homogeneous between cells under different conditions. However, the cytoskeleton labelling occurred only after two days of cultivation, so further analysis is required after long-term culture.

(Continued on next page)
Conclusions

The results show the possibility to lower the serum concentration for culturing the Atlantic sturgeon cell line AOXlar7y to 5%, without compromising their self-renewal capacity and without showing signs of stress induction or differentiation. By further investigating the properties of this cell line and the mechanisms by which it responds to certain culture conditions, it may allow us to determine the characteristics that make certain cells more proliferative even in the presence of less nutrition-rich, consequently cheaper, and more sustainable cultivation media. This principle is important not only for in vitro meat production, but also for general laboratory research, as it would make these powerful in vitro models more accessible worldwide.

Introduction
Aquaculture is recognized as the fastest-growing food-producing industry globally for human consumption (Naylor et al., 2022). The European aquaculture sector alone yields more than 3 million tons of fish yearly, as reported by the Food and Agriculture Organization (FAO, 2020). Numerous marine and freshwater aquatic organisms are vulnerable to bacterial diseases such as vibriosis and photobacteriosis, yersiniosis and aeromonosis respectively, just to mention a few very common ones. The origin of fish pathogens can be correlated to various factors, but their ability to withstand and cause disease outbreaks in aquaculture systems suggests that biofilms are a possible source of persistence, especially for multidrug-resistant bacterial strains that have adapted to the facility settings and may serve as the main source of infection for farmed fish. Therefore, the capacity to develop a biofilm represents a significant concern with possible implications in disease outbreaks as a pathogen reservoir as already demonstrated for some bacterial agents of importance in aquaculture such as Yersinia ruckeri (Coquet et al., 2002). Microbial cells can adhere to each other and to host cells and abiotic surfaces, such as glass, polystyrene plastic, and seashells which promotes colonization and the formation of biofilms. The biofilm comprises densely populated bacteria shielded by a robust exopolymer matrix that firmly attaches to a surface. Forming biofilms leads to the failure of antimicrobial agents, with 1000-fold greater resistance to them (Uruen et al., 2020). The main objective in counteracting fish pathogen infections is the identification of substances (possibly of natural origin, e.g., essential oils), which can effectively target pathogen biofilms. The first step of this approach is the study of in vitro systems, which help to demonstrate the efficacy of the selected antibiotic agents. The present work aimed to improve the currently available techniques to obtain a formed biofilm by fish pathogens as the first step in studying antibiofilm substances.

Materials and Methods
The following strains were tested: Yersinia ruckeri, Vibrio harveyi, Photobacterium damselae subsp. piscicida, Pseudomonas aeruginosa, Aeromonas salmonicida subsp. salmonicida, Pseudomonas anguilliseptica, Tenacibaculum maritimum. Each strain was grown on a specific agar medium and subsequently sub-cultured in Mueller Hinton broth. The density of the inoculum was adjusted to 0.5 McFarland standard, corresponding to approximately 1x1011 CFU/mL. To determine the optimal protocol for studying the efficacy of essential oils (EOs) on biofilm formation, a comparison was made between the growth of bacteria with and without sterilized carapace (obtained from shrimps, 1x1 cm). This assessment was carried out in 24-well plates, where the bacteria were inoculated with a 1:10 dilution of a 0.5 McFarland suspension. The plates were incubated for five days at 28 °C for biofilm development. After washing samples, the biofilm was detached from the surfaces by water bath sonicating for 30 minutes, and the resulting suspension was diluted to 50% in Mueller-Hinton broth. 100 µL of each suspension were inoculated into 96-well plates to monitor their growth curves (24h to OD= 630 nanometers) by Cytation 5 Imaging multi-mode Readers (Agilent biotek). Further, 150 µL of the microbial suspension from the biofilm was resuspended with an equal volume of Mueller-Hinton and treated by adding a commercial mixture based on EOs (MIX-GL) at the concentration of 2xMIC. The treatment was left for 20, 40, 80, and 160 minutes or for 24h. Subsequently, the samples were centrifuged at 2000 rpm for 10 minutes, and the pellet was resuspended in culture broth and inoculated in a 96-well plate to monitor the growth curves (24h at OD= 630 nanometers). The cells grown with and without carapace were tested for the sensibility to MIX-GL.

(Continued on next page)
Results
Wide differences in biofilm formation have been shown between strains with the best ability to form biofilm by *Yersinia ruckeri*. All the strains tested could attach to polystyrene plates and shrimp carapaces to some degree, but there are differences in the developed biofilm in relation to the tested surfaces. Using shrimp carapaces as attachment surfaces, it has to be noted that crystal violet can not be used for measuring directly biofilm formation because the absorbance of crystal violet has been shown to be very high, altering the evaluation of formed biofilm: this is probably due to the affinity of carapace to cristal violet also in the absence of biofilm. Therefore, biofilm formation values were calculated by cell growth measurement after detaching them from the different surfaces (polystyrene plates and shrimp carapaces). The formed biofilm on the carapace was higher than that grown on polystyrene. This result is very important to test the efficacy of antibiofilm compound activity. In fact, it is important that biofilm is allowed to grow in optimal conditions to evaluate the antibacterial efficacy of EOs properly. As shown in Fig. 1 (A), at starting point OD value of *Yersinia ruckeri* was higher in the sample where cells were grown with carapace, and this difference was maintained for all the growth cycle curves. The better performance of cells grown with carapace is accompanied by a higher resistance to the antibacterial effect of EO (Figura 1, B and C).

Conclusion
The choice of the experimental model is crucial to evaluate the antibiofilm activity better and to accurately identify the effective dose of antimicrobial natural substances, such as EOs, avoiding the use of ineffective doses that could select resistant strains.

INVESTIGATING THE EFFECTS OF INCREASING LEVELS OF EPA AND DHA ON HEALTH, LIPID METABOLISM AND STRESS RESPONSE IN JUVENILES LUMPFISH (Cyclopterus lumpus)

Di Toro, J.1*, Rey Planellas, S.1, Betancor, M.B.1, Johannesen, A.2

1Institute of Aquaculture, University of Stirling, FK7 4LA Stirling, Scotland, United Kingdom
2Fiskaaling, Við Áir 11, 430 Hvalvík, Faroe Islands
E-mail: jessica.ditoro@stir.ac.uk

Introduction
Lumpfish (Cyclopterus lumpus) is used as a cleaner fish against sea lice infestations in salmon aquaculture. It is widely used in Canada, Norway, Scotland, and Faroe Islands due to its better tolerance to cold water. However, their welfare is still poor as high mortalities occur during the deployment in sea cages. A tailored diet, that covers the nutritional requirements, is essential to provide good welfare, improve survival and maintain their delousing efficacy. Long chain polyunsaturated fatty acids (PUFA) such as docosahexaenoic acid (DHA, 22:6n-3) and eicosapentaenoic acid EPA (20:5n-3) are required for growth as well as development and reproduction (Sargent et al., 1999). This study aims to evaluate the effect of five experimental feeds with diverging EPA+DHA levels on juvenile lumpfish to investigate the effects on fish performance, lipid and fatty acid metabolism as well as stress response.

Materials and Methods
Lumpfish, approximately 20 ± 2 g (mean ±SD), were sourced from Nesvík Marine Centre (Faroe Islands) and transferred into an experimental flow through system. Each tank was stocked with 24 lumpfish and was randomly assigned to one out of six diets, in quadruplicate. A basal extruded diet was coated with either rapeseed oil (RO), krill oil (KO) (Aker Biomarine, Norway) or a blend of both oils, generating five experimental feeds with decreasing EPA+DHA levels (22.8-5.6 % total fatty acid; 0KO, 25KO, 50KO, 75KO, 100KO, respectively). A commercial diet was also used as a control (COM). All feeds were produced by Havsbrun (Faroe Islands). Feed was manually delivered at a feeding rate of 2.5% of their body weight. Uneaten pellets were daily syphoned and weighed out in order to record daily feed intake. Four sampling points were carried out throughout the trial which lasted for 52 days: a basal sampling (S0), two nutritional samplings (S1 and S2; 21 and 47 days, respectively) and a stress challenge (S3).

During S1 and S2, fish were measured for morphometric data, as well as liver and viscera weight. Three whole fish were stored at -20° for proximate analysis, while whole intestine, brain, gills, eyes and liver were dissected from two fish and stored at -20° for lipid analyses. At S3, fish were exposed to an acute stressor (chasing and confinement), after which, fish were left to recover and sampled 1 hour and 6 hours after the stress for morphometric data and plasma cortisol. Linear models were used to investigate the effects of the diets, while a post hoc Tukey HSD test was performed to identify differences between dietary treatments. Principal component analysis (PCA) was performed on fatty acid profile of tissues.

![PCA of fatty acid profile of liver (Continued on next page)](image)
Results and Discussion
Preliminary data analysis showed no significant differences in growth parameters, survival and condition indices, in both S1 and S2, between dietary treatments. Despite this, significant differences were found in the mean cumulative feed intake, with fish fed 25 – 100KO inclusion had a higher feed intake throughout the trial (on average 18.1 g), while fish fed the commercial diet had a lower feed intake (10.1 g ± 3.7). There was an interaction in terms of whole body lipid content between diet and time, indicating that some feeds (COM and 75KO) increased the lipid content of the fish faster than the others. Fish fed 25KO had the highest liver lipid content, while those fed 100KO had the lowest. There was also an effect of diet on the whole intestine lipid content, with fish fed COM showing the highest lipid content in this tissue, while those fed 100KO and 0KO had the lowest. Significant differences were observed in liver between the dietary treatments in terms of fatty acid composition. Liver fatty acid profile reflected dietary input (Betancor et al., 2014), as can be observed in the PCA (Fig.1). The increasing dietary inclusion of EPA and DHA lead to an increase of n-3 fatty acids in the liver, while fish fed diets with high rapeseed oil inclusion (50KO, 25KO, 0KO), displayed higher levels of oleic acid (18:1n-9) and n-6 fatty acids such as 18:2n-6. Significant differences were found between dietary treatments in plasma cortisol 6 hours after the stress, where fish fed a higher inclusion of krill oil (100KO, 75KO, 50KO), had significant lower levels of cortisol. In agreement, fish fed vegetable oils showed higher cortisol plasma levels than fish fed a fish oil rich diet (Perez-Sanchez et al., 2013).

Introduction
Domestication is the process by which a species bred in a captive environment, and modified across successive generations from its wild ancestors, becomes more useful to humans who control increasingly its reproduction and food supply. Domestication has been described in five levels, as the acclimatization of wild fish to human facilities (level 1), the completion of the life cycle in captivity partially (level 2), then completely with wild outputs (level 3) or without wild outputs (level 4), and, finally, to selection programs to meet specific breeding goals (level 5) (Teletchea and Fontaine, 2012). Among traits that change under a domestication process, behaviors as phenotypes are the most directly influenced (Pasquet, 2018). However, few studies have investigated the behavioural differences between wild fish at early domestication (i.e., levels 1 & 2) and fish bred for several generations in captivity (levels 3 and above), despite the fact that such changes can occur very rapidly in the domestication process (Huntingford, 2004). Using the mirror-biting test, we compared behavioral traits involved in activity, aggression and stress, between wild caught zebrafish acclimatized to captivity (F0), their offspring (F1) reared in captivity, and three laboratory wild-type strains (AB, TU, and WIK).

Materials and methods
We tested 174 zebrafish in the mirror biting test under 5 different groups considering the different levels of their domestication: F0 (level 1), F1 (level 4), AB, TU, and WIK (all laboratory strains were considered at level 5). The F0 were wild fish collected from Bangladesh and acclimatized to captive conditions from June 2022. The F1 was the first generation produced by the F0 in captive condition in March 2023. The individuals were housed in 3.5 L tanks part of a recirculated water standalone rack (Tecniplast) under conditions that met the physico-chemical requirements of the species.

An individual 18h acclimatization in the experimental tank with all sides covered occurred before the beginning of each test. All tracking was performed with the R-package trackR (Garnier 2022) in RStudio (R Core Team 2022; version 4.2.1). The tracking was conducted for each individual, when the mirror cover was removed and lasted one hour generating 90,000 frames. Behavioural analysis was done using RStudio (R Core Team 2022; version 4.2.1), by coding an optimized script to obtain behavioural results from the data table produced by trackR after tracking. The most relevant behaviors for the mirror-biting test were based on definitions used in the literature (see Audira et al., 2018; Kalueff et al., 2013)). All statistical analyses and formatting of results were carried out using RStudio. First, correlation between traits were assessed (i.e. Pearson’s correlation) and for highly correlated traits, one of the traits was randomly chosen. Second, a principal component analysis (PCA) was done to assess divergences between the groups tested. Third, the potential divergences between the five groups of zebrafish were further assessed by a global multi-response permutation procedures (MRPP) using R-package vegan (Oksanen et al., 2020) and 10000 permutations. In parallel, we also tested a potential divergence between sexes and the two AB age classes with a MRPP. As these results were not statistically significant (p-value = 0.56 and 0.62, respectively), we no longer distinguished between the sexes and ages in the analyses that followed. Fourth, when the global MRPP was significant (e.g. p-value < 0.05), we performed a pairwise MRPP between each pair of groups and applied a Bonferroni correction. Fifth, an indicator value (IndVal) (Dufrêne and Legendre, 1997) R-package labdsv (Roberts, 2023) was performed to determine which behaviors were most expressed by each of the five groups of fish. Finally, we investigated the intragroup variability by calculating the distance between individuals and the centroid of each group in PCA space. These distances were then compared between groups using a global Kruskal-Wallis test and followed, if the test result was statistically significant, i.e. p-value <0.05) by a Dunn’s test using the R-package rstatix (Kassambara, 2023).

(Continued on next page)
Results

The three first axes of the PCA were taken into consideration and they represented 27.8% of the variance (axis 1), 21.3% (axis 2) and 14.8% (axis 3) (Figure). The behaviors contributing to the maximum of variance on the three axes differed. The first axis represented activity, opposing immobility to travelled distance. The second axis represented aggressiveness opposing presence in the contact zone, and aggression to the mirror and presence in zones farther from the mirror. The third axis was more linked to stress opposing thigmotaxis and acceleration to the presence in zones near the mirror. The different strains and generation differed relatively to the PCA analysis. The overall MRPP was significant (A=0.0963, p<0.01). AB and ABw differed from all the other strains and F1. Wild (F0) differed from F1. According to IndVal, the F0 were characterized by periods of immobility and aggressiveness to the mirror. The F1 displayed more erratic behaviors to the mirror alternating aggressiveness (U-turns, aggressive acceleration) and stress (thigmotaxis). AB and ABw were more characterized by activity, and exploration of the different zones. The Dunn’s test showed intra-strains variance with AB showing less variability than Wild and F1 (Dunn test: z=4.81 p<0.0005, z=6.2, p=0.0006 respectively).

Discussion

The results showed behavioural differences between the two generations of wild zebrafish (F0 and F1), while AB differed from TU and WIK, although they are supposed to be at the same level of domestication (i.e., 5). Lower aggressiveness in F1 agrees with the domestication increasing docility scenario (Wilkins et al., 2014). Activity, stress and aggressiveness have been linked to the domestication of organisms as modifications from their wild counterparts (Milla et al., 2021). This divergence from the wild during the domestication process is due to the increasing control of humans over a species life cycle, along with the decreasing gene flow from the wild in successive generations (Teletchea and Fontaine, 2012). Behavioral traits have been described as the first to be affected by this process in fish (Huntingford, 2004; Pasquet, 2018) as well as in mammals (Sánchez-Villagra et al., 2016) with main changes involving increased docility (Lu et al., 2022), reduction in avoidance behavior (Álvarez and Nicieza, 2003), changes in risk-taking behavior and in general decreased stress response in the rearing environment (Milla et al., 2021; Pasquet, 2018).

HOW AQUACULTURE POTENTIAL CHANGES DURING DOMESTICATION: SEEKING THE BEST WAY TO MAXIMIZE IT

Emmanouil Diakos*, Pascal Fontaine, Thomas Lecocq

University of Lorraine
INRAE, UR AFPA
Nancy, France
Email: Emmanouil.diakos@univ-lorraine.fr

Introduction
Aquaculture’s contribution to the total fisheries and aquaculture production is growing, projected to be 53% by 2030 (FAO, 2022). However, to ensure food security and sustainability, it is required to increase the diversity of species that dominate global aquaculture (FAO, 2022). Thus, new domestication programs will be required. Domestication is the process by which a species bred in a captive environment, and modified across successive generations from its wild ancestors, becomes more useful to humans who control increasingly its reproduction and food supply. This process has been described through the five ‘levels of domestication’, from the acclimatization of a wild species in a captive environment (level 1) to the partial completion of the life cycle in captivity (level 2), with (level 3) or without gene flow from the wild (level 4), up to the selection for traits of socio-economic importance (level 5) (Teletchea and Fontaine, 2012). Historically, domestication has led to many success stories, with however numerous unfruitful attempts due to increased complexity in terms of time and species specificities that hindered the process (Teletchea, 2019). Success requires certain prerequisites with regards to the species biology and phenotypic plasticity making it able to adapt to the farmed environment (Braithwaite and Salvanes, 2010; Driscoll et al., 2009; Mignon-Grasteau et al., 2005). In captivity growth and survival, behavior, reproduction and nutrition shape among others, the so called ‘aquaculture potential’ being the quantified amount of expression of all traits/biological-functions favorable for domestication and subsequent production (Toomey et al., 2021). However, the aquaculture potential could be modified during the domestication process, according to the management of base populations. Different scenarios of stock management such as no selection, single function (i.e., usually growth-related traits on) selective breeding program (SBP), or multi-function (i.e., selecting on several traits simultaneously) SBP exist. Thus, the right decision for stock management could improve the aquaculture potential and eventually the resilience of stock performance.

Objective of the study
In 2022, we started a domestication program using zebrafish (Danio rerio) collected from the wild (Bangladesh) to monitor the evolution of the aquaculture potential over successive generations. The zebrafish has been chosen due to its short generation intervals, the extended information available on its breeding and biology, and since it has been proposed as a good model for aquaculture research (Piferrer and Ribas, 2020). The goal is to apply and monitor 3 stock management approaches: 1) no selection = random SBP, a 2) single-function SBP, and a 3) multi-function SBP from the onset of domestication, and assess their consequences on the aquaculture potential. Our hypothesis is that the multi-function SBP could maintain a more genetically diverse population to be exploited in selective breeding, compared with the traditionally applied in aquaculture single-function SBP, that may promote deleterious alleles, loss of genetic diversity due to increased selection pressures, and genetic correlations with undesirable traits. It is a major challenge to maintain animals’ ability to adapt to an increasingly unstable environment (climate, economic context, societal demands), and we question whether a multi-functional SBP approach could provide that higher level of adaptability even with a compromised growth potential. Thus, to validate our hypothesis a comparison from the onset of domestication is needed, with a single-function SBP, and a random selection SBP as a point of reference.

Methods
We reared separately 11 families from the base (F0) population, under 3 SBPs (Multi-function, Single-function, Random) from the onset of domestication. For each family were assigned 3 tanks, each corresponding to an SBP, in a recirculated Tecniplast™ rack (5 fish per L). A main prerequisite was to prevent inbreeding, and thus a pedigree was constructed up to the 4th generation that would not allow the breeding of candidates with same ancestry. At tagging size (70 dpf) breeding candidates were tagged with a visible implant elastomer (VIE, Northwest Marine Technology, USA) to allow the recording of a set of easily measured, least invasive, phenotypic traits. Phenotypic traits were categorized in 1) ‘Active traits’ used for the ranking and selection of the best breeding candidates (male and female) from each SBP (Multi- & Single- function, not Random) within family, and 2) ‘Consequence traits’, a broader set of traits (including all Active traits) involving behavioral (Continued on next page)
experiments, a thermal challenge, and disease resistance challenge test, used to monitor the evolution of the aquaculture potential. For the Multi-function SBP active traits were related to growth, reproduction, and welfare, while for the Single-function active traits were only growth-related. Once the best breeding candidates were selected, inter familial mating was performed and a new generation was produced.

**Expected Results**

This study, currently in progress, require the phenotyping information from more than one generation in captivity in order to be able to assess how the different selective breeding programs shape the evolution of the aquaculture potential. Here is presented the workflow to describe the hypothesis and propose an alternative way that could be beneficial for future domestication efforts in aquaculture, considering animal welfare and sustainable production. However, apparent behavioural differences have been already observed in the mirror test experiment between F0 and F1 (publication in progress), as it has been described that behavioural phenotypes are the first to be altered under domestication and more specifically in one generation in zebrafish (Pasquet, 2018).

Introduction

Every year, approximately 15 million tonnes of marine bivalves are produced for human consumption, out of which 89% come from extensive aquaculture production (Wijsman et al., 2019). The demand for these much appreciated seafood products has substantially increased over the last years, catapulting the expansion of this food production sector. Yet, the sector has been facing consistently higher mass animal mortality events worldwide (Soon and Ransangan, 2019; Soon and Zheng, 2020). The occurrence of harmful algae blooms (HABs) is among the most common factors that can lead to the drastic animal losses (Griffith and Gobler, 2020; Soon and Zheng, 2020). *Prorocentrum lima* is a toxic benthic dinoflagellate that has a cosmopolitan distribution from temperate to tropical oceans. *P. lima* is capable of producing diarrhetic shellfish toxins (DSTs), such as okadaic acid (OA) and dinophysistoxin (DTX) to which bivalves are highly exposed upon active suspension feeding during harmful algal blooms (HABs) (Corriere et al., 2021). When the occurrence of an HAB leads to the detection of these toxins in bivalves’ flesh at levels above permissible levels, extensive bivalve farming areas are obliged to close, sometimes during long periods of time, as to avoid potential human hazards related with the exposure to these contaminants. Recently, HABs outbreaks have been increasing in frequency, duration and intensity in coastal areas throughout the world, as a result of climate change effects, such as warmer average seawater temperatures, alteration of typical seasonal patterns and, especially, increased occurrence of marine heatwaves which abruptly rise temperatures during a very short period of time. These extreme weather events can be particularly critical to the aquaculture sector in two ways: on one hand, farmed bivalves are acutely forced to live in conditions outside their physiological threshold without any previous thermal acclimation, potentially leading to substantial animal losses; on the other hand, acute temperature shifts often trigger the occurrence of HABs (Maulu et al., 2021), which further defy bivalves’ resilience and hamper their harvest for human consumption. Hence, it is utmost important to acquire deeper insights on toxins’ bioaccumulation mechanisms and the deleterious ecotoxicological responses they elicit, at both optimal and altered abiotic conditions, as such data will be crucial to develop early warning tools (e.g. modelling) to mitigate the devastating consequences that HABs can have in the aquaculture sector, at ecological, economic and public health levels.

Material and Methods

*Mytilus* spp. collected from Porto Brandão (Portugal) were transplanted to laboratory facilities at the Portuguese Institute for the Sea and Atmosphere (IPMA I.P.). Here, they were distributed into 12 tanks within recirculation aquaculture systems, comprising 4 treatments (NoToxin+20°C, NoToxin+24°C, Toxin+20°C, Toxin+24°C), each carried out in triplicate. Bivalves were kept at 20 °C (the same temperature registered in their natural habitat), while being fed with a non-toxic commercial dried microalgae (*Tetraselmis* spp.) solution. After 20 days of acclimation, seawater temperature was raised to 24 °C in treatments simulating a marine heatwave (i.e. NoToxin+24°C and Toxin+24°C). The occurrence of an HAB was then simulated in half of the tanks (i.e. Toxin+20°C and Toxin+24°C treatments) by replacing the non-toxic commercial dried microalgae (*Tetraselmis* spp.) solution for a toxic *P. lima* solution. Upon 5 days of exposure to these conditions, the

(Continued on next page)
simulated HAB was stopped, i.e. all animals were fed again with the non-toxic microalgae solution for another 5 days of trial. Mussels were collected at the beginning of the trial (i.e. T20 – before exposure), after 5 days of exposure (i.e. T25 – maximum time of exposure) and at the end of the trial (i.e. T30 - recovery), in order to assess DSTs (OA, DTX1, DTX2) bioaccumulation/detoxification in *Mytilus* spp., as well as the ecotoxicological responses [total antioxidant capacity (TAC), superoxide dismutase (SOD), catalase (CAT), glutathione S-transferase (GST), lipid peroxidation (LPO), heat shock proteins (HSP70), lactate dehydrogenase (LDH) and citrate synthase (CS)] in different mussel tissues (digestive gland, muscle and gills).

### Results

Preliminary results indicate that DSTs uptake was higher at 20 ºC than at 24 ºC (T25), most likely, due to bivalves’ ability to remain inside their shells when subjected to stressful environmental conditions, which might have prevented them from being in direct contact with toxic microalgae. Yet, during the recovery period (T30) toxins’ concentrations were not significantly different in the two tested temperatures, therefore, suggesting that the exposure to a marine heatwave did not compromise mussels’ ability to detoxify these contaminants. Regarding ecotoxicological responses, even though results are still being analysed, the preliminary data already evidenced remarkable alterations of bivalves’ antioxidant (CAT, SOD and LPO) and metabolic (LDH and CS) enzymes activity upon exposure to *P. lima*, especially at warmer temperature. After 5 days of recovery period, most of the analysed biomarkers did not return to basal levels.

Aurantiochytrium sp. AS FEED ADDITIVES IMPROVED THE RESISTANCE OF PACIFIC WHITE SHRIMP TO VIRAL CHALLENGE ASSOCIATED TO THERMAL STRESS

M.E.S. Henriques, M.B. Santos, A.N. Rombenso and F.N. Vieira

Instituto Federal Catarinense - Campus Araquari
280 road, Colégio Agrícola, 89245-000
Araquari, Santa Catarina, Brazil
E-mail: delano.schleder@ifc.edu.br

Introduction
The microalgae Aurantiochytrium sp. is a rich source long-chain polyunsaturated fatty acids (LC-PUFA), containing a high lipid content ranging between 55 and 75% in dry matter, with a docosahexaenoic acid (DHA) concentration of up to 48% of the total fatty acids. Furthermore, it has a cell wall composed of β-1-3 glycans, which have been related to the increase of shrimp immune response (Gupta et al., 2012; Marchan et al., 2018, Rojo-Cébreros et al., 2017). The dietary addition of Aurantiochytrium sp. in shrimp under optimal cultivation temperature showed an improvement in the specific growth rate (Wang et al., 2017), with an increase in the level of DHA in the muscle (Guimarães et al., 2019). This work aimed to assess the effect of different addition levels of Aurantiochytrium sp. on immune parameters and resistance of Pacific white shrimp reared under suboptimal temperature (22°C) to viral infection in association with thermal stress.

Materials and methods
The rearing trial was performed at the Marine Shrimp Laboratory of Universidade Federal de Santa Catarina, Brazil (LCM/UFSC) using 400 L tanks stocked with 100 Litopenaeus vannamei shrimp m⁻³. They were reared for nine weeks in a clear water system under suboptimal temperature (22°C), and fed diets with 0 (control diet), 1, 2, 3 and 4% of Aurantiochytrium sp., all in triplicate. At the end, shrimps were transferred to Aquaculture Laboratory of Instituto Federal Catarinense – Araquari campus, Brazil (LAq/IFC – Araquari), where they were acclimated for 48 h, then infected with white spot syndrome virus (WSSV). The challenge trial lasted seven days, the first four under 22°C and the last three days under 28 °C (thermal stress). A negative control was made with animals inoculated with a WSSV-free inoculum. The mortality was monitored every 3 h throughout the challenge and hemolymph samples were collected before the infection, and at day 4 and 7 of the challenge. The hematoo-immunological parameters evaluated were total hemocyte count, phenoloxidase activity, agglutinin titre and total protein concentration. Kaplan-Meyer test was applied to mortality data and multivariate analysis was used to analyze hematoo-immunological and mortality data.

Figure1. Cumulative mortality of L. vannamei fed the microalgae Aurantiochytrium sp. (0, 1, 2, 3 and 4%) after infection with WSSV associated with heat stress. The negative control (CN) was comprised by uninfected animals submitted to the thermal stress. *ANOVA one-way, followed by Tukey test (p=0.0001)
Results
All *Aurantiochytrium* sp. fed treatments showed lower mortality after four days of viral challenge under 22 °C when compared to the control diet. However, after thermal increase only the 4% treatment showed lower mortality (Figure 1). Viral infection significantly impacted shrimp immune response. Similarly, thermal stress also affected shrimp immune response, infected with WSSV or not (negative control). Multivariate analyses (MANOVA, Mahalanobis distance and Tocher clustering) showed that animals fed control diet and infected with WSSV, in addition to animals from the 3% treatment before thermal stress, the 4% treatment before and after thermal stress, and, to a lesser extent, the 1% level before and after thermal stress, were significantly different from the remaining groups.

Discussion and conclusion
Both, viral infection and thermal stress, caused significant impact on shrimp immune response. This has been reported in previous studies (Fan et al., 2016, Immanuel et al., 2012). However, this study also revealed that *Aurantiochytrium* sp. dietary addition might help shrimp to cope with these stressors, and consequently showing great potential to be used in the shrimp farming industry. In short, the 4% supplementation of the microalgae *Aurantiochytrium* sp. resulted in better immune response and lower shrimp mortality during the viral challenge associated with thermal stress. At low temperature (22°C), microalgae supplementation, in particular the 3% and 4% levels, increased the shrimp resistance to viral infection, demonstrating great potential for use in periods of mild temperatures in subtropical regions.

Introduction

Common carp, Cyprinus carpio, is an economically significant fish species in Europe and Asia for inland aquaculture [1]. However, koi herpesvirus (KHV) and carp edema virus (CEV) infections have emerged as substantial threats to carp populations. KHV, an Alloherpesviridae family member, causes koi herpesvirus disease marked by gill necrosis and internal bleeding, while CEV, belonging to the Chordopoxvirinae subfamily of Poxviridae, results in “koi sleepy disease” with clinical signs including lethargy, congested gills, enophthalmos, and skin alterations [2,3]. However, the mechanisms of immunity to these viruses in common carp are still not well understood, especially the immune regulation in the gonad to viral infection. This study examines and compares the seminal plasma proteome of KHV and CEV-infected carp males in relation to non-infected males (CTR).

Material and Methods

In the infection experiments 4 year old common carp males were used, eight carp males were bath-exposed to KHV (320 TCID50/ml), while other native carp males were exposed to clinically affected, virus-shedding donor fish carrying CEV, as CEV cannot be propagated in vitro [2], uninfected specific pathogen free males served as control. Semen and tissues (gill and gonad) were collected seven days post-infection and stored at -80°C until further analysis. Viral load and gene expression were quantified using qPCR and tissue histology and changes in spermatocyte morphology were examined using hematoxylin-eosin and eosin-nigrosin staining. The differentially abundant proteins (DAPs) in seminal plasma were identified using data-independent acquisition mass spectrometry (DIA-MS) between the control and virus-infected groups (n=8 for each group). DAPs were considered significant if their fold change (FC) was ≥1.5 and the p-value was less than 0.05. Functional annotation was performed using Gene Ontology (GO) and Kyoto Encyclopedia of Genes and Genomes (KEGG) analyses.

Results

The highest levels of both viruses were detected in the gills, confirming the development of infection. In this tissue gene expression analysis indicated that, CEV induced strong antiviral, proinflammatory complement responses with suppression of T and B cell responses. KHV, on the other hand, induced less drastic inflammation with no adverse effects on the adaptive immunity. The changes in gene expression in the testes had a similar pattern but were less pronounced, despite the fact that both KHV and CEV were found in the testes and semen, with KHV being more abundant than CEV in the semen (Figure 1A). Histological evaluation showed evidence of necrotic changes in the testicular lobules caused by both viral infections, resulting in an increased number of damaged spermatocytes as indicated by the eosin-nigrosin staining technique.

Using DIA-MS, a total of 2,248 seminal plasma proteins were identified, with 2,143 proteins in non-infected males, 2,493 in KHV-infected males, and 2,106 in CEV-infected males. Principal component analysis (PCA) revealed a significant impact of the infections on the seminal plasma proteome (Figure 2B). In KHV-infected males compared to the control group, 660 DAPs were identified, comprising 229 up-regulated and 431 down-regulated proteins. Similarly, CEV-infected males exhibited 1,079 differentially abundant proteins, with 123 up-regulated and 956 down-regulated proteins. A comparison between CEV and KHV-infected males identified 883 up-regulated and 149 down-regulated proteins. Venn diagram

(Continued on next page)
displayed that a large number of DAPs (356 proteins) were commonly changed by both the KHV and CEV infections (Figure 1C). Among these common proteins, 54 were up-regulated, 287 were down-regulated, and 15 showed opposite direction changes. Specific proteins were identified as highly induced (FC>10) under KHV infection, including PYCARD, UBE2E1, HBA1, TTN, PLAUR, LXN, SCG3, and ARSA while CEV infection led to increase of CFB, hatching enzyme, and HBA. GO and KEGG analysis revealed that proteins associated to innate immune response, triglyceride metabolic process, complement and coagulation pathway, response to reactive oxygen species were up regulated whereas proteins related to leucocyte and neutrophil mediated immunity, carbohydrate derivative, viral process and protein folding were down regulated following CEV infection. KHV led to up-regulation of proteins related to RNA catabolic process, protein translation and localization, protein folding and viral process whereas proteins related to leucocyte and neutrophil mediated immunity, complement activation and cell adhesion were down regulated.

Conclusion

The presence of viruses in the semen and gonads indicates that both KHV and CEV can breach the blood-testis barrier, leading to the development of reproductive system infections. These infections of the testes, in combination with systemic immune responses, could affect the functioning of the male reproductive system of carp. The findings provide valuable insights into the differential abundance of seminal plasma proteins in virus-infected males, contributing to our understanding of the molecular mechanisms underlying reproductive responses in aquaculture species.

Introduction

Sturgeon species, considered living fossils, exhibit unique reproductive system, including gametes, compared to modern teleost fish [1]. Sturgeons are not only important from an evolutionary perspective but also highly valued for their black caviar and high-quality meat. Unfortunately, overfishing for meat and caviar production has led to a severe decline in the sturgeon population, with 27 sturgeon species currently listed as endangered on the Red List. Therefore, gaining a deeper understanding of the molecular processes underlying sturgeon egg formation and quality is of great scientific and practical importance. However, there is a notable lack of comprehensive data concerning the protein composition of sturgeon eggs and ovarian fluid (OF) and their functional significance. To address this knowledge gap, this study aimed to conduct a comprehensive comparative proteomic analysis of Siberian sturgeon eggs and OF.

Material and Methods

The experiments were conducted on five Siberian sturgeons females (age 9-14, body weight 16.5 ± 2.7 kg) maintained at the Department of Sturgeon Fish Breeding Inland Fisheries Institute in Pieczarki, Poland. Eggs and OF from the same female (n=5) were collected using a catheter [2]. OF was collected from the surface of the egg with a pipette, taking care to avoid any contamination with blood. Proteins from eggs (100 mg) were extracted by homogenization (4 x 30 s) in 4 volumes of lysis buffer (8 M urea, 2% CHAPS, 30 mM Tris, pH 8.5) and then sonicated (6 x 5 s) on ice. Samples were analyzed using liquid chromatography‒mass spectrometry (LC‒MS/MS) system composed of an Evosep One HPLC System (Evosep Biosystems) coupled to an Orbitrap Exploris 480 mass spectrometer (Thermo Scientific, FDR < 1%). To estimate the protein abundance, emPAI was calculated using unique precursors and normalized by total abundance. To estimate differences in composition between two sample types, median emPAI values were divided and then transformed into fold change values. Functional annotation was performed using Gene Ontology (GO) and Kyoto Encyclopedia of Genes and Genomes (KEGG) analyses. Western blotting was used to validate the mass spectrometry results.

Results

The eggs collected for analysis were characterized by high quality with a fertilization rate at the second cleavage (4 h postfertilization) of 97.5 ± 0.3 and hatching rate of 78.4 ± 6.5%. A total of 565 proteins were identified in eggs, while 617 proteins were identified in OF, with 772 proteins showing differential abundance. Among the differentially abundant proteins, 407 were more abundant in eggs, while 365 showed higher abundance in OF. Furthermore, we identified 287 proteins specific to eggs and 339 proteins unique to OF, along with the top most abundant proteins (emPAI >10) in each; in eggs, the top most abundant proteins were vitellogenins, nucleoside diphosphate kinase A2, cofilin-2, cystatin-B, ubiquitin carboxyl-terminal hydrolase isozyme L1 and zona pellucida sperm-binding protein 3 whereas in ovarian fluid abundant proteins included albumin, apolipoprotein A1, transferrin, hemoglobin, hemopexin, nucleoside diphosphate kinase A and fish-egg lectin.

In eggs, pathways related to mRNA translation (eIF signaling), protein degradation (ubiquitin‒proteasome pathway) and metabolic pathways (oxidative phosphorylation, glycolysis, fatty acid β-oxidation, and sirtuin signaling pathway) were found to be the most significant canonical pathways. Conversely, OF proteins were primarily associated with immune system processes, including the complement and coagulation cascade, neutrophil and leukocyte-mediated immunity, cholesterol metabolism, cytoskeleton signaling, clathrin-mediated endocytosis signaling, and integrin and epithelial adherens junction signaling. Eggs were enriched in proteins localized to mitochondria and ribosome components, whereas

(Continued on next page)
OF-specific proteins highlighted extracellular matrix and secretory vesicles. 117 egg proteins and 102 OF proteins were involved in the reproduction processes including ovulation cycle, oocyte maturation, prevention of polyspermy, ovarian aging, fertilization, sperm-egg interaction and embryonic development.

The changes in the abundance of four selected proteins (ALB, FGB, FN1, VTG2) analyzed using 1D Western blotting were found to be consistent with those obtained from the LC‒MS/MS analysis. Western blot analysis confirmed the absence of FGB and FN1 proteins in eggs while demonstrating their exclusive presence in OF. A strong signal of ALB was also detected in OF; however, due to its low concentration in eggs (140 times lower than in OF), it was not visualized under the current method conditions (below the limit of detection). Additionally, Western blot analysis revealed a six-fold higher abundance of VTG2 in eggs compared to OF.

Conclusion

This study presents the first comprehensive characterization of the protein composition of sturgeon OF and eggs, shedding light on their distinct functional roles. The findings not only advance our understanding of sturgeon reproduction but also shed light on egg-OF signaling and the origin of the OF proteins. Moreover, the identified proteins offer potential biomarkers for predicting egg quality, contributing to the development of effective breeding strategies for sturgeon species.

Microalgae are advantageous ingredients for aquafeeds due to their nutritional quality (such as content in omega-3 fatty acids and protein), increasing resistance to pathologies, reducing nitrogenous excretions, and may even improve growth, physiological activity and, ultimately, fish quality\(^1\). Microalgae are good alternatives to conventional fish feed ingredients with low sustainability (fish oil and meal) or nutritionally unbalanced with low levels of omega-3 fatty acids (plants)\(^2\). Despite the fact that microalgae-derived products have been widely used in several industries besides aquaculture, such as food, feed, cosmetics, and agriculture\(^1\), they present several technical and scientific challenges that still require optimizations during their production. One of the main hurdles in the application of industrially produced microalgae products are their high costs, which are influenced by factors such as contamination incidence and the usage of expensive and less sustainable production inputs\(^4,5\). ALGAE vertical project will seek to work in the current technical bottlenecks of the field, from sustainable production and processing evolving throughout the value chain to placing value-added products on global markets, such as the aquaculture sector. Novel strategies to tackle microalgae production challenges will be studied and evaluated in three Demonstration Units at Necton, Hubel Campina and GreenCoLab. This project will also investigate the optimization of microalgae production sustainability concerning the four main inputs required for their growth: water, nutrients, CO\(_2\), and energy. New prevention or mitigation strategies to avoid culture collapses due to contaminants will also be investigated, towards higher control and stability of the cultures. Additionally, a thorough characterization of the microalgae biomasses regarding their biochemical components, functionality and presence of toxic compounds will be conducted to ensure high-quality microalgae biomass applications, in particular for aquaculture. This will increase the overall sustainability of microalgae production facilities, significantly reducing their production costs, and improving the quality of the products. This work will be part of the Algae Vertical, a consortium of 19 companies and 19 research entities led by Necton. The ultimate goal of the Algae Vertical is to improve the whole value chain of microalgae production and commercialization to give rise to new microalgae-based products, patents and services. The Algae Vertical is part of the Blue Bioeconomy Pact, a project led by Inovamar and funded by the European Union through the Portuguese Recovery and Resilience Plan (PRR), to foster the growth and development of the Blue Bioeconomy in Portugal.

Introduction

Development of live feed enrichment products for marine fish larvae is crucial to improve species survival and development. Marine fish larvae have typically low survival at weaning due to the challenges in their nutrition and health management (e.g. pathologies). Altricial larvae present immature systems (e.g. nervous, digestive, immunologic) requiring highly digestible live feed in early nutrition. Live feed used in hatcheries (rotifers and artemia) are zooplanktonic species that do not present the adequate nutritional profile for marine fish larvae development and require bioencapsulation of nutrients through enrichment processes with adequate products. Currently, most efficient enrichment products still use fisheries derived ingredients such as fish meal and fish oil in their formulations, thus it is essential to develop functional and sustainable enrichment solutions to support nurseries. The development of new sustainable products based on the combination of microalgae and probiotics is a valuable formulation strategy to support fish nutrition and health in early life stages. Different microalgae species contain a variety of nutrients essential for marine fish larvae and can be used in formulations to meet specific nutritional requirements and as substitutes for the fish-derived ingredients. Additionally, the inclusion of probiotics in the enrichment formulations may support the improvement of larval resilience to pathologies and other stressful factors (e.g. transport)1. ALLARVÆ project focused on the development of microalgae products in powder with probiotics for hatcheries, generating the VITABLOOM gama. The objective of this study was to develop a live feed enrichment product based on the combination of microalgae and probiotics able to promote high gilthead seabream (Sparus aurata) larvae survival at weaning and improve their resilience to stressful events.

Material and methods

Two Allarvae pilot enrichments ALLarvae and ALLarvae POC (ALL and ALL POC) were formulated with microalgae and probiotics. ALL POC included a red microalgae Porphyridium cruentum. The enrichments were manufactured and tested according to characteristics such as decantation, microalgae agglomerates abundance and dimensions and biochemical profile. Live feed was enriched, analysed and used in Sparus aurata larviculture. The control treatment was a high-quality commercial enrichment product (CP). Larvae were cultured until weaning with commercial products or pilot ALLarvae formulation as enrichment in rotifers and artemia in triplicate (200L tanks), with an initial density of 76 larvae/L. At 38 days after hatching (DAH) a stress challenge of transport was performed (220Km). Larvae oxidative stress (glutathione peroxidase and catalase activities) and survival were evaluated.

Fig 1 – Gilthead seabream (Sparus aurata) larvae survival fed with live feed enriched in Allarvae treatments (ALL, ALL POC) or with the control (CP): A) survival (38 DAH), and B) survival post stress challenge of transport (38 DAH). Data is expressed as means and standard deviation.

(Continued on next page)
Results and Discussion
The design of the pilot enrichment products was performed according to *S. aurata* nutritional requirements, the biochemical analysis showed that both formulas were nutritionally balanced. *S. aurata* requires 46% of proteins and 22% of lipids\(^2\), ALL presented 34.5% of proteins and ALL POC 34.1%, both formulas revealed 24.2% of lipids, while control showed 19.3% of proteins and 38% of lipids. ALLarvae enrichment products (ALL and ALL POC) promoted similar larvae survival and growth compared to the commercial product (Fig 1), this result suggests that ALLarvae successfully met *S. aurata* nutritional requirements. During stress conditions ALLarvae pilot formulas promoted good biological efficiency resulting in similar survival to the control treatment (Fig 1). There were no significant differences between pre and post stress on the activity of oxidative stress enzymes, suggesting no deleterious effect provoked by the use of the new formulations.

ALLarvae POC enrichment product contained *Porphyridium cruentum*, a red microalga with bactericide properties and immunostimulant polysaccharides. The formula promoted successful larval weaning. The selected formula for final product development was ALLarvae (ALL). ALLarvae is a sustainable enrichment product in powder based in the combination of microalgae and probiotics that promoted good larvae biological performance in *S. aurata*. The availability of this sustainable and effective enrichment in powder is highly advantageous for aquaculture industry due to the logistics simplification, displaying a balanced nutrition for fish and supporting their health.

Introduction
The liver, an important immunological organ in the gut-liver axis, has also recently been linked to smoltification during seawater transfer (SWT) (1). Previous studies have shown liver plasticity when fish were exposed to a different functional ingredient (2) and variation in genotype-specific transcriptomic profiles in liver in responses to dietary interventions (3). The main objective was to evaluate the effect of functional diets containing D. hansenii yeast-based products (LAN4 and LAN6) on hepatic transcriptomic profiles in two genetic groups of Atlantic salmon during SWT. The study also investigated whether these functional diets could facilitate the parr-smolt transformation and SWT and whether genetic background affects the hepatic transcriptome and growth performance in Atlantic salmon.

Materials and methods
Fish from two genetic lines (Family A and Family B, AquaGen, Norway) were fed standard diets prior the experiment, vaccinated and transferred to 18 experimental tanks (60 fish per tank) for a total of 7 weeks in fresh water (FW) and then moved to SW for 6 weeks (20 fish per tank). During the whole experimental period, fish were fed a control diet (CD) or two experimental diets containing 0.1% of either component LAN4 or LAN6 (D. hansenii yeast-based products). Dead fish with skin ulcers were detected during a natural outbreak in the SW phase, and samples were collected for pathogen detection. At the end of each phase, fish were sampled for various tissues including liver samples for RNA-seq analysis, and comparison between groups (Figure 1) was performed using KEGG enrichment analysis in ShinyGO v.077.

Results and discussion
Fish were healthy during the 7-week FW phase with no mortalities. Seven fish died during the 5th week of the SW phase due to skin ulcers caused by Moritella viscosa. All groups tested positive for the bacterium in gill samples, but none of the fish had clinical signs of winter ulcers at the end of the SW phase. No significant differences were found in growth parameters between dietary groups within the same family, but significant differences were observed between families in both FW and SW phases, with Family A exhibiting better growth than Family B, in both water phases.

Figure 2. Top significantly upregulated KEGG pathways in Family A and Family B in LAN4 and LAN6 dietary group compared between FW and SW phase.

KEGG pathway analyses revealed unique pathways linked to distinct effects of water phase, diet, and family in SWT.

In the comparison between FW and SW, Family A showed unique significantly upregulated pathways related to lipid family changes and anabolic processes when fed LAN4 diet during SWT, while Family B had unique downregulated pathways related to immune signaling and activation when fed the same diet. (Table 1, Figure 2).

In the LAN6 group, Family A had unique upregulated pathways related to protein production and cellular growth proliferation. Family B had no unique upregulated pathways in the LAN6 group, but unique downregulated pathways related to primary bile acid biosynthesis, retinol metabolism, lysosome, fatty acid, and sphingolipid metabolism. These results suggest that LAN4 and LAN6 (D. hansenii yeast-based products) may have distinct modes of action in salmon liver, resulting in differences in their transcriptomes. These differences may be influenced by the fish’s genetic background and environmental conditions.

Introduction

Gut microbiota can contribute to regulate growth, nutrient utilisation, disease resistance and physiological stress responses to cope with dietary changes and heat stress, among other environmental stressors. Hence, the composition and function of gut microbiota varies in farmed gilthead sea bream not only with diet, sex, age and season, but also with host genetics that shapes a more plastic microbiota that co-selects with fast growth (Naya-Català et al., 2022; Piazzon et al., 2020). Experimental evidence also indicates that natural and synthetic fat emulsifiers are able to improve growth in gilthead sea bream through changes, at least in part, in gut microbiota composition (Ruiz et al., 2023a; 2023b). The potential of emulsifiers to mitigate the effects of heat stress is proven in broilers (Yin et al., 2021). However, it is not yet known whether similar microbiome shifts are observable with changes in dietary fat levels and the extreme temperature rises associated to global warming. To bridge this gap, we investigated the combined effect of fat level and emulsifier supplementation (Volamel Aqua, Nukamel) in gut microbiota and conventional blood stressor markers during the extremely hot summer of 2022 at the Spanish Mediterranean coast.

Methods

Four isoproteic plant-based diets with 6% FM and two different dietary lipid levels (14%, 16%) with/without Volamel Aqua (0.1%) were formulated and produced by Research Diet Services (RDS, the Netherlands), resulting in four experimental diets: High fat diet (HFD), high fat + emulsifier (HFD-EMS), low fat diet (LFD) and low fat + emulsifier (LFD-EMS). Juveniles of gilthead sea bream (Sparus aurata; 12 g initial body weight) were allocated in triplicate 500 L tanks under natural photoperiod and temperature conditions at IATS latitude (40°5’N; 0°10’E) from May to August and hand-fed daily until visual satiety. During the first half of the trial (46 days), emulsifier supplementation supported a 10% improvement of feed conversion ratio (FCR) with the increase of water temperature from 20 ºC to 25 ºC. Such improvement was masked during the second half of the trial with the achievement of the historical record of water temperature at our latitude (30.49 ºC, August 9th, 2022). At this time, 12 fish per diet were anaesthetized with MS-222 and sampled for blood (circulating glucose and cortisol) and for intestinal mucus (adherent intestinal microbiota) analyses. Previous samples from fish with the same genetic background not exposed to extreme heat temperatures and fed a commercial standard formulation were used as reference values (REF). Microbial DNA was extracted (High Pure PCR Template Preparation Kit, Roche) and V3-V4 region of the 16S rRNA was amplified and sequenced with Illumina platform. Sequences were quality filtered and taxonomically assigned following a custom pipeline using SILVA database.

Figure 1: Stacked bar chart representing the relative abundance of bacterial phyla for each of the experimental diets (HFD, HFD-EMS, LFD, LFD-EMS) compared with the reference group (REF) of fish with the same genetic background not exposed to extreme heat temperatures.

(Continued on next page)
Results and discussion
As shown in previous studies, *Proteobacteria* followed by *Firmicutes, Actinobacteria* and *Bacteroidota* were the most abundant phyla in the gut microbiota of REF fish (Figure 1). Conversely, with the increase of temperature, we found that *Spirochaetota* increased dramatically in HFD and secondly in LFD fish. This trend was partially reversed with the addition of the emulsifier, which shaped a microbiota profile in LFD-EMS fish closer to that of fish not exposed to extreme temperatures. At a closer look, partial least-squares discriminant analysis (PLS-DA) highlighted up to 11 genera with a high discriminant value after filtering by VIP>1 and 0.5% abundance. *Brevinema* (representing almost the total contribution to the *Spirochaetota* phylum) was the most abundant genus with a significant discriminant score, and its decrease with the emulsifier addition was concurrent with an increase in relative abundance of *Photobacterium, Vibrio, Cetobacterium*, and *Bacillus*. Other genera exclusively lowered by the emulsifier or synergistically with the decrease of dietary fat content were *Thauera*, and *Streptomyces* and *Staphylococcus*, respectively. Additionally, both dietary fat level and emulsifier supplementation altered glucose and cortisol levels, being achieved the lowest values of these blood stress markers in LFD-EMS fish.

Concluding remarks
The increase in *Brevinema* genus appeared associated to extreme summer temperature in our experimental model, confirming and extending the possible use of *Spirochaetota* phylum as a marker of heat stress in both fish (Steiner et al., 2022) and pigs (Le Sciellour et al., 2019). Intriguingly, the mitigation of microbiota dysbiosis was favoured by a low dietary fat level, which would depict that dietary intervention can contribute to alleviate in a large extent the negative impact of global warming in farmed fish, although this was not accompanied herein by the improvement of growth performance during episodes of extreme high temperatures. However, the above microbiota shifts were associated to a decrease in plasma glucose and cortisol levels, especially in LFD-EMS fish, which would be indicative of a low energy cost of growth in fish fed low fat diets with the emulsifier supplementation during extreme warming conditions.

Introduction

Land-based aquaculture systems can have an elevated content of metabolically-derived carbon dioxide (CO₂) in the water. Interestingly elevated CO₂ levels have been suggested to induce nephrocalcinosis and to increase the bone mineral content [1,2]. This raises the question if dietary phosphorus (P), one of the main components of bone minerals, can be reduced in systems with elevated CO₂ levels. The optimisation of dietary P levels is desirable, as excess of dietary P can cause water pollution [3]. Using mono-ammonium phosphate (MAP) as a dietary P supplement, this study aims to analyse if the requirements of dietary P are reduced with an elevated water CO₂ level.

Materials and Methods

Atlantic salmon post-smolt (start weight 200 g) were fed MAP-supplemented diets with a low (0.28%) (0.5P), regular (0.56%) (1P), or very high (2.34%) (3P) estimated available P for 13 weeks. Animals from all diet groups were either subjected to water with an increased CO₂ level (20 mg/L) (20CO₂) or to standard control levels of CO₂ level (5 mg/L) (5CO₂). Animals from all experimental groups were reared in duplicates. Analytics included radiography, whole mount Alizarin red S staining, mineralised and non-demineralised histology, gene expression analysis, and plasma, and mineral content analysis.

Results and Discussion

The growth of animals fed the 3P diet, 5CO₂ and 20CO₂ was reduced compared to 5CO₂ animals fed either 0.5P or 1P [3]. 5CO₂ animals fed 0.5P diet showed a known low-mineralised vertebrae phenotype characterised by extended areas of non-mineralised bone; osteomalacia. Plasma P levels in 0.5P animals were reduced. Animals fed 1P and 3P diet animals had fully mineralised vertebrae irrespective of the CO₂ level. The 3P diet had no further effect on bone mineralisation. Unexpectedly, 50% of the 20CO₂/0.5P animals showed a moderate increase of vertebral centra mineralisation, on x-ray images, whole mount Alizarin red S stained specimens, and histological sections (Fig. 1B,E,E’). This indicates that animals were able to use the dietary P more efficiently when reared in water with high CO₂ levels. Fibroblasts growth factor (fgf23) expression, a hormone synthetised by osteoblasts and osteocytes which increases renal phosphate release [4] was downregulated in 0.5P animals. This suggests that more phosphate is retained under levels of increased water CO₂ and reduced dietary P intake.

Figure 1. Representative vertebral centra of Atlantic salmon fed a low P diet and reared under low CO₂ (5 mg/L) (A,D,D’) or high CO₂ (20 mg/L) conditions visualised on x-ray images (A-C, scale bar = 1.5 cm), whole mount stained with Alizarin red S (D-F), and on non-demineralised histological sections stained by von Kossa/Van Gieson (D’-F’) (scale bar D-F’ = 1 mm). (A,D,D’) Characteristic reduced mineralisation is observed in animals fed a low P diet, characterised by the increased size of radiolucent spaces between the vertebral bodies (A) and by extended areas of non-mineralised bone at zygapophyses (arrowhead in D) and vertebral body endplates (arrowhead in D’). (B,E,E’) A moderate increase of mineralisation is observed in animals fed a low P diet and reared at increased water CO₂ levels, characterised by the reduction of radiolucent spaces (B) and reduced areas of non-mineralised bone (E-E’). (C,F,F’) A regularly mineralised vertebral bodies in low P animals reared in high CO₂ characterised by a further reduction of the radiolucent spaces (C) and areas of non-mineralised bone (F-F’).

The current study indicates that the requirements for dietary P in seawater stages of Atlantic salmon can be reduced when animals are reared in water with elevated CO₂ levels. This offers a possibility to lower the P content in salmon feeds for animals reared in systems prone to accumulate CO₂.

POTENTIAL OF LOCAL FISH MEAL PRODUCTION FROM AQUACULTURAL SLAUGHTER REMAINS FOR FISH FARMING IN AUSTRIA

University of Natural Resources and Life Sciences, Vienna, Gregor-Mendel-Straße 33, 1180 Vienna (Austria)
Email: silke.drexler@boku.ac.at

Introduction

Fish meal is a highly demanded resource when it comes to the production of formulated feed for fin fish aquaculture and furthermore in general it is an important source of protein. But in times of a biodiversity-, climate- and energy crises new paths for its provision have to be taken.

The implementation of the Austrian “Strategic Plan 2020 for Aquaculture” caused an increase in domestic production volumes of edible fish. At the same time the amount of fish slaughter by-products has increased. Most of the remains are processed away from the production site. Considering that the slaughter yield is around 50% per individual, a high percentage is eliminated from the on-farm production cycle for human consumption.

In the frame of the project “Sustainable utilization of fish carcasses for the circular economy in Austrian aquaculture” (No. 101742) financed by the Federal Ministry for Agriculture, Forestry, Regions and Water Management of the Republic of Austria and DaFNE, the processing of fish slaughter by-products is one of the main tasks besides a sociological study to clarify the potential of local aquaculture development scenarios and the interest in local fish meal production.

Materials and Methods

To process fish slaughter by-products of the African catfish (Clarias Gariepinus, Burchell 1822) a prototype of the Swiss company “Value Recovery Solutions AG” was tested – the further named “VRS Jumbo”. This machine can process 250kg of wet by-products by comminution, water evaporation and sterilization within a time span of 7 to 11 hours. After a cool down period the final products are a liquid (“fish oil”) and a solid component (fish meal). Several parameters of the default settings were adapted in the testing phase for the following experiments: In a first run 7 x 200kg fish slaughter by-products (carcasses, skins, fish-offals, heads – randomly collected) of the African catfish were processed. From the received fishmeal, samples have been put into high density polyethylene cans and these have been stored at -20°C until further analysis. The wet chemical analysis was conducted at the Feed Laboratory Rosenau – Regional Chamber of Agriculture, Lower Austria - while the amino acids were analyzed at the Institute of Animal Nutrition, Livestock Products, and Nutrition Physiology at BOKU- University, Vienna.

For the second part of the study – the sociological investigation for pin-pointing clearer directions of local aquaculture developments – consultations and opinions of stakeholders have been analyzed. For the narrative interviews three clusters of persons were targeted: (1) administration and legislation, (2) education and consulting and (3) fish producers. For each cluster a specific interview guideline was developed whereas the first question was in all three clusters covering the potential of Austrian aquaculture. The other question-blocks were specific for each cluster and its operations. Several dates were offered for persons from each cluster to participate in an online discussion. The meetings were recorded and further transcribed, analyzed and evaluated.

Results

Analysis of the first runs of the production of African catfish meal revealed that (all values are mean values of the 7 analyzed procedures) the dry matter content (DM) is 92.1%, the crude protein content (XP) is 43%, the convertible energy is 18.62 MJ ME, the crude fat content (XL) is 30%, the crude fibre (XF) is 0.4% and the crude ash content (XA) is 17%.

In comparison to other commercial fish meal (60-65% XP) the African catfish meal has a lower protein content, but it has more energy and fat, while crude fibre and crude ash are reduced.

The evaluation of amino acids shows that the ratios are similar to other commercial fishmeal. Especially lysine and methionine as the first limiting amino acids in fish meal present a mean of 2.57 g/100g (lysine) and 0.79 g/100g (methionine).

Within the sociological study limited or missing research results are-often the main reasons for consultants and teachers (cluster 2) not being able to provide education and counseling services for fish farmers in terms of fish slaughter by-products processing. Fish producers (cluster 3) actually prefer rendering plants as optimal locations for the disposal of fish slaughter by-products. Furthermore, most of them don’t have any preferences in terms of processing fish slaughter by-products at their own companies or at a central location. From cluster 1 no feedback was received.
EFFECT OF SHORT AND LONG TERM ANTIOXIDANT SUPPLEMENTATION IN Sparus aurata SPERM QUALITY

Introduction
The negative impact of oxidative stress on spermatozoa is one of the main damages suffered by these cells, as described by some authors (Guthrie & Welch 2012; Cabrita et al., 2014)). In the specific case of fish sperm, there is an increased vulnerability to this type of damage due to the high content of polyunsaturated fatty acids in their membranes. Quality parameters such as: sperm motility, cell viability, apoptosis induction and DNA integrity, are affected by oxidative stress (Cabrita et al., 2014). There are many external factors that contribute to this situation, but nutrition is crucial in the regulation of oxidative events, since it allows the incorporation of compounds to support the action of the antioxidant system present in the spermatozoa and seminal plasma (Félix et al., 2020). The main goal of this study is to assess the impact of antioxidant diet derived supplementation in fish sperm quality and compare a short and long-term administration to understand if putative effects persist over time or if the feeds lose their effectiveness.

Material and methods
Adult gilthead sea bream (Sparus aurata) were fed with 3 different diets (n=21 each): A) control diet, B) vitamins C and E supplemented diet (Vit C+E) and C) selenium and zinc supplemented diet (Se+Zn), along two years. During each reproductive season, males were sampled for sperm collection 4 times, and an average of the results from the first and second year was done in order to evaluate the short (ST) and long-term (LT) effects of the supplementation on sperm quality. From the collected sperm, different quality parameters were evaluated: spermatozoa motility using the CASA system, lipid peroxidation by MDA quantification, cell viability and reactive oxygen species (ROS) through flow cytometry, and DNA fragmentation using Comet assay. Methods have been described elsewhere (Cabrita et al., 2011, 2014).

Results and discussion
The motility analysis performed in this study showed a significantly higher spermatozoa progressive motility at long-term (LT) for both supplemented diets. At ST (short term), fish fed with Vit C+E presented significantly higher curvilinear velocity (VCL) than the control and at LT it was higher than the other two treatments. Like in this study, Sarmento et al. (2017) also reported better progressive motility (PM) in Nile tilapia (Oreochromis niloticus) fed with supplemented vitamin C. This was also observed in Solea senegalensis, once fish fed with vitamin E presented higher PM and VCL (Beirão et al., 2015). However, the effect of a single vitamin, E or C, or even other antioxidant compounds may be species-specific (Cabrita et al., 2011). Vitamin C and E deficiency produces reproductive impairments in seabream such as immature gonads and low hatching rates, demonstrating to play an important role in gamete maturation (Izquierdo et al., 2001). In terms of cell viability, there were no significant differences, neither between treatments nor between periods of supplementation. In the case of ROS production, no significant differences were found among the 3 groups at ST, but there was a significant increase in the Se+Zn supplemented group at LT, suggesting a decreasing effect of this diet over time. All 3 groups presented a significant increase in lipid peroxidation at LT, with Se+Zn showing the highest MDA levels. Regarding DNA fragmentation, at ST, Vit C+E displayed higher DNA degradation than the control. A general increase in DNA fragmentation was detected at LT, without significant differences between the control and Vit C+E group, which may indicate that more time is needed to detect the positive effects of this supplement.

Conclusion
According to these results a short-term beneficial effect of vit C+E diet in terms of oxidative stress was observed, although there were no evidence of a reduced effect at long term. On the other hand, Se+Zn diet presented a depleted action over time. Further studies concerning a longer period of supplementation should help to better understand these mechanisms.

Introduction

Haematological and biochemical parameters of blood are widely used to determine fish health status and the effect of environmental factors (Fazio 2019; Esmaeili 2021; Witeska et al. 2022). One commonly used parameter is the erythrocyte count (RBC, red blood cell count) in a set volume of blood (e.g. Huffman et al. 1997). Traditionally, erythrocytes for RBC are analyzed via manual inspection which is time-consuming and can also lead to interobserver differences (Fazio 2019). Alternative options for blood analysis, such as automatic haematology analyzers and flow cytometric methods, have been proposed (Fazio 2019), but the necessary instruments for such analyses are quite costly and may not be easily available for small labs. Nowadays automatic image recognition is well established in various areas and has become more straightforward to use in custom-tailored applications. YOLO, which stands for ‘you only look once’ is such an architecture based on a convolutional neural network (CNN) (Redmon et al. 2016; Nakahara et al. 2018). The underlying algorithm divides each picture into a grid system, in which each cell of the grid is responsible for object identification. This method is characterized by high speed in identification and rapid training results. The aim of this case study was to utilize open-source image recognition software to automate blood cell counting for salmonid fish raised at Fish Farm Kreuzstein.

Material and Methods

Blood was collected from young of the year brown trout (Salmo trutta). Due to their small size fish were anaesthetised with an overdose of MS222 and 10µl blood was collected with a pipette from the cut heart ventricle. The blood was instantly fixed in 1ml 0.1mol⁻¹ cacodylate buffered 4% glutaraldehyde solution (pH 7.4). Blood samples were put on a Neubauer counting chamber and pictures of blood were taken at a 40-fold magnification with a light microscope (Motic BA2010 LED). Identical sections of the picture were cropped using Preview (version 11.0). For image recognition, we used YOLOv5 from Ultralytics (Jocher et al. 2022). Transfer training was conducted with pre-trained model weights yolov5s (COCO128 dataset) and 78 labelled images (5487 instances) and one background image. The epoch size was 300 (default) and for image size 640 (default). The validation dataset included 17 and the test dataset nine images. We did no fine-tuning or comparisons of different models. The trained model weights were exported to TensorFlow.js format. The frontend interface for the end-user was created with VueJs and the meta-framework Quasar. Deployment was done via GitHub Pages. The annotated files, current trained weights and single-page application code is available under GNU Affero General Public License v3.0 on GitHub: https://github.com/HannesOberreiter/baw-fish.

Results and Discussion

These results exhibit the potential of object detection algorithms for research purposes and rapid prototyping. As our first MVP (minimal viable product) was already running after three days of work. While licensed software is often not accessible to small labs, object detection algorithms like YOLOv5 (now also available as YOLOv8) allow for relatively straightforward use for different recognition applications. After training with only 79 labelled images, the resulting best model weights showed a mAP50 of 97% (Precision 96%, Recall 94%) on the test dataset. The use of modern JavaScript frameworks, in our case VueJS, allowed us a rapid development of a user-friendly interface for lab personnel to upload their images and see the results. The visualization of the results was very important to allow human-based decisions in edge cases, for example, problems of overlapping cells when blood cells aggregate. The exported final model weights in TensorFlow.js format were quite small (around 20MB) and allowed to outsource the prediction to the device of the user. This means we only need static asset hosting and no expensive server hosting to do the calculations. Our goal was to find a quick solution for a previously tedious task, which was achieved with tools that have good and relatively easy-to-understand documentation and are well-established. Of course, team members with programming skills are needed to make use of these technologies, but if available, programmes like YOLOv5 grant interesting opportunities for workflow improvement and automatization. This is not only limited to blood cell counts but could also be extended to other applications like fish egg counting, the measurement of cells or cell type identification, limited only by programming skills or time constraints.

Introduction

Rapeseed/canola (Brassica napus L.) stands as an underdeveloped reservoir of beneficial nutrients for aquaculture. Aqueous extraction of soluble proteins from defatted rapeseed/canola meal represents an innovative processing method that is safe, environmentally friendly and with minimal impact on protein denaturation (Aider and Barbana, 2011; Campbell et al., 2016). This processing method can create a rapeseed/canola protein concentrate (~78% crude protein) with low levels of phytic acid and insoluble fibers, and that has potential to contribute to circular economy by increasing the use of crop by-products. In this research, the process was applied to produce an aqueous-extracted protein concentrate (APC) destined to serve as ingredient in aquaculture feeds. A series of studies were conducted to (1) evaluate the long-term effect of graded inclusion levels of APC on growth, feed and nutrient utilization, body composition, fillet color and gut histology of post-smolt Atlantic salmon, and (2) estimate the nutrient digestibility of APC in juvenile Atlantic salmon in freshwater and in post-smolt Atlantic salmon.

Materials and methods

Rapeseed/canola processing: Defatted meals obtained from rapeseed/canola crushing plants were processed at a pilot-scale facility through different steps involving protein extraction, precipitation and separation using water as solvent and no chemical such as hexane.

Long-term efficacy: Post-smolt salmon (228.0±4.9g) were fed graded inclusion levels of APC over a six-month study. Eight isoproteic and isolipidic experimental diets containing 0 (Diets A, E), 10% (Diets B, F), 15% (Diets C, G) and 20% (Diets D, H) APC were randomly allocated to 24 750-liter tanks at 33 fish per tank. Diets A through D were formulated to mimic commercial salmon feeds in geographies where processed animal proteins (PAPs) are used (e.g. Americas), whereas diets E through H included no PAP (European-type diets). The proximate (protein, lipid, dry matter, ash) and amino acid composition of the test ingredient, diets and whole-body of salmon were analysed according to AOAC methods. Effect of APC inclusion levels on growth performance, nutrient utilization, fillet color, gut histology and pellet physical characteristics were measured and analysed statistically.

Nutrient digestibility studies: Juvenile salmon (57.3±6.7g) were fed with a reference diet and three test diets combining the reference diet with APC in 90:10, 80:20 and 70:30 ratios in freshwater (14.9±0.4°C). Feces were collected using the settling column passive method. Another digestibility study was conducted with post-smolt Atlantic salmon (227.7±4.1g) also fed a reference diet and three test diets combining the reference diet with APC in 90:10, 80:20 and 70:30 ratios in saltwater (25ppt; 13.7±0.5°C). Feces were collected using the manual stripping method. For both studies, the proximate (protein, lipid, dry matter, ash) and amino acid composition of the test ingredient, diets and feces were analysed according to AOAC methods. The apparent digestibility coefficients were estimated using equations from NRC (2011) and results were analysed statistically.

(Continued on next page)
Results

**Rapeseed/canola processing:** The crude protein content of APC was consistent across the three lots processed during this project at 77-79% (as-fed). The amino acid profile was comparable to that of fishmeal.

**Long-term efficacy:** Growth performances, measured using the thermal-unit growth coefficient (TGC), varied between 0.143 and 0.160, and were not significantly different among treatments (P>0.05). Feed conversion ratios (FCR) were ≤1.08 and, although there was a significant APC effect (P=0.003), differences were marginal and did not correlate with APC inclusion. Over the 168-day study, the best TGC and FCR were obtained with salmon fed 10% CPC, regardless of formula type. Proximate composition, nutrient deposition rates and retention efficiencies were similar across treatments. Although not significant, fillet redness improved with APC inclusion. APC inclusion level correlated positively and significantly with distal intestine villi length (P=0.031). Villi length of salmon fed 20% CPC (1053.3 ± 28.0 µm) was significantly superior to that of fish fed the control diet (931.7 ± 21.4 µm) (P=0.006). The proportion of distal intestine with no inflammation of the lamina propria and submucosa increased with APC inclusion.

**Digestibility studies:** The results of both digestibility studies are summarized at Table 1.

Discussion and concluding remarks

**Rapeseed/canola processing:** The environmentally friendly aqueous processing method is suitable for producing protein concentrates from oilseeds.

**Long-term efficacy:** APC stood as a promising sustainable and safe protein alternative for salmon feeds in this long-term study. With a high protein content and an amino acid profile comparable to fishmeal, dietary inclusion of APC at all levels tested in this study supported growth and optimal nutrient utilization while improving fillet redness and gut health of post-smolt Atlantic salmon.

**Digestibility studies:** Digestibility of protein, lipid and essential amino acids of APC was high at all life stages and unaffected by APC inclusion level.

To conclude, the next steps will consist in describing further the positive effects of APC on fish welfare/health in challenged fish and assessing the environmental impact/performance of this innovative ingredient.

QUALITY AND QUANTITY: THE EFFECTS OF LIGHT CONDITIONING ON Palmaria palmata BIOMASS PRODUCTION FROM VEGETATIVE CULTURE

M.D. Edwards*, S. Whelan, A.T. Idowu¹, A. Soler-Vila, M. Amigo-Benavent¹, R.J. Fitzgerald¹

Irish Seaweed Consultancy
Galway, Ireland
¹University of Limerick
Limerick, Ireland
maeve.edwards@irishseaweed.com

Palmaria palmata is a valuable Atlantic seaweed; Ireland is a major producer. Current retail value is €80-€120 kg⁻¹ (dry), with 80-100 tonnes (wet weight) wild-harvested annually. Cultivation is also possible; at sea (longlines) and on shore (tanks). In a series of vegetative growth trials, frond tissue (‘tips’) were grown to assess 1) effect of photoperiod (12:12 and 16:8 light:dark; L:D) with nutrient addition (seawater control, 50 % or 100% F/2 culture medium twice wk⁻¹, 100 % F/2 once wk⁻¹); 2) effect of light quality on cultures in 16:8 L:D red, green, blue and white light LEDs compared to older cool white LEDs 3) effect of 12 days in green light, then 12 days in blue light (12:12 L:D in 20 (25%), 40 (50%) and 80 (100%) µmol m⁻² s⁻¹ blue light, 100% green light control, 100% blue light control). Specific Growth Rates (SGRs) of tips were highest (13.89 % day⁻¹) in 16:8 (L:D) and 100 % F/2 twice wk⁻¹. However, 12:12 L:D cultures had significantly higher Total Nitrogen (4%) than 16:8 cultures. Light quality affected biomass of cultures; greatest biomass achieved jointly under Green LEDs and old cool white LEDs, followed by red light, with blue light the least effective. SGRs ranged from 12.2-8.9 % day⁻¹. In the green/blue light experiment, green light alone produced significantly the best biomass results, with overall increases of 220%, compared to green-then-blue light cultures, with 50% and 100% blue cultures not significantly different with 105% and 130%, respectively). Blue light controls increased the least (50%), indicating that initial green light enhanced biomass of blue cultures. Protein results of all trials will be discussed.
EFFECTS OF FISHMEAL REPLACEMENT BY DEFATTED *Hermetia Illucens* ON METABOLISM AND IMMUNE RESPONSES OF EUROPEAN SEABASS (*Dicentrarchus Labrax*)

Introduction

Fish meal is currently the major protein source for use in aquafeeds, however, due to its dependence on finite fish stocks, a vast amount of research effort is focused on finding alternative protein sources. The use of insect protein as sustainable alternative to animal- and plant-based feeds has been proposed for human and animal consumption. Insects have advantages as feed components, since they reproduce easily, grow fast, have low feed conversion ratio and small need of arable land and water. Moreover, insects are rich protein sources, with well-balanced essential amino acid profiles, rich sources of fat, vitamins, minerals and healthy compounds (i.e. chitin, antioxidants, antimicrobial peptides). It has been found that insect-based diets modulate fish microbiota and improve their immune system, reducing the use of antibiotics in aquaculture. Recently, the European Union (EU) authorized the use of insect meal in aquafeeds (Basto A, 2021), (Kotzamanis Y, 2020). In that frame, the present study aims to explore the impact of partial replacement of fish meal by defatted *Hermetia illucens* (HI) focusing on the underlying mechanisms involved in immune responses, in European sea bass, an economically important fish species for European aquaculture.

Materials and methods

Five experimental diets containing different percentage of fish meal substitution by defatted *H. illucens* (HI6 20%, HI6 30%, HI6 40%, HI6 50% and HI6 60%) and a positive control diet (commercial diet without HI) were used. European seabass juveniles were assigned to experimental tanks and each diet was allocated in triplicate groups. The feeding trial was continued over a period of 73 days. At the end of the feeding trial, fish were weighed and analyzed for whole body composition. Blood was drawn by the caudal vein of fish and serum was isolated by centrifugation. Head kidney and spleen tissues were removed and either used immediately for leucocyte cell suspension or stored at – 80 °C. All animal handling and sampling procedures were conducted in accordance with Greek and EU laws and regulations.

The serum samples were used for serum biochemistry and immunological parameters assessment, according to well established protocols. The factors which were studied include total protein amount, glucose, hemoglobin, nitrite ions (NO2–), lysozyme, myeloperoxidase, proteases, proteases inhibitors, immunoglobulin (IgM) and complement C3. Total RNA was extracted from fish head-kidney and spleen and real-time PCR assays were carried out to analyze the expression pattern of different immune relevant genes (IRF7, ISG12, MxA, IL-1β, IL-10, STAT3, IgHM, CD4, CD8α and hepcidin). Leucocyte cell suspensions were prepared for evaluation of macrophage activation by phagocytosis, reactive oxygen intermediates (ROI) and nitric oxide assays. The proliferative ability of the leukocytes was also assessed.

Results and Discussion

The total protein amounts weren’t noticeably modulated by any of the experimental diets similarly to serum hemoglobin levels. On contrary, the glucose levels were significantly altered by the HI6 30% experimental diet compared to control diet while all other diets didn’t show significant differences on the glucose levels. Non-specific immune responses were assessed in fish serum by measuring the levels of nitrite ions, lysozyme, complement C3, myeloperoxidase, as well as protease and anti-protease activities. A significant decrease in nitric oxide levels of fish fed HI6 40 – 60% diets was observed when compared to the control diet. A more intense decrease was evident for lysozyme levels, since all experimental diets had less serum lysozyme than the control diet. The myeloperoxidase levels were also altered by the experimental diets: The HI6 60% MPO levels was significantly lower compared to the control diet, while the MPO levels in the other experimental diets were slightly decreased. The remaining parameters (C3 levels, proteolytic and anti-proteolytic activities) were not affected by any of the experimental diets. The immunoglobulin M (heavy chain) expression was determined both in the molecular

(Continued on next page)
and protein level. In serum, the IgM levels were slightly increased with experimental diets compared to the control diet, however no significant modulation was observed. Accordingly, the IgHM gene expression levels were slightly down-regulated. Gene expression profile was analyzed to evaluate the modulation of immune-related genes in sea bass fed with two experimental diets: HI6 30% and HI6 60%. The studied genes in sea bass head kidney were related to cytokines (IL-1b, IL10) and interferon pathway (ISG12, IRF7, MxA, and STAT3) whereas those analyzed in spleen were T-cell markers (CD8a and CD4) and an antiviral peptide (hepcidin). All analyzed genes were differentially expressed to some extend but gene expression differences were not statistically significant for any of the tested groups.

The possible immunostimulant effect of fish diet replacement was assessed by means of the phagocytic, respiratory burst, and nitrite production activities as well as clonal expansion of HK cells obtained from fish fed with increasing diet replacements after incubating them with various microbial stimuli in vitro. The phagocytosis ability of HK macrophages exhibited a concentration dependent increasing pattern despite the fact that the phagocytic capacity of the HK cells was the same among the groups tested. The respiratory burst activity was significantly increased in 60% substitution diet while nitrite production unveiled that diet substitution did not further enhanced cells capacity to respond. Accordingly, diet substitution did not affect mitogen-induced proliferation of HK cells after simultaneous triggering with ConA and PMA in comparison with control cells.

Concluding, the experimental diets containing different percentage of fish meal substitution by defatted *Hermetia illucens* didn’t induce any immune response, which would indicative harmful effects of insect meals on the fish physiology.

Introduction
Water is a vital resource for the sustenance of life and it forms the basis of the blue economy. Water quality is often threatened by pollution such as nutrient pollution (eutrophication) and microbial contamination. This causes a deterioration of water quality, infections and in worse cases, death of both humans and animals. Various methods have been used in the removal of microbiological contaminants in water such as physical treatments (filtration), biological processes, chlorination, ultra violet (UV) disinfection and ozonation. However, these methods are not effective in removing nutrients such as phosphates from the same wastewater. Adsorption is one of the methods used in the removal of phosphate from wastewater. The use of low-cost materials makes adsorption a cheap and easy method to use. Mollusc shells are by-products generated during shell processing and the sustainable use of these by-products is key to the actualization of a blue economy within the shellfish processing industry. Can these ‘waste shells’ and low-cost material, be used in the removal of nutrients (specifically phosphate) and water-borne bacteria? This study aims to investigate the phosphate removal capacity and antimicrobial activity of mollusc shell waste powder in both its non-heat treated and heat-treated forms, against four bacterial strains which affects both humans and fish.

Materials and methods
Waste shells were cleaned and oven dried at 105°C for 2 h, sieved to their respective particle size and calcined for 2 h. Two Gram-negative bacteria, Escherichia coli Pseudomonas stutzeri, and two Gram-positive bacteria, Staphylococcus aureus and Bacillus subtilis, which are widely distributed in the environment (such as in water and soil), were selected as the indicator organisms. The indicator bacteria were prepared following the National Committee for Clinical Laboratory Standards (NCCLS) protocol. The antibacterial activity of the non-heat treated and heat treated mollusc shell waste powder were determined using the well diffusion method at a concentration of 25 mg. Batch experiments were conducted to determine the phosphate removal efficiency of the shells. The shell samples were characterized using physico-chemical methods such as Scanning Electron microscopy (SEM), energy-dispersive X-ray spectroscopy (EDX), Fourier transform infrared spectroscopy (FTIR) and X-ray powder diffraction (XRD) analysis.

Results
Non-heat treated mollusc shells showed no antibacterial activity against all the bacteria strains. However, the heat treated mollusc shells had good antibacterial activity with activity highest for B. subtilis and P. stutzeri, followed by E. coli and S. aureus. Furthermore, the results of the batch experimental study showed that the non-heat treated shells had a lower phosphate removal efficiency when compared with the heat-treated shells. The result of the characterization study showed that heat treatment of the shell powder resulted in a change of structure, morphology and elemental composition all of which contributed to its increased phosphate removal capacity and antibacterial activity.

Conclusion
Heat treated mollusc shells used in this study exhibited antibacterial activity against all the bacteria strains, thus demonstrating a broad spectrum of activity for both gram-negative and gram-positive bacteria. Furthermore, the heat-treated shells show a higher phosphate removal capacity when compared with the non-heat treated shells. Research is currently ongoing on the use of the shells for the simultaneous removal of phosphate and water-borne bacteria from both synthetic and industrial wastewater.

INSECT OIL AS A DIETARY INGREDIENT IN AQUAFEEDS FOR SILURIFORM FISH

Robert Egessa*, Zsuzsanna J. Sándor

Research Centre of Aquaculture and Fisheries
Hungarian University of Agriculture and Life Sciences
Anna liget. u. 35

Introduction
Cheaper alternatives to fish oil are necessary due to the growth of aquaculture and the unfavourable costs of fish oil. Although several alternatives to fish oil have been tested and potential benefits demonstrated, the effects of insect oils on growth and health of siluriform fish are less well defined. To narrow this gap, we highlight the importance of black soldier fly (Hermetia illucens) larvae oil as an ingredient in the diets of siluriform fish. The insect oil, which was produced by a defatting procedure was used as a test ingredient in the diets of African catfish (Clarias gariepinus) and European catfish (Silurus glanis). Here, we present first results on growth, nutrient utilization, plasma biochemistry, enzyme activities, and antioxidation capacity in both species.

Materials and methods
Three isonitrogenous (430 g/kg) and isolipidic (110 g/kg) diets (reference and two experimental) were formulated for the two species, the main difference being the oil source. The reference diet contained a mixture of fish oil and rapeseed oil (1:1 ratio) while the two experimental diets contained either a 1:1 mixture of insect oil and rapeseed oil (H50) or insect oil only (H100). Two feeding trials, one for European catfish and another for African catfish were conducted, lasting for eight weeks. The first trial involved a total of 630 European catfish juveniles (average body weight of 28.1 ± 0.17 g) originating from the institutional hatchery facility at the Research Centre for Aquaculture and Fisheries (HAKI). Fish were distributed into three dietary groups (REF, H50 and H100), each replicated three times (70 fish per tank) and reared in a recirculation aquaculture system equipped with nine 1 m$^3$ fiberglass tanks. A second trial involving 900 juvenile African catfish (average weight: 29.1 ± 1.69 g) were treated similarly to the first trial. During the eight weeks period, fish were fed daily until apparent satiation using automatic feeders. Water quality parameters (temperature, dissolved oxygen, and pH) were monitored regularly, while nutrients (ammonia, nitrites and nitrates) were monitored on a weekly basis.

Results
All the diets (REF, H50, and H100) promoted adequate growth and feed utilization in both species. Fish growth was more than five-fold of the initial body weight, with no significant differences in growth performance, nutrient utilization, or body indices between fish fed the reference and experimental diets. The plasma cholesterol, glucose, phosphorus, calcium, and total protein contents were not significantly affected; only the globulin (for S. glanis) and albumin, and the albumin to globulin ratio, significantly differed between the dietary fish groups in each species. This may indicate upregulated nutritional or metabolic activities in insect-based diets since albumins are involved in transport functions. Plasma alanine transaminase (ALT) activity did not differ between dietary groups of fish for both species, while for the alkaline phosphatase (ALP), significant differences were observed only for S. glanis but not in C. gariepinus. The activity of plasma lipase significantly differed between dietary groups of S. glanis and not in C. gariepinus, but overall was highest in fish fed H50 diet and lowest in fish fed H100 diet for both species. No significant differences were observed in lysozyme activity, immunoglobulin and myeloperoxidase content of plasma from the different dietary fish groups in both trials. The activities of intestinal digestive enzymes (amylase, lipase and trypsin) were insignificant in S. glanis while in C. gariepinus, only amylase activity was significantly higher in H50 than REF and H100 fish groups. The liver antioxidant indices of both S. glanis and C. gariepinus were nonsignificant between the different dietary groups, but indicated better performance of insect-based diets.

Conclusion
Overall, these results indicated that complete substitution of fish oil or vegetable oils with black soldier fly larvae oil is possible in the practical diets of siluriform fish, without causing deleterious effects on the growth, nutrient utilisation, plasma biochemical parameters, and antioxidation capacity.
FEEDING DURING RAS OFF-FLAVOURS DEPURATION: DOES FEEDING HELP REDUCING DOMINANT OFF-FLAVOURS IN RAS-REARED FISH?

Introduction

The presence of water-borne off-odour compounds in fish, such as geosmin and 2-methylisoborneol (Abd El-Hack et al., 2022), or less commonly reported feed-borne compounds, such as beta-ionone, butanoic acid, or indole (Podduturi et al, 2017; Mahmoud et al., 2018), can drastically reduce its palatability, leading to consumer rejection and lower market demand of recirculating aquaculture systems (RAS) products. A common off-flavour mitigation strategy is to purge the fish in flow-through systems prior to harvesting while ceasing feeding. However, this procedure results in the loss of fat content and precious market weight, as well as in a far greater consumption of water. Other technological strategies utilise intense ozone and ultraviolet (UV) light, which further increase costs in RAS farms (Abd El-Hack et al., 2022). In one recent study, feeding was observed to increase excretion rate of geosmin in Nile Tilapia (Schram et al., 2021), with important implication on reducing the negative impacts of standard off-flavour purging methods. The aim of this study was to isolate the effect of water born vs feed born off-odour odours in juvenile male Russian sturgeon (*A. gueldensteadtii*) reared in RAS as well as to understand the effect of feeding during standard purging practices.

Methods

A commercial scale experiment was designed to trial four groups of test fish: two groups reared in clean flow through (FT) water and two in RAS water. In each water type, one group of animals was starved for 3 weeks and one fed at standard feeding regime with a commercial feed previously in use. After 3 weeks in experimental conditions, three animals were sampled per test group, euthanised, filleted and frozen at -20°C. Subsequently, the dominant off-odour compounds in the two water sources, in the commercial feed and in the fish fillets of each test group were determined via olfactometric detection of single odour-active volatile compounds coupled with instrumental analytical methods. Aroma distillates were obtained from fish fillets by using solvent assisted flavour evaporation (SAFE), the dominant off-odorants – i.e., exhibiting higher sensory detection thresholds and concentrations – were determined by aroma extraction dilution analysis (AEDA) and finally identified by gas chromatography-mass spectrometry/olfactometry (GC-MS/O) as described by Mahmoud et al., (2016).

Results

Dominant off-odour compounds present in the fish fillets were sourced from both commercial feeds and water types. RAS water was found to be more diverse in off-odour compared to FT water, and ubiquitous dominant off-odours to be detectable with higher AEDA dilution factors (FD) in the RAS water. Geosmin and 2-MIB were present in both water types yet reaching higher FD in RAS water. The dominant off odours present in the commercial feed comprised feed-borne compounds previously published (see Podduturi et al, 2017; Mahmoud et al., 2018), being dominated by butanoic acid (“cheesy, sweaty”), methyl butanoic acid (“sweaty”), thymol (“thyme-like”), heptanoic acid (“pungent, sour, wax-like”) and 4-hydroxyphenyl acetaldehyde (“horse stable-like) notes. Juvenile male Russian sturgeons reared in RAS water were more diverse in dominant off-odour compounds compared to those reared in FT water. Geosmin and 2-MIB were observed in all four test groups with different FD factors, being in general higher in RAS water. Within each water type, feeding was observed to reduce the FD levels of highly dominant odour compounds, being a strong indication of reduced concentrations, while increasing on the other hand the overall diversity of the odorants, albeit all with relatively low FD factors. Accordingly, feed-borne off-odour compounds were absorbed into fish fillets either by ingestion or by excretion-reabsorption via respiration from RAS water, yet these substances were not detectable in the group starving in FT water. Of the four test groups, the animals fed in FT water yielded the least concentrated dominant off-odours and the highest organoleptic palatability.

(Continued on next page)
Points of Discussion
In line with the results published by Schram et al. (2021), this study confirms that feeding during standard RAS off-odours purging practices in FT water helps reducing the levels of highly dominant off-odour compounds, such as geosmin. Therefore, feeding during purging should be taken into consideration by aquaculture farmers to reduce the economic loss of standard purging practices. In general, we are convinced that the lack of understanding of the biochemical mechanisms improving off-flavour depuration during feeding should receive greater attention in future research. At the same time, the uptake of highly unpalatable feed-borne odorants in fish fillets is confirmed in this study, in accordance with findings of previous studies. As feed-born volatile organic compounds are obviously absorbed into fish fillets, this source of off-odours should be addressed by feed manufacturer in the future, and the potential for flavour modulation should be considered. Finally, the possibility to create “purging” fish feed formulas resulting in highly palatable fish products from RAS is a promising strategy as demonstrated by this study.

DURATION OF INCUBATION & LARVAL DEVELOPMENT OF STERLETS (A. ruthenus) IN RIVER WATER UNDER NEAR_NATURAL CONDITIONS

H. Eichhorn*, J. Neuburg & T. Friedrich

Institute for Hydrobiology and Aquatic Ecosystem Management
University of Natural Resources and Life Sciences Vienna
E-Mail: thomas.friedrich@boku.ac.at

Day-degrees, also known as cumulative temperature units (CTUs) have been used to predict the duration of early development in fish. For most sturgeon species, the available data in literature was conducted under constant conditions. However, there is a lack of information on CTUs of early development in sturgeons under natural or near-natural conditions. The aim of this study was to observe the duration of incubation and the duration from hatch until feeding of sterlets (Acipenser ruthenus) under near-natural. This study was embedded within the LIFE Sterlet project and data was gathered from the year 2018 to 2022. The rearing of fish larvae took place in the LIFE Sterlet hatchery container with Danube water without biological, chemical or thermal water treatment to simulate natural conditions. Temperatures were monitored on a daily basis and day-degrees were calculated by summing the temperature over time. Preliminary results indicated slower larval development of the sterlet than described in literature. Hatching started at about 106 day-degrees earliest and took maximal 213 day-degrees. Feeding started between 171 and 2012 day-degrees. The findings of this study provide valuable insights into the temperature-dependent development of sterlet larvae under near-natural conditions and can assist in the design of optimal rearing of sturgeons for conservation efforts.
BLACK SOLDIER FLY LARVAE (*Hermetia illucens*) MEAL IN DIETS FOR ATLANTIC SALMON SUSTAINS GROWTH AND GUT HEALTH DURING FIELD CONDITIONS

Introduction

To support the rapid growth in the aquaculture industry, there is a need to develop sustainable feed resources as alternatives to fish meal and plant ingredients. Insect meals such as black soldier fly larvae (BSFL) meal are promising alternatives with a low environmental footprint. Previous controlled short-term experiments suggests that BSFL meal is a suitable protein source for Atlantic salmon (1). The aim of this experiment was to investigate how insect meal inclusion impacts growth performance and gut health of Atlantic salmon during the grow-out period in seawater under production field conditions.

Methods

A total of 320,000 Atlantic salmon (*Salmo salar*) with an initial and final weight of 1,200 and 4,500 g, respectively, were fed diets containing either 0, 4, and 8 % defatted BSFL meal (IM0, IM4, IM8) for 5 months in a field experiment on a commercial salmon farm (Nordfjord, Norway). The experimental diets were produced in a twin-screw extruder and the technical quality was assessed for expansion, hardness, durability and sinking velocity. Samples from intestinal content were taken from distal intestine (DI) for microbiota analysis with 16s ribosomal RNA sequencing and DI tissue was histologically analysed with haemotoxylin and eosin, periodic acid-Schiff and Alcian blue staining. In addition, samples were taken from DI for RNA sequencing.

Results and discussion

The physical pellet quality of all diets was high, but expansion, durability and sinking velocity decreased significantly with 8 % BSFL inclusion, indicating that high inclusions of BSFL may reduce pellet quality. No significant differences in growth rate, feed conversion ratio or mortality were observed between the dietary groups. Histological findings were not significantly attributable to diet, but there was a tendency of increased numbers of ectopic goblet cells in the IM4 diet (*p* = 0.058). For gut microbiota, alpha diversity was not significantly affected by insect meal inclusion, however, beta diversity significantly increased (Fig. 1A and 1B). These findings suggest that insect meal inclusion changed the microbial composition without increasing microbial richness. *Bacillaceae* and *Lactobacillaceae* were significantly more abundant in groups fed BSFL. This is in line with previous studies on salmon smolts [1] and post-smolts [2] fed BSFL. Many bacterial species of *Bacillaceae* can produce chitinase [3] and lactic acid bacteria are considered beneficial in the fish gut [4]. RNA-seq of the DI revealed that IM4 compared to IM0 showed only down-regulated terms related to lipid metabolism and biosynthesis (Fig. 2A). When comparing IM8 to IM0 (Fig. 2B), two terms were up-regulated (response to estrogen and positive regulation of gene expression) and one was down-regulated (fatty acid biosynthesis). Moreover, the comparison between IM4 and IM8 (Fig. 2C) showed twenty-one up-regulated terms related to immune signaling, cell proliferation and extracellular components, possibly corresponding to the tendency of increased prevalence of ectopic goblet cells in the DI in the IM4 group.

Conclusion

Replacing conventional protein sources with moderate levels of defatted BSFL meal did not compromise growth performance or health in Atlantic salmon under field conditions. These findings suggest that black soldier fly larvae meal at moderate inclusion levels is suitable as a sustainable, alternative protein source for Atlantic salmon in seawater.

PRICKLY PEAR FRUIT (*Opuntia ficus-indica*) PEEL IMPROVES STRESS TOLERANCE, IMMUNE RESPONSE, AND ANTIOXIDANT ACTIVITY IN NILE TILAPIA (*Oreochromis niloticus*)

Heba M. Abdel-Ghany*, Mohamed El-S. Salem*, Hebatollah M. Almisherfi†, Abdel-Fattah M. El-Sayed*, Sarah O. Makled*

National Institute of Oceanography and Fisheries, NIOF, Cairo, Egypt
Oceanography Department, Faculty of Science, Alexandria University, Alexandria, Egypt

*Presenting author, heba_elshamy85@yahoo.com

**Introduction**

Opuntia plants and their by-products have been gaining research interest due to their contents of natural bioactive compounds, such as ascorbic acid, betalains, phenols, tannins, and flavonoids, terpenes α-amyrin, β-amyrin, oleanolic acid and cycloartenol. Despite the attributes of prickly pear fruit (*Opuntia ficus-indica*), limited information is available on its use as a feed additive in aquaculture. This experiment was conducted to evaluate the effects of prickly pear fruit (*O. ficus-indica*) peel (PFP) on growth performance, feed utilization, digestive enzymes activity, antioxidant activity, immune response and salinity tolerance of Nile tilapia (*Oreochromis niloticus*) juveniles.

**Materials and methods**

PFP was incorporated into four iso-nitrogenous (280 g kg⁻¹ protein) and iso-energetic (18.62 MJ/Kg DM) diets at 0, 1, 2 and 4 g kg⁻¹ diet. The diets were fed to *O. niloticus* juveniles (9.69 ± 0.2 g) for 75 days.

**Results**

The growth rates, feed utilization efficiency, body protein, digestive enzymes activities, liver function enzymes, immunological responses, and antioxidant status were all improved with increasing supplemental PFP up to 1 g kg⁻¹ diet, followed by significant retardation with further increase in dietary PFP levels (Tables 1 and 2). However, the quadratic regression analyses of the results revealed that the maximum performance and the optimal fish health status occurred at about 2 g kg⁻¹ of dietary PFP (Fig. 1). Moreover, salinity challenge showed that PFP supplementation at 1 g kg⁻¹ diet significantly decreased stress indicators in fish. These results suggest that dry PFP can play a significant role in feed digestion and absorption and enhancing fish performance and innate immune response. About 2 g kg⁻¹ diet would be sufficient for the optimum performance and health status of juvenile Nile tilapia.

AQUAPONICS R&D AT CSIRO: BEGINNING OF A NEW JOURNEY, CHALLENGES AND OPPORTUNITIES

Mauricio G. C. Emerenciano*, Cathryn O’Sullivan, Paula Lima, Chris Stratford, Dean Musson, George Koster, Bert Koster, Donna Glassop, Maja Arsic
Commonwealth Scientific and Industrial Research Organisation (CSIRO), Livestock & Aquaculture Program
Bribie Island Research Centre, 144 North Rd, Woorim, QLD, Australia
and Crops Program, Qld Biosciences Precinct, 306 Carmody Rd, St Lucia, QLD, Australia
(URL: https://research.csiro.au/aquaculture)
*E-mail: mauricio.emerenciano@csiro.au

Aquaponics production is growing either as an alternative for aquaculture diversification, or as a new farming ‘close-to-market’ system, enabling high-quality low carbon footprint food production. As a powerful ‘bio-converter’, Aquaponics is a tool to enhance the circularity in Agri-Aqua food systems, and allows growers to save water, maximise production from their farm footprint and make productive use of nutrient-rich effluents as a fertiliser source. As a result of these benefits, commercial aquaponics farms are growing at a rate of 17%/year worldwide. However, high construction and running costs (e.g. labor, aquafeeds, electricity) are some of the main constraints for further development. The proper nutrient ratio and feed loads will dictate the size of the ‘aquaculture component’, heavily influencing the construction costs.

In 2021 CSIRO started applied research in Aquaponics with the aim of generating knowledge to help the industry grow and scale. The key focuses so far have been (i) creation of a R&D foundation and new capabilities, and (ii) establish connection, understanding and dialogue with the industry. To date, six experimental trials have been conducted with barramundi (Lates calcarifer) and Jade perch (Scortum barcoo) juveniles, exploring the nursery phase (~10 to 30g as initial weights, over ~6-8 weeks). We evaluated the fish performance in aquaponics (AQP) versus conventional recirculating aquaculture systems (RAS); and the plant performance (butterhead lettuce Lactuca sativa, as an initial biological model) in aquaponics versus conventional hydroponics (HYD). Later experiments explored different plant species (spring onions, basil and parsley), loop approaches (coupled versus decoupled), nutrient ratios (e.g. 1 to 3g grams of fish feed/ plant/day) and key mineral supplementation (including aerobic digested fish sluge-based one); assessing impact on plant performance and the incidence of visual symptoms of plant nutrient deficiencies. The system design in RAS consisted of a fish tank, media-based clarifier and biological filter. In AQP, RAS design was applied with the addition of a floating bed hydroponic units. In HYD, floating bed and reservoir (same fish tank) were utilised. The results demonstrated performance differences for both fish and plant; according to systems, loop approaches, feeding ratios and mineral supplementation. We also conducted an industry survey aiming to understand the barriers of commercial aquaponics in Australia. In addition, during the past 20 months, several industry engagements were carried-out aiming to better understand the field constraints and potential needs for R&D.

Looking towards the future, a pilot-scale Aquaponics facility is being built at CSIRO and will enable research at scale, allowing us to produce and collect “real-world” data to feed into economic-sustainabilily models & Decision Support Tools to facilitate industry development and growth.
Investigation of Proximate and Micromineral Compositions of Rapana Whelk (*Rapana venosa*) Meal for Fish Feed Industry

K.M. Eryalçın1, M. Sayar1, Z.S. Pınarbaşı1, S.S. Turk1, M. Türkr1

Introduction

Rapana whelk (*Rapana venosa*) is an invasive mollusc species distributed in the sea bed of Marmara and Black Sea, Turkey. It has high potential for aquaculture feed industry due to its nutritional value. In this study, we evaluated proximate, mineral (Cu, Fe, Zn, Se, Mn, I) composition of Rapana whelk (*Rapana venosa*) caught in Black Sea. Fish meal and fish oil are the major feed ingredients which provides protein and lipids. In order to sustainable aquaculture, alternative protein sources should be introduced in aquaculture feed industry. For that purpose, we analyzed nutritional composition of rapana whelk meal for future utilization as marine fish diet ingredient.

(Continued on next page)
Conclusion

Rapana whelk is the high protein source and potential ingredient for replacing fish meal. Moreover, it contains high level of essential microminerals such as Copper, Selenium and Iodine. Future trials with rapana meal inclusion in formulated diets should be evaluated for marine fish species.

Introduction
The mitochondrion is a crucial cellular organelle that organises a wide range of biological processes (Basu et al., 2021). The status of mitochondria is also relevant to the phenotype and function of immune cells. Moreover, Shewanella putrefaciens Pdp11 is a strain isolated from healthy sea bream (Sparus aurata L.) and is described as a probiotic for use in aquaculture. Its use has been shown to exert a stimulatory effect on the immune system in fish (Lobo et al., 2014). It has also been shown to modulate fatty acid mobilisation in the liver in fish. The way in which the probiotic affects the metabolism of sea bream may be of great interest when using the probiotic in vivo.

Material and methods
Under this premise, six sea bream were sacrificed and liver samples were obtained and preserved in supplemented L-15 medium. They were then mechanically disintegrated and after different washes, the liver cells were obtained. In parallel, the sea bream fibroblast cell line (SAF-1) was cultured using routine methods (Espinosa-Ruiz et al., 2022). Liver cells and SAF-1 were quantified and arranged in 96-well plates prepared for mitochondrial stress assay. SpPdp11 was routinely placed in culture (Lobo et al., 2014). The bacteria were quantified and adjusted to 10^7 cfu. On the one hand, filtered culture medium (22µms) was obtained, containing all the extracellular products (ECPs) generated by the probiotic. At the same time, the bacteria were inactivated by incubating at 60ºC for one hour. Then, cells obtained from sea bream liver, and SAF-1 cells were incubated for 24 hours with these two extracts (ECPs and inactivated SpPdp11). A mitochondrial stress test was then performed to assess the bioenergetic capacities of the cells after incubation with the extracts.

Results and discussion
The results show that SAF-1 cells were hardly affected, with only the respiratory turnover capacity of the mitochondria being increased by incubation with the ECPs. These results suggest that the ECPs gave the SAF-1 cells an increased ability to carry out respiratory processes (Espinosa-Ruiz et al., 2022). In a stressful situation, characterised by an increased need for energy or reducing power (e.g. oxidative stress, toxicity, hypoxia...), these results suggest that the cells could be more responsive (Azevedo et al., 2020).

As for liver cells, the parameters of maximal respiration and non-mitochondrial oxygen consumption were significantly increased by both extracts. In general, the incubation with Pdp11 extracts enhanced the mitochondrial capacities of liver cells related to anaerobic processes (Espinosa-Ruiz et al., 2022). In parallel, inactivated Pdp11 increased the energetic responsiveness of liver cells (including maximal respiration, spare respiratory capacity and coupling efficiency) suggesting an increased mitochondrial plasticity and stress responsiveness.

Overall, liver cell mitochondria were more susceptible to be affected by the different SpPdp11 extracts. These results hold promise for future studies, whether toxicological, metabolic or otherwise, to further investigate the mechanisms by which SpPdp11 mobilises fatty acids in fish liver.

Introduction
Microalgae play a crucial role in aquaculture nutrition, which is the farming of aquatic organisms such as fish, shrimp, molluscs and others in controlled environments. These organisms are rich in essential nutrients, such as proteins, lipids, vitamins, minerals, etc. Among these, the omega 3 fatty acid content (such as eicosapentaenoic acid (EPA) and docosahexaenoic acid (DHA)) have a key role in cardiovascular health, nervous system development and brain function in aquatic organisms, as well as in humans who consume aquaculture products. Interestingly, the microalgae fatty acid profile could change depending of the culture conditions.

Material and methods
Under this premise, one litre of some species of microalgae belonging to the family of the Bacillariophyte, Chlorophyte and Rhodophyte were cultured under different conditions in marine sea water. Different source of nitrogen (NH3 or NO3) and different temperature (15 or 25ºC) were used during the trial. After 15 days, the microalgae were collected by centrifugation (3000g 4ºC 45 min). The lipid content was extracted using the method of Folch et al. (1957). Fatty acid methyl esters (FAME) were prepared by acid-catalysed transesterification of total lipids according to the method of Christie (2003). All analysis were carried out by triplicate.

Results and discussion
The production of fatty acids in microalgae was significantly affected by the temperature difference and the nitrogen source in their culture environment. These two factors play a key role in the lipid and fatty acid composition of microalgae. Some strains of microalgae grown at 25ºC increased the production of fatty acids. In this sense, temperature could affect the metabolic activity of microalgae because, under warmer conditions, metabolic rates may increase, which may influence lipid accumulation and thus fatty acid production. Furthermore, under heat stress conditions, some microalgae species may accumulate lipids as a protective response (Katayama et al., 2020). This may result in an increase in the concentration of fatty acids in the stored lipids. Finally, lower temperatures may promote the accumulation of saturated fatty acids (Katayama et al., 2020), while warmer temperatures may stimulate the production of unsaturated fatty acids, such as omega-3 fatty acids. Our data seem to be in agreement with these observations.

As for the change in nitrogen source, nitrogen is essential for microalgae growth, and the source of available nitrogen can influence the metabolic pathway (Ahmad et al., 2022). Different nitrogen sources can trigger different lipid and fatty acid synthesis pathways (Katayama et al., 2020). Certain nitrogen sources, such as nitrate, can promote lipid accumulation and thus influence fatty acid production. Stress conditions, such as the nitrogen limitation that occurred in our experiment, can increase the accumulation of fatty acid-rich lipids.

In summary, both temperature and nitrogen source in the culture environment had a significant impact on fatty acid production in microalgae. Understanding how these factors influence lipid and fatty acid composition is essential for optimising culture conditions to obtain desirable fatty acid profiles for nutritional, pharmaceutical and bioindustrial applications.

THE LONGER ROAD TO FUNCTIONAL ANNOTATION: THE USE OF FULL-LENGTH NANOPORE RNA-SEQ FOR ALTERNATIVE ISOFORM DISCOVERY IN ATLANTIC SALMON (Salmo salar) EMBRYOGENESIS

Oliver Eve*, Manu Kumar Gundappa¹, Diego Perojil-Morata¹, and Daniel Macqueen¹

¹Roslin Institute, College of Medicine & Veterinary Medicine, University of Edinburgh, EH25 9RG
Email: oliver.eve@ed.ac.uk

Introduction

Atlantic salmon is an important commercial aquaculture species worth billions to the global economy. The generation of a high-quality reference genome for Atlantic salmon (Lien et al., 2016) and the increased availability of ‘omic tools has led to a significant drive towards the annotation of functional genome elements and causative genetic variants underpinning phenotypic traits (Macqueen et al., 2017; Houston & Macqueen, 2019).

Transcriptomics via RNA-seq is a powerful tool for genome functional annotation. Whilst highly accurate, short-read RNA-seq methods such as Illumina struggle to properly capture exonic chaining and identify alternative splice sites, which can lead to inaccurate gene and transcript annotation. Long-read Nanopore RNA-seq captures the full-length of transcripts in a single molecule. Compared with short-read RNA-seq, this aids identification of alternative splice sites, thus allowing better characterisation of transcript diversity and identification of novel isoforms (Kuo et al., 2017; Kuo et al., 2020). Thus supporting the discovery of causative gene and isoform variants through improved transcriptome annotation.

Embryogenesis is a critical stage of ontogeny where many cell types arise and differentiate. As such, the embryonic transcriptome is a valuable resource for functional annotation due to the high diversity of cell types and patterns of gene expression present during early development.

This study falls within the framework of the European project AQUA-FAANG, which aims to develop functional annotation maps for 6 commercial aquaculture species, including Atlantic salmon. Long-read nanopore RNA-seq was performed on Atlantic salmon embryos, at 6 key stages of development (mid-blastula, mid-gastrula, early-, mid-, late-somitogenesis and eyed stage) as defined by the AQUA-FAANG consortium.

Methods

Total RNA was extracted using a phenol-chloroform method before mRNA isolation via Dynabeads mRNA isolation kit. Sequencing libraries were prepared in accordance with protocols detailed in ONT Direct cDNA Sequencing kit (SQK-DCS109). Samples were barcoded before sequencing for 72h on a PromethION device using R9.4.1 chemistry.

Basecalling and demultiplexing was carried out with Guppy_v5.0.11. Reads with q-score <7 were filtered from the data using NanoFilt_v2.7.1. Full-length reads were identified using Pychopper_v2.5.0 and then mapped to the latest Ssal_v3.1 genome assembly using minimap2_v2.22 (Li et al., 2018). Reads were collapsed into consensus transcript models using TAMA (Kuo et al., 2020). Then, single-exon transcript models with read support <50, and all models with read support <3 were discarded. The final long-read transcriptome was compared with the reference annotation using SQANTI3 (Tardiguila et al., 2018).

Results

Approximately 50 million raw reads comprising 56 Gb were obtained in 72 hours from a single PromethION flowcell. Of those, approximately 10 million high-quality, full-length reads (N50 = 1,366 bp) were obtained. 31,230 genes and 243,991 unique isoforms were characterised by the long-read transcriptome. 78% (189,751) of isoforms were deemed be novel by SQANTI3 possessing either a new combination of known splice sites or at least one novel splice site. An example of the identification of novel transcript isoforms can be seen in Figure 1.

(Continued on next page)
Discussion

Long-read RNA-seq is a powerful tool for isoform discovery. In this study, the average number of isoforms per gene doubled, from 3.9 in the reference Ensembl annotation, to 7.8 in the long-read annotation, thus describing a wealth of previously unannotated transcripts. Such improvements in genome annotation could aid in identification of causative genes and variants for traits of relevance to salmonid production and welfare, as well as traits of ecological importance.

Further investigation will examine differential transcript isoform usage across the 6 developmental stages. This data could contribute to future improvement in publicly available transcriptome annotations through the AQUA-FAANG project.

IDENTIFICATION OF BEHAVIOUR OF FARmed ATLANTIC SALMON (*Salmo salar*) UNDER THE INFLUENCE OF EXTERNAL IMPACT FACTORS

L. D. Evjemo*, M. Mulelid, E. Eilertsen, E. Kelasidi, N. Blöcher

Department of Aquaculture Technology, SINTEF Ocean
E-mail: linn.evjemo@sintef.no

Introduction
In this abstract, results are presented from the study of the behaviour change of Atlantic salmon (*Salmo Salar*) in an industry scale fish farm when exposed several different influence factors. Data is gathered to study the fish behaviour change when exposed to structures with varying shape, size, light, color and sound, shown in Figure 1. Utilizing these data, the fish reaction to the structure can be studied for different case studies to identify and quantify the distance that the fish keep from the different structures and how the fish reacts when exposed to the different impact factors.

This work was financed by the Research Council of Norway through the project: CHANGE and RACE Fish Machine Interaction [1].

Methods
The structure was in each case equipped a stereo camera, and two BlueRobotics Ping360 echo sounders set to collect data in 360° swipes with a range of 5 meters. Four EK15 echo sounders and an underwater speaker were also installed on the structure for parts of the trials. Stereo camera videos and echo-sounder data have been obtained from cages in an industrial scale fish farm which is part of SINTEF ACE [2] during field trials in the fall of 2022 and compared to outcomes from results obtained in 2021.

Sound tests were carried out using the big yellow cylinder structure, which was lowered to 8 meters depth within the fish cage, as illustrated in Figure 1. The fish was then exposed to frequencies of 200 Hz and 600 Hz, as well as propeller sounds, for a period 1 minute, followed by 10 minutes of silence between tests. Furthermore, experiments for light were done for the base structure without the yellow or white outer layer, as shown in Figure 1, with additional EK15 echo sounders installed. The structure was lowered to 8 meters depth within the fish cage and four different light intensities were tested to see the reaction of the fish. Finally, tests for shape, size and color were done using the six different structures shown to the right in Figure 1.

Results
Sound tests from previous field trials showed that the fish generally had a flight response to 200 Hz and 400Hz when played for a shorter period (10 seconds). As it can be seen in Figure 2, the distribution of the fish in much smaller when the sound is activated. These observations were also supported from statistical analysis outcomes and behavioural biologist analysis. However, based on the observations made from watching the stereo camera feed and 360 ping data during the trials in 2022, it was not possible to see any clear flight response or other reaction from the fish in any of the sound tests, see Figure 3. The same goes for the light tests, the fish did generally not show any clear reaction based on what can be said from the visual observations from the stereo camera feed. Processing of the echo sounder data and the stereo camera videos can show if there was in fact any change in the general behaviour of the fish and the distance it kept to the structure that did not show clearly on the video feed.

Conclusion
Large data sets for different case studies have been collected from field trials in industrial scale fish farms to study the fish behaviour change under the influence of different impact factors. Both acoustic and video data were observed to check the fish behaviour change, however, the fish did not show any clear reaction to the sound, light or motion. Based on previous field trials, Atlantic salmon seemingly change behaviour when exposed to audio signals with a frequency between 200 Hz and 400 Hz. It is therefore interesting to investigate further why the fish did not show any clear reaction to the same frequency for the case studies presented here. If the data processing of the sonar data and formal statistical analysis gives the same results, the next step could be to look more closely into the size of the fish, as well as the time of day when the field trials were performed.

Introduction

In 1991, the first paper reporting a viral infection associated with mass mortalities in European sea bass (Dicentrarchus labrax L.) was published (Breuil et al. 1991). The viral infection, presently known as viral nervous necrosis (VNN), still represents a major threat for the sea bass industry. The lack of chemotherapeutics and vaccines that can be effectively used to control the disease and the significant additive genetic variation for resistance to VNN in sea bass (Doan et al. 2017; Palaiokostas et al. 2018; Faggion et al. 2021; Griot et al. 2021) make selective breeding directed to the enhancement of host resistance a promising and sustainable approach to prevent and control mortality derived from VNN outbreaks. Traditional selective breeding approaches rely on estimated breeding values (EBV) predicted using individual phenotypes of the breeding candidates or their relatives through estimated additive genetic relationships based on their pedigrees (Zenger et al. 2019). Routine individual phenotyping for complex traits such as disease resistance is either difficult or unfeasible due to high costs and time requirements, and the implementation of genomic selection procedures might be greatly beneficial. Recently, the integration of functional genomic information into genomic prediction models has been proposed as a strategy to improve genomic prediction accuracy: expressed and regulatory genomic regions are characterized and all the obtained resources are used to efficiently predict phenotypes or EBV (Clark et al. 2020). This strategy is expected to more efficiently detect causative variants and to enhance the prediction accuracy of the genetic merit of future breeding candidates across generations, when the reference population is likely to consist of gradually distant relatives of the animals to be predicted. In this study, we assessed whether the integration of functional data into genomic prediction models could improve the prediction accuracy of breeding values for VNN resistance in European sea bass.

Materials and methods

906 juvenile fish (body weight: 6 to 20 gr) produced in a full-factorial mating (25 sires × 25 dams) were subjected to a 29-days VNN challenge test. VNN resistance was recorded both as a binary trait and as time to death. The experimental fish (N = 906) were genotyped using a high-density SNP panel (Peñaloza et al. 2021; ~27,740 SNPs after quality control), while their parents (N = 50) were whole-genome sequenced and used to impute the offspring to whole-genome genotypes. A genome-wide association study was performed to identify SNP markers associated to the traits of interest. Loci that explain a fraction of the genetic variance of gene expression phenotypes were detected through an eQTL (expression quantitative trait loci) analysis, and ATAC-Seq analysis were performed to detect open chromatin regions corresponding to active regulatory or functional elements in the genome.

SNP genotypes were used as predictors of VNN resistance EBV and Bayesian models were fitted to the data. Genomic predictions were performed following different criteria: 1) pre-filtering genetic markers on the basis of their localization in open chromatin regions; 2) weighting genetic markers on the basis of their localization in regulatory regions; 3) weighting genetic markers on the basis of the p-value of eQTLs; 4) weighting genetic markers on the basis of chromatin status score; 5) combining all the aforementioned criteria in an index and using it to filter the SNPs.

Accuracies of the models were assessed in a cross-validation approach generating training and testing sets consisting of animals of varying genetic relatedness according to the genomic relationship matrix, to mimic genomic selection scenarios where the genomic prediction equation is generated by training models using data from a reference population that is either more closely or more distantly related to the animals to be predicted.

Results

Genome-wide association analyses revealed a major QTL associated with VNN resistance phenotypes on linkage group 12. A total of 528 and 578 SNP markers were identified as significantly associated with VNN resistance phenotypes, both as a binary trait and time to death (false discovery rate, FDR, < 0.05). Using evidence from eQTLs and chromatin accessibility data, a putative causal variant was identified.

(Continued on next page)
Discussion

Results from the GWAS are consistent with those reported in the literature (Griot et al. 2021; Vela-Avitúa et al. 2022). Prediction accuracy of complex traits, such as disease resistance, can be increased by filtering genetic markers depending on whether the genetic variations are located in functional sequences and by developing prediction models that can take into account the biological priors. Integrating functional information into genomic prediction models have also the potential to deal with the decrease of predictive accuracy which occurs when the reference population consists of distant relatives of the animals to be predicted.

Research efforts on genome and functional annotation can be effectively made accessible and translated into application, promoting and facilitating the global implementation of genomic selection, either in the sea bass industry to enhance VNN resistance or in other aquaculture species for complex traits of economic importance.

SPERMIATION ENHANCEMENT OF F1 GREATER AMBERJACK (*Seriola dumerili*) IN RESPONSE TO GnRHa OR hCG

I. Fakriadis*, M. Papadaki and C.C. Mylonas
Hellenic Centre for Marine Research
Institute of Marine Biology, Biotechnology and Aquaculture
Heraklion, Crete, Greece
E-mail: fakriadis@hcmr.gr

Introduction

The greater amberjack (*Seriola dumerili*) in the Mediterranean is a species with high potential for the diversification of the aquaculture production, however, reproductive dysfunctions in captivity have been observed in wild-caught breeders. Milt production was decreased compared to the wild, and lower fertilization success has been recorded in greater amberjack compared to other farmed species. Agonists of gonadotropin-releasing hormone (GnRHa) and human chorionic gonadotropin (hCG) have been used to overcome reproductive problems in many fishes, and in the present study we i) compared these hormonal spermiation enhancement methods in terms of plasma sex steroid production and sperm quality, and ii) applied the best spermiation enhancement method in an industrial egg production scenario.

Materials and methods

Four-year-old hatchery-produced (First generation – F1) male breeders were maintained in a sea cage (Salamina, Greece) and were fed with a broodstock diet (Skretting, Vitalis Cal, 22mm). On May 18th 2021, after blood and sperm collection, the fish (7.4±0.7 kg, mean±SD) were PIT tagged and were treated either with a GnRHa implant (n=6) with an effective dose of 139±17 µg GnRHa kg⁻¹ or GnRHa injection (n=6) with an effective dose of 24±7 µg GnRHa kg⁻¹ or hCG injection (n=6) with an effective dose of 972±120 IU kg⁻¹ or left untreated (n=6)(day 0). Fish were sampled again for blood and sperm on day 7 and 13 after the hormonal treatments.

For egg production, and based on the result of the above experiment, wild-captured breeders were maintained similarly in a sea cage (Salamina, Greece). On June 7th 2022, after reproductive stage evaluation through ovarian biopsies and sperm collection, the males were treated either with a hCG injection (n=5) with an effective dose of 1083±93 IU kg⁻¹ (day 0) or GnRHa implants (n=5) with an effective dose of 118±10 µg GnRHa kg⁻¹. Six females were implanted with GnRHa at 57±8 µg GnRHa kg⁻¹, while two females at the oocyte maturation stage were left untreated; all females were equally divided in two 70-m³ tanks (OUT 1: with hCG treated males, OUT 2: with GnRHa implanted males). For the following days, egg production and quality were evaluated and on day 13 males were sampled again for blood and sperm, and females for oocyte diameter through ovarian biopsies. Plasma testosterone, 11-ketotestosterone, 17-β estradiol, 17α,20β-dihydroxy-4-pregnen-3-one and cortisol were quantified with the use of liquid chromatography tandem mass spectrometry (LC-MS/MS). Sperm quantity was evaluated according to their spermiation condition –which is a measure of the available milt in the testes- after gentle abdominal pressure was applied, determined by a subjective scale from 0 to 3, as follows: Spermiation index S0 = no milt released, S1 = only a drop of milt released after multiple stripping attempts, S2 = milt was released easily after the first stripping attempt and S3 = copious amounts of milt released with very little pressure. The sperm quality parameters that were evaluated using computer assisted sperm analysis (CASA) included: (a) sperm density (number of spermatozoa ml⁻¹ of milt), (b) survival of spermatozoa under cold storage at 4°C (days), (c) motile spermatozoa immediately after activation (%), (d) progressive motile spermatozoa (%), (e) rapid motile spermatozoa (%), (f) straight-line velocity (VSL, µm sec⁻¹), (g) curvilinear velocity (VCL, µm sec⁻¹), (h) average-path velocity (VAP, µm sec⁻¹) and (i) straightness (STR, %).

Results and discussion

In 2021, neither plasma sex steroids (ANOVA, P>0.05) nor sperm quality parameters were statistically different among the four groups (Control, GnRHa implants, GnRHa injections, hCG), while plasma cortisol was elevated in all fish after handling. However, all the hCG treated males were spermiating on day 13 compared to only 33% of those treated with GnRHa implants or injections, while no spermiating male was found in the Control group. In 2022, no statistical differences were observed in egg production and quality-even though 11 spawns were recorded in OUT 1 compared to the 7 spawns in OUT 2 tank- and plasma sex steroids on day 13 between the two groups. However, the hCG treated males had significantly higher percentage of motile, progressive and rapid spermatozoa, compared to those treated with GnRHa implants (ANOVA, P<0.05) (Fig.1). The study demonstrated that hCG was better compared to GnRHa in enhancing sperm quality parameters, but this enhancement was not translated to improved spawning performance (egg fecundity and fertilization) in greater amberjack in the Mediterranean.

(Continued on next page)
Fig. 1. Mean (± SEM) percentage of motile spermatozoa (szoa), motile progressive szoa, rapidly-moving szoa, motility duration (min), survival at 4° (days), curvilinear velocity (VCL, μm sec⁻¹), straight-line velocity (VSL, μm sec⁻¹), average-path velocity (VAP, μm sec⁻¹), straightness (STR, %) and density (10⁶ szoa ml⁻¹) of greater amberjack males treated on day 0 with hCG injection or GnRHa implant. Lowercase letters indicate significant differences (2-way ANOVA, Tukey HSD, P < 0.05).

Introduction

The Intergovernmental Panel on Climate Change (IPCC) has again emphasised that there are widespread and rapid changes occurring in the atmosphere, cryosphere, oceans and across the land (IPCC, 2023). Climate change will directly and indirectly affect many different aspects of aquaculture production and the wider supply chain (Falconer et al., 2022). Species diversification has been suggested as a potential adaptation response to changing conditions, allowing national economies and local communities to build resilience through a range of activities rather than heavy reliance on single species. Establishing a new commercial aquaculture species requires considerable knowledge, time, and resources. To ensure such investments are worthwhile, it is important to assess the long-term potential, so information is required on how climate change may affect the suitability of a location for a particular species.

Norway is one of the world’s top aquaculture producers, with over 1.6 million tonnes produced in 2021, worth over 80 billion NOK (Directorate of Fisheries, 2022). However, Norway also has the lowest species diversification amongst major producing countries, since approximately 95% of Norwegian aquaculture production is Atlantic salmon (Salmo salar).

The aim of this study was to evaluate how changing temperatures under different IPCC scenarios may influence marine aquaculture species diversification in Norway.

Materials and Methods

This study used future temperature projections for three of the Shared Socioeconomic Pathways (SSP) climate scenarios (SSP1-2.6, SSP2-4.5, SSP5-8.5). The temperature projections were obtained from a regional downscaling of the Norwegian Earth System Model (NorESM) that had been forced with the NEMO ocean model (Hordoir et al., 2022). The temperature projections were calibrated to farm-level (Falconer et al., 2020), for twelve aquaculture sites in four geographic areas (South, West, North and Arctic). The temperature projections for 2020 – 2099 were then reclassified to a Challenging Conditions Index (CCI) based on thermal tolerances and preferred aquaculture temperatures for 35 different species (including fish, bivalves, crustaceans, echinoderms, and algae).

Results and Discussion

The results revealed differences in challenging conditions (cold and hot temperatures) for different species between the geographic areas, and between sites within each area, emphasising the importance of considering location and site characteristics. There are also differences between the scenarios, particularly in mid to end of the century. This study only focused on temperature, but the results still show that climate change will have important consequences for species diversification.

Introduction
Zinc (Zn) plays the essential role in vertebrates including fish as it could exert various physiological function such as catalytic, structural and regulatory (Lall and Kaushik, 2021). Due to the limited availability of marine resources, aquatic feed increasingly utilizes plant-based resources as ingredients substitutes. However, compared to fish meal, plant protein contains lower Zn level. Besides, plant-based resources contain antinutritional factors such as phytate, which can bind with Zn\(^{2+}\) during absorption and thus reduces the Zn utilization of fish (Read et al., 2014). On the background of applying plant-based sources in aquatic feeds, there are two strategies to meet the Zn requirements of Atlantic salmon: increasing the level of dietary Zn and increasing the availability of Zn. Increased dietary Zn levels can improve the welfare of Atlantic salmon, but this strategy poses environmental challenges since less than 10% of the dietary Zn is retained in the body (Prabhu et al., 2019). Therefore, improving the knowledge on dietary Zn availability of Atlantic salmon has gained importance. In this regard, the present study aimed to investigate the interaction between dietary Zn and fat on Zn utilization in Atlantic salmon, by a short-term and a long-term nutritional intervention.

Material and Methods
Four experimental diets were produced by BioMar with difference levels of fat (high fat (HF, 35%) or low fat (32%)) and Zn (high zinc (HZ, 180 mg kg\(^{-1}\)) or low Zn (LZ, 120 mg kg\(^{-1}\)), coded as HFHZ, HFLZ, LFHZ and LFLZ respectively. In trial 1, Atlantic salmon (initial weight: 741 ± 77.3g) was fed one of four experiment diets at Matre Research Station by indoor tank for 4 weeks and then the fish plasma were collected at different post-prandial time points (0, 2, 4, 8, 14, 24, 36h) for Zn level analysis. In trial 2, Atlantic salmon were fed with above description feeds by outdoor net pens from approximately 1.5kg to 2.5kg. At the terminal of trial 2, whole fish and different tissues such as plasma, liver, head kidney, muscle, bone were obtained for Zn retention analysis. Two experimental fish were fed twice a day to apparent satiation and feed intake monitored. During the start and at the end of the feeding periods, length and weight were recorded. The Zn analyses of the feed and fish samples were performed through ICP-MS. The calculating method of area under the curve (AUC) in trial 1 was based on the principle of trapezoidal rule (Prabhu et al., 2014).

Results
In trial 1, the final weight of Atlantic salmon among groups was 888 ± 108.2 g and they did not differ significantly. As presented in figure 1 and table 1, the higher baseline of post-prandial plasma Zn was observed in high-Zn supplementation group than those in low-Zn group. Furthermore, higher AUC value was found in low-fat diet group compared to high-fat diet group. In trial 2, The Atlantic salmon in high-Zn group obtained the high Zn level in their plasma, liver, muscle and bone, whereas fish in high-fat group obtain the low Zn level in their plasma and liver (Table 1). In two experiments, no interactive effects between dietary Zn and fat were observed in terms of Zn levels.

![Figure 1: The post-prandial plasma Zn curves of Atlantic salmon in trial 1; Table 1: Different indexes related to Zn level in Atlantic salmon in two experiments.](image-url)
Discussion and conclusion
Sub-optimal dietary Zn supplementation may not reduce the fish growth, but it did impact on the Zn level in tissues and whole fish (Antony Jesu Prabhu et al., 2018). Therefore, growth may not be the only criteria on Zn statues evaluation in fish. Antony Jesu Prabhu et al. (Antony Jesu Prabhu et al., 2016; Prabhu et al., 2014) proposed that the AUC of post-prandial plasma Zn could reflect the absorption and utilization of minerals while Zn retention in whole-body and vertebra might be the better indexes in long-term experiment. In the present study, compared to the high-fat diet group, low-fat dietary intervention fish obtained the higher AUC value of post-prandial plasma Zn in trial 1 as well as higher plasma and liver Zn concentration in trial 2, indicating low-fat diet could enhance the Zn absorption and utilization in Atlantic salmon. Similarly, the reduction of plasma and femur Zn caused by high-fat diet treatment also reported in weanling rats (Weigand and Boesch-Saadaatmandi, 2012). The present study provides a new perspective on improving Zn utilization in Atlantic salmon. Other findings in this experiment will be presented along with further data from ongoing analyses.

Introduction
A substantial factor that makes parasites a serious pest is their high reproductive ability. Therefore, understanding how parasites produce plentiful offspring and how their reproductive capability can be suppressed constitutes a major subject in pest control and management research. Sea lice are ectoparasitic copepods that cause significant economic losses in both wild and farmed marine finfish by feeding on the hosts’ mucus and blood, resulting in skin injuries and increased susceptibility to secondary infections. Among these parasites, Caligus rogercresseyi is the most important species affecting salmon aquaculture in the southern hemisphere. To mitigate the adverse impacts caused by this species, it is critical to identify the molecular mechanisms involved in its reproductive and developmental processes. Therefore, this research aims to achieve two goals: i) to identify the expression patterns and localization of selected genes putatively involved in germ cell differentiation and gonad development in C. rogercresseyi, and ii) to investigate the effects of RNAi-induced gene silencing of candidate targets on the reproductive output of this sea lice species.

Materials and Methods
We characterized a panel of gene homologs that are putatively involved in reproduction and gonad development in this species. RNA-seq and qPCR were used to profile the expression levels of these genes at different developmental stages and between sexes. To clarify the anatomy of the reproductive system and gonadal organization of this parasite, we performed histological and immunohistochemical assessments. We identified the localization of candidate reproductive genes, including Vasa, Ecdysone Receptor (EcR), and Retinoid X Receptor (RXR), using in situ hybridization (ISH). We designed and synthesized dsRNA for the gene silencing of Vasa and RXR, and we adapted a method for subcuticular hemocelic microinjection of dsRNA for the first time in this species. Finally, we assessed the effects RNAi-induced gene silencing on the egg strings formation and embryo development and examined the ovarian organization of treated females using histology.

Fig. 1. External phenotype of adult females of C. rogercresseyi obtained after RNAi injection. (A-D): Females microinjected with dsRXR. (E-H): Females microinjected with dsGFP (control). (A, B): Short egg strings (ES) with abundant inclusions were commonly observed. (C, D) Females without formed egg strings were also detected. (E-H): Females microinjected with dsGFP, exhibited longer normal egg strings with antero-posteriorly compressed embryos (F, H). GS = Genital segment. (A, C, E, G) Bar = 2 mm. (B, D, F, H) Bar = 0.6 mm.

(Continued on next page)
Results
The expression of a panel of 18 nuclear receptors (NRs) transcript sequences was identified using RNA-seq and RT-qPCR data. Higher relative expression was found in females compared to chalimus and male stages for Cr-RXR, Cr-EcR and hormone receptor 3 (Cr-HR3). Localization of Cr-RXR and Cr-EcR transcripts was examined using ISH, showing strong labeling in ovaries, oocytes, and intestine of sea lice. Furthermore, RNAi-induced gene silencing of Cr-RXR caused delayed egg string production, severely reduced fecundity, and generated abnormal gonad and embryo development (Bustos et. al 2023) (Fig. 1). The Cr-Vasa gene expression patterns were assessed by qPCR, and the results showed a significantly higher relative expression level in adult females compared to copepodid, chalimus, and adult male stages. In situ hybridization revealed strong positive signal in male testes, but also in the intestine and cuticle, while in females, it was observed in the ovaries, oocytes, cuticle, intestine, and egg strings. RNAi-mediated gene silencing of Cr-Vasa impacted embryonic development and reproductive output in adult female lice. Females from the dsVasa-treated group displayed unusual phenotypes, including shorter egg strings with numerous extra-embryonic inclusions, irregularly shaped abnormal embryos, and aborted egg strings.

Discussion
The study expands the knowledge of NRs in parasitic copepods, examining their diversity, expression, and localization in C. rogercresseyi. The findings suggest a physiological role for NRs in C. rogercresseyi reproductive tract development, expanding our knowledge of genes involved in reproduction and development in sea lice. Cr-Vasa gene expression was significantly higher in adult females compared to copepodid, chalimus and adult male stages, indicating a potential role in female reproductive development. Tissue-specific localization of Cr-Vasa mRNA showed strong expression in the testes and ovaries of male and female lice, respectively, as well as in other tissues such as the cuticle and intestine. Finally, RNAi-mediated gene silencing of Cr-Vasa resulted in abnormal embryo development and impaired reproductive output, indicating the crucial role of Cr-Vasa in C. rogercresseyi embryonic and ovarian development.

Conclusions
This research provides insight into the molecular basis of reproduction in C. rogercresseyi, enhancing the value of this copepod as a novel model for molecular research. Furthermore, the functional characterization of specific genes involved in reproduction and development might be useful to identify potential targets for novel therapeutics approaches to control sea lice infestation in aquaculture.

Introduction
Since insect meals have begun to take center stage as next generation feed ingredients, there has been a pressing need to validate its effects on popular species such as Atlantic salmon (*Salmo salar*). Currently, there are only a few published trials evaluating the inclusion of black soldier fly larvae meal (*Hermetia illucens*) to replace fish meal in the diet of salmonids (Fisher et al., 2020; Weththasinghe et al., 2021), yet the substitution of soy protein concentrate (SPC) and the use of full-fat yellow mealworm (*Tenebrio molitor*) remains novel. Thus, the aim of this trial was to evaluate the impact these two insect meals have on the growth performance and nutrient utilization of post-smolt Atlantic salmon.

Material & Methods
An 11-week trial was conducted at the Mørkvedbukta Research Station, Nord University (Bodø, Norway) under a continuous light regime (24L: 0D) with 520 fish with an average initial weight of 143.05 ± 12.89 g divided into 4 replicates of 26 fish per diet group randomly assigned to one of 20 tanks (870 cm$^3$) in a saltwater flow-through system equipped with feed collectors. The experimental diets consisted of a control (CTRL) diet based on 20% FM, 14.46% wheat gluten, and 20% SPC as primary protein sources, two diets substituting wheat gluten and SPC with 5 and 10% full-fat black soldier fly larvae meal (BSF5 and BSF10), and two diets containing 15 and 30% full-fat mealworm (MW15 and MW30), respectively. FM inclusion of 20% was maintained constant in all formulations. Fish were fed by automatic feeders at a rate of 1.6% body weight. Uneaten feeds were collected twice daily. Biometric data of all fish was recorded prior to and at the end of the experiment. In addition, samples for chemical composition (whole fish and feces) were collected to study digestibility and nutrient retention.

Results
Results based on data collected at the end of the trial indicated that the inclusion of insect meal in the diet of post-smolt Atlantic salmon had no significant effects on growth performance or organosomatic indices (weight gain, condition factor, feed conversion ratio, specific growth rate, hepatosomatic index and viscerosomatic index). All groups underwent a roughly three-fold increase in weight with no mortality during the experimental period. Additionally, there were no significant differences observed in macronutrient retention with an average percent amongst the groups of 60.5, 58.3, and 47.8% for lipid, protein, and energy, respectively. Lastly, no significant differences were observed in the apparent digestibility coefficients (ADCs) of dry matter (DM), ash, or energy. However, protein digestibility in the MW30 diet (80.4%) was significantly lower ($P \leq 0.05$) compared to the CTRL diet (84.5%). The ADC of lipid will be available at the time of the conference.

Discussion
The growth performance data revealed no significant differences between the dietary treatment groups, with weight gain following a similar trend as that of other trials that investigated the replacement of FM with BSF meal (Belghit et al., 2019; Li et al., 2020), and the absence of mortality during the trial period. Our growth results are in agreement with previous studies on inclusion of BSF meal; in Atlantic salmon diets up to 12.5% (Weththasinghe et al., 2021) and up to 15% (Belghit et al., 2019), and in rainbow trout (*Oncorhynchus mykiss*) diets up to 18% (Melenchón et al., 2022). Similarly, inclusion of MW meal at 18% in rainbow trout diet (Melenchón et al., 2022) did not negatively affect growth. As observed in our study, previous studies by Weththasinghe et al., (2021) and Fawole et al., (2021) have also reported that insect meal inclusion does not influence protein and lipid retention, respectively in Atlantic salmon. Lastly, results of protein ADC in the experimental diets showed significantly lower digestibility in the MW30 diet compared to the control. There are few studies for comparison which utilized meal worm in salmonid feeds. The closest trial by Rema et al., (2019)we studied the effect of a gradual replacement of fishmeal with insect meal from yellow mealworm on juvenile rainbow trout performance. Overall, fish grew faster with the incorporation of the insect meal in the feed, and their capacity to convert feed into fish

(Continued on next page)
biomass also increased. The retention of ingested key nutrients also increased with the incorporation of insect meal in the feed. In summary, juvenile trout fed an insect-based diet grew faster and required lower feed intake to grow than juvenile trout fed on a common diet with standard levels of fishmeal. These results support the transition of fishmeal to insect meal in aquafeeds, which will improve the sustainability of the aquaculture industry. Abstract: Insects are emerging as a sustainable alternative to fishmeal and fish oil in aquafeeds. This study assessed the effect of graded incorporation levels of defatted yellow mealworm (Tenebrio molitor) found that up to 100% (25% FM) could be replaced without any effect on protein digestibility. However, our trial differs in that it replaces non FM protein sources with full-fat insect meal rather than defatted meal.

Conclusion
The overall results of this study show that the inclusion of either BSF meal or MW meal in the diet of Atlantic salmon does not have any significant negative effects on growth performance, nutrient retention. However, there were differences in protein ADC with 30% inclusion of mealworm. This demonstrates that insect meals can be used as an alternative to, not only fish meal, as has been validated in previous studies, but also to plant derived sources as well. These results contribute to the growing body of knowledge on insect meal inclusion and thus the increased diversification of aquafeed ingredients for greater sustainability in the aquaculture sector.

Introduction
The establishment of a breeding stock requires the sexing of the specimens -by non-invasive or minimally invasive methods- as an essential step in the configuration and management of breeding groups. For that, the most reliable and widely used method is gonadal biopsy. However, this method is not always suitable outside the period of sexual maturation, having to resort to other methods. In this study we evaluate the use of sex steroid hormone levels in blood plasma -11-keto testosterone (11-KT) and estradiol (E2)- as an alternative method to gonadal biopsy for sex identification in *Chelon labrosus* during the non-breeding season. On the other hand, the determination of reproductive maturity stage is key in breeding programmes involving hormone induction. So, we also monitored the gonadal development in captive males and females of *C. labrosus* to verify the appropriate time to carry out hormonal induction.

Material and methods
With the aim of creating a broodstock of *C. labrosus*, adults and sub-adults specimens (0.3 – 2.0 kg) were captured in the wild during the non-breeding season (June-October) in 2021 and 2022. After one month of adaptation to captivity, fish were anaesthetized (clove oil: eugenol 80%) and PIT-tagged, and a blood sample was taken from the caudal vein, the plasma was extracted by centrifugation and the levels of 11-KT and E2 were determined by ELISA methods. According to de las Heras et al. (2012), fish were initially considered as males when 11-KT levels were higher than those of E2, while fish with E2 levels higher than 11-KT levels and with 11-KT/ E2ratio << 1 were categorized as females. The specimens caught in 2021 were not biopsied in the 2022 breeding season, but in 2023 together with those captured in 2022. In the 2023 breeding season, we begin to monitor gonadal maturation by gonadal biopsy in 11 females and 7 males (Bw > 1.0 kg). From mid-January, a gentle abdominal pressure was performed to males to determine if they were fluent, and the Spermiation Index (SI: 0-3) was recorded. Females underwent gonadal biopsy by cannulation. From that initial sampling until mid-May, gonadal biopsies were performed biweekly in females, and 3 times (beginning, middle and end of the breeding season) in males. The oocytes were examined under a microscope and measured for diameter (n = 20 per female).

Fig. 1. Oocyte diameter and Spermiation Index throughout the 2023 breeding season (bars = standard error of the mean).

(Continued on next page)
Results and Discussion

A total of 27 specimens were subjected to steroid hormone analysis and subsequent gonadal biopsy. According to de las Heras et al (2012), 13 individuals were categorized as males and 14 as females after hormone analysis. All individuals that were sexed as female after gonadal biopsy had higher levels of E2 than KT, and a 11-KT/ E2 ratio < 0.4 (13/13: 100 % success rate), and all of them weighed more than 1 kg and had a size larger than 40 cm. All fish sexed as males through gonadal biopsy had a 11-KT/ E2 ratio > 0.4, but not all of them had KT levels higher than those of E2. Only 3 male identifications after hormone analysis were erroneous after gonadal biopsy (11/14: 78.6 % success rate). The common factor in these contradictory cases was that they all sized less than 35.5 cm, the length at first sexual maturity according to Ben-Tuvia (1986), and two of them weighed less than 350 g when the blood sample was taken. The other misleading case was sexed as a male after hormone analysis when it weighed less than 0.7 kg (35 cm in size), whereas when it was identified as a female through gonadal biopsy two seasons later it weighed almost 1.9 kg (48 cm in size). It can therefore be concluded that sexing by steroid hormone analysis in C. labrosus outside the breeding season provides a 100 % success rate in females, as well as in males when their size is above the size of first sexual maturity. It can also be concluded that a value above or below 0.4 in the 11-KT/E2 index is applicable to distinguish males from females, respectively.

As shown in Fig. 1, there was a clear trend towards increasing oocyte diameter as the breeding season progressed. However, from the middle of season the oocytes diameter of about half of the females began to diminish showing signs of atresia, while the oocytes from the other half of the females continued to mature. The number of fluent males was high at the beginning (6/7) and middle (6/7) of the season. SI was about 2 in most males early to mid-season. However, at the end of the season, although the number of flowing males was high SI decreased significantly.

According to Besbes et al. (2020), the right time to induce egg-laying in females is when they reach an advanced stage of vitellogenesis, once mean oocytes diameter is about 550 µm, which occurred in mid-season. At that time, hormonal induction was performed in 4 adult females stocked in a 8 m³ tank with 5 fluent males, according to Besbes et al (2020): a priming dose of 10.000 IU kg⁻¹ of human chorionic gonadotropin (hCG) (on March 15th) and a resolving dose of 10.000 IU kg⁻¹ hCG + 100 µg kg⁻¹ of Luteinizing Hormone-Releasing (LHRH) 5 days later. One of the hormonally induced females swelled extremely a few days after resolving dose. Spawning occurred on March 25th, and we suspect that the fertilized oocytes came only from this female. No spontaneous spawning occurred in any of the broodstock batches under natural temperature and photoperiod conditions.

Monitoring of gonadal development showed that not all females progress in gonadal maturation in the same way and at the same time. Also, no spontaneous spawning was obtained, so hormonal induction for spawning is necessary for the time being. But it would be necessary to identify, at the level of individual females, the most suitable timing for induction, as well as the protocolization of sperm cryopreservation for this species for a correct planning of potential artificial fertilization.

**Introduction**

The use of nereid polychaetes as fishing bait or for gonadal maturation in finfish and shrimp farming is widespread. Additionally, the recognised capacity to *de novo* synthesise long-chain polyunsaturated fatty acids (LC-PUFA) in some nereid species such as *Hediste diversicolor* (HD) (Kabeya et al., 2018) represents an opportunity to investigate new alternative nutritional uses in aquaculture. It is known that rearing conditions and diet can modulate LC-PUFA production in HD. The consolidation of HD production as a business involves, among other issues, the use of a low-value feed that provides good growth and an adequate resulting nutritional profile. From a circular economy perspective, the use of by-products from agri-food industries would increase the sustainability of HD farming of sustainability to the HD farming. Following a decoupled integrated multitrophic aquaculture scheme, we used several agri-food industry wastes to feed HD assessing their influence on growth and final fatty acid composition.

**Material and methods**

HD juveniles taken from de COST-IEO stock with a mean body weight (BW) of 38.4 mg were placed in *ad hoc* experimental units (Rasines et al., 2023) at a density of 1000 individuals m⁻² within a RAS system. Five groups in triplicate were each fed one of the following diets: i) brewers spent grain (BSG), ii) crushed corn plant (CP), iii) fish (*Chelon labrosus*) faeces (FF), iv) fishmeal waste (FM), and v) fish feed as a control diet (CD). Feed was provided *ad libitum* on a daily basis for 2 months.

Every two weeks all specimens of each replicate were weighed and weight gain was recorded and plotted. Differences in weight over time (*t*) among diet treatments was checked using one-way ANOVA with *t* as a repeated measures factor, and Tukey’s honest significance distance (HSD) test for post-hoc comparisons.

The fatty acid (FA) profile was analysed in the five diets and HD at the end of the experiment. Differences in body weight over time among diets was checked using one-way ANOVA with *t* as a repeated measures factor. PCA was used to select those FA contributing the most to the explained variance. Then, FA percentage values were expressed over 100% of the selected FA, divided by their respective 18:0 (stearic acid) values for normalization and log-transformed (Wang et al., 2007). Differences in FA composition between in HD fed different diets was performed by mean of permutational multivariate analysis of variance (PERMANOVA) based on Bray-Curtis dissimilarities.

**Results and Discussion**

Variations in weight over time for the different diets given were significant (ANOVA *P* < 0.01; Fig. 1). Notably, the CD diet exhibited the highest average body weight increase, followed by the BSG and FM diets, which yielded similar results. The FF diet led to a comparatively lower weight increase, while the CP diet resulted in the lowest.

Similarly, feed type influenced significantly the resulting FA composition in HD (PERMANOVA, *P* < 0.001) Once the FAs were grouped into the abovementioned FA classes and subjected to n-MDS analysis, a greater similarity was observed between HD fed the CD and FM diets (Fig. 2). This observation seems reasonable since FM is a typical raw material used to produce CD.

Evaluation of the difference in FA classes between diets and the subsequent composition in HD fed these diets (Fig. 3) showed that HD transformed the lipid profile in the diets by increasing the proportion of PUFA’s, specifically ω3 and ω6, while decreasing the levels of SFA’s, MUFA’s and ω9. This effect was particularly evident in HD fed the FF diet.

These results indicate that agri-food industry wastes can serve as suitable feed for HD. The high capacity of HD to biotransform their diet resulted in an improved lipid profile, particularly in terms of sought-after PUFA’s and ω3. Notably, residues from the beer and aquaculture industry, such as BSG and FF, provided satisfactory growth and an improved FA composition, respectively. Further research is required to optimize the diet formulation for HD, aiming to achieve similar or even higher growth rate than that obtained with CD, as well as improving their FA composition.

ENDOGENOUS AND EXOGENOUS MELATONIN EFFECTS ON SPERM QUALITY OF FIRST-GENERATION SENEGALESE SOLE

F. Félix*, L. Ferrão1, V. Gallego1, C.C.V. Oliveira1, E. Cabrita1

1CCMAR, University of Algarve, Campus de Gambelas, ed 7, 8005-139 Faro, Portugal

Introduction
Melatonin is not just a time-keeping hormone that controls circadian and seasonal functions, such as reproduction. Our team has previously shown that this potent antioxidant is also present in fish seminal plasma (Félix et al., 2023). The use of melatonin as a supplement has been increasing, inclusive in cryopreservation processes. Especially for Senegalese sole (Solea senegalensis), a species with reproductive constraints whose production has been growing on the Iberian Peninsula, would be interesting to study if melatonin could increase the quality of sperm, either fresh or cryopreserved. This study comprehends a set of experiments that aimed to better understand the endogenous and exogenous effects of melatonin on first-generation (G1) Senegalese sole sperm quality.

Methodology
An established broodstock of Senegalese sole from the CCMAR research facilities - Ramalhete (Faro, Portugal), was used for this study. Fish were distributed within 6 fiberglass tanks, with 18 animals each, kept on a semi-closed system with a 2:1 sex ratio (male:female). Males were sampled in two consecutive reproductive seasons. First, sperm samples were collected at mid-light (ML, n=42) and mid-dark (MD, n=36) daytimes, to evaluate the effects of endogenous melatonin on sperm motility. In the second year, samples were collected at ML to evaluate the exogenous melatonin toxicity and its potential usage as an antioxidant during a cryopreservation assay. A toxicity test (n=11) was performed using different melatonin concentrations (0.01, 0.1, 1, and 10 mM) and exposure times (3, 5, 15 and 30 min), and sperm motility parameters were registered (TM, PM, VCL, VSL, LIN) using the CASA system. Since only melatonin concentrations influenced sperm motility, the best conditions from the toxicity test (0.1 and 10 mM) were used to evaluate the protective effect of supplemented melatonin during the cryopreservation assay (n=11), performed according to the protocol established by Riesco et al. (2017). Therefore, a set of quality analyses were performed [motility, viability, Reactive Oxygen Species (ROS) (flow cytometry), lipid peroxidation (MDA), and DNA fragmentation (Comet assay)]. Using confocal microscopy, a sperm sample was stained with FITC-melatonin to determine if melatonin enters fish spermatozoa. Statistical analysis was performed on SPSS software, and significant differences were considered when p<0.05.

Results
Motility results analyzed at ML and MD revealed significant differences in all parameters, but especially in the velocities (VCL, VSL, VAP) that were significantly higher at MD from the beginning of the activation until the end of the movement. In what supplemented melatonin is concerned, it did not influence spermatozoa motility, MDA content, or DNA fragmentation, although a lower percentage of viable cells was obtained on the 10 mM treatment. Altogether, it is suggested that supplemented melatonin did not confer extra protection to spermatozoa during cryopreservation. Even though, it was demonstrated that melatonin enters the nucleus and mitochondria area of fish spermatozoa.

Discussion
Overall, the obtained results suggest that endogenous melatonin can improve the motility parameters of Senegalese sole sperm, which can be of interest to the aquaculture industry to explore the possibility to obtain good gamete quality in a non-invasive way. Moreover, regarding exogenous melatonin, its toxicity to spermatozoa was proved to depend mainly on the concentration of this compound, and supplementing melatonin to the cryoprotectant medium did not confer extra spermatozoa protection against oxidative stress, as hypothesized. Even though, at the confocal microscopy, it was demonstrated that melatonin easily enters the cell. Further research is being done in order to understand if endogenous melatonin is produced by the gonads or up taken from the bloodstream.

Introduction

The proportion of plant-based ingredients being used to replace marine resources in Atlantic salmon (Salmo salar) feed is in constant growth. Hence, the lipid profile of the diets is changing, what can in turn affect the performance and health of fish. According to Lucas (1991), exposure to specific conditions during critical early life periods can lead to stable and long-lasting changes in the DNA, resulting in potential lifetime consequences during adult life. The application of nutritional programming in freshwater stages of Atlantic salmon has shown benefits in feed efficiency and nutrient retention when using plant ingredients in a stimulus diet compared to marine during first feeding (Clarkson et al., 2017). Moreover, physiological adaptations have been described at gene expression level in vegetable stimulated groups after challenged (Vera et al., 2017). These changes could have improved the use of nutrients as well as enhanced the fish tolerance to vegetable-based feed. However, it is important to determine whether these benefits can be extrapolated to seawater stage and if a “booster” is needed. Methylation of the DNA is one of the most important epigenetic modifications, and it is well characterized that various environmental factors, such as diet or stress, can result in changes in DNA methylation which can persist through life and even become hereditary (Skjærven et al., 2022). The aim of the present study was to validate the long-term effect of nutritional programming and the possible interactions of nutrition with factors such as genotype and epigenetics.

Materials and methods

A trial was performed with Atlantic salmon from six families characterised by either high or low pigmentation genotypes. Fish were distributed into four groups and exposed to two stimulus diets; with either marine or vegetable ingredients, both delivered within the first three weeks of exogenous feeding. After that period, they were maintained with a commercial marine diet until 14 weeks after seawater transfer. All the groups were then challenged with a vegetable-based feed which was delivered from week 66 until the end of the trial when they reached harvest size. Body weight and total fork length were recorded before fish were processed for sample extraction. Samples were taken during freshwater and in four sampling points through seawater. Nutritional analyses included proximate and fatty acid composition of feed, whole fish and tissue samples. Additionally, DNA from liver fragments was extracted and used for the Reduced Representation Bisulphite Sequencing (RRBS) libraries which were sequenced for all the samples.

Results

Genotype had a significant effect on body weight at the start of the marine phase, with high pigment group showing larger weights compared to low pigment, however, these differences disappear at the end of the intermediate phase. The same factor dictated differences for SGR throughout the seawater phase and for nutrient retention. In the last, genotype explained the variations between all the nutrients analysed (protein, lipid, LA, ARA, ALA, EPA, DPA, DHA), yet again, these differences weren’t extended until the end of the challenge. On regards of biochemical composition for whole fish during freshwater, both dry matter and lipid content were affected by the stimulus diet, with vegetable stimulated fish presenting larger values compared to those marine stimulated groups. Lipid content and dry matter also showed differences in seawater during the intermediate phase, although differences were explained by genotype rather than by stimulus diet. All differences disappeared by the mid challenge sampling point. In general, changes observed in growth parameters and nutritional composition were related to genotype rather than to a specific stimulus diet and differences disappeared at the end of the challenge. The exception was anterior intestine from which differences in the proportions of ARA, DHA, n-3 PUFA and total PUFA were explained by the nutritional stimulus and the effects maintained until the end of the challenge.

(Continued on next page)
When looking at the impact of nutritional stimulus in DNA methylation, only a couple of differentially methylated CpG (DMCpG) sites were found after a 3-week exposition to stimulus feed, with 1 showing increased methylation levels (hypermethylation) and 1 presenting decreased levels (hypomethylation) in the marine compared to the vegetable treatment. In seawater, and before the vegetable challenge started, the number of DMCpG sites increased, with 109 hypermethylated and 21 hypomethylated in the marine-stimulated group relative to the vegetable-stimulated. After 14 weeks of challenge in seawater the number of sites were 4-fold above the previous values, with 112 hypermethylated and 508 hypomethylated in the marine stimulated group relative to the vegetable stimulated. Finally, after 36 weeks of vegetable challenge in seawater, the number of DMCpG sites decreased compared to the last sampling with a total of 21 sites identified with 17 hypermethylated and 4 hypomethylated in marine relative to vegetable stimulated groups. The same trend is shown when looking at the differences between low and high pigment retention genotypes. These preliminary results show that nutritional stimulus had a clear impact on the methylome of the fish. Differences between marine and vegetable stimulated fish became larger during the challenge diet phase, suggesting that nutritional programming may alter the response of the fish to a vegetable-based diet via epigenetic mechanisms. The ability of the fish to retain pigment also has an impact on the epigenetic response to the diet, suggesting that different genotypes may be more adaptable to vegetable diets.

Introduction

Infectious diseases represent a bottleneck for the sustainable development of the aquaculture industry. They are associated with an increase of mortality, a feed conversion worsening, and a decline in animal welfare, hampering the farms’ production and their economic viability (Lama et al., 2020). Understanding the economic impact they may have is pivotal for a proper investment on health management measures. One of the most important infectious diseases in Mediterranean aquaculture is viral encephalopathy and retinopathy (VER), previously described as viral nervous necrosis (VNN). The causative agent of this disease is the nervous necrosis virus or betanodavirus (Bellance and Gallet de Saint-Aurin, 1988; Glazebrook et al., 1990; Breuil et al., 1991). Due to its virulence and rapid spreading, VER outbreaks are associated with growth reduction and high mortality of fish, affecting mostly juveniles (Vendramin et al., 2016; Lama et al., 2020; Muniesa et al., 2020). In addition, the infections of bacterial disease vibriosis, photobacteriosis and tenacibaculum spp. are also considered among the most important diseases for European sea bass (Zrncic and Pavlinec, 2020).

The aim of this work is to evaluate the direct costs of a nodavirus and vibriosis outbreak as well as their economic impact on a typical Mediterranean grow-out farm culturing European sea bass of 450g with two different sizes according to the biomass produced: small farm (540 tons/year) and large farm (2,250 tons/year). For it, we have employed a deterministic static model proposed by Fernández Sánchez et al. (2022) as well as the economic framework proposed by McInerney et al. (1992) to evaluate the direct costs caused by these disease outbreaks (see Table 2) and their economic impact on the annual income statement of the farms (see Table 3). Our estimations show that the higher is the mortality and as the larger is the farm, the larger are the direct cost of a disease outbreak. However, the economic impact on the net operating profit is significantly worse in smaller farms, which points out the importance of investing on disease prevention and control in small scale aquaculture. Finally, we have included an estimation with the improvement of the net operating profit depending on different reductions in the disease mortality (see Table 4) to facilitate a future break-even analysis of different decisions related to the implementation of vaccination, treatments, or health management in these farms.

Introduction
More than 95% of the world’s seabream and seabass production comes from aquaculture, of which 97% is produced by Mediterranean countries. The main producers are Turkey and Greece, while the main consumers are Spain, France, and Italy (Carvalho and Guillen, 2021). The Greek aquaculture industry is highly export oriented as approximately 80% of production is exported, while the remaining 20% is sold in the domestic market. On the other hand, Turkey is the biggest non-EU competitor in the Mediterranean species (Boufidis-Asimakopoulos, 2019). Both countries are neighbors whereby they share the same water and consequently have the similar potential in this kind of species production (Boufidis-Asimakopoulos, 2019). However, being outside the European Union, Turkey’s aquaculture is not subjected to the European Commission Directives addressing the mandatory standards for such activities, the ban of subsidies for exports, and extra tariffs on imports (Boufidis-Asimakopoulos, 2019). This fact gives a significant advantage for Turkish products with lower production costs and lower prices.

The purpose of this work is to analyze the differences in profitability between the Greek and Turkish marine aquaculture firms, as well as which are the most relevant factors to explain firms’ profitability. This analysis is important to evaluate the competitiveness of the Greek aquaculture industry and to plan future policy actions. Different variables should be jointly merged to capture the overall complexity of the firm performance since firm competitiveness is considered as “multi-faceted” in nature (Dvouletý and Blažková, 2021). Thus, profitability is subjected to simultaneous effects of many factors (internal and external) and jointly determine the competitive strength of an individual firm and, consequently, its financial performance (Szymańska, 2017). In accordance with theoretical perspectives of the industrial organization and the strategic management (e.g., the structure-conduct-performance paradigm, the market-based view, or the resource-based view), different empirical studies have been carried out to explore the determinants of firm profitability. Their findings indicate that there are three different categories that those determinants can be classified into (Slade, 2004; Pervan et al., 2019): (i) firm-specific variables, (ii) industry-specific variables, and (iii) macro-economic variables. A sample of marine aquaculture firms from Greece and Turkey operating over the 2011-2020 period have been identified in the Orbis database and selected for this research. Annual economic and financial data of those firms was collected to carry out our analysis (see Table 1). In addition, we also use industry (meso) and country (macro) data to complete this analysis (see Table 2). The results obtained with our profitability model are showed in Table 3.

**Introduction**

The crucial roles of prokaryotes in the recirculating aquaculture system (RAS) highlight the need to characterize the prokaryotic communities in the system. Understanding the communities can lead to improvements in system control, system function, and future system design of RAS, and therefore are indispensable steps. Using two universal primer pairs and two Illumina sequencing runs, we characterized bacteria and archaea communities sampled from eight different sampling points from two identically designed commercial RAS systems (Fig 1).

**Results**

In this short abstract, we only shared the two most interesting findings. Firstly, we found that the bacterial communities in the biofilm and the water were different both in term of abundance and species present (Fig. 2). The finding contrast with the general belief that recirculation of water in the system would promote the dispersal of bacteria communities between RAS compartments, which the biofilter may serve as the primary bacteria source through continuous seeding from the shedding of old biofilm. Secondly, the diversity of archaeal communities was not high as previously thought. We found only 30 ASVs, with Nitrosopumilus as the dominant group (Fig. 3). This study further supplements our existing knowledge on bacterial and the archaeal community in RAS.

---

*Fig. 1. Schematic design of the recirculating aquaculture system (not for scaling). The solid star symbols represent five different water sampling points: I-FT = inlet of fish tanks, O-FT = outlet of fish tanks, S = sump, O-FBBF = outlet of fixed-bed biofilters, and O-MBBF = outlet of moving-bed biofilters. The solid triangle symbols represent three different biofilm sampling points: FBBF = fixed-bed biofilters, MBBF = moving-bed biofilters, and TF = tricking filter.*

Introduction

White shrimp (*Penaeus vannamei*) production is the most relevant aquaculture sector with a production of 4,966 million kg in 2020 and a commercial value of 28,782 million US$. Biofloc Technology (BFT) is a sustainable aquaculture system based on the principle of recycling waste nutrients, particularly nitrogen, into microbial biomass, which can be used *in situ* by the animals produced or collected and processed. It should be noted that the protein content of feed and feeding regimes can affect not only the growth performance, but also influence water quality through nitrogen excretion, thereby inducing eutrophication. *Penaeus vannamei* requires 30–50% crude protein (CP) in its diet, but it is important to take into account the supplementary nutrients supplied by biofloc, that it has been demonstrated that dietary protein levels of 24% gave comparable results to 32 or 40% protein (Panigrahi et al., 2019). The feeding regime is a controversial research field that needs to be more studied. Up today, most farmers fed shrimp based on conventional tables, which consider the size and biomass of the organisms to adjust the feeding rate. Tables do not consider the availability of natural productivity of BFT, resulting in a possible overfeeding or underfeeding that eventually might lead to adverse consequences. As consequence, the aim of the present study was to optimize the protein feeding rate using feeds with low protein content at different feeding regimes.

Material and Methods

In the present study, five protein content levels: 30, 34, 38, 42, and 46% were assayed using three feeding rates: 100, 85, and 70% using as reference the feed intake (FI) proposed by Kureshy and Davis (2002) as 100% group. Each group had 4 replicates, therefore a total of 60 experimental units. The feeds were manufactured by adjusting the carbohydrate (Panigrahi et al., 2019) and dietary lipid levels to 10%. All experimental groups were manually fed three times a day. Once shrimp reached an average weight of 0.5 g, they were introduced into the tanks at final densities of 350 shrimp/m\(^2\) (super-intensive production conditions). To assess both survival and growth performance, shrimp were sampled weekly (Kuhn et al., 2010). The animals were housed in 90 L tanks at a salinity of 21±0.15 g/L, temperature of 28 °C, pH 7.5-8.5, oxygen >5 mg/L, and alkalinity >150 mg/L monitored daily by the multiparametric HANNA equipment, HI19829 Model. Ammonium, nitrite, nitrate, nitrite, alkalinity, and phosphate values were measured weekly using colorimetric kits in a spectrophotometer (Hanna Instruments). Total suspended solids (TSS) were determined following the protocol of Strickland and Parsons (1972), by weighing the solids retained on glass-fiber Whatman filters (0.45 microns) after filtering the water samples.

Results and discussion

The water quality parameters behaved as expected within the pre-established values, showing tolerable levels for white shrimp production. Regarding the evolution of nitrogenous compounds, as expected in a culture with a mature biofloc, it assimilated the ammonium, nitrite, and nitrate resulting from shrimp production, and the levels remained below 0.09, 0.06, and 170 mg/L, respectively.

In terms of growth performance, the evolution of weight based on protein content or feeding rate showed similar results, finding significant differences mainly at the end of the trial (Figure 1).

(Continued on next page)
As is expected feeds with a higher protein content (46, 42 and 38%) achieved the highest final weights (5.5 ± 0.3, 4.4 ± 0.6, and 4.7 ± 0.2; Table 1), in agreement with Correira et al. (2014), with higher growth in diets containing 40% protein. In addition, no distinctions were related to growth according to feeding rate, which may be explained by the consume of natural microbiomase present at Biofloc. In contrast, Kureshy and Davis (2002), obtained better growth with higher feeding rates; and determined that due to a restriction of feed intake and consequently protein intake, diets with low protein content did not support maximum weight gain. No significant differences were observed in relation to survival between experimental groups (64%).

In conclusion, up to 5g in super-intensive production a reduction of 70% is possible, what is translate not only into better productivity but also water quality management.

Introduction
The European seabass (Dicentrarchus labrax) is a marine fish of great importance for Mediterranean aquaculture. Disease outbreaks, especially viral infections, represent severe threats that can interfere with the progress and sustainability of intensive aquaculture systems. Knowledge of the complex molecular mechanisms and signaling pathways underlying host response to pathogen is of crucial importance to improve understanding of genome function and regulation. Changes in chromatin structure, in terms of chromatin accessibility for transcription machinery, and histone modifications (HMs) are considered to play a key role in transcriptional regulation.

As part of the AQUA-FAANG (www.aqua-faang.eu) project, the present work aims to profile in vivo and in vitro response to stimulation with viral (Poly I:C) mimics. RNA-seq, ATAC-seq and ChIP-seq methodologies were applied in order to define a comprehensive genome-wide map of chromatin states and gene expression upon stimulation with viral mimics.

Material and methods
In vitro challenge was conducted on head kidney isolated leucocytes stimulated with PBS or Poly I:C (6 replicates/condition). Cell cultures were collected 12 hours post-infection (hpi) and employed for RNA-seq, ATAC-seq and ChIP-seq library preparation. For in vivo challenge, adult individuals were stimulated by injection with PBS or Poly:IC (6 replicates/condition). Animals were sacrificed 24 hpi and head kidney sampled for RNA-seq, ATAC-seq and ChIP-seq library preparation. The histone marks investigated: H3K4me3 (promoter regions), H3K27ac (active enhancer and promoter regions) and H3K27me3 (associated with Polycomb repression). All sequencing data analyses were conducted by using dedicated NF-core pipelines (https://nf-co.re). Differentially expressed genes (DEGs) analysis was conducted with EdgeR and functional enrichment analysis on the DEGs were performed using the package clusterProfiler. ATAC-seq data were employed in order to investigate for differential DNA accessibility between PBS and Poly:IC stimulated samples by using DiffBind package. ATAC-seq and ChIP-seq peaks from the in vivo and the in vitro experiments were employed to predict genome-wide chromatin states using the software ChromHMM.

Results
Differential expression analysis identified a total of 516 and 1467 DEGs from in vitro and in vivo datasets, respectively. The two challenges showed peculiar response not only in terms of number of DEGs, but also in terms of enriched biological pathways. The top GO terms in over-expressed genes in in vitro stimulated leucocytes were mainly associated with immune system activation (i.e. GO:006955-immune response, GO:0098542 – defense response to other organism), in this context IFN-stimulated genes and IFN regulatory factors are highly significant. In vivo challenged head kidney showed a great enrichment on biological processes involved in DNA replication and RNA processing while immune related pathways are associated to down-regulated genes.

Analysis of ATAC-seq peaks revealed weak or no differential DNA accessibility between treatments for in vivo and in vitro challenges, respectively. Accessible chromatin regions were found to cover up to the 20% of the genome with variations mainly due to cell source rather than treatment indicating that those regions are transcriptionally enabled prior to stimulation.

HMs analysis through ChromHMM software allowed to define the first chromatin state map of non-stimulated and Poly I:C stimulated cells. Comparison between groups highlighted a 4-fold increase of active state regions in Poly I:C stimulated samples.

Conclusion
The present study provides the first genome-wide functional annotation map of the European seabass response to immune stimulation. This represent a significant increase on our fundamental understanding of the genomic basis for immune function and disease resistance in an important aquaculture species.

Introduction
Marine areas in the coastal zone have a variety of uses including fisheries, aquaculture, tourism, recreation, and other activities, all dependent on ecosystem services. Marine spatial planning (MSP) seeks to optimize coastal resource use to minimize conflict and maximize sustainability. In practical application, most MSP has been a GIS exercise in which the boundaries of various activities are mapped and perhaps zoned in order to reduce conflict.

However, these multiple activities have an influence on the environment that goes beyond, and is often not indicated by, their simple location. Moving beyond static GIS layers to a more realistic portrayal of influences and footprints in the ecosystem provides much greater potential for management and is necessary in order to address carrying capacity and sustainability. Among the activities amenable to such management, aquaculture has huge potential for dynamic planning since (a) farm boundaries are specifically defined, (b) stocking density and biomass of cultured organisms is tightly controlled, (c) there is abundant scope for management operations including site location, stocking, harvesting, and fallowing, (d) environmental interactions such as waste dispersion can be modelled and measured.

This is particularly the case for areas such as North America and Western Europe, where the legislative and governance frameworks are both established and well-tested, but the core principles that underpin sustainable aquaculture management are key to the development of the industry across the whole world and are a fundamental part of the drive for food security and food safety in light of population expansion and climate change.

We present the Farming In Natural Systems (FINS) framework, developed to address the key management questions related to carrying capacity.

The FINS framework includes models to represent the production and ecological pillars (e.g. Inglis et al, 2000; McKindsey et al, 2006) of carrying capacity, including water circulation, harvestable biomass of cultivated species, organic deposition and diagenesis, and dispersal of inorganic waste.

The main objectives of FINS are:

1. To produce a software platform for practitioners (i.e. farmers and managers) that allows for dynamic review of alternatives for siting, stocking, and general husbandry practice, taking into account both the environmental consequences of aquaculture and the ways in which the environment conditions aquaculture;
2. To include and model a range of key performance indicators (KPI), ranging from compliance with loading thresholds to pathogen management and eutrophication, addressing both near- and far-field effects;
3. To test the scientific validity of the framework and the degree to which accuracy and usability can be jointly optimised in order to deliver a robust product for practitioners.

Approach
FINS is used by means of the application shown in Fig. 1. Liverpool Bay, in eastern Canada, is shown in this example, together with various layers such as water circulation and dispersal of ammonia from the cage grid, a medium to far-field effect that is often ignored but a key driver for water column eutrophication.

The following set of FINS capabilities is highlighted:
1. Georeferenced display of bathymetry for any area of the world. In the example in Fig. 1, a high-resolution dataset is used; in other parts of the world; sources such as GEBCO might be required;

(Continued on next page)
2. Display and animation of current velocities obtained from mathematical models and/or measurements from e.g. ADCP moorings; the bathymetry and current velocities are key to drive other models in the framework that simulate specific aspects of the aquaculture activity;
3. Positioning and editing of aquaculture structures, definition of stocked species, stocking status, stocking density; in the example shown and results presented, the cultures species is Atlantic salmon (\textit{Salmo salar});
4. Multiple grids can be placed in any coastal area (or in a lake) to examine the interactions at a wider scale;
5. Application of models to simulate growth of finfish (salmon, trout, seabass, seabream, tilapia etc) and shellfish (oysters, mussels, clams etc) in order to determine farm production and environmental externalities;
6. Definition and export of a zone of interest for application of specific models to determine deposition, diagenesis, shellfish food depletion, and other KPI;
7. Import of outputs from such models for display and analysis by FINS users. Fig. 1. shows imported layers for loading of POC to the sediment and for dispersal of $\text{NH}_4^+$ by advection and diffusion to a broad area;

The ORGANIX model (Cubillo et al, 2016) was designed to simulate loading of POC to the sediment, using both Eulerian and Lagrangian approaches. In addition, ORGANIX simulates emission and dispersion of ammonia, oxygen demand, and for bivalve shellfish, chlorophyll uptake and its consequences for food depletion.

The FINS framework has been applied to a number of ecosystems on the Canadian east coast, including Liverpool Bay, Whitehead Bay, Port Mouton, and Saddle Island. Hydrodynamic inputs were generated through the application of the FVCOM model and optimised for offline coupling, since one of the priorities for FINS is a very fast execution.

(Continued on next page)
Results and Discussion
The results provided in this paper are divided into two parts: (i) the first provides an illustration of the outputs from the ORGANIX model; and (ii) the second provides details of validation of outputs by comparison to previously published work.

The results in Fig. 2 (left) show the loading of POC to the sediment for three conceptual salmon grids, using an Eulerian model. As expected, the deposition fields in this relatively shallow bay are approximately bounded by the grid area; each cage is 30 m in diameter and stocked with 50,000 fish at an initial weight of 80 g, grown for 500 days, resulting in a final individual weight of 5 kg, with an FCR of 1.13.

In the central pane of Fig. 2, the same conceptual grids are used to grow mussels (1,500,000 individuals per structure). The culture starts with 1 g (live weight) seed and the animals grow to 19 g over a 730 day period. Each individual will clear 7.4 m³ of water during this period and remove (net) 26.3 mg of chlorophyll. The figure shows that there are ammonia peaks to the west of the structures, and unlike the deposition profile, a clear interaction can be seen among the three grids, although the ammonia concentrations at peak are very low (0.18 mM).

The right pane shows ammonia concentrations resulting from a trout (*Oncorhynchus mykiss*) grid at Port Mouton—this farm is no longer active, but a comparison can be made between these results and other work to provide validation for the FINS framework.

It should be noted that in all three examples given, the loading varies in time as determined by the underlying growth model—in other words the FINS approach does not use averaging for emissions, for both finfish and shellfish.

The modelling framework was validated for several bays in eastern Canada, including Liverpool Bay, Port Mouton and Whitehead Bay. Some results of validation for ammonia emissions from a legacy trout site in Port Mouton are shown below.

The dynamics of dissolved nitrogen were simulated for a historic farm in Port Mouton that usually held 400,000 steelhead trout over a production cycle of 16 months. Fish were typically stocked in cages at 150 g in April and were harvested at 2 kg during July or August of the following year. During the growout period, the fish were fed to near satiety.

The pens usually occupied the top 8-10 m of the water column, which averages 10-12 m depth at the farming site. This aquaculture scenario was simulated using two approaches: 1) a fully-spatial dynamic hydrodynamic model in which the mass of dissolved nitrogen released was estimated using a nutrient loading model (Reid et al. 2017), and 2) FINS, which uses the residual currents for the study area and the AquaFish individual growth model to estimate the release of nitrogen.

In both simulations, the dissolved nitrogen is considered a conservative tracer in which the only source of nitrogen comes from fish excretion, and the only sink is the tracer that is exchanged through the boundary.

The outcomes of both simulations (Filgueira et al. 2021 and Figure 2 – right pane, for the hydrodynamic and FINS approaches, respectively) differ slightly in the shape of the footprint. While both approaches predict the major concentration of dissolved nitrogen on the eastern side of the vicinity of the farm, FINS predicts a low-concentration plume that extends beyond this area towards the northeast of the bay. The different shapes could be a consequence of comparing the output of a dynamic hydrodynamic model (Filgueira et al. 2021) with the integrated temporal pattern generated using residual currents (FINS).

Despite the difference in shape, it is important to highlight that the maximum values were in both cases comparable, with maximum values between 9 and 10 µM. Further, the total area with a concentration over 3 µM was similar and, in both cases, restricted to the vicinity of the farm. The similar outcomes suggest that the management decisions that could stem from both approaches would be similar. In this particular case, they would indicate the maximum concentration of dissolved nitrogen is below the toxicity levels for seagrass.

Although not shown due to space constraints, we present also simulations of pathogen spread using particle tracking models, and results on the application and validation of diagenetic models driven by POC loads simulated in ORGANIX. The representation of these results is shown in the FINS application.

FINS is applied to eight coastal systems in the Canadian Maritimes, in order to support management, increase sustainability, help create jobs, and contribute to food security.

Introduction
Pisciculture is an economic activity that has been growing worldwide in the last few decades becoming an important source of food and income for numerous producers. Although China is the world’s largest fish producer in total production volume, Brazil ranks fourth in the world in tilapia production, indicating a Brazilian tendency to expand its participation in the global fish market. This can be explained by the fact that fish in general are a healthier source of protein than other kinds of meat.

In recent years, emergent viral diseases have been worrying fish farmers due to the great economic losses they may cause. Among them is the infectious spleen and kidney necrosis disease (ISKN), whose etiological agent is a DNA virus (ISKNV) belonging to the Iridoviridae family. ISKNV is not classified as mandatory notification in Brazil but can easily decimate big populations of fingerlings. The diagnosis can be done by observing clinical signs or by PCR. Additionally, to study the virulence of the strains, isolation in cell culture is essential. In this regard, the number of scientific papers involving cell cultures for viral agents of importance in pisciculture has increased. Despite being a laborious and relatively expensive method, it has also been applied to the study of the modulation of gene expression, mainly related to immune responses, characterization of cytopathic effects, and obtaining adequate amounts of viral load for next generation nucleic acid sequencing. Furthermore, prior to the implementation of experimental protocols, the selection of the best methodology to be applied is a necessary step, and for this purpose, systematic literature reviews adequately meet this objective.

Objective
The objective of the present study was to conduct an extensive survey of the literature associated with the use of cell cultures for isolation of ISKNV/Megalocytiviruses, considering publications from 2000 to 2022.

Material and Methods
We used PRISMA methodology and worked with secondary data taken from the platforms Scopus, Web of Science and CABI Direct. A central keyword was established (ISKNV) and several others secondary words (n=15) were used in an advance search with a time frame of 22 years (from 01/01/2000 to 31/10/2022). We also used articles both in Portuguese and English. To assist our search, we used the software Rayyan and only included scientific articles which presented information about ISKNV or its family and details about the viral isolation process fish cell line cultures. All other papers that investigated tracking, genomic expression or phylogeny were discarded.

Results
Following the settled criteria during the first step we gathered 6006 articles which were submitted to Rayyan. A total of 4969 of them were found to be exact duplicates with 100% similarity and were excluded. From the 1037 articles left, we manually searched for other non-exact duplicates and found another 408 papers which were also excluded leaving us with only 629 files to be sorted by reading both title and abstract. In this step, we discarded 586 articles that were not related to our question remaining 43 papers which were eligible and included in our qualitative synthesis to answer our objective. We found that a great majority of the articles selected were from Asian groups which can be explained by the great relevance the aquaculture has in the Asian countries. The oldest article among ones that were eligible was dated from 2008. Most of the studies aimed to investigate different kinds of cell cultures in different viruses to set which type of cell lineage would fit best for the cultivation of different pathogens. There were a total of 17 different cell linages including: MFF-1 (Mandarin fish fry); GF (Grouper fin cell); CBP (Chinese perch brain); YFSB (Yellowfin seabream); PSF (Pearlspot fin); ARB8 (Aequidens rivulatus brain); MSH (Micropterus salmoides heart); SCSC e SCC (Siniperca chuatsi); GP (Giant gourami); GB e GS-1 (orange-spotted grouper); RoBE-4 (rock bream embryo); OmB (primary cell culture); EAGS e EAGSB (grouper Epinephelus akaara); PMF (Pagrus major fin); ELHK (kidney grouper); SBP, GBC1 e GBC4 (brain

(Continued on next page)
tissue) and SK-9 (Cellosaurus-oncogenic). Most studies were combining new or existing cell lines with different viruses to study cell-virus interactions. The most used medium was Leibovitz-15 with 10% fetal bovine serum and temperature around 25-30°C. The most present cell lineage was the MFF, found in 10 different papers, followed by CPB (8) and GF (6). There were also a few studies that used DMEM as the cell medium and others that tried to use different concentrations of fetal bovine serum. We also found a systematic review from 2011 that compiled studies that were published since the last systematic review in 1994. Some papers searched the apoptotic roles of the cell in viral replication, demonstrating the association of ISKNV with apoptotic involvement in cell cultures infected by this viral agent.

**Conclusion**

We verified the predominance of cells of fibroblast origin in cell culture isolation procedures for ISKNV. Asian research groups are also a constant in this systematic review, which can be explained by the great cultural relevance of this continent in fish production. We observed a great effort in the attempt to produce new strains of different fish cells, which demonstrate that we are still trying to find the most suitable cell strains for each type of virus that we know.
Introduction
The production of farmed fish has been growing at an average rate of 5.5% per year in Brazil since 2017, with Nile tilapia (Oreochromis niloticus) being the highest-producing organism in the country, reaching approximately 550 tons in 2022. Despite working within the guidelines of good practices, there has been an emergence of emerging pathogens in some fish farms in the Southeast and South regions of the country, leading to economic losses. In 2021, the infectious spleen and kidney necrosis virus (ISKNV) was officially reported in Brazil. This virus belongs to the family Iridoviridae, which has seven genera: Megalocytivirus, Lymphocystivirus, Ranavirus, Chloriridovirus, Iridovirus, Daphniairidovirus, Decapodiridovirus (the latter two recently described). Outbreaks of ISKNV have been reported in several countries such as China, Israel, Africa, Australia, and India. It is not a notifiable disease (OIE), but it is potentially a cause of significant losses in aquaculture, as it can infect both marine and freshwater fish.

Objective
The objective of this study was to detect circulating strains of ISKNV (infectious spleen and kidney necrosis virus) in the Southwest region of the state of São Paulo, Brazil.

Materials and Methods
During the month of April 2023 (autumn in the Southern Hemisphere), 171 specimens of tilapia (O. niloticus) weighing between 17.12 + 8.42g were collected from a fish farm in the Upper Paraná Basin in the city of Ilha Solteira, SP. Samples were taken from net cages, prioritizing symptomatic fish. Euthanasia was performed using eugenol, and necropsy was directed towards the collection of the target organs for ISKNV (i.e. spleen and kidney). Organ pools were made with tissues from three animals and stored in 99% alcohol for molecular analyses. The samples were stored in a refrigerator. Total DNA extraction was performed using the Wizard® Genomic DNA Purification Kit (A1120 Promega), followed by conventional PCR and agarose gel electrophoresis. The primer sequences used are described in Table 1.

Table 1: Primers used for ISKNV (infectious spleen and kidney necrosis virus) detection. Samples from Ilha Solteira, SP, Brazil (2023).

(Continued on next page)
The positive samples were subjected to Sanger sequencing, and the obtained sequences were aligned using BioEdit software to fill gaps in the genome present in the databases.

**Results**
Molecular analyses showed positivity in 38.60% of the samples analyzed for ISKNV, with 52.70% being detected in fish of higher weight (21.33 ± 6.95). Several collected animals showed ascites, exophthalmia, and low mucus secretion. Reports from fish farmers indicate that tilapia fingerlings undergo a weakening process resulting in high mortality after 21 days of being stocked in net cages within the reservoir. This mortality is more significant during the transition between seasons.

**Discussion and Conclusions**
We conclude that the ISKNV virus is present in the Ilha Solteira reservoir, Southwest region of the state of São Paulo, Brazil. This raises interest and concern since virus transmission can occur through water. Further investigations are needed regarding the native ichthyofauna (spillover), as this virus can infect a wide variety of species. This is the first official report of this Iridovirus in the state of São Paulo in the year 2023.

Inland brackish-water recirculating aquaculture systems (RAS) must reuse water as much as possible due to challenges such as saline effluent discharge and inhibitory salt costs. Brackish water aquaponics systems using kale have been shown to reduce nitrate and phosphate that build up over time in RAS. Kale is marketable, but marketability of kale grown in saltwater is unknown. This trial analyzed sensory characteristics and preferences using a panel of volunteers who tasted Winterbor F1 kale grown in a range of salinities (0, 5, 10, 15 and 20 ppt salinity) in decoupled brackish water aquaponics systems containing reused shrimp culture water.

Participants (n=112) were presented with five raw kale samples (one from each salinity) and instructed to taste them in a counter-balanced order and rate their overall liking, taste liking, texture liking, and aftertaste liking on a 9-point hedonic scale anchored by “dislike extremely” and “like extremely”. Participants then rated their perceived intensity of basic tastes (sweet, salty, bitter) using a 0-100 line scale anchored by “not at all” and “extremely”. Following the sample evaluation, participants were presented with a brief description about aquaponics and asked whether this influenced their opinion and willingness-to-pay. Differences in liking and intensity were assessed using one-way ANOVA followed by Tukey’s post-hoc comparisons.

The 5 ppt kale was significantly more liked (overall liking, taste liking, and texture liking) than then 0 ppt kale. Focusing only on taste liking, the 5 ppt was also liked significantly more than both the 15 ppt and 20 ppt samples. No sample was liked less than the 0 ppt control. However, a closer examination of liking ratings revealed a bimodal distribution of the 20 ppt but not 5 ppt samples; in other words, participants were either “likers” or “dislikers” of the 20 ppt sample and very few provided a neutral rating. Aftertaste liking of kale samples grown in any salt concentration was significantly higher than the control 0 ppt sample. Saltiness intensity ratings increased in a dose-response manner, with the 10 ppt, 15 ppt, and 20 ppt samples all rated as significantly saltier than both the 0 ppt and 5 ppt samples. The 5 ppt sample was rated as significantly less bitter than the 0 ppt sample. Together, the saltiness, bitterness, aftertaste, and liking ratings suggest that a low level of saltiness in the kale samples masked the bitter kale flavor, which softened the aftertaste and improved taste liking. Information about aquaponics growing conditions resulted in an average willingness-to-pay of $2.06 USD per bunch, a 38% increase above the reference price of $1.49 USD. Overall, this study demonstrates that kale grown in brackish-water aquaponics is likely to be accepted by the consumer.
EMPLOYING INDIGENOUS MICROALGAE BIOMASS PRODUCTION FOR THE VALORIZATION OF HYDROPONIC WATER EFFLUENTS

Introduction

Hydroponic farming produces large amounts of wastewater overloaded with nutrients, mineral pollutants, and organic matter. Thus, disposal of agricultural effluents is an emerging challenge of important environmental and economic impact. Exploring means to effectively recycle and reutilize wastewaters, microalgae offer an innovative solution for viable bioremediation, while simultaneously producing high value bioproducts with various biotechnological applications. In the present study, effluent water from hydroponic cultures was used for isolating naturally present microalgal species that may possibly be of biochemical interest and play a crucial role in wastewater treatment.

Material and Methods

The isolation process of indigenous microalgal strains from hydroponic effluents was roughly divided in five successive steps: size separation, general enrichment and 3 separation stages including serial dilution, agar plating, agar streaking and micropipette isolation. Four different strains were isolated and characterized with morphological, biokinetic and molecular taxonomy methods. The microalgal strains were subsequently cultured under steady conditions in both commonly used media and hydroponic water effluents in order to estimate a) the potentiality of hydroponic wastewater as an alternative medium for microalgae b) microalgae exploitation for wastewater bioremediation c) the valorization of the biomass derived and its potent in vitro bioactivities. Nutrient removal from the microalgae cultures was used for isolating naturally present microalgal species that may possibly be of biochemical interest and play a crucial role in wastewater treatment.

Results

Our results revealed that all microalgae species included in the study were able to efficiently grow in hydroponic water effluents utilizing the available nutrients (Fig.1)

Using the TufA and RBCL genes from the isolated microalgal strains and the corresponding sequences from reference strains deposited in NCBI a concatenated phylogenetic tree was created using the Maximum Likelihood method (Bootstrap 1000, Kimura 2-parameter) (Fig. 2). Based on the results, it’s safe to state that PR2 exhibits strong resemblance to C. reinhardtii and PR4 strongly resembles S. reticulata and S. rubescens.

Biochemical characterization of microalgal biomass (Table 1) highlighted the high-efficiency biomass of the isolated strains using hydroponic effluents. In order to obtain more data on the accumulation of a wide range of compounds spanning both primary and secondary metabolism, GC-MS based metabolomic platform was also used.

Custom produced extracts from the above microalgae presented no cytotoxicity on Caco2 cells whereas PR4 (0.1-2.5μg/ml) exhibited even greater viability of Caco-2 vs to control (Fig 3). The ability of these extracts to protect Caco2 cells against H2O2 induced oxidative stress was also demonstrated (Fig. 4). To this end, transcriptome analysis of Caco2 cells pre-treated with PR2 (0,5μg/ml) and PR4 (0,1μg/ml) followed by H2O2 induced stress revealed significant alternation at several human genes expression.

Introduction
Shrimp are one of the most important groups of animals in global aquaculture. The Pacific whiteleg shrimp (Litopenaeus vannamei) is the most cultured shrimp species, accounting for over 50% of worldwide production. Unfortunately, the industry’s efficiency and sustainability are threatened by significant annual losses due to infectious diseases, 60% of which are caused by viral pathogens such as white spot syndrome virus (WSSV). Efforts to limit the impact of disease caused by this pathogen are impeded by a lack of effective treatments available.

Materials and methods
In order to establish whiteleg shrimp primary cell cultures, we extracted haemolymph, lymphoid organ and hepatopancreas samples from sterile shrimp and cultured them as dissociated cells or explants in a range of cell media mixes while monitoring the growth and survivability of cells. For RNA sequencing, we isolated nuclei from snap-frozen hepatopancreas tissue and processed it using 10x Chromium Next GEM Single Cell Dual Index kits. The sequenced samples have been analysed and the cell atlas was built using cell cluster marker genes.

Results
Our team has established an in vivo infection model in juvenile and adult stage shrimp and developed primary cell culture systems for the study of host response to WSSV using haemocytes, hepatopancreas and lymphoid organ tissues from adult L. vannamei (Figure 1). Additionally, we have establish a novel protocol for nuclei isolation and single nuclei RNA-sequencing, and in doing so, create a hepatopancreas cell atlas for the species (Figure 2).

Conclusion
The novel protocols will help us use high throughput transcriptomic analysis to identify priority candidate genes for WSSV resistance via single-nuclei RNA sequencing of WSSV-infected and non-infected shrimp. The results will serve as a foundation for future studies using in vitro models and single nuclei sequencing in whiteleg shrimp and set a new foundation for developing therapeutic strategies to combat WSSV in shrimp aquaculture.

Introduction

Due to current restrictions on the use of chemicals or antibiotics in aquaculture production, effective and sustainable preventive treatments against systemic infections in cultured species are required (Yilmaz et al. 2022). To evaluate its effectiveness, the development of new standardized fish health models is needed. In this scenario, a bath infection model for European sea bass (Dicentrarchus labrax) against Tenacibaculum maritimum has been developed in this study. This bacterium, represents one of the most worrying pathogens for Mediterranean aquaculture species. It is a gram-negative filamentous bacterium which, on top of producing high mortality rates, increases fish susceptibility to other pathogens in a variety of marine aquaculture species. Specifically in this study, this model has been used to test a probiotic (Vibrio lentus) characterized, in vitro analyzed and cultured by AZTI. The use of probiotics as a method for prophylaxis and control of disease outbreaks in aquaculture has been proposed in recent years (Wanka et al. 2018). These compounds included in functional diets have a huge potential optimizing growth and feed conversion and boosting the immune responses, increasing the resistance of fish to diseases. Therefore, in this study, fish performance parameters and innate immune indicators have been evaluated as well as fish disease resistance through a new standardized fish health model consisting in exposing fish to T. maritimum and comparing relative percentage of survival (RPS) against a control group (non-probiotic diet). Complementing these results, a cohabitation infection model with the same bacterial strain is under development. Cohabitation models simulate more accurately disease outbreaks in production farms. However, their development is generally more complex as they are more susceptible to other variables such as fish density or ratio naive/infected fish. Preliminary results are very hopeful so a European sea bass against T. maritimum cohabitation model is expected to be standardized in forthcoming studies.

Materials and methods

European sea bass were fed during 6 weeks with a diet including probiotic V. lentus at 0.5% (probiotic group) or a control diet without probiotic (control group). At the end of the treatment phase, survival, weight gain, specific growth rate and feed conversion factor were calculated. In addition, kidney, plasma and mucus samples were collected to evaluate innate immune indicators using microscopy and absorbance and/or fluorescence techniques. Specifically, phagocytic activity, lysozyme activity, protease activity, anti-protease activity and total proteins have been analyzed. After the treatment phase, fish were exposed to different concentrations of T. maritimum to evaluate the RPS. The strain used in this challenge pertains to CTAQUA strains collection (CT0013 T. maritimum strain) and prior to fish exposure, it has been cultured in FMM (Flexibacter maritimum medium) at 22 °C and 250 rpm during 24 hours (Pazos et al., 1996). The infection by bath has been carried out in 10-litre buckets, in which fish have remained for 1 hour with aeration exposed to different concentrations of the pathogen (7.50x10^4, 5.00x10^5 and 1.00x10^6 CFU/ml, in triplicates). Each concentration has been obtained by diluting the original bacterial culture in seawater with a starting concentration of 1.00x10^9 CFU/mL. After exposure to the pathogen, fish were transferred the tanks of the RAS (Recirculation Aquaculture System) holding system, controlling all culture parameters throughout the test. For the cohabitation tests, infected a non-infected fish were allocated in the same tanks in triplicate in a 1:1 ratio (fish density 10 Kg/m^3). Infected fish acted as infection vectors and were previously exposed to the pathogen strain following the methodology described above for the bath model. In this case, after infection (1.00x10^6, 1.00x10^5 and 1.00x10^4 CFU/ml), fish were transferred to the system tanks together with no-infected fish). In order to differentiate the infected/naive populations, naive fish were marked with visible implant elastomer (VIE).

(Continued on next page)
Results

Results did not show differences in growth and feed conversion neither in activity of immune system indicators evaluated between probiotic group and control group but there were differences in the percentage of survival after exposure to the pathogen between groups (table 1). For the development of cohabitation model, we have observed a relation between pathogen concentration and mortality percentage (figure 1).

In sight of the results, it can be concluded that bath infection model with *T. maritimum* has allowed the validation of the probiotic, which has a potential effect as a preventive treatment. Blue line: infected. Orange line: naive.

Introduction
Aquaponics is a sustainable food production system combining aquaculture with hydroponics to simultaneously produce fish and economic crops. Disease infestation is a critical challenge in aquaponics due to the limited available safe curative methods. Biological control and natural fungicides can be crucial to sustainable control of diseases in aquaponics. Therefore, we examined the use of entomopathogenic fungi (Isaria fumosorosea and Lecanicillium attenuatum), mycoparasitic fungus (Trichoderma virens) and the risks associated with the use of natural (clove oil and lecithin) and synthetic (tebuconazole) fungicides on a biofilter and Nile tilapia, Oreochromis niloticus, in aquaponics. Our study identified that T. virens, besides its biocontrol property, can improve the growth of basil plants in aquaponics at a concentration of 1 x 10^7 spores per ml. The foliar application of clove oil (eugenol), lecithin, and tebuconazole at recommended dosages, spray-drifted, and were detected in aquaponics water at a percentage runoff rate of 0.3%, 2.3% and 0.3% respectively. In the biofilter, tebuconazole and clove oil at the maximum runoff concentration showed no significant effects on the nitrification processes during a 96 hr exposure period. In contrast, lecithin altered the ammonium and nitrite levels by substantially increasing ammonium-nitrogen levels from an initial 5 mg L-1 at the 1st hour to ~13 mg L-1 at the 6th-hour post application. These runoff concentrations were further evaluated on the physiology of Nile tilapia in a 28-day semi-acute toxicity test. The tebuconazole-treated group showed a significant effect on hematological (haemoglobin, red blood cell, MCH, etc.), biochemical (total protein, albumin, globulin, etc.), and antioxidative (glutathione peroxidase and glutathione reductase) parameters. Eugenol, on the other hand, showed no significant effects on the fish physiology, indicating its suitability for all aquaponics systems. The use of lecithin and tebuconazole should only be limited to decoupled aquaponics due to their effects on the biofilter and fish.

Materials and Methods
For ethical concerns regarding the unmeasured effects of fungicides on fish, three experiments were conducted separately. The first, a pre-requisite experiment, was conducted on monitoring the runoff of the active ingredients of applied fungicides in the water of decoupled aquaponics over 72 hr timepoints. Using the concentrations detected in the aquaponics water in the first experiment, we exposed a matured biofilter to the maximum concentrations of the active experiment to investigate their effects on nitrification and nitrifying bacteria. In the third experiment, Oreochromis niloticus were exposed to the maximum concentrations in a semi-acute toxicity test over 28 days to determine subacute toxicity from the runoff concentrations.

(Continued on next page)
Result

Figure 1. A graphical abstract showing the effects of disease treatments, biocontrol agents and pesticides on aquaponics basil and nitrification. Graph A shows that *T. virens* (TVI), improved the growth of basil in aquaponics over a period of 4 weeks. Graph B shows that lecithin fungicide (PC) runoff in aquaponics, significantly altered the ammonium and nitrite levels.
THE NUTRITIONAL COST OF MOUNTING THE IMMUNE RESPONSE IN A. SALMON (Salmo salar)

C. Zarza, L. Jensen, P. Lisik and R. Fontanillas

Skretting Aquaculture Innovation
Sjøhagen, 3. Stavanger 4016, Norway
E-mail: ramon.fontanillas@skretting.com

Introduction
Mounting the immune response and maintaining a competent immune system is thought to be a nutritionally demanding process. In terrestrial animals, the influence of an immune challenge on animal growth is well established (Huntley et al., 2018). In fish, and particularly in A. salmon, it remains to be investigated. An immune challenge and the associated lower feed intake can theoretically partition energy and nutrients away from productive processes such as muscle growth, and negatively impact efficiency. In this work, two experimental trials were carried out to first estimate the nutrient costs of immune stimulated A. salmon, and second to design diets to support the adequate immune response and performance during an immune stimulation, using vaccination as challenge model.

Material and Methods
To validate vaccination as a model to estimate nutrient utilisation during immune challenge a pilot trial (trial 1) was carried out in fresh water with A.salmone from 50 to 70g. Two groups of fish were vaccinated with either commercial vaccine 1 (V1) or commercial vaccine 2 (V2), a third group of fish was injected with a saline solution (S) and a fourth group was used as a control (C). All fish were fed with the same commercial diet. At the beginning of the trial and after 24 days post vaccination fish were sampled for body composition for nutrient balance estimation. To evaluate the dietary support to the immune response, a second trial (trial 2) was carried out with fish from 65 to 100g in fresh water. Three groups of fish were immunized with a commercial vaccine after 17 days of feeding with one of the following diets: energy rich (E), amino acid rich (A) and energy and amino acids (EA). A fourth group consisted in non-injected fish (C) fed a commercial diet served as control. After 41 days post-immunisation, performance, nutrient retention, immune response, and gene expression were the response parameters measured.

Results
In trial 1, the immune stimulation response affected nutrient retention. Vaccinated fish (V1 and V2) showed between 7 to 16% lower energy retention efficiency, between 15 to 20% lower fat retention and between 4 to 13% lower protein retention, in comparison with the non-vaccinated control group (C). Moreover, V2 fish showed lower amino acid retention efficiency for most of the amino acids in comparison with the rest of fish groups. In trial 2, immunized fish ate 7% less compared to non-immunized. Increasing dietary energy improved protein retention with approximately 8%, suggesting higher energy requirement of immunized fish. Immune response was not different between dietary groups suggesting the primary importance of immune function. There were differences in gene expression regulation between dietary treatments and immune stimulated fish.

Conclusion
Overall, the results showed for the first time, the cost of mounting an immune response through vaccination in A. salmon. Nutrient retention and gene expression is modified under immune stimulation towards energy utilization, while the immune response was shown to be prioritized. It is possible to design feeds to precisely support performance under an immune challenge.

Introduction
The fish gut is a unique biological system that functions as a barrier against pathogens and regulates osmoregulation, immunological and inflammatory responses (Peñaranda et al., 2020).

The immune system comprises innate and acquired responses and can be modulated by functional additives like Short Chain Fatty Acids (SCFA) (Ahmadifar et al., 2019; Semple & Dixon, 2020). SCFA are bacterial fermentation products, formed by a short hydrocarbon chain (2-6 carbons) and a carboxylic acid moiety (Corrêa et al. 2016). Acetate (C2), propionate (C3), and butyrate (C4) are the most abundant SCFA in the fish intestine and are transported through intestinal cells by passive diffusion or by active transport of dissociated SCFA anions using different transporters, namely anion exchange with bicarbonate (den Besten et al., 2013). In the intestinal epithelial cells, SCFAs are partially used as a source of ATP, contributing to the maintenance of gut homeostasis, and playing an important role in the enhancement of anti-inflammatory and antimicrobial responses (Parada Venegas et al. 2019).

Ex vivo techniques allow the evaluation of tissue’s response to external stimuli and reduce the number of experimental fish compared to the in vivo approach (Bello and García-Arrarás 2022).

Thus, this study aimed to evaluate the intestinal interactions between the SCFA acetate, propionate, and butyrate and pathogenic bacteria in intestinal explants of European sea bass (Dicentrarchus labrax) juveniles.

Material and Methods
The anterior intestine of 12 fish with an average weight of 100g and killed by excess anesthesia with 2-phenoxyethanol were sampled, sliced into pieces with an average weight of 1.3 mg, and placed in 24-well plates (3 pieces per well). The experimental treatments consisted of a control and 1mM and 10 mM of sodium acetate (SA) sodium butyrate (SB) and sodium propionate (SP), and each treatment was replicated 6 times. After being incubated with a pre-treatment medium (penstrep 500U, FBS 10%, glutamine 2mM, and glucose 5.5mM) for 1h at 22ºC and 100 rpm, one piece of tissue per well was collected (pre-treatment) and stored in RNAlater at -80ºC until analysis. The two remaining explants were incubated for 2 hours at 22ºC and 100 rpm with DMEM medium (penstrep 100U, FBS 10%, glutamine 2mM, and glucose 5.5mM) supplemented with each SCFA at a concentration of 1 or 10mM and then one piece of tissue per well was collected (SCFA treatment) and stored in RNAlater at -80ºC until analysis. The remaining explant was challenged with Vibrio anguillarum at 1×10⁷ for 2 hours at 22ºC and 100 rpm and then collected (bacteria challenge) and stored in RNAlater at -80ºC until analysis.

The expression of pro- and anti-inflammatory genes, namely tumor necrosis factor β (TNF-β), interleukin 8 and 10 (IL-8 and IL-10), transforming growth factor β (TGF-β), caspase 3 (Casp 3), and nuclear factor k β (NF-kβ) was evaluated according to (Machado et al., 2021).

Results
Incubation with 1 or 10 mM of each SCFA increased NF-Kβ and TGF-β expression. Regardless of the concentration, incubation with sodium acetate and sodium propionate increased the expression of caspase 3 compared with sodium butyrate.

At 1mM concentration SA, SP and SB increased the expression of NF-Kβ compared with the control diet, on the other hand the higher concentration of 10 mM increased the expression of IL-8 and Caspase 3.

(Continued on next page)
Regardless of SCFA, the bacterial challenge increased the expression of all immune-related genes analyzed, except for IL-10.

Overall, the incubation with SCFA increased the anti-inflammatory NF-κβ and TGF-β, and the bacterial challenge modulates the expression of inflammatory responses.

BEST PRACTICES FOR PREVENTING WINTER ULCERS IN ATLANTIC SALMON (Salmo salar L.) IN NORTHERN NORWAY

Lars Føsker1, Shruti Gupta1, Mette Remen2, and Birger Venås 2

1LetSea AS, Sandnessjøen, Norway
2Sintef Ocean, Trondheim, Norway
Email: lfosker@letsea.no

Introduction
Winter ulcers in Atlantic salmon generally lead to reduced welfare and downgraded product quality. Wound development is mainly linked to the winter ulcer bacteria, particularly Moritella viscosa or a cocktail of other bacteria, i.e., M. viscosa, Tenacibaculum spp, Vibrio spp. These pathogens thrive at low temperatures (< 8 °C). Naturally enough, the winter ulcers outbreak in salmon aquaculture is a significant fish health challenge in northern Norway, where temperatures are lower and production time is longer.

An essential measure against winter ulcers is avoiding handling the fish as much as possible. However, due to high salmon lice infestations, the fish must undergo delousing treatments. These treatments can be both medicinal and non-medicinal. In the case of non-medicinal delousing treatments (which are more effective), there are unavoidable injuries to the fish skin, where the outcome is usually ulcer outbreaks at low temperatures. The severity of the outcome depends on many factors, but handling intensity; among others, how hard or gently the fish is handled, is very important. From our field experience, there is a significant knowledge gap in the cause-and-effect relationships and limited knowledge about the factors associated with this variation. Results from our pilot studies show that sedating the fish during crowding and delousing operations makes fish calmer, reducing the risk of ulcer development. In addition, there is little data about which indicators can be used to assess the risk of winter ulcers. This lack of knowledge gives limited room for action to adapt the production plan or implement measures to reduce the risk.

Furthermore, there is no systematized knowledge about how crowding affects the risk of winter-ulcer outbreaks during delousing operations. We will fill in this knowledge gap by documenting the effects of handling and different crowding intensities (CI) on the susceptibility of Atlantic salmon to winter ulcer outbreaks. We will document this by answering the following questions -

1. Does the level of CI during cold seasons significantly affect ulcer outbreaks?
2. Is it primarily the physical damage to the skin and mucous layers, stress, a compromised immune system, pathogens, or combinations of all these factors that are decisive for wound development after handling?
3. Can indicators for ulcer risk be established to be used as decision support when preventive measures against ulcers are to be defined?

The main goal of this study is to identify best practices for crowding and mapping wound risks in connection with handling second autumn and winter at sea to reduce the risk of, or extent of, winter ulcer outbreaks in Atlantic salmon. Results from this project will help to shed light on what is today’s best practice for crowding and how it should be adapted to a situation with low temperatures and an increased risk of wound development. The author will present and discuss the experimental design at Aquaculture Europe 2023.

Material and Methods
The project is financed by the Norwegian Seafood Research Fund (FHF 901835), with a total budget of 1,112,261 Euros. The project (named ReduSår; duration: 2023-2025) will be a close collaboration between the Norwegian industry and research institutes/Universities.

The experiment will be performed at the R&D Sea facility of LetSea AS at Donna, Norway, in October 2023. We will use mesoscale cages (n=12) in triplicates with large pit-tagged salmon (approx. 2.5 kg; n = 200 per cage). All cages will be treated uniformly, except for crowding methods during the corresponding delousing. We will test different combinations of CIs, i.e., grades 1 and 3, according to FISHWELL (referred to as T1 and T3) with or without sedation (referred to as S+ and S-) during a 60-minute crowding operation, giving us three test groups T1 S+, T3 S-, T3 S+ and a control group (T1 S-). Grade 1 is an acceptable CI in the Norwegian aquaculture industry, whereas Grade 3 is an undesirable practice (see (Continued on next page)
FISHWELL for more info). Water and fish mucus samples will be collected throughout the experiment to investigate the presence of wound bacteria; furthermore, camera-based monitoring of wounds at the fish group level will also be done. The aim is to utilize the detailed monitoring of wound development in the experiment to test indicators for predicting (“early warning”) of wound outbreaks.

Results
Sedation as a measure for more gentle handling must be systematically investigated. In the short term, our results will help salmon breeders learn from each other’s experiences and increase the basis for decision-making when planning and carrying out handling operations. In the longer term, knowledge developed in the project will provide a basis for optimizing production planning, methods, or measures for lice prevention or treatment.

The project will also map possible new indicators for increased winter ulcer risk or “early warning” in case of ulcer outbreaks. Such indicators can initially help to improve the decision-making basis for crowding methods or adjusting handling procedures before and during delousing. Over time, new mapping tools can be established to develop knowledge about the causes of an increased risk of winter sores. The project will be able to contribute both knowledge and new tools that can improve preventive and mitigating measures to reduce wound problems in the industry, thereby improving fish welfare, profitability, reputation, and sustainability.

Introduction

Pikeperch is a species with growing value for aquaculture, but its rearing has proven to be a bottleneck for the industry (Policar et al., 2019). One factor affecting larval quality is deformations, exemplarily spinal curvatures such as lordosis and scoliosis. While many factors are known to influence the occurrence of vertebral malformations (Boglione, Gavaia, et al., 2013; Boglione, Gisbert, et al., 2013; Di Biagio et al., 2022), one factor that can be influenced by the husbandry conditions are mechanical stressors as water currency and the handling, exemplarily during size sorting procedures. The resulting deformations can negatively affect pikeperch health, welfare, and performance. Consequently, understanding the underlying mechanisms and the developmental timing of vertebral formation and the impacts of vertebral deformations in pikeperch is essential for developing effective management strategies, to improve fish welfare, and optimize aquaculture practices. This study aims to investigate the occurrence and mechanisms of vertebral column deformations in pikeperch resulting from mechanical stressors.

Materials and methods

The study involved the examination of over 1000 farmed pikeperch specimens, collected from the aquaculture pikeperch rearing facility. Hereby, the sampling focused on specimens of different age stages between 17 and 40 dph to allow observation of vertebrae formation and older postlarval specimens of 67 dph to analyse malformations that may occur. The fish were examined for the presence of lordosis using visual inspection and clearing and staining procedures (Taylor & Van Dyke, 1985). Additionally, the fluorescent properties of the Alizarin red staining were utilized to verify for the formation of vertebrae and to investigate the changes in the spinal structure.

Results

Based on external observations, the specimen of the oldest group had a almost 65% occurrence rate of vertebral column defects. Among them, scoliotic deformations occurred at a higher rate (47.6%) than lordotic (30.5%). Caudal vertebral column deformations occurred in 26.7% of the specimens. Further analysis of the cleared and stained specimen in this age group showed that even some of the specimens with externally normal body shape possessed deformations of the vertebrae. In these cases, inconspicuous caudal vertebral column deformations were revealed by the clearing and staining procedure. This caudal spinal area proved to still be less ossified in the stages just before the onset of size sorting. In these, vertebral formations were present up to centrum 37-40 of the total 44-45 vertebrae. Fluorescence analysis indicated that influences on the vertebral deformations might be associated to the osteological developmental status of the larvae.

Discussion

The observed higher incidence of caudal vertebral deformations suggests that this issue might be linked to aquaculture practices, especially size sorting procedures. Generally, sorting procedures are necessary for pikeperch rearing, because of the high growth rate during larval development (Franz et al., 2021) and the occurrence of cannibalism, especially between different sized specimens. Therefore, sorting procedures are an important tool to reduce losses in pikeperch aquaculture (Kestemont et al., 2003; Szczechowski et al., 2011; Zaleś et al., 2004). Adjusted timing and handling protocols could effectively reduce the incidence of lordosis in farmed pikeperch in this regard. In conclusion, this study sheds light on the occurrence and impacts of vertebral column deformations in pikeperch due to mechanical impact, emphasizing the need for further research and management practices aimed at reducing the incidence of this issue in the aquaculture industry.

Introduction
Sea lice are parasitic crustaceans that infest Atlantic salmon (Salmo salar). They attach to the skin of salmon and feed on tissue, mucus and blood, causing abrasion-like lesions, open injuries and stress that in turns lead to reduced growth rates, secondary infection due to opportunistic pathogens and increased mortality. Sea lice represent one of the most important threats to salmon aquaculture and welfare, causing millions of losses worldwide. Several species of lice can affect Atlantic salmon, with Lepeophtheirus salmonis being predominant in the northern hemisphere and Caligus rogercresseyi in the southern hemisphere. Better understanding of genetic resistance to both parasites is a prerequisite to include in selective breeding strategies to improve lice resistance. Here we study resistance to both L. salmonis and C. rogercresseyi in Atlantic salmon, working with the same salmon families in the two hemispheres to assess whether resistance to both parasites has the same genetic background.

Material and methods
During three consecutive years, 2017 to 2019, a total of 4 375, 3 730 and 5 346 Atlantic salmon fish were produced, respectively, belonging to 160 to 200 full-sib families from Benchmark Genetics breeding programme. For each year-class (YC), the offspring were separated into two groups at the eyed eggs stage and sent to two different locations for rearing and disease challenge. Half of the offspring were challenged in Iceland with L. salmonis, while the other half were challenged in Chile using C. rogercresseyi. A similar challenge protocol was used across locations and year-classes. Briefly, fish were raised in separate family tanks until tagging, and then mixed. For the challenge, fish were separated into 2 to 4 tanks with a recirculating system, and 30 (in Iceland) or 40 (in Chile) copepodite of lice per fish were deposited in each tank. After 7 to 15 days, the number of lice (at sessile stage) attached to each fish were visually assessed and reported as sea lice count (SLC). The body weight (BW) of each fish was recorded before and after the challenge.

The fish were genotyped using 57K (Chile, YC2017) or 65K SNP (all other year-classes) arrays (with 33K shared SNPs). Standard quality controls on SNPs and individuals were performed using PLINK [1] in each dataset separately, and then all were merged into a single dataset. Genotype imputation using FImpute3 [2] was performed to obtain a final dataset with 61,065 SNPs.

Table 1. Heritability and genetic correlation estimates for resistance to two sea lice species and body weight measured in two locations.

</table>

h² = heritability (± sd) and Rg = genetic correlation (± sd), SLC= sea lice count, BW= body weight.

(Continued on next page)
Genetic parameters (variance, heritability and genetic correlation) were estimated using blupf90 [3]. Genome wide association studies (GWAS) were performed with a mixed-linear-model implemented in GCTA [4] to detect QTL associated with resistance. The animal model used for variance component estimation and GWAS included tank, sex and counter (when available) as fixed effect and body weight as covariate.

**Results**

Heritability of Atlantic salmon resistance to each lice species was consistent across year-classes and estimated to be low for *L. salmonis* and moderate for *C. rogercresseyi* (Table 1). A low to null genetic correlation was observed in YC2017 and YC2019 between resistance to the two lice species. In YC2018, a high positive genetic correlation was estimated for resistance to *L. salmonis* and resistance to *C. rogercresseyi*.

Body weight was highly heritable in both locations, with a higher heritability in Iceland than in Chile for YC17 and YC18. High positive genetic correlations were estimated across locations for body weight measured within a year class.

The GWAS performed showed that resistance to both sea lice species is highly polygenic. Only one QTL above the 5% genome wide significance threshold was identified, located on chromosome Ssa15 for resistance to *C. rogercresseyi* in YC2017.

**Discussion and conclusion**

Resistance to *L. salmonis* and resistance to *C. rogercresseyi* in Atlantic salmon are highly polygenic. It is unclear whether resistance to the two species share common genetic mechanisms. The absence of genetic correlation for resistance to the two sea lice species in YC2017 and YC2019 and the high positive correlation observed in YC2018 might be because of differences in the challenge methods and the parasite counting procedure. Indeed, the size of the fish at challenge and the number of days of challenged and the number of people involved in the counting of the lice varied according to the location and the year, reflecting normal practices in the farms. A meta-analysis combining all three year-class will be performed to better understand the genetic architecture of sea lice resistance using a powerful dataset of over 10,000 fish.

LIFE - BOAT 4 STURGEON - AN INTEGRATIVE EFFORT TO SAVE DANUBE'S STURGEONS

Thomas Friedrich

thomas.friedrich@boku.ac.at

The project LIFE-Boat 4 Sturgeon builds upon the methods and results of the LIFE-Sterlet project. It has the aim to establish a genetically diverse captive broodstock of mature animals for all four remaining Danube sturgeon species in at least two locations (AT and HU). Those stocks will be maintained over the long-term to preserve the gene pool and to support all four species with genetically diverse, autochthonous and fit juveniles. In Austria, a floating rearing station in the Danube in the centre of Vienna will be built in addition to the existing LIFE-Sterlet hatchery container. The mother fish stock of all species will be constantly expanded through different genotypes and the reproduction through a studbook enables the greatest possible genetic diversity of the offspring. Existing monitoring efforts are to be continued and intensified to document the development of the populations. Furthermore, an investigation along the whole Danube for possible residual populations, will be carried out. For the whole Danube Region and other European catchments a long-term database and manual for ex situ actions and monitoring in sturgeon conservation will be provided. Further objectives are the coordination with fishing authorities and communities along the Lower Danube and Black Sea to reduce IUU fishing and to raise general public awareness.
SEA STAR MEAL AS A NOVEL PRODUCT FOR AQUAFEEDS

Vanessa I. Fuchs*, Matthew J. Slater

Alfred Wegener Institute - Helmholtz Center for Polar and Marine Research,
Am Handelshafen 12, 27570 Bremerhaven, Germany
* E-Mail: vanessa.fuchs@awi.de

Introduction

An extraordinary biomass resource in marine habitats is present in the form of sea stars, which are scarcely utilised in European marine environments. The InEVal project approaches diverse value chains related to increasing and adding value to echinoderm biomass to create new processes, products and industry. One aim is the up-valuing of waste sea star biomass from European inshore shellfish industries and mussel farms by developing and evaluating new products. Sea star biomass offer a valuable resource as a sustainable and low prized alternative protein source from sidestreams and further processed as a feed ingredient for aquafeeds. A previous study (van der Heide et al., 2018) already revealed promising nutrient compositions of the sea star species *Asterias rubens*. The aims of this study were to process sea star biomass to meal and to determine the suitability of using *A. rubens* meal as replacement for fish meal (FM) in shrimp (*Litopenaeus vannamei*) and European sea bass (*Dicentrarchus labrax*) diets.

Materials and methods

Sea stars *A. rubens* were harvested at a mussel farm (Kieler Meeresfarm, Kieler Förde, Germany), dried, ground to meal and analysed for nutrient content and amino acid profile (Table I). Diets for Whiteleg shrimp (*L. vannamei*) and European sea bass (*D. labrax*) were formulated with increasing levels of sea star meal (SM) as FM replacement. In two feeding experiments, the acceptability of SM inclusion in diets were investigated in shrimp and sea bass in a recirculating aquaculture system. Survival, growth performance, feed intake and metabolic parameters were evaluated.

Results showed an annual variation in the composition of the nutrients and amino acids in sea stars *A. rubens* showing highest crude protein, crude fat, lysine and methionine content and lowest crude ash content in spring. Shrimps accepted all diets containing SM. Growth performance increased with increasing SM in diets showing significant higher growth with 21.6% SM (One-way anova, p < 0.05) compared to the 0% SM diet (Figure I). Health performance was not effected by SM inclusion.

In comparison to shrimps, sea bass did not accept high inclusion of SM in diets. Feed intake and growth performance (Figure II) decreased with increasing SM content. Final weight of fish fed the 25% diet (25% FM replacement with SM) was significantly different to fish fed the 0% SM diet after 60 days of feeding. However, no significant difference in final fish growth was found in fish fed the 25% diet and the commercial feed.

(Continued on next page)
Conclusion

Sea star biomass of *A. rubens* can very efficiently replace FM in diets for *L. vannamei* providing high-level protein and fat sources without impairing growth or health of shrimps. For sea bass diets, however, SM inclusion is limited and can replace a maximum of 20-25% of FM without significant growth or health reduction.

E-mail: fukaharu@kochi-u.ac.jp

Introduction

Fish meal (FM) is an important protein source in fish feed, especially for carnivorous fishes. Yellowtail, a marine carnivorous fish, is the most popular aquaculture fish in Japan, with a production of approximately 100,000 tons/year. Generally, yellowtail diets contain high levels of FM (approximately 30–50% for adult fish); therefore, reducing the FM content has become imperative for sustainable farming. However, reducing dietary FM levels sometimes results in low feed palatability (low feeding amount) and, subsequently, low growth (Murashita et al., 2019; Senzui et al., 2020). A casein-based non-FM diet supplemented with a water-soluble fraction of FM (FMS) was prepared to investigate the function of FM. Growth performance in feeding trials, and the gene expression of appetite-related hormones, digestive hormones, and digestive enzymes were evaluated.

Materials and methods

Yellowtail (mean body weight = 9.5 g) were divided into 12 × 1100 L capacity FRP tanks (15 fish/tank in triplicate). The experimental diets, i.e., an FM-based diet (FM diet), a casein-based diet (C diet), C diet supplemented with water-soluble fraction of Chilian jack mackerel meal (C+JM diet), and C diet supplemented with water-soluble fraction of Peruvian anchovy meal (C+A diet), were prepared as single moist pellets (Table 1). FMS was prepared as follows: 100 g of each FM was mixed with 600 mL of water and allowed to settle for 1 hour. The supernatant (400 mL) was used as the FMS for 1 kg of diet. The fish were fed the experimental diets once a day (6 days/week) for 6 weeks. The total fish weight per tank was measured every two weeks by counting the number of fish. Growth performance was calculated based on the total fish weight and feeding amount. At 6 weeks, the hypothalamus and pyloric ceca were collected from three fish pre-feeding and three fish post-feeding (3 h) per tank. Gene expression of appetite-related (orexigenic) hormones (neuropeptide Y [NPY] and agouti-related protein 1 [AgRP1]) in the hypothalamus and gene expression of digestive hormones (cholecystokinin 1 and 2) and digestive enzymes (trypsin and lipase) in the pyloric ceca were measured using RT-qPCR.

Results

Growth performance (Fig. 1): Significant differences in body weight were observed at 6 weeks in the order: C+A group > C+JM group > FM group > C group. The feed efficiency followed the same order. The total feed intake (g/fish) was significantly higher in the FM group than in the other dietary groups.

Gene expression in the hypothalamus (Fig. 2): Significant decreases were observed in npy mRNA expression in the FM group and agrp1 mRNA expression in the C+A group from pre- to post-feeding. Except for group C, a decreasing trend in agrp1 mRNA expression was observed after feeding.

(Continued on next page)
Gene expression in the pyloric caeca (Fig. 2): A significant increase in cck1 and cck2 was observed from pre- to post-feeding in the FM and C+A groups. The gene expression of lipase increased after feeding, except in group C.

Discussion

FMS supplementation of the casein-based diet improved growth performance, indicating a better value than the FM group. The improved response of agrp1, digestive hormones, and digestive enzymes to FMS supplementation might have resulted in higher growth in the C+JM and C+A groups. FMS contains high levels of free amino acids, peptides, and nucleic-related substances. In our previous studies, the addition of free amino acids and FMS to rearing water affected brain NPY expression and feeding behavior (Senzui et al., 2020; Senzui and Fukada, 2023). Furthermore, oral administration of FM solution increases cck1, trypsin, and lipase mRNA expression (Furutani et al., 2012). FMS contains important substances that stimulate physiological responses in fish. By determining this substance, better fish diets, including low-FM or non-FM diets for carnivorous fishes, can be developed.

Introduction
The aquaculture sector has experienced rapid development, providing economic benefits to countries utilizing the industry. However, continuous growth and reduced wild fish stocks have led to reduced availability and increased prices of fishmeal and fish oil for fish feeds. Alternative protein sources of low ecological footprint and at affordable prices for fish feed formulation are key to the sustainable development of aquaculture. Nevertheless, they often impact fish physiology and metabolism due to the presence of various endogenous antinutritional factors and phytoestrogens (1). The deposition of proteins in the white muscle, which is the largest and continuously increasing tissue in fish and constitutes 58-80% of their total body weight, is the ultimate goal in fish farming. The growth of fish is affected by phytoestrogens and antinutritional factors, whose effects vary depending on their concentration, fish species, and other factors. Phytoestrogens may compromise growth and disrupt reproductive function, while antinutritional factors can reduce growth and cause health issues. The demonstrated negative effect of phytoestrogens on white muscle development and growth highlights the need for tools to screen for potential myostatic action of raw materials and fish feeds (2). This study combines different approaches to validate white muscle gene markers (3) in the gilthead seabream, Sparus aurata L., as indicators of compromised myogenesis when fed alternative protein sources.

Materials and methods
Three diets were formulated - a soy-free diet (C), a 20% soybean meal diet (SBM), and a 20% soy protein concentrate diet (SPC) – and they were fed to triplicate groups of gilthead seabream of 27g average initial BW for two months. After the three-month period, sampling was conducted in all three groups and samples were stored in RNAlater at -20oC until RNA extraction. In a second approach, extracts of the diets and of raw materials were applied in primary cultures of myogenic progenitor cells from seabream for three different exposure times and four different quantities of the food extract (0, 2, 4 mg) following the onset of differentiation. Cells were collected at the end of the exposure and RNA was isolated. The expression levels of mylpfa (myosin light chain phosphorylatable, fast skeletal muscle a, associated with hypertrophy), mylpfb (associated with hyperplasia), and myog (myogenin) in white muscle were determined at the end of the experiment using real time RT-PCR. The results were analysed using the R programming language.

Results and Discussion
In teleosts, muscle growth occurs through two main mechanisms: hyperplasia, which involves the recruitment of new muscle fibers, and hypertrophy, which involves an increase in the size of existing muscle fibers. The effects of SBM and SPC on hyperplasia and hypertrophy in the feeding trial were consistent with the effects recorded in vitro. Hyperplasia as marked by mylpfb expression was significantly reduced in fish fed on SBM and SPC, whereas hypertrophy as marked by mylpfa expression was significantly reduced only in fish fed on SBM. Myogenin (myog) expression remained unaffected.

Similar results were recorded in primary cell cultures after 48h of exposure to diet extracts; both SBM and SPC were potent in downregulating mylpfb expression, whereas mylpfa expression was significantly affected only in the presence of SBM extract. Increasing the extract quantity in the SBM and SPC diets resulted in reduced expression levels for mylpfa. In contrast, mylpfb expression was not greatly affected by increasing extract quantity in SBM and SPC.

Myogenin expression remained largely unaffected by the presence of the raw materials extracts in the primary culture. However, there are noteworthy findings: mylpfb expression significantly increased in the presence of corn gluten extract, and mylpfa expression was elevated in the presence of either corn gluten or wheat gluten extract, suggesting their potential influence on muscle growth.

(Continued on next page)
To our knowledge this is the first study to demonstrate that primary cultures of myogenic progenitor cells can be used as a screening tool for potential myostatic action of raw materials and fish feeds containing alternative protein sources.

Conclusions
Our results offer new insights into the mechanisms behind myostatic action of plant raw materials rich in phytoestrogens. Differences recorded in fish growth in vivo could be attributed to differentiated white muscle hyperplasia and hypertrophy with the help of molecular markers. The validation of the myostatic action of raw materials and fish feeds in vitro comes with an added value as a tool for wide-scale screening in search for sustainable raw materials for fish feeds.

INTEGRATED SUBMERSIBLE AQUACULTURE FOR WARM WATER OPEN OCEAN

Langley Gace
Innovasea Systems
266 Summer Street
2nd Floor
Boston, MA, 02210 United States
LGace@innovasea.com

The expansion of warm water aquaculture is trending away from sheltered sites to either land-based or open ocean production. The industry consensus is that to safely farm in the open ocean, equipment needs to be submerged to avoid the surface energy of waves and storms. Other benefits of being submerged include less stakeholder conflict, optimal growing temperatures as a result of seasonal thermoclines, and the ability to evade parasites or blooms that are commonly found at the surface.

Until now there has not been an integrated suite of equipment and services capable of addressing all the key steps of fish production, from stocking to harvesting, with submerged equipment.

For the past five years, Innovasea has been developing a family of products to address the unmet needs of submerged open-ocean aquaculture. The cost-competitive SeaProtean pen provides the same walkway as traditional surface pens as well as a centered variable buoyancy chamber that affords a much more controlled linear descent and ascent than other circular submersible pens. The three discrete volumes in the buoyancy chamber allow the operator to choose from multiple depths and hold station at those depths. This is especially useful when targeting optimal growing conditions due to temperature and parasitic events.

Reliable waterborne feeding is now available at commercial volumes with the modular FlowFeeder, which delivers the pellets in a gentle flow of water using 50% less energy than air-blown systems. The feed rides in a cushion of fluid, minimizing pellet damage and improving food conversion ratios. Other benefits of the water cushion are less pipe damage and deposits of microplastics in the ocean.

Finally, AI-powered software and hardware solutions monitor underwater activity in real time to help optimize production. aquaEnvironment provides precise data on water conditions such as temperature, salinity, and dissolved oxygen in and around the pens to protect fish while BiomassPro instantly estimates the size and weight of fish stocks in real time to reduce feeding costs and better predict sales schedules.
THE EFFECT OF DIETARY VITAMIN D₃ AND PHOSPHOROUS ON GROWTH AND SKELETAL HEALTH ON JUVENILE BALLAN WRASSE

Introduction

Farmed ballan wrasse (Labrus bergylta) are produced as cleaner fish in salmon aquaculture and this relatively new industry faces several challenges in its pursuit of producing sustainable, high quality, robust fish. Slow growth (Brooker et al., 2018) and a high frequency of nephrocalcinosis and skeletal abnormalities (Cavrois-Rogacki et al., 2021; Fjelldal et al., 2021) are crucial challenges. While there are likely many factors involved, identifying the nutritional requirements of this species will be essential to improving performance and skeletal health. Phosphorus is an essential element of skeletal tissue and is involved in a wide range of metabolic processes (Antony Jesu Prabhu et al., 2013) making it a key target for dietary optimisation to improve both skeletal health and growth. Vitamin D₃ (VD) plays an important role in Ca and P uptake and directly interacts with osteoblasts to regulate mineralization (Lock et al., 2010). It has also been implicated in the development of nephrocalcinosis in mammals (Letavernier and Daudon, 2018). This study aims to investigate the impact of 3 levels of P and 2 levels of VD on juvenile ballan wrasse performance and skeletal health.

Materials and Methods

Ballan wrasse (4.3 ± 1.1g) from Otter Ferry Seafood Ltd. (Tighnabruaich, Argyll, UK) were randomly distributed into 18 100L flow through tanks (140 fish per tank; 2520 fish in total). Tanks were allocated to one of six experimental diets, formulated to two different levels of VD (1500 IU/Kg or 3000 IU/Kg) and three levels of P (1.1, 1.9 and 2.7 %; Table 1) in a 2x3 factorial design. Each condition was conducted in triplicate and fish were fed the experiment diets to satiation for 10 weeks.

(Continued on next page)
After 10 weeks, 33 fish per tank were weighed, measured, and welfare scored before storing in 10% neutral buffered formalin for x-ray, whole mount staining and histology analysis. Growth results were analysed with a two-way ANOVA after testing for assumptions followed by a Tukey’s post-hoc test. Welfare scores were analysed using the Kruskal-Wallis test followed by a Dunn’s test.

Results
After 10 weeks, growth (SGR) was significantly impacted by significantly impacted by P (two-way ANOVA, \( p = 0.003 \)) but not VD\(_3\) (\( P = 0.599 \)). The highest P level (2.7%) performed the significantly better than the low P condition (figure 1).

There was a high frequency of pectoral fin erosion across all groups (90-98% with a score of 1 or greater), though in both VD groups the high P conditions scored the highest, with median scores of 1.5 compared to 1 in the other groups (Kruskal-Wallis, \( p < 0.01 \)).

Chemical composition analysis of the final formulated diets showed lower P and higher than expected VD3, resulting in no low P/low VD3 diet.

These general performance and welfare indicators will be complemented with radiological analysis which is currently in progress to investigate vertebral health and nephrocalcinosis frequency.

Discussion
The nutrient requirements for this species have yet to be established and most commercial diets currently in use contain ~2% P and ~2000 UI/kg. This study suggests higher levels of P may improve growth performance. However, P requirements for optimum bone mineralisation are often higher than the levels required for optimum growth (Antony Jesu Prabhu et al., 2013) and pectoral erosion scores shows initial indications that this level of P may not be optimum for welfare.

Email: jose.gallardo@pucv.cl

Introduction

Fillet color is a key trait which determines the quality of farmed salmon, and has been identified as a polygenic trait in nature, with some QTL (quantitative trait loci) being associated with carotenoid and lipid metabolism genes. The Lochy strain of Atlantic salmon has shown high variation in fillet color between families and between males and females. Thus, identifying QTL associated with color could help improve the quality of this strain through the use of genomic selection. This study presents a genome-wide association study (GWAS) of fillet color in a domesticated population of the Lochy strain. Additionally, we assessed the potential to predict fillet color using genomic information for broodstock selection.

Materials and methods

1194 pit-tagged fish (from 200 full-sib families; 589 females and 605 males) were harvested from a marine fish farming center in Chile belonging to the salmon breeding program of Salmones Camanchaca company. Fillet color was digitally measured using the QMCOLOR software (Quality Metrics SPA), and expressed as a quantitative variable ranging from 20 (low color) to 34 (high color) (Figure 1). All fish were genotyped with a customized 62 K Affymetrix genome-wide SNP-chip. The genomic association analysis was conducted using the GMMAT package of R; then, breeding values were estimated using the Genomic Best Linear Unbiased Prediction (GBLUP) with the BGLR package of R. The predictive ability of GBLUP was obtained from a 5-fold-cross-validation with BGLR, while the ICSASG_v2 genome in the NCBI database was used to identify genes associated with color.

Results and Discussions

The average fillet color, measured in the belly region, was 24.2 ± 0.98 (Females: 24.4 ± 0.94; Males: 24.0 ± 0.98). A total of 35 SNPs were found to be significantly associated with belly color, distributed in Ssa26 (33 SNPs) and Ssa29 (2 SNPs) (Fig. 2). The heritability of this trait was 0.29, and the genetic variance explained by QTL markers ranged from 8.6% to 26.4% in Ssa26 and from 6.8% to 7.0% in Ssa29. Notably, Ssa26 harbors two genes, bco1 and bco11, which are involved in the metabolism (oxidation) of carotenoids (Helgeland et al., 2019; Sae-Lim et al., 2022). The correlation between breeding value and phenotype varied from 0.72 to 0.79 for the training populations, but was only between 0.32 and 0.44 in the test populations.

Conclusion

In conclusion, two genomic regions were associated with fillet color variation in the Lochy strain of Atlantic salmon. The first, located on chromosome 26, has already been identified in other domesticated fish strains such as Mowi and Aquagen. A new chromosomal region was detected on chromosome 29 in the Lochy strain, but the explained variance was lower than that on chromosome 26. These results demonstrate that genomic selection can be used to accelerate the genetic progress of color measurement digitally in this strain.

COLLECTION AND TREATMENT OF WASTEWATER FROM RECIRCULATION AQUACULTURE SYSTEMS, WITH THE SCOPE OF PRODUCING BIO-BASED FERTILISERS, AS PART OF THE EUROPEAN FUNDED HORIZON PROJECT SEA2LAND

Tamás Bardócz*, D. O’Brien, A. Chantzaropoulos, G.M. Cusimano, T. Eisenbeck, J.C. Chiang, N. Guerra, E. Martinez

Introduction
AquaBioTech (ABT) Group in the SEA2LAND project is responsible for providing marine aquaculture sludge for the nutrient extraction methods employed by UVIC (Universitat Central de Catalunya). Based on the circular economy model, SEA2LAND promotes the production of fertilisers in the EU from raw materials. This solution is expected to reduce the soil nutrient imbalance in Europe. However, there are still technological difficulties surrounding the concentration of sludge, therefore there is a need to modify and change the existing concept in order to search for other ways of concentrating more sludge and perhaps of better quality (nutrient concentration).

It is well known that ozone causes clumping of solids (micro-flocculation), which facilitates their removal by foam-fractionation, filtration, and sedimentation. It was thought that ozone treatment could be effective after drum-filters or even before the drum-filter. In this case, the backwash of drum-filters could provide not just normal sludge but also more flocculated solids (treatments with ozone lead to flocculation). This will result in more sludge removed (parts filtered by the drum and solid clumps) and hopefully could solve the problem identified in the project.

Wastewater was treated with ozone on many occasions at ABT with different protocols of dosing. However, there were not any positive results in the flocculation of solids. Effective doses of ozone for such treatments were found to be above 2mg/L in literature (Bogner et al 2018; Ji et al 2019). However, when the trials were carried out, these levels could not be reached. The saturation level was reached early before ozone reached 1mg/L. Hence, after the saturation point (the highest observed was 680µg/L in 30 minutes post ozone application), ozone started to spread in the atmosphere, becoming dangerous for humans. If that was the case on an experimental level, on a bigger scale these levels of ozone could be lethal for humans. Therefore, it was decided that other alternatives should be trialled.

Specific, water-soluble polymers are widely used in wastewater treatment to remove suspended solids and/or contaminants from the water, and therefore can be found in municipal, industrial and stormwater treatment systems. The liquid/solid separation, that can take hours or days when left to gravity alone, can typically be achieved in minutes or seconds with properly prepared, activated, and applied polymers. A coagulant added to wastewater creates a coagulation process that neutralizes the particles’ negative charge. Once neutralized, the particles can come together to form larger particles called micro-flocs, creating a larger particle with a higher mass-to-drag ration and hence speeding up the natural process of sedimentation.

Research shows most polymers used in wastewater come from the backwash of drum-filters. It is believed that perhaps the application of polymers in the wastewater before entering the drum-filter could flocculate solid particles, increase their size, and therefore increase the efficiency of the drum-filter in terms of solid removal which will be increased furthermore with the application of filter-bags to the wastewater leaving the filter after the backwash. In 2009, Sharrer et al. tried and successfully implemented the use of flocculants after the drum-filter and before geotextile bags. In 2005, Ebeling et al. showed 99% removal of Total Suspended Solids using commercially available polymers from various companies. After being taken off-line and allowed to dewater and dry, a sludge cake is sufficiently dewatered, i.e., to approximately 20% solids dry weight (Sharrer et al. 2009). At the same time, this removal led to 92-95% reduction of reactive phosphorus (orthophosphate).

(Continued on next page)
Materials and methods
The wastewater from two species will be used in the trials: Atlantic salmon (*Salmo salar*) and European sea bass (*Dicentrarchus labrax*). The trials will take place in the facilities of AquaBioTech Group and use a recirculating aquaculture system.

As wastewater is leaving the drum-filter with the use of back-wash pump, it will be collected in a tank (125L). The sludge tank will be connected, through a pipe, with the filter bag (secured in a frame). The filter bag will provide wastewater for each sample to a graduated cylinder, with the initial temperature recorded. To ensure the validity of the results, all water samples will come from the same cycle of backwashing every time.

Collected sludge will be treated with the solutions of flocculants, provided by DERYPOL S.A., in a stirrer/flocculation tester. The flocs will be allowed to settle for 15 minutes. For all screening and flocculation tests, turbidity and reactive phosphorus will be measured. Turbidity will be used as an indicator of suspended solids and reactive phosphorus for phosphorus content. Another important factor that is useful in wastewater treatment is the speed of settling of the flocculated particles, these analyses will also be carried out.

Apart from the quality of the filtered water either with pre-treatment using flocculant or not, an assessment will be carried out for the retained (inside the filter bags) solids composition and define what is their nutrient content. Solids will be collected after settling, without and with filter bags. The samples will be sent to an external lab, where the analysis for the content of these solids will be identified. Any positive results could be further exploited, by upscaling into commercial systems.

INFLUENCE OF ENVIRONMENTAL FACTORS AND PATHOGENS ON PREFATTENING STAGES OF CUPPED OYSTERS *Crassostrea gigas* RAISED IN THE MIDDLE ADRIATIC SEA

Livio Galosi1*, Alessandro Bellato2, Gian Enrico Magi1, Giuseppe Arcangeli1, Federica Tosi3, Alessia Vetri3, Adolfo Maria Tambella1, Anna-Rita Attili1 and Alessandra Roncarati1

In last decades, demand for bivalves has significantly increased almost worldwide. In the Adriatic Sea, offshore bivalve molluscs farming is almost entirely based on mussel farming although some companies started to diversify their production. The impact of environmental factors and host/pathogens interaction on growth performance and mortality of Cupped oysters (*Crassostrea gigas*) were analysed on different batches, during the years 2018 and 2019. Sea Surface Temperature and Chlorophyll-a measures were obtained from the database provided by Moderate Resolution Imaging Spectroradiometer (MODIS) instruments aboard NASA’s Aqua satellite. Our results show a significant growth rate of the oysters reared in the Adriatic Sea, but an increase of mortality in summer months. Histological analysis does not show the presence of specific pathogens, recording only a strong positivity with immunohistochemistry for *Vibrio* spp. in summer 2018, but not in 2019. The research of OsHV-1 and *V. aestuarianus* shows negative results in all the time points, but we demonstrated that there was a combined effect of Sea Surface Temperature, Chlorophyll-a and *Vibrio* clade *splendidus* concentration on oysters’ mortality. Despite the high mortality and the resulting economic loss during the summer months, oysters farming seems to be a feasible activity in the Adriatic Sea. To maximize production and the profitability of the farm, new locations for product finishing could be suggested based on the findings of this study.

THE IMPORTANCE OF SUBSTRATE IN THE IMMUNE RESPONSE IN THE ATLANTIC BLUE CRAB (*Callinectes sapidus*) AFTER A BACTERIAL CHALLENGE WITH *Vibrio alginolyticus*

R. Gálvez, J. Meseguer, F.A. Guardiola*.

Introduction

The Atlantic blue crab (*Callinectes sapidus*, Rathbun, 1896) is a species of decapod crustacean belonging to the family Portunidae. It is native to the coastal areas and estuaries of the west coast of the Atlantic Ocean, but in recent years has spread to the Mediterranean Sea (Falciai and Minervini, 1992). On the western Atlantic coast, it is a species of high commercial value. Its sometimes-excessive fishing has led to an 80% decline in stocks in recent years in places such as the Chesapeake Bay (US East Coast) (Lipcius and Stockhausen, 2002). This fact is leading to numerous studies and interested people in the profitability of large-scale farming of this species, which would provide relief to wild populations in most cases (Zmora et al., 2004). Decapod crustaceans are sentient beings, which not only respond to noxious stimuli, but are also capable of feeling pain, discomfort, and stress (de Souza, 2022). Given that the Atlantic blue crab inhabits sandy and muddy bottoms in which it tends to bury itself (Falciai and Minervini, 1992), we considered that the presence or absence of substrate in the facilities in which these animals can be cultured could be fundamental for the welfare of these animals, as well as contributing to a significant reduction in stress. Therefore, the aim of this study is to demonstrate how the use of substrate can improve the immune response of Atlantic blue crabs when exposed to a pathogenic bacterium.

Materials and methods

Twenty specimens of Atlantic blue crab (217.5 ± 142 g) were obtained from the fish market (San Pedro del Pinatar, Murcia, Spain) and carried to the Marine Facilities at University of Murcia (Spain). The crabs were randomly separated in two groups, each group (n=10) was introduced into a tank with individual compartments for a single crab each one but sharing water and filtration (rack system) with the aim of avoiding fights. One of the groups (control) had no substrate at the bottom of the tanks, while the other one had 7 cm of sterile sand. After 30 days of acclimatising, a sample of 2 mL of haemolymph were extracted as initial time (t=0). Then both groups were challenged by bath with *Vibrio alginolyticus* (35 min, 2 x 10^6 ufc mL^-1). After this, crabs were sampled after 24, 48, 72 and 96 hours. After each experimental time, 2 mL of haemolymph were extracted from the V right pereiopod and the total haemocyte count and the cell’s percentage populations were determined. In addition, the obtaining of haemocyte lysate supernatant was used to measure the total quantity of protein, as well as the phenoloxidase and the lysozyme activities were measured. The results were expressed as mean ± standard error of the mean. Data were analysed by One-way ANOVA (followed by Tukey tests) to determine differences between experimental groups. The level of significance used was p < 0.05 for all statistical analysis.

Results and discussion

The percentages of each cell population under basal conditions (time 0) showed that the percentage of granulocytes was the lowest in both groups, followed by the number of hyalinocytes and semigranulocytes. However, our results showed a change in the cell percentages of the animals challenged with *V. alginolyticus*. More specifically, a decrease in the percentage of hyaline cells was observed at 24, 48, 72 and 96 hours in the crabs maintained with substrate. In the experimental group without substrate, this decrease was also observed, although it occurred at 72 and 96 h. In the case of semigranulocytes, no time-dependent variations were observed in the animals maintained without substrate, although in the crabs maintained in the presence of substrate a significant increase in the percentage of these cells at 24, 48 and 72 h was observed. Comparing between experimental groups, a higher proportion of hyalinocytes in the haemolymph of crabs maintained with substrate at 0 and 96 hours were observed compared to the crabs maintained without substrate. In the case of semigranulocytes, the

(Continued on next page)
percentage of this cell type was significantly higher in animals without substrate at 24 and 72 h compared to results observed in crabs maintained with substrate. However, no variations were detected in the number of granular cell population between both experimental groups. All these data indicate the great capacity for adaptation and plasticity that these crustaceans can present in the face of a biotic stress factor such as the challenge by pathogenic microorganism. This can be related to the data provided by Du et al. (2012) in the giant freshwater shrimp (M. rosenbergii) challenged with Spiroplasma, where the cell populations varied over time. The quantity of proteins in the haemocyte lysate supernatant varied between both experimental groups at 0, 24 and 48 h. Regarding the time, protein concentration increased at 24, 48 and 72 hours in both experimental groups. These values could be since the pathogen caused a reaction that triggered intracellular antimicrobial protein synthesis at 24 hours, which remained active until 72 hours, at which time the protein synthesis reaction subsided. In relation to the immune-related enzymes, the lysozyme did not show any variation between experimental groups or experimental times. However, the phenoloxidase activity showed a great variability between animals, being undetected at 0 and 24 h in the crabs from both experimental groups. After 48 h of challenge, the phenoloxidase was detected although their activity was stronger at 72 h, being expressed in three crabs of the group without substrate and eight of the group maintained with substrate. Furthermore, the quantity of enzyme per animal was higher in the experimental group maintained with substrate. This fact could indicate that the phenoloxidase is not present in the haemolymph of animals not exposed to any pathogen, which could be released at 48 hours of challenge, being more efficient in the immune response in the case of animals maintained in presence of substrate.

Conclusions

The results obtained could contributed to the knowledge about the immune response and the requirements necessary to improve the animal welfare of brachyurans. Recently, Zhu et al. (2022) reported that the use of substrate significantly benefited South Korean blue crabs (Portunus trituberculatus), reducing their cannibalism, improving their condition inside the tanks, and resulting in behavioural patterns of interaction with the substrate. Therefore, we could conclude that the substrate may not only act as a factor contributing to animal welfare in animal behaviour, but also that this state may be reflected in a better immune response to certain pathogens that often cause huge losses to aquaculture farms based on decapod production.

FIRST INSIGHTS FROM A SURVEY ON SHRIMP FARMING

P. Gamberoni*, M. Boegner, M. J. Slater

Alfred Wegener Institute Helmholtz Centre for Polar and Marine Research
Am Handelshafen 12
27570 Bremerhaven, Germany
E-mail: paolo.gamberoni@awi.de

Introduction
According to the Animal Welfare Act, species-appropriate husbandry must be ensured in animals kept for commercial purposes. The animal owner must collect and evaluates suitable, species-related animal welfare indicators for his assessment (Franks et al., 2021). Although regulations do not yet apply to crustaceans, an expansion is expected shortly (E. Parliament, 2021; TierSchG A, 2000). The effect of chronic stress on crustaceans and its markers are still poorly analysed (Wuerz et al., 2023). The CrustaWohl project focuses on welfare to optimise whiteleg shrimp (Litopaeneus vannamei) farming in RAS systems. Chronic stress is aimed to be investigated, with approaches on health observation, histology, physiology, genomics and shrimp behaviour.

As the first step of the project, a survey for shrimp farmers and experts was originated, in order to calibrate the experiments and to acquire data from shrimp farming practices. Some insights from the provisory results are presented with the aim of enriching the archive.

Materials and methods
A questionnaire of 19 points has been generated, which comprises aquaculture system management, species biology and water chemistry fields. Literature review, OCEANLOOP project partners’ consultation and the project guidelines have been taken into account in its preparation. The survey was advertised in the EUROSHRIMP newsletter at the following link: https://www.euroshrimp.net/crustawohl-survey/.

Shrimp farmers and experts are invited to fill in. The estimated duration is expected in 10-15 minutes. It is anonymous and observes GDPR rules.

Results
Multiple selections to the same question are allowed. At the moment, the number of replies is still limited, with only 9 participations. 55% of the interviewees utilize a RAS and 27% Biofloc as a system. Aquaponics and other systems are also reported. According to Figure 2, bad water quality, mineral deficiencies and high stocking densities are indicated as the most limiting factors for shrimp welfare. System technical issues follow with a 20%. The most common abnormal biological observations comprise shortened antennae, gills erosion, eye lesions and uropods redness, which are noticed by more than 70% of the shrimp experts (Fig. 1). “Shortened antennae” and “uropods redness” affects more often a larger rate (15-30%) of the population. In Figure 3, irregular swimming dominates as abnormal behaviour observed, while 30-40% of the voters describe, also, lethargy, surface swimming, strong escape behaviour in response to stimuli, cramped body and no feeding.

Discussion
More contributions are aimed to get new insights and more accurate results. Some limiting factors are reported for shrimp welfare. For this purpose, the CrustaWohl project addresses stocking densities and water chemistry analyses, which could provide helpful outputs. Deficiencies in minerals might be an interesting matter for future projects. Health observations and behaviour related to stress have been already described in decapods, with a degree of similarity with the ones reported by shrimp experts (Sellars et al., 2004; Pedrazzani et al., 2023). The visible perceptions are supposed to be associated with physiological chronic stress markers. The project comprises, also, a larger scale environment, to reach a higher degree of meaningfulness and practical utility for farmers.

Conclusions
This investigation shows the limitations to farmed shrimp welfare from the shrimp experts’ perspective. Some interesting insights are highlighted to address CrustaWohl and future projects.

Introduction
The employment of good water management practices is of extreme importance in aquaculture farming, including adequate dissolved oxygen levels. Sub-optimal oxygen levels impact respiration rate, stress and immune response, water quality, optimal fish growth, parasite occurrence, and fish survival. Some parasites, especially those that affect fish gills and skin, thrive in low-oxygen conditions (Schäfer N., et al, 2021; Jerônimo G. T., et al, 2022). By ensuring sufficient dissolved oxygen, fish farmers can mitigate the impact of parasites and support the overall health status and enhance productivity of their fish stocks (Akhter et al, 2021). The target of this work is to analyze the histopathological effects in the gills, at three different dissolved oxygen levels and evaluate the impact on overall fish performance.

Methods
The experiment was conducted at the Aquaculture Research Station (EPPO) facilities of IPMA (Olhão, Portugal), where meagre with mean body weight of 256.0 ± 1.8 g were distributed in 9 fiber-glass tanks (1.5m³), with a density of 10.9 ± 0.1 kg m⁻³ per tank, in triplicates. Meagre were kept in natural temperature conditions, salinity 37 ppt, photoperiod 14L:10D and fed *ad libitum*. Fish were maintained with three different levels of dissolved oxygen: DO1 - low oxygen (2.5 - 3.0 mg/L); DO2 - medium oxygen (4.0 - 5.0 mg/L); DO3 - high oxygen (6.0 - 7.5 mg/L), for 4 weeks. At the end of the trial, gill samples were collected to evaluate the histopathological impact. The first gill arch was collected, fixed in formol (4%) and transferred to ethanol at 70%, after 24h. Then the tissue was processed using a standard histological technique (Martoja & Martoja-Pearson, 1970). Mounted slides were scanned with a Hamamatsu NanoZoomer C13140-01 and images were analyzed with the NDP.view2, Image viewing software. Histopathological changes were examined, using the semi-quantitatively analysis described by Mishra and Mohanty (2008).

Table 1. Gill histopathological analyses in *Argyrosomus regius* exposed to three different dissolved oxygen levels: DO1 - low level (2.5 - 3.0 mg/L); DO2 - medium oxygen levels (4.0 - 5.0 mg/L); and DO3 - high oxygen levels (6.0 - 7.5 mg/L).

(Continued on next page)
Results and Discussion

In this study, the histopathological lesions were used to determine the general health of fish and the overall condition of their aquatic environment. While some lesions may be permanent, others may be reverted under the correct water quality conditions (Nascimento et al., 2012). The results of the histopathological lesions in this study revealed that there were no notable variations between the different oxygen levels. The lesions observed, were infiltration of leucocytes, epithelial edema, telangiectasia and lamellar aneurysm, can be categorized as mild. However, the DO1 treatment presents a moderate hemorrhagic state compared to the other treatments (D2 and D3). These results can be explained by the fact that the fish attempt to increase the flow of blood over their gills to enhance the oxygen uptake. This increase in blood circulation can make gill blood vessels more fragile and sensitive to rupture, causing bleeding and hemorrhagic lesions. Hemorrhagic state can also be caused by other factors such as infections with ectoparasites, as described by Ribeiro et al (2023).

Introduction

The search for alternative sustainable raw materials to improve current fish diets would be supported by reliable and predictive *in vitro* models. The H2020-FETOPEN project Fish-AI, aims to develop such an in vitro screening platform based on rainbow trout digestive enzymes and intestinal cells to evaluate nutritional and health values of novel aquafeeds. As part of this project, we used two different bicameral culture platforms to evaluate the effects of prolonged exposure to fish feed on intestinal health. We compared a simple system consisting only of an epithelial monolayer and a complex organotypic system that combined a stroma-like scaffold populated by rainbow trout (RT) fibroblasts with a functional epithelium.

Material and Methods

To generate the *in vitro* platforms, RT proximal and distal intestine epithelial cells (RTpiMI, RTdiMI) were seeded onto ThinCert (TC) inserts (Greiner BioOne, 0.4 µm pore size), a permeable PET membrane or onto the synthetic scaffolding Alvetex™ (Reprocell) (AV) previously populated with RTskin01, a fibroblast cell line derived from the trout dermis. Both were cultured at 20°C under ambient atmosphere. We used a diet rich in fish meal with crude protein and lipid level of 46 and 23% respectively. Feed pellet were digested *in vitro* with enzymes extracted from the RT gastric and intestinal segments of the digestive tract.

Barrier integrity and functionality were assessed through the measurement of transepithelial electrical resistance (TEER), apparent permeability (Papp) to 100 µg/mL 4 KDa FITC-Dextran (FD4) and *in situ* detection of the alanine aminopeptidase (ALP), a brush border enzyme. Once the models established an effective epithelial barrier, they were exposed for 21 days to increasing concentrations (6, 12, 25, 50%) of *in vitro* digested feed (IVD) diluted in Leibovitz L-15 medium supplemented with 10% FCS. Controls were run incubating cells with L-15 medium without IVD. Samples were fixed in 4% paraformaldehyde in PBS, processed for histological analysis and stained with hematoxylin and eosin (HE).

![Fig. 1 Multilayered barriers formed by RT intestinal cells cultured on TC and AV after 21 days of exposure to different concentrations of in vitro digested feed (IVD).](Continued on next page)
Results

During the 21 days of exposure to IVD, barrier integrity was conserved along the course of the experiment as indicated by the limited paracellular flux of FD4 compared to the respective inserts without cells. TEER values significantly increased from the baseline values in both cell lines cultured in both systems. The morphological analysis revealed that in all the combinations of IVD concentration, cell lines and culture platform, epithelial cells lost their monolayer arrangement and formed a multilayered barrier, with the only exception of RTpiMI exposed to 6% IVD cultured in AV, in which the cubic and polarized monolayer observed in the control was preserved. In AV, ALP activity significantly decreased in both cell lines exposed to 25 and 50% IVD affecting cellular functionality. This was not evident in the TC system, in which high IVD concentration did not reduce the enzymatic activity but rather increased the proteolytic activity in the RTdi-MI cell line.

Conclusion

High concentrations of IVD generated a mildly stressful environment in both platforms since long-term exposure led to increased proliferative activity at the expense of cellular differentiation. The fact that irritation occurred even with high levels of marine ingredients may be due to the lack of mucus-secreting cells that would provide the physiological protection for the epithelium. Interestingly, this reaction reminds our recent data, demonstrating that nutritional stress induces de-differentiation and proliferation of mature enterocytes in the RT proximal intestinal mucosa. The fact that we observed a similar response in vitro, suggests that the data generated by the artificial intestinal platforms can be representative of in vivo trials. Since the cells grown on the Alvetex™ scaffold reacted with higher sensitivity to the exposure to the digesta this looks as the more reliable platform.

Introduction
To keep up with an increasing demand for animal protein, the aquaculture sector has seen an increase in production over the past decades. The intensification of this sector has been accompanied by an increase in disease incidences. Besides prevention of diseases through vaccination and treatment of diseases by antibiotics, dietary supplementation with immunomodulators may provide an alternative route to maintain animal health in aquaculture. Among the better-known immunomodulatory feed additives are non-starch polysaccharides, with probably the best characterized compounds being β-glucans [as reviewed by: (Dawood et al., 2018; Petit and Wiegertjes, 2016)]. Another group of immunomodulatory substances are marine sulphated polysaccharides (MSPs) isolated from macroalgae. While MSP-rich extracts are gaining interest from the aquaculture sector as containing health-promoting compounds, their immunomodulatory effects are not always clearly defined.

Materials and methods
Green macroalgae (Ulva sp.) and red macroalgae (Solieria sp.) were processed to produce eight different crude extracts enriched for marine sulphated polysaccharides (MSP).

Antimicrobial activity of the MSP-rich extracts was investigated against 13 fish bacterial strains. Concentration of bacteria (CFU/mL) was determined and strains were diluted to 10⁵ CFU/mL in Mueller Hinton Broth (MH broth). For all eight different MSP-rich extracts, extracts were first dissolved in ultra-pure water and sterilized by autoclaving, subsequently a two-times serial dilution was made from 12.5 mg/mL – 0.0061 mg mL⁻¹. In a sterile culture plate, 100 µL bacterial suspension was combined with 100 µL MSP solution dissolved in MH broth. Bacteria were incubated for 24h, or 72h for slow growing bacteria (i.e. *Aeromonas salmonicida*, *Aliivibrio salmonicida*, *Streptococcus agalactiae*, *Streptococcus iniae*). Each plate included a positive control with bacterial strain alone in MH broth, and two negative controls: only MSP extract at the different dilutions, and MH broth alone. Following incubation, optical density was measured at O.D. 600 nm and plates were photographed. Antimicrobial effects were determined as the lowest MSP extract concentration required to completely inhibit visible growth (O.D. 600 nm, or visually determined from photographs) of tested microorganisms after 24h, or 72h of incubation. Three replicates were made for each microorganism.

Nile tilapia (*Oreochromis niloticus*) were reared at 28 ± 2 °C temperature with a 12-12h light-dark cycle. The fish were fed a commercial diet twice per day. Rainbow trout (*Oncorhynchus mykiss*) were reared at 14 ± 0.5 °C temperature with a 12-12h light-dark cycle. The fish were fed a trout specific research diet twice per day.

Fish were killed with 0.3 g/L tricaine methanesulphonate in aquarium water buffered with 0.6 g L⁻¹ sodium bicarbonate (Nile tilapia) or 2-phenoxethanol (1 mL L⁻¹) in aquarium water (Rainbow trout) and bled via the caudal vein. Head kidney was removed aseptically and total head kidney leukocytes (HKLs) were separated on a Percoll density gradient (51%), as previously described for Nile tilapia (Kumar-Velmurugan et al., 2012), and for Rainbow trout (Chettri et al., 2011).

Production of ROS was determined by a real-time luminol-based luminescence assay, as previously described with minor modifications (Petit et al., 2021). Cells were stimulated with one of the following: RPMI cell culture medium (control), zymosan (tlrl-zyd, 50 µg mL⁻¹), or one of the extracts at a concentration of 250, 500, 750, 1000 and 1500 µg mL⁻¹. Chemiluminescence emission was measured in real time at 27°C (Nile tilapia) or at 19°C (Rainbow trout) and expressed as area under the curve, as previously described (Petit et al., 2019). Fold changes were calculated as the area under the curve of stimulated HKLs relative to unstimulated HKLs (treated with RPMI).

(Continued on next page)
HKLs were seeded at a density of 4.5 x 10^6 per well in a 24-wells plates and stimulated with RPMI, zymosan (tlrl-zyd, 50 mg/ml,) or one of the extracts at a concentration of 500 µg mL^-1 and incubated at 27°C (Nile tilapia) or at 19°C (Rainbow trout). At 3 and 6 hours post stimulation, cells were lysed in RLT lysis buffer and stored at -80°C until RNA isolation.

Total RNA from cell lysate in RLT lysis buffer was isolated and stored at ~80°C. Prior to cDNA synthesis, total RNA was treated with DNase I, Amplification Grade, and cDNA was synthesized using random primers (300 ng) and Superscript III First-Strand Synthesis for RT-PCR. cDNA samples were diluted in nuclease-free water prior to real-time quantitative PCR (RT-qPCR) analysis.

Gene expression was measured with RT-qPCR using ABsolute qPCR SYBR Green Mix in a Rotor-Gene Q, and fluorescence data were analysed using Rotor-Gene Analysis software version 2.3.5. The relative expression ratio (R) of each sample was calculated according to the Pfaffl method (Pfaffl, 2001) based on the take-off deviation of sample versus each of the PBS controls and normalized relative to elongation factor 1α (elf1α) as reference gene.

Statistical analysis was performed in IBM SPSS statistical data editor version 26. Data presented as fold changes were transformed with natural logarithm, prior to statistical analyses. Subsequently, transformed data was tested for normality using a Q-Q plot and performing a Shapiro-Wilk test. Data was then analysed using a repeated measures linear mixed model followed by a Bonferroni post hoc test. All values are means and expressed with their standard deviation (SD), and data were considered significant for p<0.05.

Results
While all extracts showed direct anti-bacterial effects to some degree, two red algal extracts in particular, had high activity against several pathogenic fish bacteria in vitro. Stimulation of head kidney leukocytes (HKLs) in vitro with MSP-rich extracts showed fish species specific differences. In Nile tilapia, HKLs showed a dose dependent reactive oxygen species (ROS) production following stimulation with Ulva-derived extracts, while stimulation with Solieria-derived extracts did not induce ROS production. In Rainbow trout, HKLs showed relatively high reactive ROS potential and Solieria-derived extracts could induce significant ROS production, albeit without clear dose dependent responses. Gene expression of in vitro stimulated HKLs showed a clear induction of most cytokines measured (il1b, il10, tnfa, ifng, il12p40). Although cytokine gene expressions were more prominent in Nile tilapia than in Rainbow trout, immunomodulatory effects of both, Ulva- and Soleria-derived extracts could induce significant ROS production, albeit without clear dose dependent responses. Gene expression of in vitro stimulated HKLs showed a clear induction of most cytokines measured (il1b, il10, tnfa, ifng, il12p40). Although cytokine gene expressions were more prominent in Nile tilapia than in Rainbow trout, immunomodulatory effects of both, Ulva- and Soleria-derived extracts appeared evident. HKL might sense the presence of MSP via unknown pattern recognition receptors with known downstream signaling pathways. For genes associated with Toll-like Receptor (TLR) signaling, regulation of irak1 in Nile tilapia was evident. For genes associated with C-type Lectin Receptor (CLR) signaling, regulation of both card9 and bcl10 was found, again in Nile tilapia, confirming earlier observed fish species specific differences. Possibly, immunomodulatory effects of MSP could be regulated by CLR-mediated signaling, at least in Nile tilapia, for which most if not all red algae and green algae extracts induced changes in gene expression.

Conclusion
Overall, induction of ROS production and gene expression read-outs suggest immunomodulatory effects of MSP-rich extracts derived from green algae (Ulva sp.) and red algae (Solieria sp.), at least in vitro. The observed effects suggest clear fish species specific differences between the effects of MSP-rich extracts.
MICRO- AND MACROALGAE AS FUNCTIONAL INGREDIENTS FOR GILTHEAD SEABREAM (Sparus aurata) INTESTINE RECOVERY

Introduction
Gut health is crucial for aquaculture and a proper balance in intestine homeostasis and permeability has implications for fish feed efficiency, performance and health status. Over the last decades, innovation in aquaculture feed formulation has been directed towards functional feeds. Currently, macro- and microalgae aroused interest in their application as functional ingredients due to the biotherapeutic role they can play to enhance fish intestinal health, including modulation of the immune system, antioxidant status and gut integrity. Therefore, the objective of this study was to assess the effects of dietary inclusion of the microalgae Phaeodactylum tricornutum and/or the macroalgae Gracilaria gracilis on the gilthead seabream (Sparus aurata) intestine recovery after provoking an insult based on the administration of soy saponins. Physiological and genomic responses to macro-and microalgae inclusion on intestine homeostasis recovery and gut health were evaluated through the integration of data on plasma metabolic enzymes, and anterior intestine histology and gene expression analysis.

Material and methods
A control (CTRL), commercial-like diet, was formulated for gilthead seabream juveniles. Based on the CTRL formulation, three experimental diets were formulated by supplementation with microalgae (P. tricornutum; PHA) or macroalgae (G. gracilis; GRA) at 2.5%, or a blend of micro- and macroalgae at 5% (50:50; BLEND). The experiment was conducted at the Ramalhete Station of the Centre of Marine Sciences of Algarve (CCMAR, Faro, Portugal). Gilthead seabream juveniles with a mean body weight of ~176 g were distributed into 15 flat-bottom 500 L tanks under natural photoperiod conditions.

To study the intestine recovery after an insult in gilthead seabream juveniles and the recovery through nutrition, five dietary treatments were evaluated: a positive control (PCTRL), where fish were assisted-fed with two empty gelatine capsules, and for the remaining treatments (NCTRL, PHA, GRA, and BLEND), fish were assisted-fed with two gelatine capsules filled with soy saponins (850 mg saponins). The assisted feeding procedure was performed after 24 h of fasting, and the capsules were gently inserted into the anesthetised fish’s stomach and pushed into the oesophagus (as tested preliminarily to avoid injury) in a 10 sec time-frame. Once recovered, the fish was transferred to the respective tank. After a period of 72 h without feeding, fish were fed their respective experimental diet for 20 days. Gilthead seabream from the positive (PCTRL) and negative control (NCTRL) were fed the CTRL diet during the experiment. Fish from PHA, GRA and BLEND treatments were fed the PHA diet containing microalgae, the GRA diet containing macroalgae, or the BLEND diet with the blend of micro- and macroalgae, respectively. The experimental diets were randomly assigned to triplicate tanks. Fish were fed by hand to apparent satiety. Water average temperature during the experiment was 15.2 ± 0.9 °C.

At the end of the trial, fish were fasted for 24 h. Fish from each replicate tank were bulk-weighed and counted. Three fish from each tank were euthanized. Blood was collected from three fish from each tank (n = 9 per treatment) and centrifuged. The collected plasma was used to study the enzymatic activities of alanine aminotransferase (ALT), aspartate aminotransferase (AST), and alkaline phosphatase (ALP). The anterior intestine (AI) of each of these fish was dissected and approximately 1 cm was sampled for histological analysis. For gene expression, ~25 mg of the AI of each fish was used to analyse the gene expression of twelve genes related to antioxidant, immune system and epithelium permeability responses. Results from five genes are still under analysis.

Results and Discussion
The activity of ALT and AST was not affected by the treatments (p>0.05). The ratio ALT:AST that indicates possible liver damage and the ratio AST:ALT that identify a possible disorder in other organs were also not affected by the treatments. On the other hand, fish fed the BLEND diet presented a significant (p<0.05) lower level of ALP. Lower ALP levels could in some cases indicate a lower anti-inflammatory response.

(Continued on next page)
Histological features of the AI showed a significant (p<0.05) increase in the number of mucosa cells in fish fed the NCTRL, PHA, GRA and BLEND diets, suggesting an intestinal recovery response. Fish fed PHA and GRA diets presented a significant (p<0.05) increase in mucosa vacuolation. A higher amount of cell vacuolation could be interpreted as a sign of intestine disruption.

Results from gene expression shed some light on intestine recovery responses in gilthead seabream juveniles. The expression of tight junction protein (tjp) gene was significantly (p<0.05) higher in fish from NCTRL, PHA, GRA and BLEND. Occludin (ocl) expression was significantly higher in fish fed PHA, GRA and BLEND. The upregulation of tjp and ocl may imply a protective effect on the fish intestinal epithelial barrier. Catalase (cat) gene expression was significantly (p<0.05) higher in fish fed NCTRL, PHA, GRA and BLEND diets. There was a significant (p<0.05) upregulation of the glutathione peroxidase (gpx) expression in fish fed PHA diet. The upregulation of cat and gpx could be an indicator of oxidative stress response and a compensatory mechanism for reducing oxidative stress. The levels of the immunoglobulin M (igm) gene expression were significantly (p<0.05) upregulated in fish from PHA. Tumor necrosis factor alpha (tnf-α) activity was significantly (p<0.05) higher in NCTRL, PHA, GRA and BLEND. Upregulation of igm and tnf-α expression may indicate an activation of the immune response. Fish fed BLEND showed a significant (p<0.05) upregulation of the proliferating cell nuclear antigen (pcna). Pcna upregulation indicates possible cell proliferation and epithelial regeneration in the intestine.

In conclusion, these results may indicate a positive regulation of both PHA and BLEND diets in gilthead seabream gut health. PHA and BLEND diets may be used as functional diets to preserve intestinal homeostasis and accelerate the healing process acting as immunostimulants activating the immune system and alleviating cellular oxidative stress.

E-mail: irene.garcia@ub.edu

Introduction

Increasing inclusion of plant-based products and highly lipid commercial diets due to the elevated cost of fish meal highlights the need of the sustainable development of aquaculture through the formulation of functional diets. In this sense, olive (Olea europaea) juice extract incorporation in aquafeeds has been found to enhance immune properties, gut health and functionality, and somatic growth (Gisbert et al., 2017; Rong et al., 2020), possibly due to the presence of bioactive compounds such as phenols, mainly hydroxytyrosol, which has anti-obesogenic properties (Lutfi et al., 2017).

The aim of this study was to evaluate the digestive process in gilthead sea bream (Sparus aurata) fed a high-fat diet, administered at two rations, ad libitum or restricted, and to test the effects of an olive juice extract rich in hydroxytyrosol as an additive.

Materials and methods

Gilthead sea bream juveniles (± 80.8 g) were acclimated to the animal facilities of the Faculty of Biology at the University of Barcelona (Spain). An experimental high-fat diet (24% lipids, 47% protein and 23 MJ/kg of digestible energy) was formulated and produced by Skretting ARC (Stavanger, Norway). The diet was produced in the absence (HF) or presence (HF-HT) of an olive hydroxytyrosol-rich extract (HIDROX®, 1.66%) provided by Oliphenol LLC. (Hayward, CA, USA). To establish two different conditions in terms of energy intake, the diets were administered at ad libitum (1.8% of body weight (BW) in the morning and 1.2% in the afternoon), or at restricted ration (1.8% of BW only in the morning, named R-HF and R-HF-HT groups). After 8 weeks of growth, samples of pyloric caeca (PC) and proximal intestine (PI) were obtained from nine animals per condition and time, just before feeding in the morning and at 5h post-feeding. Samples were directly frozen in liquid nitrogen and stored at −80 ºC for later analysis. Intestinal pH was measured, and after sample homogenization, the activity of digestive enzymes (alkaline protease, α-amylase, and lipase) and the trypsin/chymotrypsin ratio were analyzed.

Results and Discussion

No significant differences were found in growth between the HF and HF-HT groups, whereas food restriction significantly diminished it (-22.1%) (Balbuena-Pecino et al., 2023). Regarding digestive enzyme activities (Figure 1), higher levels were found in PC before feeding, as pancreatic enzymes can be released in this intestinal region prior to food intake to improve the digestive process. Conversely, 5h after feeding, the highest digestive activity was found in PI, where the digestion was taking place. When comparing HF and R-HF groups, in PC, a significant reduction in α-amylase activity was observed in PC, both anticipatory and 5h post-feeding, and lipase anticipatory activity was also down-regulated. However, both groups showed similar enzyme activities in PI. HYDROX addition to the high-fat diet tended to up-regulate the anticipatory activity of α-amylase in PC, and alkaline protease, α-amylase, and lipase activities in PI. In addition, it also increased the digestive activity at 5h post-feeding in the PC for all the enzymes studied. Finally, R-HF-HT fish showed the highest PC lipase anticipatory activity and an intermediate α-amylase activity between R-HF and HF-HT fish in both intestinal segments before feeding, as well as at 5h post-feeding in PC. Additionally, both restricted ration groups presented similar alkaline protease activity in PI before feeding.

(Continued on next page)
Conclusion

Food restriction promoted an optimization of the digestive function in fish, leading to relatively good growth performance despite a reduction in food intake. The observed growth reduction was less than what would be expected with a 40% food restriction. On the other hand, the effect of HT needs further studies as the observed increase in anticipatory activities suggests in general an adjustment of the digestive function to optimize the use of the given diet.

Introduction
Salmon (Salmo salar) aquaculture is an industry that has raised controversy and debate in Norway, Canada and Scotland (Flaherty et al. 2019; Osmundsen and Olsen 2017). The discourse surrounding the aquaculture industry includes a wide array of environmental and socio-economic matters (Weitzman and Bailey 2019), which can influence and shape public acceptance and trust in the industry. In all the aforementioned countries, open net pens sited along the coastline has been the primary production method of salmon. This production method is associated with several environmental risks, and despite being a relatively cost-efficient method, these challenges have hampered production growth. As a result, fish farmers are exploring new technological avenues that can reduce the environmental impact and utilize new production sites. Exposed, closed floating cages and land-based aquaculture are among the new production methods that are being developed and used by fish farmers. However, there might be potential drawbacks that can draw negative attention. On the other hand, there could also be advantages that could increase willingness to pay (WTP), trust and the reputation of the industry.

This study will explore public perceptions of new aquaculture production systems, and the public’s willingness to pay for price premiums. The research question for this study is: what, according to the public, are the most important advantages and drawbacks of different production systems, and are consumers willing to pay for salmon produced using these production systems?

Methods
To investigate public perceptions of new production systems and willingness to pay for salmon produced using these systems, we are conducting an experimental panel survey in the salmon-producing countries of Norway, Scotland, and Canada. The survey is in the process of being fielded by the international, online polling company, YouGov.

We first examine how the public views conventional, land-based, closed floating, and offshore aquaculture by asking them to rank a series of real-world advantages and drawbacks to each production system. We next investigate their willingness to pay for salmon farmed using new production systems through a choice experiment where price is manipulated. After receiving information about the benefits and drawbacks of the production system (i.e., land-based, closed floating, or offshore), respondents are asked if they would rather buy salmon farmed using conventional methods or salmon farmed using the new production system. In Panel 1, the price for salmon farmed using the new production system is higher than the price for salmon farmed using the conventional system. In Panel 2, the price for salmon farmed using the new production system is the same as the price for salmon farmed using the conventional system. The survey design also includes general questions regarding attitudes towards conventional aquaculture, and what the respondents perceive to be the most negative environmental externalities from conventional aquaculture.

Once the results are ascertained (in June 2023), they will be analysed using SPSS.

Results
As of May-June 2023, the survey is in the process of being fielded, and the key results will be presented at the conference.

We hypothesise that respondents will favour new production methods over conventional methods, but not at an increased price.

Furthermore, we hypothesize that perceptions of conventional aquaculture will vary between the salmon producing countries; with Canadian respondents being more negative towards conventional aquaculture than Norwegian and Scottish respondents.

We also expect to see differences in the level of public support for the new production systems across countries. In Canada, we expect production methods that reduce the release of organic matter to receive the most public support whereas in Norway and Scotland we expect production methods that reduce lice and increase fish welfare to receive most public support.

Introduction
Given the growing importance of aquaculture to supply human demands for protein, it is necessary to optimize the farming techniques to obtain a product of excellent quality and concurrently reduce the impact on the environment (FAO, 2022). In this regards, new alternative foods that reduce the amount of organic pollution have been proposed. Among these, a replacement food has recently been developed with a substitution of fish proteins using black soldier fly (*Hermetia illucens*) full-fat prepupae enriched with spirulina (Zarantoniello et al., 2022). Although this insect-based meal has been demonstrated to reduce organic pollution of wasting feed in the environment by converting low-value organic waste into high-value ingredients (Barragan-Fonseca, 2017), its impact on animal welfare, and indirectly to the quality of product, has marginally been investigated.

Behavioral changes may raise because of stressful situation, such as recurring manipulation and wrong feeding regimes. Underfeeding, a state of lesser caloric intake assumed by individual, increased individual competitiveness and high stress levels with, consequently, reduce growth and survival rate. Although the physiological mechanisms of stress have been widely documented (4), a characterization of the behavioural indicators, especially for applying them to the farming context, is still demanding. Recently, it has been proposed a set of Operational Welfare Indicators (OWIs), which offer an unbiased assessment of the welfare state that can be practical implemented to the farm reality (5). Here, we applied this ethological approached to examine the behavioural response to a novel situation, i.e., open field test, of the European seabass (*Dicentrarchus labrax*) fed with different regimes of insect-based meal.

Materials and methods
The feeding treatment was conducted at Mj Energy srl Società Agricola (Treia, Macerata, Italy). After a first acclimation period, European seabass juveniles were randomly divided and assigned to one of the treatments. We administered two experimental diets characterized by 3 and 20% of fish meal replacement with full-fat spirulina-enriched black soldier fly prepupae meal. A group of control was feed with diet characterized by 0% of spirulina-enriched black soldier fly mean. Seabass juveniles undergone a 90-day feeding regime in aquaponic systems equipped with mechanical, biological, and UV filtration.

After the treatment, we performed the behavioural tests. Firstly, we observed individual fish exploration activities in an open field test, a standardize behavioural procedure for measuring personality and explorative activity in animal research. Twelve-fish per each experimental diet condition was individually collected and placed into a 75×75×30cm square-shape white arena, which was positioned into a larger tank connected to a circulating aquaponic system that provided constantly fresh water. Individual behaviour was recorded for 20-min. A second subsample of 60 fish (15 per each treatment) was observed in 4-fish group in the same experimental conditions 20-min.

Experimental recordings were then analysed with EthoVision XT software (ver. 11.5, Noldus Information Technology, Wageningen, The Netherlands). We extracted different individual and collective variable to investigate whether diet regime affected fish behavioural response to the novel situation. As individual variables, we measured distance covered, time spent in the immobility state, time exploring the center of the arena, mean turn angle of swimming activities (6). As group variables, we measured two categories of explorative behaviour (7): swimming activity (i.e., distance covered, mean acceleration, and time of immobility state), and spatial exploration traits (i.e., inter-distance from the centroid of the group, distance between subjects, and total perimeter of group). We additionally measured the ventilation frequency at the first 2-minutes and at the final 2-miutet for each individual in both behavioural tests as an indicator of the metabolic stress (8).

(Continued on next page)
Results
By using several behavioural OWIs, no significant differences emerged among treated groups from the individual and collective group experiment when dealing with a novel environment, indicating a positive outcome for applying spirulina-enriched black soldier fly prepupae meal in aquaponic systems for fish rearing.

**Introduction**

Aquaculture production is increasingly looking towards innovative solutions to further improve gut health and production sustainability. Marine probiotics have the potential to support the control of infections and to improve zootechnical performances, while minimizing the environmental impact. We investigated the probiotic potential of *Bacillus* multi-strain consortium extracted from the marine environment and encapsulated in algae on white shrimps, *Penaeus vannamei*.

**Materials and methods**

20-day and 60-day feeding trials were conducted respectively on healthy *Penaeus vannamei* PL10 (n=3500, triplicate) and PL25 (n=350, triplicate) to evaluate the effects on growth and health parameters of a marine probiotic consortium (MPC) made of four marine *Bacillus* strains encapsulated in algae when used as dietary supplement.

**Results**

At the end of the 60-day trial, the treatment with MPC at 0.1% significantly improved growth performance (final body weight, weight gain, specific growth rate) and significantly decreased feed conversion ratio of White Shrimp *P. vannamei* (*P* < 0.05). Supplementation with MPC at 0.1% also significantly decreased the occurrence of total *Vibrio* spp. count in shrimp’s hepatopancreas under normal conditions (*P* < 0.05). Overall, MPC significantly enhanced the mRNA expressions of (1) digestive genes in hepatopancreas, such as Trypsin, α-Amylase, Triacylglycerol lipase and Chymotrypsin BII; (2) immune-related genes, such as proPO, crustin genes in hepatopancreas and Dual Oxidase, mucin-like peritrophin, Penaeidin-3α in intestine genes (*P* < 0.05), especially with MPC at 0.25%. Under challenge conditions, MPC significantly increased disease resistance of shrimp larvae against *V. parahaemolyticus* (VpAHPND) (*P* < 0.05).

The results of high-throughput sequencing showed a significant improvement in White Shrimps digestive tract bacterial communities when supplemented with probiotics. Moreover, the MPC enhanced the hepatopancreas gene pathway related to metabolisms of endocrine, immune and digestive systems. In addition, the beneficial effects observed in intestine gene pathway were mainly related to translation, transport catabolism, and signal transduction.

**Conclusion**

This study demonstrated the ability of the marine *Bacillus* spp. consortium encapsulated in algae to improve White Shrimp growth performance, digestive tract & immune status and disease resistance during both larval and grow-out phases.
EFFECT OF SULPHATED POLYSACCHARIDES DERIVED FROM BRINE WATER ON THE IMMUNE SYSTEM

Introduction
Living organisms that live in marine environments produce sulphated polysaccharides (SP) that are highly soluble in water and remain as one of the most abundant compounds in brine water. These compounds have been described as presenting important biological activities, such as antioxidant (Wang et al., 2019) immunomodulatory and anti-inflammatory (Geng et al., 2018) properties. Since SP represent a large part of organic material present in sea salt polymeric material (Silva et al., 2015) we have investigated its activity on the immune system, using zebrafish (Danio rerio) as a model. The immunostimulant properties of SPs derived from salt pan brine water have been studied by Nunes et al., 2019, referring the possible use as functional ingredients to be incorporated functional food, for increasing the well-being of fish produced in aquaculture or for research models in laboratory systems. Zebrafish is an established animal model in research, that has been validated for studies in ecotoxicology, immune resistance and for testing ingredients for nutrition in aquaculture (Lawrence, 2007; Ulloa et al., 2014). Our objective was to test the effect of dietary delivery of SP from brine water in the resistance of zebrafish to Aeromonas hydrophila infection.

Materials and methods
Two experimental diets supplemented with 10 and 100 mg/kg with sulphated polysaccharides (SP10, SP100), were used to feed zebrafish during 40 days, starting from 15 days post fertilization. Larvae were reared in standard conditions until day 15 and groups of 100 larvae were transferred into 3 L tanks, in triplicates for the feeding trial. Larvae were fed 3x per day with each of the dietary treatments: control diet; SP10 continuous; SP10i 1x/week; SP100 continuous; SP100i 1x/week.

Lethal bacterial concentrations (LD50), were established in a preliminary trial with two different bacterial concentrations (10⁶ and 10⁷ CFU.mL⁻¹) added to 1L tanks and with three different exposure times.

After the dietary trial, 15 zebrafish juveniles from each replicate were stressed by caudal fin amputation and placed in a 1L tank containing 5.1x10⁷ CFU.mL⁻¹ of A. Hydrophila and exposed for 4, 7 and 24 hours. After the bath, the fish were placed in 1L tanks with clean water, and mortality was recorded for three days.

Samples were collected for gene expression analysis of immune markers, immediately before exposure and during the 3 days after exposure to A. hydrophila.

Figure 1- Cumulative mortality after exposure of SP treated zebrafish juveniles to A. hydrophyla by bath.

(Continued on next page)
Results
Cumulative mortality upon exposure to *Aeromonas hydrophila* was significantly higher in zebrafish fed continuously with the diets supplemented with 10 and 100 mg/kg of sulphated polysaccharides from salt pan brine water. The groups that were fed intermittently, only once a week add mortalities similar to the control group.

Gene expression analysis revealed a strong response immediately after exposure followed by a downregulation after 24 hours of exposure.

Discussion
No beneficial effects were observed by the dietary supply of sulphated polysaccharides isolated from salt pan brine water in zebrafish larvae. However, the expression of immune marker genes revealed that the immune response was exacerbated in fish fed with the experimental diets compared to control group.

Further research is necessary to establish the dietary doses necessary to modulate immune response and optimization of the dietary protocols to be used.

Introduction
Yellow perch, Perca flavescens (Michill, 1814), is one of the most commercially important species of the Percidae family, most abundant in the inland waters of the northern regions of the North American continent. However, the reduction in the wild catch due to overfishing (Saoud et al, 2004), and the devastation of the natural habitat (Clapp and Dettmers, 2004) has resulted in an increased interest in research of the biology of this species, and the development of appropriate culture technologies. The slow growth rate ascribed to yellow perch usually evidenced in open pond culture conditions. Controlled conditions in a closed recirculation rearing system should prevent most of the problems which are common in outdoor cultivation systems and provide for optimal growth of yellow perch (Westers and Weeks, 2002). Perch proved to be very timid (compared to sea bass, trout and tilapia grown in the same culture systems) reacting to any activity above and inside the tanks. It was important to provide optimal tank design and hydrodynamic water flow characteristics while not disturbing the fish, so that they could maintain efficient positioning while feeding. The aim of the study was to observe feeding and behavior of yellow perch in two different tank designs, rectangular and round, and quantify the effect of these conditions on their growth.

Materials and Methods
15 g yellow perch fingerlings were stocked in two round and two rectangular 12000-liter tanks at maximum density of 50 kg/m³. The final size was set at 160 g. As the fish grew, they were transferred to more tanks of the same design to maintain a constant stocking density. The round tanks had a tangential water inlet below the water surface, and a central effluent port, thus creating a circular flow. The “crossflow” rectangular tanks had a series of water inlets at one side, and drains on the other side of the bottom creating a tubular cross tank current. Fish were raised at constant temperature of 24-25°C. Dissolved oxygen level was maintained at saturation using oxygen injection. Calcium hardness was maintained between 80-150 mg/l using calcium chloride, and pH was maintained between 7.2 and 7.4 with the addition of sodium bicarbonate. Chlorides were adjusted to 300 - 400 ppm using sodium chloride and calcium chloride. During the entire experimental period perch were fed continuously with commercial slow sinking pelletized feed (“Ziegler Brothers”, PA), contained 45% of crude protein and 12% fat, using automatic belt feeders. Fish were fed 5% of the body weight per day in the first month, 4% in the second, 3% in the third and fourth, 2.5% in the fifth and sixth month, and 1.5% in the last four months of the growing period (Jug-Dujakovic and Van Gorder, 2002). A sample of 50 fish was taken every month from the tanks to obtain a measure of average weight. Dead fish were counted every day to calculate the survival at the end of the experiment. The analysis of variance followed by the SNK multiple comparison procedure was used to test variations in growth rate.

(Continued on next page)
Results and Discussion
When not feeding, the fish would swim indiscriminately, not always orienting against the flow of the water, a posture which was more pronounced in the rectangular tanks. In round tanks the administered pelleted feed would follow the current while slowly sinking, and the fish would position themselves to consume the moving food pellets. This pattern was less noticeable with crossflow tanks. Instead of maintaining perpendicular position to the water flow direction, fish would swim more randomly. More feed would reach the bottom of the tank and be removed uneaten.

At the beginning of the study, the 120-day old fish stocks had an average wet weight ranging between 14.7 and 18.1g. Eight months later, at the end of the experiment, the mean weight of fish was 176.1 g in the round tanks, and 160.1g in the rectangular tanks (table 1).

The difference of 16 grams of growth between tank designs represents an approximately 10% weight difference, or expressed in time, a month of growth under comparative rearing conditions. The grow-out phase of yellow perch (10g to 150g) in recirculating systems has been successfully demonstrated by Jug-Dujakovic and Van Gorder (2002). Effects of tank wall color and positive up-welling water flow on growth and survival of Eurasian perch larvae (Perca fluviatilis) was recorded by Jentoft (2006).

Conclusions
The circular flow of the water in round tanks elicited a natural swimming and schooling behavior with a common orientation by the fish populations (into the flow). This positioning and swimming behavior, and the accompanying effective feeding behavior resulted in increased feed conversion efficiencies, and improved overall growth and survival characteristics compared to those of populations cultured within cross-flow raceways.

Status of grass carp aquaculture
In last two decades the climate changes and overfishing resulted in the intensificated research on introduction of new species in aquaculture, or the possibilities of increased cultivation of herbivorous and more climate resilient fish species that are already cultivated. In terms of sustainability, herbivorous species that tolerate high water temperatures are the best candidates. Such an example of a species that is already cultivated, but still has a great potential for intensification of farming in Europe is grass carp, *Ctenopharyngodon idella* (Valenciennes, 1844), a naturally active and fast-growing species. This species tolerates a wide range of temperatures, from 0° to 38°C, salinities up to 10 ppt and oxygen levels down to 0.5 ppm (Frimodt, 1995). Wu et al. (2023) found that juvenile grass carp exposed to different dissolved oxygen concentrations over prolonged time period showed different susceptibility and adaptation mechanisms. Low dissolved oxygen concentration greatly improves blood gas transport capacity of grass carp, while high dissolved oxygen concentration slightly improves aerobic respiration level. Its main feed are higher aquatic plants and submerged grasses, but it also takes detritus, insects and other invertebrates (Frimodt, 1995).

Grass carp was introduced in Europe in the 20th century for aquatic weed control and aquaculture purposes. Today, it is grown as a food fish in polyculture in carp ponds (Frimodt, 1995; Woynarovich et al., 2010), but it is also of special interest for sport fishing (Siyi et al., 2022). In its homeland of China, it is currently the most important freshwater aquaculture species. In this country, it is mostly farmed in monoculture, with yearly production of 5.76 million tons in 2021, what was 18.08% of China’s total freshwater aquaculture production (FAMA, 2022). According to EUMOFA (2021) the main grass carp producers in Europe are Poland, Czechia, Hungary and Croatia, with the 1.761 tonnes. Its European production remained fairly stable, while the amount of all other farmed Asian carp species decreased by 60% over the ten-year period from 2008 to 2018. Although grass carp is one of the world’s most important aquaculture species, it is considered as a pest outside of its native range due to negative impact on the aquatic, water quality and biodiversity (Dibble and Kovalenko, 2009). With regard to legislation related to non-native species in Europe, its cultivation is allowed in most countries in waters where population has already been established. Exceptionally, all non-native species could be farmed, but their spread into open waters must be prevented. One possible solution could be its farming in the closed RAS systems with the complete control of output water. Despite the mentioned facts affect the development of grass carp production in Europe, the results of numerous researches conducted in recent years can justify the intensification of its production, either in mono- or polyculture.

Production intensification possibilities
High stocking density in polyculture, may cause high total ammonia and phosphorus concentrations, and consequently, algal blooms (Dibble and Kovalenko, 2009). Li et al. (2019) showed that the use of artificial substrata could be one of the technological solutions to increase pond farming density of grass carp by increasing the bacteria that participate in nitrogen and phosphorus cycles. Except in the pond culture, grass carp growth was tested in different technological systems, such as in-pond tank culture system for high-intensive fish production and in RAS. In-pond partitioned aquaculture system that was used in last two decades for intensification of the production of the pond farmed species, and for reducing the use of land, showed that intensive high stocking density had a negative impact on the growth performance and muscle quality of grass carp (Lu et al., 2022). Opposite to the in-pond system, survival and growth rates of the juvenile grass carp overwintering in the RAS were significantly higher. At the same time, the RAS ensured production profit when compared to the loss in the in-pond system (Kristan et. al., 2018). Similarly, as for the common carp (Gavrilović et al., 2019), properly designed RAS, used for overwintering of juveniles in combination with pond farming during warm period could possibly provide the basis for the intensification of grass carp production with economically feasible results.

It could be concluded that technological improvement can be applied for the intensification of grass carp culture. Considering European market, parallelly with the production intensification, relevant marketing strategy that would include product diversification and development should be considered.

Introduction
Fish shape is highly relevant in aquaculture since it acts as a driver of consumer decision-making. Shape of the flatfish Senegalese sole is characterized by an elliptic and lanceolate midbody, long caudal and dorsal fin sizes and short jaws with a scarce number of reference landmarks. Hence, outline-based methods such as the Elliptic Fourier descriptors analysis (EFA) seem to be highly useful as predictor of these body curved shapes. Hence, EFA could be useful to assess shape variation and evaluate genetic components in sole. In this species, it is estimated that approximately 12-15% of farmed soles show external morphological alterations that impedes their commercialization (de Azevedo et al., 2019). Guerrero et al., 2021 reported moderate-high heritabilities for body ellipticity as inferred from standard length and body height, however, these traits do not capture complete whole-body variation. Thus, this study aims to evaluate whole-body variation using EFA. Phenotypic information was analyzed and compared with a new set of distance-based and ellipse fitting estimator traits. Genetic estimates for these traits were determined.

Materials and methods
A total of 2,271 soles from in eight evaluation batches (EB) were individually photographed at harvest, and the weight and length were in situ recorded. A piece of caudal fin (CF) was preserved for genotyping. Body contours were individually processed in Fiji 2.1.0/1.53c and images in binary format were imported into the package SHAPE to calculate the Elliptic Fourier descriptors (EFDs). A principal component analysis (PCA) of the EFDs was carried out to extract information for symmetrical (PCs) and asymmetrical (PCa) features of body shape. Coefficients of EFDs were calculated at ± two standard deviations and scores of PCs and PCa were used in subsequent genetic analysis.

Additionally, some well-established and new ellipse descriptors based on morphometric distance and ellipse fitting parameters were calculated: standard length (SL), maximum body height (MBH) to caudal peduncle height (CPH) ratio, ellipticity (ELL; (SL-MBH)/(SL + MBH)), whole-body perimeter (PER), the aspect ratio (AR; SL/MBH) as distance-based trait and the aspect ratio from the fitted ellipse (ARe), and solidity (SOL). ANOVA analysis were carried out to test statistical differences associated with gender, EB and the presence of amoebic nodules (AN). Genetic parameters were estimated by REML as implemented in the package WOMBAT with gender, EB and AN as fixed factor.

Results
PCA identified four significant PCs for EFDs that explained 94.0% of shape symmetric variation and 68.6% of the total variation, and four PCa that explained 90.7% of asymmetric variation and only 24.5% of total variation. PC1s and PC1a represented 52.8 and 58.7% of symmetric and asymmetric variation, respectively.

Statistical analysis of PCs and PCa indicated that males were statistically more elliptic (lower PC1s and higher PC3s) with wider CFs (as revealed by lower PC2s and higher PC3s) than females. Also, males tended to have obtuse angles in the CF (PC3a) with the head orientated toward the abdominal cavity (PC4a). Statistical differences in AN were highly influence by fish weight. Significant differences among EBs were found for all components. Statistical analysis of ellipse descriptors indicated that females were 12.7% heavier and 2.2% longer than males. Moreover, males were 2.4% more elliptic than females (AR, ELL and ARe) with a 1.6% lower MBH/CPH, but no differences in PER.

Heritability estimates were very high for PC1s (0.702), moderate for PC3s and PC4a (0.390-0.400) and low for PC2s, PC4s and PC1a-PC3a (0.039-0.168). Heritabilities for MBH/CPH, ELL, ARe and AR were high or very high (0.513-0.804) and moderate for SOL (0.273) and PER (0.432). Genetic correlations were very high between ELL, ARe and AR (≥ 0.90) and between PER, weight and SL (≥ 0.93). ELL, ARe and AR were strongly correlated with PC1s and PC4a (≥ -0.873 and ≥ 0.705, respectively). ELL and AR showed a high genetic correlation with PC3s (≥ 0.574). SOL was highly and negatively correlated with PC2s (0.916) and PC3a had the highest genetic correlation with ARe (-0.583).

(Continued on next page)
**Discussion**

Shape quality is very important during fish commercialization since consumers preferably buy products whose external appearance resemble wild fish (Calanche et al., 2020). Senegalese sole’s lanceolate body shape is considered a high-quality shape standard and major attention had been paid to mid-body ellipticity as the main trait to select for shape quality (Guerrero-Cozar et al., 2021). In our shape model, 20 harmonics were sufficient to capture main symmetric and asymmetric variation through the tested population. This study demonstrated that EFA and ellipse fitting estimators are effective and powerful traits to assess shape quality in Senegalese sole.

Captured variation of EFD was primarily related to the adjustment of whole and midbody to an ellipse and CF variation, and secondarily to head orientation. Very high heritabilities for body ellipse fitting traits indicated a high potential to improve it via selective breeding and suitable to be included with growth traits (negatively correlated) to avoid an excess of roundness bodies after some selection rounds. Moderate-high heritabilities were also found for traits related to head and CF peduncle (SOL or MBH/CPH). The latter could be relevant to select specifically CF functionalities and fish swimming capabilities. Heritabilities for CF-related traits were low, however, due to the influence of CF on consumer’s perception and its use as a heath indicator, indirect selection using other correlated traits would be more efficient in genetic gain.

All the information here provided is highly useful not only for designing breeding programs but also for the improvement of operational methods to preserve shape quality and monitor health and welfare in the aquaculture industry.

Introduction
Efficiency and cost in aquaculture depend largely on feeding, making it crucial to optimize feeding strategies to reduce feed loss and improve fish health and welfare. One way to achieve this is by monitoring individual and group swimming patterns, especially in response to external factors like feeding. Intelligent feeding control that utilizes behavioral changes and growth status is gaining attention as a useful tool for improving husbandry practices. Efforts are underway to identify behavioral indicators that can detect satiation levels and regulate feeding for different species. In this study, we investigated two behavioral-based indicators, speed and the feeding behavioral index (a newly defined metric), across different feeding scenarios for E. seabass. Our findings suggest that fish exhibit distinct behavior patterns in response to various feeding situations, and both the speed and feeding behavior index can identify threshold values that correspond to satiation levels, facilitating controlled feeding.

Materials and methods
A group of E. seabass fish of 300 g body weight was reared in a circular polyester cage (40 m diameter, 9 m depth) located at the pilot scale netpen cage farm of HCMR at Souda bay, Crete (certified as an aquaculture facility from the national veterinary authority; code GR94FISH0001). A submerged network camera (Fyssalis V3.1) capturing at 10 fps was used for monitoring and video recording during daylight hours. The camera was positioned at 4 m depth using a gyroscopic gimbal stabilizer to ensure it pointed upwards. We trained YOLOv5 (a machine learning model for object detection) to detect fish and adapted Deepsort (a model for tracking people) to track fish individually (using OPENCV/Python) and extract their speed and direction. In addition, we used computer vision techniques that detect changes in the crowding behavior of the fish, and we called the parameter feeding behavior index. To detect behavioral changes as response to satiation levels we modified the feeding schedule of the fish by varying three crucial feeding parameters: the feeding frequency (once, twice and three times a day), the feeding time (morning, afternoon and evening) and the feeding quantity (normal, reduced, overfeeding and no feeding). The experimental trial lasted from June 2022 until April 2023.

Results
Our preliminary results show that the feeding behavioral index shows different qualitative and quantitative evolution across the three different feeding quantities. The excitation step at the start of the feeding is significantly larger when fish are underfed than when overfed or fed normally (Figure 1). In addition, the duration of the excitation is longer. The speed on the other hand shows a significantly different qualitative behavior (Figure 2). There is a change in activity relative to the start of the feeding. When feeding is normal, fish show symmetry in the activity pattern relative to start of the feeding. They gradually increase their activity before feeding and gradually decrease it after feeding. In contrast, during reduced feeding fish appear to show increased activity before feeding, while during overfeeding periods, fish show more increased activity as response to the start of the feeding.

Conclusion
Our results indicate that fish show distinct patterns of behavior under different feeding situations, and both the speed and feeding behavior index can be used to detect threshold values that correspond to satiation levels and facilitate controlled feeding in marine cages. Under reduced feeding, fish show an early and prolonged excitation before feeding and a slow relaxation to the baseline activity after feeding times indicating strong anticipation for feeding and increased appetite. The sudden increase in the feeding behavior index also contains important information about the fish appetite, as larger activation steps in the feeding index suggest lower satiation levels. Last, the duration of excitation is also an important parameter that can reveal the satiation levels of the fish, suggesting that fish with higher satiation levels show longer excitation times in their feeding behavior index. Further studies are required to help us understand the contribution of other factors such as the human presence, or the internal circadian rhythm to the variation of the activity.

References
Despite their high abundance and species richness, tilapiines have been compromised by various factors especially overfishing, climate change, and un-controlled fish translocations. Fish translocations have negatively impacted native tilapiine populations through competition, predation, hybridization, and introgression compromising their genetic integrity. The hybridization levels of different tilapiines in the Lake Victoria basin remains an understudied aspect relatively. The study utilized nuclear microsatellite and mitochondrial DNA (mtDNA) genetic markers to investigate hybridization signals and compare the genetic diversity of different tilapiines in Lake Victoria, Kenya, using next-generation sequencing. Low levels of hybridization from *Oreochromis niloticus* into other *Oreochromis* species were detected by Bayesian clustering analysis and principal coordinate analysis (PCoA). The results contribute to the need for conservation measures of these fish species.

Introduction
Worldwide, several sturgeon species are facing the threat of becoming extinct in the wild, and in Europe some are only surviving because of the success of ongoing recovery programs that include last resort measures such as ex situ conservation. Ex situ conservation involves captive rearing and propagation under controlled conditions and can serve as a stop gap measure while other recovery actions are implemented. It is critical that these programs preserve the different components of genetic diversity, on the one hand the differentiation between populations, which could reflect adaptations to different environmental conditions, on the other hand, the genetic diversity within populations which represents their adaptive potential. This attention to the genetic integrity will increase the chances of long-term population persistence even after the cessation of ex situ measures.

Discussion
In many cases, small population sizes or ex situ programs that were initiated long after population declines began result in difficulties to meet genetic diversity goals. Accordingly, programs must ensure an approach that maximizes genetic outcomes, through the integration of all suitable resources. While Recommendation 22 of the Vienna Declaration on Global Sturgeon Conservation by global sturgeon experts (Rosenthal et al., eds. 2018) stated that “Commercial farms, culturing sturgeons for consumer markets, may be important partners in conservation programs to bridge the time-window until the required public infrastructure for ex situ conservation is in place...” it has become that, despite numerous biodiversity programs and funding tools, the implementation or long-term maintenance of such public facilities in Europe has not been feasible in most cases. It is therefore mandatory to search for practical alternatives for species recovery.

Several sturgeon species are in the unique condition that while being threatened in the wild, they are raised successfully and economically in large quantities in private companies. This opens opportunities to explore private-public partnerships for the benefit of these species at risk. In this presentation we will outline prerequisites to implement such collaborations as well as the limitations. This will include the importance of maintaining genetic differentiation and diversity of subpopulations; as well as the separation of commercial and conservation rearing facilities to prevent disease transfer and to meet the criteria for fitness for release of juveniles.

Outlook
In the Conservation Session, it is anticipated to build on the discussion that has started at the EAS 22 in Rimini in 2022. In order to guide the discussion to a target oriented output, it is foreseen to focus on the following questions in the round table discussion:
• Which processes would lend themselves for engagement of private farms?
• What could be the benefits for the farmers?
• What could be benefits for the conservation program?
• What could increase the profitability of collaboration?
• How could a joint strategy look like?

ANALYTICAL PLATFORM FOR MONITORING NITROGEN SPECIES IN RECIRCULATING AQUACULTURE SYSTEMS

Renato L. Gil*, Marília B. dos Santos, Álvaro Geraldes, João Piteira, Begoña Espiña, Raquel B. Queirós

International Iberian Nanotechnology Laboratory, Avenida Mestre José Veiga, 4715-330 Braga, Portugal

Corresponding author: renato.gil@inl.int

Recirculating aquaculture systems (RAS) represent a new way to farm fish in land-based aquaculture, in which the water is filtered and cleaned for recirculating through the fish culture tanks. However, the current RAS facilities still lack a fit-for-purpose digital control of the water chemical parameters to adjust/tailor the treatment trains and quickly identify problems related to the quality of the recirculated water [2].

In this work, a novel analytical platform for monitoring of chemical species in RAS is presented, namely nitrate and nitrite ions to better understand if the treatment of recirculated water is effective and adequate. The platform combines the powerful features of electroanalytical sensors with technological advances in terms of microfluidics and electronics to provide the control of water quality. It is divided into different modules, namely the sample processing and detection module which are controlled by an electronic module (Figure 1).

The sample processing module enables the collection of the water and the performance of pre-treatment steps to overcome interfering matrix effects, such as solid particles, salinity, and pH. For this purpose, the sample filtration is followed by two serial microfluidic chambers fabricated in poly(methyl methacrylate) (PMMA). The first includes a cation-exchange membrane and a pair of electrodes (Ag as working and Ag/AgCl as reference/counter electrodes) in which an anodic potential is applied to oxidize the Ag and remove the chloride ions by the formation of AgCl at the surface of the working electrode. The applied anodic potential, silver thickness, sample volume, and reusability are under optimization to achieve the best efficiency of the desalination cell. The second chamber enables the mixing of the desalinated sample plug with an acidic media to reach the required pH for analysis.

The detection module comprises solid-contact ion-selective electrodes for nitrate and nitrite ion as well as a custom-made Ag/AgCl reference electrode, both integrated into a PMMA microfluidic cell. Commercial carbon screen-printed electrodes modified with graphene oxide were used to prepare the sensors by drop-casting the corresponding polymeric ion-selective membrane on top (Figure 2). The proposed potentiometric sensors were evaluated in terms of analytical response, selectivity, robustness, and durability. Nitrate-sensors showed a sensitivity of 52.0 mV/decade within the linear range of 0.2-612 mg/L and a limit of detection of 0.1 mg/L at 0.1 M phosphate buffer background (pH 5.0). A fast response time (<20s), good reproducibility (RSD<1.4%), potential stability (0.3 mV/h), and durability of four weeks are some of the remarkable properties. Likewise, the nitrite-selective electrodes provided a sensitivity of 45.4 mV/decade over the linear range from 0.05 to 454 mg/L and a limit of detection of 0.04 mg/L within the same conditions. A response time <50s,
excellent reproducibility (RSD<0.4%), potential stability of 2.0 mV/h but a shorter lifespan of about a week were observed, mainly attributed to the leaching of the sensing element from the polymeric membrane. Additionally, the proposed nitrogen sensors showed great selectivity to the target species against common interfering ions present in seawater. Cations do not impose any interference due to the perm-selectivity of potentiometric sensors while the most interfering anions were iodide and perchlorate, however their common low levels in water are not a cause of concern.

The applicability of nitrate sensors was assessed, first, by the analysis of different natural water samples. Appropriate recovery percentages (88-108%) and an excellent agreement with a commercial nitrate probe (difference<8.5%) in the analysis of freshwaters confirmed the great reliability of the proposed sensors. Nevertheless, the presence of chloride at high levels in seawater worsened the accuracy, justifying the use of the aforementioned cell for the decrease in salinity.

Future work envisage the tailoring of the proposed analytical platform for on-site monitoring of chemical parameters in RAS. This innovative technology brings major advantages when compared to conventional techniques such as cost-effectivity, autonomous performance, and improved spatial/temporal analytical resolution, offering new opportunities to the aquaculture sector.

Introduction
Mortality at sea transfer is one of the major culprits for economic loss in the Norwegian salmon industry, reinforcing the tendency towards shortening the rearing time in open net pens. Recirculating Aquaculture Systems (RAS) have increased significantly in the last 10 years, RAS is expected to surpass flow-through systems in the next 5 years. Current production protocols favor high temperatures, the use of continuous light, and increased salinity to accelerate growth, where production of larger post-smolts (500-600 g) is becoming a common practice. Even though RAS is one of the most common production systems, there is a lack of standardized protocols, and the biological requirements of the fish are not always considered. Thus, optimizing the rearing strategies in RAS is crucial for producing robust (post-) smolts with better performance after seawater transfer. This study aims to understand the implications of different RAS protocols, in terms of photoperiod, salinity, and producing large post-smolts, on plasma metabolites related to energy status and expression of genes codifying the gut signals regulating the appetite and food intake and peptide transporters in Atlantic Salmon (Salmo salar).

Materials and methods
Atlantic salmon (113 g) was reared in RAS at 12 °C and different photoperiod regimes simulating no winter (NW, constant light 24L/0D), early winter (EW, standard winter signal 12L/12D and spring signal 24L/0D), late winter (LW, delayed winter signal of 12L/12D, normal spring signal of 24L/0D), and late long winter (LLW, prolonged winter signal of 12L/12D and standard spring signal 24L/0D); two salinities (fresh- (FW) and brackish (BW) water); and two sizes at seawater transfer (300 and 800g). Fish were sampled before each transfer size. Pentra 400 was used to measure the metabolites related to energy status (glucose, triglycerides, cholesterol, and total protein) in the plasma. Expression of genes coding for gut appetite regulator hormones (cholecystokinin; cck, and neuropeptide Y; ppy) and peptide transporters (PepT1; slc15a1a, slc15a1b, and PepT2; slc15a2a, slc15a2b) were quantified in the anterior and posterior intestine, using the ΔΔC_T method. Data were subjected to Two-way ANOVA, followed by Tukey (p < 0.05).

Results
Photoperiod and salinity significantly affected the metabolites in 300 g fish, with NW showing generally higher levels compared to EW and LW. On the other hand, neither photoperiod nor salinity had a significant effect on the metabolites in 800 g fish, except for triglycerides (Fig. 1). Expression of ppy was unaffected by the addressed parameters (data not shown). We are currently analyzing the cck results that will be presented at the conference. At 300 g, the photoperiod regime was the only factor significantly affecting almost all peptide transporters. At 800 g, on the other hand, only slc15a2a was affected by the photoperiod. Expression of slc15a1 showed an approximately opposite trend to slc15a2; the former was upregulated in NW and EW, while the latter was in LW (Fig. 2).

Discussion and conclusion
Higher variations in the metabolite levels in 300 g fish might be because they have recently gone through the energy-demanding process of smoltification and are still adjusting their energy budget. While at 800 g, they have had more time to acclimatize to the environmental conditions. In agreement with this, the highest triglyceride levels were observed in NW and EW. This might suggest triglycerides as a more sensitive indicator of energy status in larger smolts. While plasma provides a good idea of the amount of ready-to-be-used energetic substances, it would be interesting to study the hepatic triglycerides and glycogen reservoirs to obtain a complete picture.

(Continued on next page)
The opposite trends in the expression of members of PepT1 and 2 may point to different physiological roles (nutrient absorption and/or molecule sensing) of these groups, differentially responding to environmental conditions (Gomes et al., 2020). Short-term starvation of Atlantic led to the downregulation of slc15a1 and b, while the upregulation of slc15a2a and b (Del Vecchio et al., 2021). Similarly, in our study, LW with the lowest energetic substances in the plasma, showed the lowest expression levels for slc15a1b, and the highest for slc15a2a and b.

Introduction
The continued expansion of the aquaculture industry requires a sustainable supply of nutrients for aquafeeds. Single-cell protein (SCP) results from the culture of monocellular microorganisms such as yeast, bacteria, or microalgae. SCP are a promising avenue for ingredients in aquafeeds due to their high protein content and suitability for circularity through valorising side stream from agro-industrial activities (Sharif et al., 2021). Although growth and digestibility are important when assessing the suitability of novel alternative feed ingredients, comparatively understudied physiological aspects (stress resilience, health and welfare) are equally critical. This study assessed the effect of fishmeal (FM) replacement by yeast (Candida utilis) and microalgae (Microchloropsis gaditana) on stress and osmoregulatory responses in rainbow trout.

Materials and methods
Rainbow trout (initial body weigh approx. 185 g) were allocated between 4 isonitrogenous and isoenergetic diet treatments (in triplicate tanks) in freshwater RAS: Diet 1) control, 15 % FM and 40 mg. kg⁻¹ astaxanthin, Diet 2) 5 % yeast (33 % of FM replacement) and 40 mg. kg⁻¹ astaxanthin, Diet 3) 5 % microalgae and 40 mg. kg⁻¹ astaxanthin, Diet 4) 5 % microalgae and 20 mg. kg⁻¹ astaxanthin. During the experiment (57 days) water temperature, stocking density, and photoperiod were 14.8 °C, 29.4 kg. m⁻³, and 12:12 L/D. At the end of the trial, 18 fish from each group (N=6 per tank) were sampled, from which 9 were immediately euthanised by anesthesia overdose (pre-stress) and the other 9 were subjected to acute stress challenge (ACT, i.e., 15 minutes of crowding at 300 kg. m⁻³, followed by 45 minutes of recovery before euthanasia). Plasma levels of cortisol, using ELISA, ions (e.g., sodium, magnesium, and chloride) and metabolites related to the energy status (e.g., lactic acid) were measured using Pentra 400. Expression of genes involved in stress response (mineralocorticoid receptor; mr, glucocorticoid receptors; gr1 and gr2) and neural plasticity (brain-derived neurotrophic factor; bdnf, neurogenic differentiation factor; neurod) were measured in the telencephalon, using RT-. Data were subjected to One-way ANOVA followed by Tukey to compare among diets, and to Student’s t-test to compare between the two stress states (p < 0.05).

Results
Fish final average body weight was around 490 g. Diets incorporating SCPs exhibiting a reduction in SGR ranging from 5 % to 7.8 % along with an elevation in FCR by 2.3% to 4.7 %. However, Diet 4 was associated with low cortisol levels following the ACT, effects not seen for any of the other treatments. Additionally, the telencephalic expression of cortisol receptors in the pre-stress state mr, gr1 (data not shown), and gr2 were the lowest in Diet 4, while the expression of these markers was significantly higher following ACT. Regarding gene markers related to telencephalic neural plasticity (bdnf and neurod), although no significant differences were observed among treatments, Diet 4 again was the only group with significantly higher expression after ACT (Fig. 1).

The plasma ion levels of sodium were similarly more elevated following the ACT. However, in the case of magnesium and chloride, this elevation was statistically significant only in the case of Diet 4. Also, plasma levels of these ions and lactic acid were consecutively higher in Diet 4 at a pre-stress state, while magnesium showed reduced levels in response to the ACT (Fig 2).

Discussion and conclusion
Reduced levels of astaxanthin in Diet 4 were associated with changes in filet coloration (data not shown), as well as disturbances to the fish stress response during the ACT. Although cortisol responses were less clearly affected, downregulation of cortisol receptor genes (mr and gr) suggests cortisol induced overstimulation as a preservation mechanism to neural integrity (Vindas et al., 2017). Likewise, upregulation in neural plasticity markers (bdnf and neurod) in stressed ACT fish from Diet 4 suggests a larger effort needed to cope with the challenge and consistent with the presence of mild chronic

(Continued on next page)
stress. This was consistent with the higher plasma ion and lactic acid concentrations observed in basal fish prior to the ACT that suggested elevated osmoregulatory and metabolic challenges even before the ACT. This is consistent with fish on Diet 4 that had received reduced astaxanthin levels being subjected to regulatory disturbances in physiology and having a hindered ability to cope with added stressors.

These results indicate that SCPs is a suitable dietary substitute for FM in trout without negatively impacting fish health and welfare, provided dietary requirements for astaxanthin are sustained, as the carotenoids naturally present in the *N. gaditana* do not seem to adequately fulfil the fish requirements. Besides coloration, astaxanthin is known to have anti-inflammatory and stress-reducing properties consistent with the poorer responses seen in fish exposed to Diet 4 (Lim et al., 2018).

Introduction
Genomic functional annotation goes beyond genes to describe regulatory functions of the genome that control genes and underpin genotype-to-phenotype determination. Such information is crucial for strategic improvement of farmed animals through genomic selection. Aquatic species however have limited functional annotations available to date. There is an international initiative through the ‘Functional Annotation of Animals Genomes’ (FAANG) project (Giuffra et al. 2019) to deliver quality functional annotations of farmed species. The AQUA-FAANG project (https://www.aqua-faang.eu/) extends this initiative to commercially important fish species for aquaculture, including the salmonid fish Atlantic salmon (Salmo salar) and rainbow trout (Oncorhynchus mykiss). This project produced multi-omic assay data for several species for integration to deliver functional annotations of their genomes. Here we describe the standardized bioinformatic workflows implemented to produce from nearly a thousand matched RNA-Seq, ATAC-Seq, and ChIP-Seq assays, functional annotations of Atlantic salmon and rainbow trout genomes. We showcase the quality of assay data and resulting annotations, and how this data may be publicly accessed.

Methods
Multi-omic assay data for Atlantic salmon and rainbow trout was generated through standard protocols development by AQUA-FAANG. This included five stages of embryogenesis and a common panel of tissues (brain, gill, liver, muscle, ovary, and testis) from males and females at sexually immature and mature stages. This produced datasets for mRNA-Seq, ATAC-Seq, and ChIP-Seq (H3K27ac, H3K4me1, H3K4me3, H3K27me3 histone marks). Primary analysis of sequencing data utilized nf-core pipelines (Ewels et al 2020); rnaseq, atacseq, and chipseq pipelines respectively, to align read data to reference genomes. Custom blacklist regions from ChIP-Seq input controls removed signal artifacts from downstream analysis. We used ChromHMM (Ernst and Kellis, 2012) to model combinations of signals of ATAC and ChIP marks to segment the genomes into annotations of chromatin states, for each sample type and species.

Figure 1. Overview of salmonid functional annotation.

(Continued on next page)
**Results**

Quality analysis of assay data showed the success of the protocols. Once such metric was the enrichment of ATAC and ChIP mark reads, showing active regulation of genes, enriched around the transcription start sites (TSS) of genes, with the exception of the gene repressor mark H3K27me3 (Figure 1A). We assigned distinct functional labels to the chromatin states we annotated (Figure 1B), including active and bivalent promoters, active, primed and poised enhancers, polycomb repressed regions, and unmarked open chromatin. Functional labeling of states was based on their combination of ATAC and ChIP mark signals, as well as other statistics such as coverage of genomic features, compared to literature on functional features. We observed some overall patterns in regulatory regions across the genome. We report on the genomic coverage of different states for different sample types (Figure 1C). Developmental stages had more promoter and enhancer activity that adult tissues. Genomic coverage of regulatory elements was similar across different tissues. Looking at distinct numbers of reproducible ATAC peaks of open chromatin, and the chromatin states of those regions (Figure 1D), we saw progressively more active regulatory regions across early development. Brain contained the most active regulatory regions of any tissue. We saw distinct different in mature and immature ovaries and testis.

(A) Distribution of reads from assays around all gene regions in the Atlantic salmon genome. Each sample is plotted per developmental stage or tissue. The range is 3kb upstream of gene transcription start site (TSS) to 3kb downstream of transcription end site (TES). All gene regions are normalized to the same length. The height of lines show the relative abundance of reads in the range, scaled per sample for a mean of zero. (B) Chromatin states annotated from modeling assay data. Two models for Atlantic salmon developmental stages (DevMap) and tissues (BodyMap) show 12 states with associated intensity of assay signal from high (blue) to low (white), and the associated label of chromatin state to the left. (C) Proportion of the Atlantic salmon genome covered by each chromatin state for developmental stages and tissues, excluding states unknown and quiescent. Tissues are separated into immature/mature male (m/M) and female (f/F) samples. (D) The number of robust, reproducible open chromatin regions from ATAC-Seq and their underlying chromatin states for the same conditions as (C).

**Discussion**

We present the functional annotation data to aid future efforts into precision breeding of desired traits of these salmonids for aquaculture. The protocols and workflows of the annotations will also be published to aid additional similar functional annotation of other important species. The functional annotations presented here were further analysed by will be showcased by co-authors through other oral and posters presentations at this conference.

The potential of the sustainable use of aquatic resources is far from exhausted in Germany. Germany has a high level of education, high purchasing power and a well-developed awareness of the environment and sustainability. Nevertheless, the degree of self-sufficiency for aquatic products in Germany is only 25%. A lot of research is done here in the field of aquaculture and product development from aquatic resources. The challenge, however, is that the research results find their way into products and services of our everyday lives.

The AQUATOR is a business accelerator aiming at developing, accompanying and supporting entrepreneurial commitment. The AQUATOR was launched as one of eight sub-projects in the BMBF-funded innovation space “Blue Bioeconomy”. The team consists of different experts from a total of six universities, institutions and companies. We provide tailor-made advice and services in various subject areas, such as aquaculture, algae expertise, environmental balances, toxicology and socio-economic aspects. We are well connected to the authorities and a large, trust-based network; thus, we are able to overcome hurdles more quickly and create synergies.

After just two years, we are supporting more than 10 startups and companies of all kinds. For example, we offer access to scientific partners and to specific biomass, conduct scientific tests at laboratories with corresponding toxicological analyzes, organize access to relevant authorities, and support with scientific expertise and access to funding for the development of new products based on residual materials.

Our vision is a large number of companies in the field of the blue bioeconomy that support each other and are both economically and ecologically sustainable. The national bioeconomy strategy, launched in 2020, has six main goals. The AQUATOR contributes to each of these goals by supporting start-ups and companies. The focus of the AQUATOR is currently in northern Germany. In the long term, however, we want to support the entire industry as a central player and expand both nationally and internationally. In doing so, we rely on targeted and broad networking in order to be able to deal with the unique challenges of the aquatic bioeconomy.

The AQUATOR is currently a project funded by the BMBF. We are in a phase of restructuring and consolidation towards a suitable company form in order to be able to function more independently of project funds in the long term.
INTEGRATING SALICORNIA AND FLATHEAD GREY MULLET FARMING IN MARINE AQUAPONIC SYSTEMS

Aquaculture Program
Institut de Recerca i Tecnologia Agroalimentàries (IRTA)
Centre de la Ràpita, la Ràpita, Spain

Email: enric.gisbert@irta.cat

Introduction

Nowadays, the principle of sustainability is widely used by practically all the economic sectors and most of activities presume to be sustainable. Sustainability is not a final condition nor an achievable goal; sustainability is a way ahead and a way of economic and social development. Under this scenario, sustainable strategies for improving blue food economies are essential to design a new approach for transitioning towards more responsible, comprehensive, exploitable, and favourably positive impact-generating food production systems. Among them, aquaponics presents an innovation in traditional aquaculture systems by combining fish farming and hydroponics (the soilless cultivation of plants). Potential advantages of aquaponics include enhanced sustainability, less resource consumption, and fewer environmental impacts compared to conventional aquaculture and agriculture practices (Baganz et al., 2022). The objective of this study was to evaluate the farming of *M. cephalus* in an aquaponic marine coupled system and compared to a conventional recirculating aquaculture system (RAS) in terms productivity, farming costs, fish performance and operational welfare indicators (OWIs). This approach will double the sustainability of aquaculture farming practices by testing a low-trophic fish species like *M. cephalus* in an aquaponic system in order to improve the sustainability of this practice by using the nutrient waste from the fish culture system as a nutrient source for growing the halophyte *Salicornia spp.*

Materials and Methods

Two different trials were conducted in this study. In a first one, the assay was set-up for testing the viability of growing salicornia in combination with a low trophic species under seawater conditions (35 ppt) in a coupled aquaponic system. We used three independent aquaponic systems in which we grew-up 100 flathead grey mullet fish (50-52 g in BW) per tank at an initial stocking rate of 3.5 kg m⁻³ that was connected to the plant unit that contained wild seedlings of *Salicornia spp.* in 6.4 m² (141-145 of plants per unit). The second trial consisted of rearing flathead mullet in conventional RAS unit. For this purpose, 381 fish (30-50 g in BW) were evenly distributed among the three experimental tanks connected to the RAS unit (127 fish per tank; initial stocked biomass = 2.5 kg m⁻³).

In all trials, fish were fed the same commercial diet (Nutra MP, Skretting; 55% crude proteins, 17.5% crude lipids). Fish were fed a feed ration of 2.5% of the stocked biomass using automatic belt feeders. In both trials, water quality parameters (temperature, oxygen, salinity) were measured daily, whereas nitrogenous compounds in water (ammonia, nitrites, and nitrates) were measured twice a week by our technicians. At the end of the trial, all animals were measured in length and BW, the apparent feed conversion ratio was determined, and the aquaponics plant yield (APY, kg m⁻²/year) was calculated taking into consideration the yield of salicornia per m² in each aquaponic unit and the duration of the experimental period. Operational welfare indicators (OWIs) related to skin and fin conditions were recorded and compared between both farming systems.

Results and Discussion

In aquaponic systems, the increase of stocked fish biomass grew from 3.5 kg to 10.7 kg per tank (9.8 - 12.2 kg/tank), growth that was coupled with an increase in the stock density, values that increased from 3.5 kg m⁻³ to final stocking values that ranged from 6.5 to 8.1 kg/m³. This increase in biomass was a result of an increase in the average individual weight of flathead grey mullets that reached 183.7 to 195.3 g (SGR = 0.94-0.99% of increase in body weight per day). Mortality rates in all three aquaponic systems was lower than 5% (98.4± 1.5%). Regarding the yield of salicornia, plants in all systems grew very well with survival rates higher than 95%. The final yield (plant biomass) per aquaponic unit ranged from 43.1 to 50.1 kg (6.7-7.8 kg/m²). The increase in plant biomass from the beginning to the end of the trial ranged from 290 to 346 times. Flathead grey mullet reared on RAS units grew linearly from 39.2 g to 143.6 and 145.1 g, depending on the tank considered (Figure 16). Values of SGR were similar among the three replicate tanks (1.1% BW/day) and apparent FCR

(Continued on next page)
values ranged from 2.1 to 2.3. Fish survival was 96.1 ± 3.1%. The analysis of the OWIs of flathead grey mullet reared in the coupled marine aquaponic system and RAS revealed that this species adapted very well to both farming systems since no moderate or severe lesions were observed in animals. Most of the alterations were considered as very mild (disarrangement of fins) or loss of few scales over the skin. The loss of scales may not be attributed to rearing conditions since this species is very sensitive to handling and generally, some scales are lost when fishing, sedating, and measuring fish.

The energy cost (kW) for running each aquaponic unit based on the consumption of the water pump (0.1 kW/h/unit) and air blower (0.3 kW/h/unit) for the duration of the trial (142 days) was estimated at 340.8 kW/unit for the water pump and 1,022.4 kW/unit. In total, each aquaponic unit consumed 1,363.2 kW, which represented an energy cost per kilogram of salicornia of 0.029 ± 0.002 kW/kg. In contrast, the electric costs of the RAS unit composed of a water pump, air blower, UV lamps and heat exchanger was 1.0 kW/h, 2.5 times higher than that for the coupled aquaponic system.

**Conclusion**

Flathead grey mullet showed good adaptability to farming conditions in RAS and aquaponic systems, even though the species is more difficult to handle and acclimate to intensive rearing conditions than initially expected. Fish performed similarly in terms of growth performance, FCR and OWIs between both tested farming systems. Coupled aquaponic systems are a sustainable strategy for the combined production of fish and salicornia with a minimal use of water (<5% of water renewal), an efficient use of land and water, and a reduced cost in terms of electricity (aquaponics are 2.5 times cheaper in running costs than RAS units). Furthermore, growing plants coupled to fish rearing provides a sustainable economic profit to the fish farmer by producing a high quality fresh product to the consumer. Present results indicated that this technology might be applied to commercial, or community based urban food production, industrial scale production in rural areas, small scale farming in developing countries (backyard aquaculture systems) or as systems for education.

**Introduction**

In recent years microalgal biomass has become one of the most promising sources of bioactive compounds in aquafeeds, especially in terms of lipids and fatty acids (Soto-Sánchez et al. 2023). Among the several species Microchloropsis gaditana, Phaeodactylum tricornutum, Schizochytrium sp. and Tisochrysis lutea are of great interest to aquaculture with the first two well known as source of EPA and the last rich in DHA. That being the case, a dietary combination of these four species could potentially substitute fish oil in fish diets satisfying the essential fatty acids requirements. Ergo, the aim of this study was to evaluate the fish oil substitution by different blends of these four microalgal species in the diet of Gilthead seabream (Sparus aurata).

**Materials and Methods**

Juvenile seabreams of 8.77±0.01 g initial mean weight were obtained from a commercial fish hatchery and distributed after an acclimatization period of 15 days in triplicate to 18 closed seawater circulation system tanks (125L) (27 individuals/tank, 3 reps/dietary group). The groups were fed six different isoenergetic (21 MJ/Kg), isonitrogenous (48% CP) and isolipidic (15.5%) diets that satisfied the EPA+DHA requirements of the species (>1.8% of diet). The control diet (C) contained 8% fish oil, 4% soybean oil and 25% fishmeal resembling a commercially available seabream diet. Four other diets were formulated replacing 50% of the dietary fish oil of the control diet by a blend of microalgae biomasses of the species: Schizochytrium sp. and M. gaditana (SM), Schizochytrium sp. and P. tricornutum (SP), P. tricornutum and T. lutea (PT) and M. gaditana and T. lutea (MT). A sixth diet was also used as a reference containing 12% of fish oil as the sole dietary oil (FO). The inclusion level of each microalgae contributed a certain amount of proteins in the diet and as such fishmeal protein was also subsequently substituted. Fish were hand-fed to apparent satiation twice a day for 11 weeks.

*(Continued on next page)*
Results and Discussion
The SM, SP and MT groups of fish had similar final body weight, weight gain, SGR and FCR with both control groups (C, FO) (Table 1) indicating that dietary fish oil can be partially replaced by the blends of *M. gaditana* and *Schizochytrium sp.*, *Schizochytrium sp.* and *P. tricornutum*, *M. gaditana* and *T. lutea* without impairing the growth of *S. aurata* nor feed efficiency. A growth retardation occurring in the PT-fed fish was due to their lower feed intake, which denotes a lower acceptability of either *P. tricornutum* or *T. lutea* by *S. aurata*. A lower feed intake was also obvious in the SP group but not in the MT group, implying that the inclusion of *P. tricornutum* was probably the responsible factor for this decrease. Up to date, the strategy of mixing different microalgae species to balance dietary fatty acids and to replace dietary fish oil has been scarcely studied. The blend of *Microchloropsis sp.* and *Schizochytrium sp.* has been previously proven successful as a fish oil replacement for *S. aurata* (Karapanagiotidis et al. 2022) as well as for other species (Qiao et al. 2014; Seong et al., 2021., Sarker et al., 2020a). A blend of *Tisochrysis lutea* with *Tetraselmis suecica* successfully replaced 36% of dietary fish oil in *Dicentrarchus labrax* without adversely affecting fish growth performance (Cardinaletti et al. 2018). Sarker et al. (2020) using different combinations of *Microchloropsis* *sp.*, *Isochrysis* *sp.*, and *Schizochytrium* *sp.* in the diet of *Oncorhynchus mykiss* reported that *Schizochytrium* *sp.* and *Isochrysis* *sp.* are good candidates for DHA supplementation and that the latter is better than *Nannochloropsis* *sp.* as a substitute for fish oil.

The present study showed that blends of specific microalgae species is a promising strategy for further fish oil replacement in the diet of *S. aurata*, that in turn can promote a more sustainable aquaculture production. Certainly, the effectiveness of such dietary manipulation for increasing the n-3 fatty acids in fish tissues should be further investigated.

Introduction

Aquaculture sector is on a continuous search for suitable and sustainable protein sources that could successfully replace fishmeal in aquafeeds. Microalgal biomass can serve this need due to their high protein contents and low environmental impact (Glencross et al. 2020). *Chlorella vulgaris* is the most common microalgal species that can be easily grown in outdoor facilities, but still has not received adequate attention in fish nutrition. Thus, the aim of this study was to evaluate the dietary fishmeal replacement by graded levels of a *C. vulgaris* meal on the growth performance and feed utilization of an important Mediterranean farmed species, the gilthead seabream (*Sparus aurata*).

Materials and Methods

A total number of 360 *S. aurata* juveniles of 2.6 g initial mean weight were stocked at 12 tanks (125L) in a closed seawater recirculation system. Fish in triplicate groups (30 fish/tank, 3 tanks/dietary group) were fed to satiety, twice a day, four isonitrogenous (46%) and isoenergetic (21 MJ/Kg) diets differing in the inclusion level of a *C. vulgaris* (CV) meal: CV0 diet contained fishmeal at an inclusion level of 200 g/Kg and zero levels of CV, while in the rest diets the CV meal was included at 48 g/Kg (CV48), 72 g/Kg (CV72) and 240 g/Kg (CV240) corresponding to 20%, 30% and 100%, respectively of fishmeal protein replacement. After 60 days of feeding, fish were weighted to measure growth and feed utilization parameters. Data were analysed using one-way ANOVA and differences between means were determined by Tukey’s multiple-range test (P=0.05).

Results and Discussion

Survival was high and similar among the groups (Table 1). Fish fed the diet with the highest inclusion level of *C. vulgaris* meal (CV240) had significantly lower feed intake (g/fish) compared to the rest groups denoting a lower palatability of *C. vulgaris* meal compared to fishmeal. This in turn has led to a reduced (P<0.05) fish growth performance in terms of final weight, weight gain and specific growth rate (SGR) in this group. Additionally, the increased feed conversion ratio (FCR) and decreased protein efficiency ratio (PER) denoted that *C. vulgaris* protein was not efficiently metabolized when totally replaced dietary fishmeal. On the other hand, fish growth performance and feed utilization were not significantly impaired in CV48 and CV72 groups. These findings suggest that *C. vulgaris* meal can successfully replace a part of fishmeal protein if it is used in low inclusion levels up to 78 g/Kg in the diet. The later was the maximum tested level that corresponded to 30%

(Continued on next page)
fishmeal protein replacement. This agrees with the findings of our previous study with the same species (Karapanagiotidis et al. 2022) where 30% fishmeal protein replacement was achieved by *C. vulgaris* meal, but that level corresponded to a much higher inclusion of CV in the diet (190 g/Kg).

*C. vulgaris* meal has been successfully used to partially replace fishmeal protein (FM) in diets of other fish species such as *Sciaenops ocellatus* (9.4 g/Kg dietary inclusion replacing 5% of FM, Patterson and Gatlin 2013), *Oreochromis niloticus* (171 g/Kg replacing 50% of FM, Badwy et al. 2008) and of crustaceans such as *Macrobrachium rosenbergii* postlarvae (80 g/Kg replacing 24% of FM, Maliwat et al. 2017). A total FM replacement was achieved in *Litopenaeus vannamei* (389 g/Kg dietary inclusion, Pakravan et al. 2017), while CV meal had even a growth promoting effect by totally replacing FM in *Pontastacus leptodactylus* (410 g/Kg dietary inclusion, Safari et al. 2022) and in *C. auratus* (711 g/Kg dietary inclusion, Shi et al. 2016). The present findings could help the aquaculture of gilthead sea bream to further decrease the dietary fishmeal levels by *C. vulgaris* meal towards more sustainable aquafeeds.

Introduction
The transformation of aquaculture into urban regions and the integration of highly efficient automated fish aquaculture systems into agricultural and industrially circulation systems is progressing rapidly. Thus, fish aquaculture is now an integral part of the blue bioeconomy. One problem with this development is the insufficient knowledge of fish physiology, behavior, and the species-specific demands, which is required to improve animal health and welfare in new farming systems and increase harvesting gains. Research priorities of the project are therefore the monitoring of fish and the development of new animal-based welfare parameters to assess and improve fish performance and product quality. The analyses of species-specific molecular indicators (Rebl et al., 2020), including stress hormones (Seibel et al., 2021), and digital measurement technologies newly developed in the project allow the assessment of stress and health of salmonids in different rearing phases. They thus contribute to improve husbandry conditions in farming facilities and to optimize aquaculture processes. The project explores the welfare of Atlantic salmon during the rearing process using molecular methods and AI-based monitoring. The analyses conducted provide baseline data on the effect of dietary additions of microalgae of the genera Arthrospira, Chlorella, Schizochytrium, and Tetraselmis on animal welfare and product quality of the fish under the influence of stressors such as a salinity change from 12% to 32% or after a common sanitization of the farm water with peracetic acid. The research is closely related to the development of novel microalgae feeds (Michl et al., 2019; Microganic GmbH), detection of microbial patterns and their nitrification efficiency in recirculating systems (Hüpeden et al., 2020), parasitological and bacteriological studies (Unger & Palm, 2016), and testing the product quality of fish as human food (Molkentin et al., 2015).

Results
We used a set of putative biological markers testing the welfare of salmon (Muilekom et al., submitted; Müller et al., submitted). At the molecular level, we detected no negative effects after feeding any of the above microalgae diets (Müller et al., submitted, and 2023). Furthermore, we developed two AI-based neural networks (object-detection and keypoint-detection) for AI based fish monitoring (MonitorFish GmbH). No parasites affecting the results were detected in the fish. Our data show that the turnover rates of ammonia and nitrite oxidizing bacteria were sufficient to prevent accumulation of toxic ammonia and nitrite (Malinowski et al., 2023) and no notable negative impact of diets and stressors on the microbial patterns in recirculating systems, nor on tested fish fillet quality could be observed. With the Schizochytrium diet (SL 14%), the fish fillet quality improved. The synergistic summary and provision of all subprojects on the design of salmon-specific molecular biochips together with all other technologies used, can contribute to fish-based biological monitoring and thus to the testing of optimal farming conditions in aquaculture.

Introduction

Hemp seed oil (HSO), a derivative with notable health benefits and high nutritional value has gained global attention for its positive effects. Extensive research has explored incorporating *Cannabis sativa* in livestock diets (Fallahi et al., 2022). This study investigates HSO’s potential as a growth and health enhancer in marine fish like gilthead seabream, a significant European species. The aim of the present study is to showcase the aquaculture industry’s beneficial utilization of medicinal plants, as a growth and health enhancer in marine fish like gilthead seabream, a significant Mediterranean species.

Materials and methods

280 gilthead seabreams (*Sparus aurata* L.) with an average weight of 4.91±0.05g were kept in 9 glass tanks (125L). Over 74 days, they were hand-fed to satiation. Diets were formulated with 535 g/kg crude protein and 21.3 MJ/kg energy, including 1% and 2% HSO-replaced soybean oil and control (CTRL) diets. After the trial, three fish per tank were euthanized (300 mg/L MS-222) for blood collection, cortisol levels, haematological parameters, and gut and liver histological examination. Body composition, fatty acid profile, and DNA damage (Comet Assay) in the liver, spleen, gut, and kidney were analyzed from three fish, while growth parameters were assessed.

Results

The inclusion of HSO in fish diets had limited impact on the examined parameters, except for ash content, which was notably lower in the CAN2% group compared to the control (Table 1). While total saturated fatty acids (SFA) remained unaffected, specific SFAs like 18:0, 20:0, and 22:0 increased in the CAN1% groups versus the control. Palmitic (16:0) and stearic acid (18:0) were the primary SFAs present, with myristic acid (14:0) in smaller amounts across all groups. Total monounsaturated fatty acids (MUFA) showed no significant change. Additionally, CAN1% groups displayed reduced levels of total n-6 polyunsaturated fatty acids (PUFA). Linoleic acid (LA, 18:2n-6) significantly increased in CAN2% groups compared to CAN1% groups. Arachidonic acid (ARA, 20:4n-6) exhibited higher levels in CAN1% compared to the control. Total n-3 PUFA remained unchanged in both CAN1% and CAN2% groups. Levels of a-linolenic acid (LNA, 18:3n-3) were significantly higher in CAN2% compared to the CAN1% group, while 20:5n-3 (EPA) and 22:6n-3 (DHA) were not significantly affected. The n-3/n-6 ratios significantly increased in the CAN1% group compared to the control. Intrahepatic fat content aligned with histopathological changes, revealing hepatocyte steatosis upon using *C. sativa* 2% as a feed additive. The liver tissue showed hepatocellular vacuolation due to lipid droplet accumulation, with no necrotic tissue or inflammatory cell infiltration observed. Cortisol levels and DNA damage in the liver, spleen, gut, and kidney remained unaffected by HSO supplementation in fish diets, as no significant differences were observed between the dietary groups and the control group.

Discussion

The study explored hemp seed oil’s (HSO) impact on gilthead seabream. HSO had positive impacts on survival rates, growth, and food consumption, yet statistical significance compared to the control group was lacking. It’s possible that longer experiments would reveal significant differences. Saoud et al. (2018) attributed reduced growth and higher FCR in tilapia fed with HSO to the potential presence of another cannabinoid like cannabidiol (CBD) in the seeds. HSO successfully replaced soybean oil in diets while maintaining fatty acid profiles promoting a beneficial effect as observed in sows (Vodolazska & Lauridsen, 2020) and hens (Raza et al., 2016). However, a 2% HSO addition led to hepatic steatosis and lipid accumulation. Haematological parameters stayed within normal ranges, suggesting minimal fish stress while proper concentrations of medicinal plant extracts are crucial to avoid potential toxicity within the food chain, even though these extracts enhance stress tolerance.

Contextualisation
The increasing demand for European seabass (Dicentrarchus labrax) led to the intensification of farming practices, resulting in increased stress and disease outbreaks in aquaculture. The immune system of fish comprises a complex population of immune cells with functions that remain not fully understood. Specifically, there is an urgent need to address the knowledge gap concerning the intestinal immune system of fish. This is essential for the development of efficient tools aimed at enhancing fish health.

Advances in European seabass in vitro model research are being supported by two ongoing projects, AquaCell and BASSinCELLS, coordinated by Interdisciplinary Centre of Marine and Environmental Research (CIIMAR) and Nord University. The multidisciplinary team is pursuing an innovative approach: creating an in vitro intestinal model for E. seabass. This model will serve as a valuable tool for understanding cell population-specific mechanisms in disease states and within the context of immunonutrition, with an emphasis on the gut immune cells and their function.

In vitro intestinal model for European seabass
Up to now, the researchers have achieved significant progress in developing protocols for isolating, culturing, and evaluating the phagocytic ability of immune cells from European seabass intestine. These findings hold the key to unlocking exciting and valuable research opportunities that will significantly benefit fundamental research on fish immunology and nutrition, contributing to the long term sustainability of the aquaculture sector.

European seabass in vitro models: A look into the future of aquaculture
These groundbreaking projects aim to achieve the following outcomes:
1) Establish a cutting-edge in vitro model to understand how the immune cell populations operate to shape the farmed fish immune function, particularly in the context of disease;
2) Reduce the need for animal-based in vivo experiments and associated costs;
3) Develop novel strategies to enhance fish robustness, leading to a reduced need for antibiotics, while simultaneously increasing commercial production efficiency and promoting sustainability within the aquaculture sector;
4) Investigate the potential of alternative feed formulations to modulate the immune system, thereby reducing the use of antibiotics and improving management practices in aquaculture.

Introduction
There is continued pressure to intensify aquaculture production to fulfil market needs. The expansion of the industry and increased diversity of materials used to build and maintain open, and recirculating aquaculture systems (RAS) have paralleled the development of synthetic polymers over the last decades (Astudillo et al., 2009). Synthetic materials offer greater strength and durability than natural fibres for the construction of ropes, infrastructures, and pipes, whilst often also being less costly and easier to handle. All plastic material within an aquaculture site is maintained and controlled for chemical degradation, biofouling and corrosion, and regularly inspected to ensure strength and stability. Broken and fragmented equipment as well as debris released from intense use however are sources of plastic emission from aquaculture operations at a local and global level, whilst accurate estimations of their contribution remain unknown (Lusher et al., 2017).

The ASTRAL project (All Atlantic Ocean Sustainable, Profitable and Resilient Aquaculture) focuses on integrated multi-trophic aquaculture (IMTA) farming, aiming at defining, supporting, and promoting this type of sustainable aquaculture production across the Atlantic area. To estimate the environmental sustainability, the fingerprint of different IMTA production systems is needed. ASTRAL is looking at the challenges related to the release of microplastics from aquaculture operations in both open and recirculating systems as well as quantifying the marine derived sources of plastics potentially impacting the IMTA labs. A monitoring plan was designed and applied at selected IMTA labs, using a novel sampling equipment able to preconcentrate large volumes of seawater onto appropriate filtering membranes.

Materials and Methods
Three sites were selected within the present study: A) the coastal open multi-trophic aquaculture facility located in Port-a-Bhuitlin (Scotland) managed by the Scottish Association for Marine Science. Being productive throughout the year, the farm aims at adding shellfish (native oysters, king scallops) to traditional seaweed production; B) the coastal open multi-trophic aquaculture facility located in Bertraghboy Bay (Ireland), managed by the Marine Institute. The farm aims at introducing new species combinations and C) The onshore partially (50 %) recirculating multi-trophic aquaculture facility “BuffelJags Abalone” located near the city of Cape Town, South Africa and managed by Viking Aquaculture. The farm aims at culturing a sub-tropical sea urchin species in temperate seas as well as integrating aquaculture of urchins with Ulva spp. and abalone. The occurrence of plastic fragments in different environmental compartments potentially affected by aquaculture production activities such as seawater and marine sediments was investigated at increasing distances from the open systems aquaculture facilities. The sampling grid was defined in relation to the site’s location, and the direction and intensity of the main surface and sea bottom currents present at site. Three sampling sites were selected from each of the open systems. In the partial RAS system, sampling sites were selected in the water inlet, outlet, as well as in some selected areas inside the recirculating system (abalone & Ulva raceways). For the seawater collection a Compact Large Volume Microplastics sampling device was developed. A large volume of seawater is conveyed by a compact stainless steel pump unit to a cascade of two stainless steel filters of 10 and 300 µm mesh size where particles (including micron-sized plastic fragments) are trapped. After each sampling, filters can be easily released from the small portable filter holder unit (fig.1) and accommodated on pre-cleaned glass petri dishes of appropriate size, sealed, kept in cold and dark conditions prior to the sample preparation and analysis steps. The sediments were collected by means of a Van Veen grab device. The first 0 to 5 cm sediments layer was collected for analysis. The extraction and purification method for all samples included a combination of a multistep enzymatic-strong alkali-oriented incubation followed by density-based separation to extract plastic fragments from digestates. Extracted samples were analysed first by µ-FTIR (Fourier Transform Infrared) microscopy and finally by GCMS-pyrolysis technique.

(Continued on next page)
Results and Discussion
The evaluation of the seawater samples and sediments using a vibrational microscopy-oriented technique shows the occurrence of 27 different polymer types. Among them the most recurring ones were polyethylene (PE), polystyrene (PS), polypropylene (PP), ethyl vinyl acetate (EVA), polycarbonate (PC), polyurethane (PU), (polyvinyl chloride) PVC and polyamide (PA66). Furthermore, the same samples were analyzed by pyrolysis mass spectrometry. The mass-based analysis back confirmed the occurrence of these polymers and further detected the occurrence of styrene butadiene rubber as a proxy of Tyre and road wear particles. The observed fragments were mapped against the IMTA lab inventory of polymers used in their daily operation. The sites targeted as reference in the study showed a similarly representative pool of polymers but with different accumulation levels. The preliminary results point out a complex distribution of polymers which hamper the interpretation of the source of microplastics in the aquatic environment. The ongoing work will contribute towards an improved understanding of the complexity, introduction, and potential emission of synthetic polymers in open and recirculating IMTA systems that will contribute towards the improved sustainability of modern aquaculture systems.

Introduction
The cultivation of industrial hemp (Cannabis sativa L.) is a rapidly growing branch of agriculture globally with an expected annual growth rate of 16.9 % by 2030 (Polaris Market Research 2021). Hemp cultivation area has increased by 75% between 2015 and 2019 in EU and probably will rise further due to hemp environmental benefits like high carbon storage, prevention of soil erosion, increase of biodiversity and low need for pesticides. Hemp fiber is used in textile industry, construction, biofuels production and many new innovative applications. Hemp seeds are source of nutrition for both human and animals. The attempt to use of hemp seed in striped bass feed has given promising results (Sample 2022). The aim of this study was to test feasibility of hemp protein powder (HPP) as an ingredient of extruded feed for Eurasian perch Perca fluviatilis L.

Materials and methods
Experimental feeds. Four extruded feeds containing 0% (control group), 10% (HP10), 20% (HP20) and 30% (HP30) of HPP (50% of crude protein; commercially available diet supplement for human) were prepared. Additionally the feed containing 30% of HPP and phytase addition (2000 IU per kg) has been extruded.

Fish and the experiment design. Eurasian perch from pond culture of National Inland Fisheries Research Institute in Olsztyn, Station in Żabieniec was used for test. Fish of 68.1 g ± 2.7 mean body weight (N=500) were equally distributed to ten fiberglass tanks (0.3 m³) working in RAS. Tanks were randomly assigned to experimental groups. Each group was present in duplicate. Fish were fed experimental feed appropriate for given group using belt feeders for approximately 10 hours a day for 10 weeks. Then, fish sample (n=15) from each tank was taken for body measurements. Sampled fish were euthanized and dissected. All the viscera and separately the liver were weighed. The remaining fish were weighed to determine the final total wet weight. Growth indicators (SGR, FCR, PER, VSI, HIS) were calculated based on collected data.

Statistical analysis. The analysis was done using Statistica 13 software (Statsoft, USA). Shapiro-Wilk test and Levene’s test were used to assess data normality and variance homogeneity respectively. As SGR, FCR and PER data revealed lack of variance homogeneity, The Kruskall-Wallis ANOVA was used to test difference significance. For remained data, ANOVA procedure and Tuckey’s post hoc test were applied.

Results
The growth of fish was very similar in all experimental groups. No significant differences were found in final body length and weight and specific growth rate. The mean body length varied between 16.7 cm and 17.0 cm and body weight between 92.8 g and 100.3 g in control and HP30F, respectively. Specific growth rate varied from 0.39 to 0.59 in HP30 and HP30F, respectively. The lowest mortality was noticed in HP30F group (1%) and the highest one in the control group (7%).

Hemp protein content did not influence significantly the feed conversion ratio (FCR)(varied between 2.00 and 3.31) and protein efficiency ratio (PER)(varied between 0.54 and 1.08) although the differences seems rather high. The only significant difference (ANOVA p<0.05) was found in the liver weight. HSI was significantly higher in the control and HP10 groups (2.44% and 2.19%, respectively) when compared to remaining groups (1.56% - 1.76%). Generally it has been noticed that results were slightly better with rising hemp powder addition up to 20%. The worst results were achieved in HP30 group (SGR 0.39, FCR 3.31, PER 0.54), however the best results were achieved in HP30F group (SGR 0.59, FCR 2.0, PER 1.08).

(Continued on next page)
Conclusion
Hemp protein powder addition to feed up to 30% does not influence on the growth of Eurasian perch. However, results obtained for HP30 group suggest that higher content of HPP can limit feed conversion and fish growth. The positive effect of phytase is rather unexpected result as it is considered that hemp seed do not contain phytic acid. HPP addition did not cause increased mortality during the experiment and HSI level was significantly lower in groups fed higher levels of HPP. Presented results a quite promising, however more intensive study is needed especially to explain the role of phytase.

Introduction

Algae are rich in bioactive compounds with a strong nutraceutical potential for human and animal health. However, the utilization of these compounds in aquafeeds has been limited by the bioavailability of these compounds and the limited capacity of most species to digest and extract them from intact algae.

Biorefinery arrives as a valuable set of tools that process algae in different manners, hopefully unleashing their potential as functional boosters in aquafeeds. The application of mechanical and chemical processes to break the cells and its compounds, extractions of soluble compounds to enhance and/or isolate their characteristics, and separation methods such as membrane filtration to separate soluble fractions from residual biomasses are only some of the strategies that have been applied to pave the way for bringing functional algae-derived ingredients to aquaculture nutrition.

The aim of this study was to assess the functional potential of two microalgae, *Nannochloropsis oceanica* and *Phaeodactylum tricornutum* broken and hydrolyzed biomasses and a macroalgae *Gracilaria gracilis* broken cells biomass in a Gilthead seabream (*Sparus aurata*) intestinal explant model.

Material and Methods

Broken cells of *Nannochloropsis oceanica* and *Phaeodactylum tricornutum* were obtained by high-pressure homogenization (HPH), whereas *Gracilaria gracilis* was obtained by bead milling. Microalgae broken cells were further processed by different enzymatic hydrolysis. The resulting products were freeze-dried and applied in two different dosages in an intestinal explant model, under previously standardized conditions. The intestinal response to the biorefinery-derived ingredients was evaluated through the transcriptional modulation of genes encoding for proteins related to innate immune response (e.g., *cox2*, *IgM*), antioxidant response (e.g., *cat*, *gpx*, *nrf2*) and to epithelial integrity and permeability (e.g., *tjp*, *cldn12*, *ocl*).

Results and Discussion

Ingredients derived from biorefinery process of *P. tricornutum* and *G. gracilis* presented the strongest functional potential. Here, *P. tricornutum* broken cells and hydrolyzed fractions triggered the stronger epithelial immune response and prompted a modulation of the tight junction complex. Interestingly, hydrolyzed *N. oceanica* had a boosting effect on the expression of genes related to epithelial integrity and permeability regulation, but not on immune-related ones, indicating that each algae species presents different potential and requires dedicated processing to unrestraint their bioactivity to be applied in aquafeeds.

In shrimp farming viral diseases produce important economic losses. The use of prophylactic methods as natural additives without immune resistance and environmental problems were proven. Medicinal plants powder, yeast and *B. licheniformis* were used in the survival in the digestive and immune systems of *P. vannamei* challenged against *V. parahaemolyticus*.

Four bioassays were carried. Postlarval white shrimp stage were used to analyze the digestive and immune-related genes expression by RT-qPCR.

The combination of MP in the food and *B. licheniformis* in the water (3 x 10^6 CFU / L) significantly improved the survival of *P. vannamei* challenged with *V. parahaemolyticus*. *B. licheniformis* inoculated in the water, did not alter the expression of the trypsin digestive gene.

*B. licheniformis* in the water decreased the expression of the SOD gene (related to the immune system), which plays an important role as an antioxidant, decreasing the concentration of superoxide anion, the product of the phagocytosis process. *B. licheniformis* in the water did not alter the expression of the genes of the immune system penaeidine4 and lysozyme. The mixture of MP added in the feed and *B. licheniformis* in the water prevent the AHPND in *P. vannamei* cultivated in the laboratory.
PROSPECTS AND PITFALLS OF USING BRAIN FUNCTION TO ASSESS THE EFFECTIVENESS OF STUNNING IN FISH

Albin Gräns
Department of Animal Environment and Health
Swedish University of Agricultural Sciences
Email: albin.grans@slu.se

Background
Countries within the European Union (EU) often take pride in its comparatively stringent and comprehensive animal welfare legislations (https://api.worldanimalprotection.org/). In the EU, all animals should be protected from any unnecessary pain, suffering or injury (COUNCIL DIRECTIVE 98/58/EC). In addition, during killing and slaughter, all animals must be stunned before the method of killing is applied, and the animal must not regain consciousness before it dies (Article 4, EC No. 1099/2009). When the European Commission reviewed the welfare of its five key aquaculture species during slaughter in 2017, they identified serious shortcomings when it came to safeguarding the welfare during slaughter. For most species and in most countries, the methods used for stunning did not comply with humane killing. The report also highlighted that it essential to neurologically investigate (e.g. using electroencephalograms, EEGs) the humaneness of the stunning method in order to verify whether the fish immediately loses consciousness or not instead of relying solely on the visual verification of consciousness.

Material and methods
Recently, we have developed, validated, and implemented a non-invasive technique to measure and interpret EEG in fish (Bowman et al. 2019, Fig 1). With our technique, three silver chloride disc electrodes are fitted to a custom-made silicone suction cup. The electrodes are connected to three shielded wires that are threaded through the silicon cup and connected to an animal bioamplifier that fed the signal to a PowerLab system. A thin layer conductive EEG paste is applied in to each of the electrodes to ensure good contact between the skin of the fish and the electrodes. During EEG measurements, the cup is centered above the approximate location of the left optic lobe and secured using suction generated by the peristaltic pump. Using this technique, a fish can be judged to be unconscious and insensible if the EEG shows abolition of evoked electrical activity in the brain, e.g. visual evoked responses (VERs) and/or changes that are incompatible with consciousness (i.e. grand mal epilepsy, frequency shifts and/or prolonged quiescent periods on the EEG).

Results
Using this technique, we have successfully carried out a series of studies and identified several serious welfare hazards with the various stunning and slaughter procedures that are currently used (Bowman et al. 2019, 2020, Brijs et al. 2021 & Hjelmstedt et al. 2022). Our studies show that the technique can be used to investigate the effects of various stunning/killing methods, including electrical stunning, CO₂-narcosis, percussive stunning and chemical narcosis, on brain function (Bowman et al. 2019, 2020, Brijs et al. 2021 & Hjelmstedt et al. 2022). Furthermore our findings strongly support that it is critical to apply neurological investigations when the humaneness of the slaughter method is investigated rather than relying on visual verifications alone, as the latter is unreliable and underestimates the time it takes for a fish to become unconscious. In addition, our results indicated that some neurophysiological indicators of unconsciousness that traditionally have been used to validate electrical stunning procedures in birds and mammals might not be appropriate for fish. For example, our results clearly show that the presence of an epileptic-like seizure following an electrical stun does not guarantee a prolonged period where the fish is unresponsive to visual stimulation (i.e. absence of VERs). Instead, the fish can regain responsiveness within seconds after the seizure ends (Hjelmstedt et al. 2022).

Conclusion
These findings have severe welfare implications since many stunning methods thought to render fish unconscious may only cause paralysis, which means that fish are still sensible when exsanguinated and eviscerated. In addition, the loss of sensibility can be a gradual process, during which it is unclear when the fish is no longer susceptible to anthropogenic stress and, therefore, not capable to experience pain, distress, and anxiety. In such situations, it is difficult, even for a trained expert, to make an objective and evidence-based interpretation of an animal’s level of consciousness. Collectively, these results highlights the necessity to carefully consider and evaluate how neurophysiological indicators of unconsciousness should be used to validating different stunning methods and to safeguard the welfare of farmed fish during slaughter.

Introduction

*Porphyra* sp., also known as Nori, is a red alga and one of the most valuable edible seaweed in the world. The global Nori production mostly occurs in Asia (China, Japan and Korea) with farming of *Pyropia* species (phylogenetically close to *Porphyra* species) with 3 million tons for 2.7 million USD in 2018. In Europe, the production of Nori comes almost exclusively from harvesting of wild populations of *Porphyra* species, and so far, the commercial culture is performed by only one company located Portugal. In France, *Porphyra* production exclusively comes from wild hand-harvesting, especially in Brittany (30 tons in 2021).

With the increase of Nori demand, harvesting pressure on wild *Porphyra* populations increases as well. Therefore, it becomes essential to develop and optimize new cultivation methods of *Porphyra* in Europe, to promote local economy and suitability with already existing aquaculture activities.

The western coast of Normandy region has a great potential for *Porphyra* productions, wild populations grow on its rocky shores and have been noticed growing abundantly in many intertidal oyster farms as well. In this study, we explore the potential of two production methods of *Porphyra* species in intertidal oyster farms in the West Cotentin area:
- Natural seeding by natural recruitment of *Porphyra* on oyster pockets
- Artificial seeding and nursery cultivation of plantlets before transfer at sea

Materials and Methods

For natural seeding, empty oyster pockets (0.5m² each) have been placed in 3 and then 4 oyster farms monthly from November to March, and at 3 different bathymetric levels (high, middle and low intertidal) in order to identify the time and bathymetry that promote natural seeding. The biomass was harvested in June to avoid damages caused by summer heatwaves. The experiment was renewed three years: 2020-21 (3 locations), 2021-22 and 2022-23 (4 locations). In 2021-22 and 2022-23, other species of seaweeds colonizing oyster pockets were also harvested and weighted.

Artificial seeding was performed in 2021-22 by cultivating the filamentous phase (*Conchocelis* of *Porphyra purpurea*) in lab in order to obtain conchospores to seed oyster pockets in tanks. The plantlets were then kept in nursery cultivation ponds for 2 months before being transferred in oyster farms for open sea growth until harvesting in June 2022.

Results & Discussion

Natural seeding gave harvestable biomass values, especially during the year 2020-21 on pockets from the site located in low intertidal, and laid out in December and January. The mean dry biomass could reach 137g±80gDW/pocket (Fig.1). In 2021-22, the biomasses were very low for the 4 locations, but the maximum was still observed on oyster pockets laid out in December and January in low and middle intertidal (12.6±6.6gDW/pocket). The year 2021-22 was indeed unusually affected by a mild winter with sometimes brutal frost waves, and then precocious heatwaves in spring, compared to 2020-21. These climates factors may have affected both recruitment on pockets and growth of young plantlets. The year 2022-23 showed better results but the biomass was less important than in 2020-21. More biomass was harvested in oyster farms in the low intertidal, on pockets put in January (88.8±49.2gDW and 52.9±27.8gDW/pocket). Besides, one of the locations in low intertidal showed similar results for oyster pockets placed in November 2022. Biomass variations within each site still remains high (Fig.1). In terms of purity, the other seaweeds species growing among *Porphyra* were filamentous *Ulva* sp. (Fig.1). In farms were *Porphyra* biomasses were the most important, the proportion of *Ulva* biomass was the lowest on pockets put in January 2022 and January 2023 (<30%), which confirmed January as the best time for natural *Porphyra* seeding.

(Continued on next page)
Artificial seeding worked as well. The seeded oyster pockets where *Porphyra* plantlets grew successfully gave 50.6±12.1gDW/pocket. These values are much more important than those obtained by natural seeding the same year 2022, and the standard deviation is lower than those calculated for artificial seedings in 2020-21 and 2022-23 (Fig.1). Besides, no other undesirable species like *Ulva* sp. was noticed, the purity was 100% (Fig.1). Artificial seeding and nursery cultivation of plantlets had an effect on these results: the seeding was more homogenous, precocious stages of plantlets protected against climate issues, avoiding contaminations from other seaweed species like *Ulva* sp.

**Conclusion**

Both techniques showed interesting results for *Porphyra* cultivation. Natural seeding is easier and cheaper as it does not need all the nursery culture systems, only empty oyster pockets. The best time and bathymetry to put oyster pockets for *Porphyra* recruitment should be in winter, especially December and January, in the low and middle intertidal. It can give high biomasses of *Porphyra*, but this technique remains highly variable between years and within culture areas: vulnerability to climate events, undesirable species recruitment (*Ulva* sp.) and heterogeneity of conchospores fixation. Artificial seeding requires aquaculture and lab systems that can quickly have a significant financial cost. However, this cultivation method improves the homogeneity and quality of produced biomass.

*Figure 1. Mean dry biomass of Porphyra sp. harvested on oyster pockets in June during the three years of natural seeding in the four oyster farms and by artificial seeding in June 2022 (red bar). Errors bars stands for standard deviation. Pictures give a look of the harvested biomass in terms of purity and integrity on oyster pockets.*
MARITIME SPATIAL PLANNING WITHOUT AQUACULTURE-SPECIFIC LEGAL FRAMEWORK MAKES EU AQUACULTURE GROWTH TARGET UNATTAINABLE

Introduction

Over a million tonnes of seafood is imported to the EU annually to meet the growing demand, while aquaculture production from most coastal EU States remains stagnant at zero (0) to 50 thousand metric tonnes annually. This is just under 26% of the 3.2 million metric tonnes produced by only 6 European countries: Norway, Spain, the UK, France, Greece, and Italy. This low level of aquaculture production has been largely attributed to a lack of access to space and water and bureaucratic legislation. This study aims to highlight that while MSP is an important tool for the futuristic growth and development of Aquaculture, the absence of aquaculture-specific legislation in the planning system is primarily responsible for the low productivity and must be addressed in tandem with the development of Maritime Spatial Planning if there is to be any significant growth in aquaculture. Many articles have pointed to the social and spatial hindrances and bureaucratic regulations and call on Maritime Spatial planning to provide a solution. However, a very important and necessary consideration is having a specific legal framework that clearly outlines how aquaculture is to be developed; the type of aquaculture that is supported, and the permit/licenses required. By examining the countries with the highest production of aquaculture, it can be observed that while they also have challenges with social acceptance, spatial conflicts, and bureaucratic obstacles, there is a legal framework in place that fosters aquaculture. It is therefore not a surprise that the countries with more aquaculture-specific regulations are the highest-producing countries. Consequently, it is recommended that countries seek to update or develop aquaculture-specific regulations in concert with their Maritime Spatial Plans in order to foster real growth. The absence of this is not making aquaculture growth a priority.
IMPACT OF BIOACTIVE COMPOUNDS DIETARY INCLUSION IN GILT HEAD SEA BREAM (*Sparus aurata*) AND SEA BASS (*Dicentrarchus labrax*) FILLETS SENSORY QUALITY; PRELIMINARY RESULTS

**Introduction**

Dietary inclusion of polyphenol-rich natural products for farmed fish has been subject to contemporary research (Ahmadifar, et al., 2020). However, there is very little knowledge on the effects of such supplementations in the sensory quality and storage stability of the produced fish fillets.

The present study aimed to examine the effect of the dietary supplementation of polyphenol-rich olive oil by-product compounds and bioactive *Spirulina* peptides, on the sensory quality of European sea bass and gilthead sea bream, freshly slaughtered or after 8 months of deep-freeze storage.

**Materials and methods**

European sea bass and gilthead sea bream of commercial weights (300 to 400g) having previously received one control (Ctrl) and one olive-oil pomace and *Spirulina*-supplemented (Sup) experimental diet were used. Diet characteristics and feeding protocols have been previously described (Fountoulaki et al., 2022). Fish were ice-slaughtered in accordance with the commercial practice. Fillets of both studied species and from both the dietary groups were then tested for their sensory properties, both as fresh (t0) or after 8-month (t8) of deep-freeze (-20°C) storage. A trained panel of 12 panelists conducted the tests and a conventional descriptive analysis (DA) method with 24 descriptors for odour, taste, flavour and texture was used (Alexi et al., 2018). Principal Component Analysis (PCA) was used to explain the results statistically.

**Results**

In gilthead sea bream the two first principal components (F1 & F2) explain the 82.5% of the total variation (Fig 1) while in sea bass the 82.7%, respectively (Fig. 2). The panellists could distinguish between both the storage time and the dietary group the fillets belong. For both studied species F1 separates samples according to the storage time point. In gilthead sea bream F2 separates samples according to diet treatment, while in sea bass it is the third component (F3, explains 17.3% of the total data variation) that functions similarly.

In respect to the individual descriptors bream at t0 has a more intense fish oil odour compared to t8 (p<0.1). Bream Ctrl_t8 was found more chewy (p<0.1) compared to the rest of the samples. Bass Ctrl_t8 was also found more chewy (p<0.1) but also had a more intense grilled meat odor (p<0.05) compared to its counterpart at t0. Bass fed with Sup exhibited a higher odor intensity at t0 compared to t8 (p<0.05).

**Conclusions**

In the current study, it becomes evident that dietary inclusion of bioactive polyphenolic compounds, can have an effect in the sensory quality and stability of fish fillets. The complementary chemical evidence is still required to understand these differences.

DIFFERENCES IN UTILISATION OF DIGESTIBLE MACRONUTRIENTS FOR ENERGY GAIN BETWEEN 30 AND 90 GRAM RAINBOW TROUT (Oncorhynchus mykiss)

Ruben Groot1,2*, Philip Lyons2, Johan W. Schrama1

Introduction
Whereas in the past feed formulation in aquaculture was predominantly based on digestible energy (DE) it is now shifting towards a net energy (NE) approach (Kaushik & Schrama, 2022). The main advantage of this approach is that it takes into account differences in the utilisation efficiency of digestible protein, digestible fat and digestible carbohydrates and therefore leads to a more accurate feed evaluation (Schrama et al., 2018; Groot et al., 2021). However, it has been observed that at least the composition of growth (protein versus fat gain) can influence the efficiency of digestible macronutrients for energy gain in such a NE approach (Groot et al., 2022). Since composition of growth also changes with increasing fish size (higher fat to protein gain) it was hypothesized that fish size could also influence the utilisation of digestible macronutrients for energy gain.

Materials & methods
Four different diets ranging in protein, fat and carbohydrates were fed to two size classes of rainbow trout, 30 and 90 gram, at three different feeding levels. Growth, feed intake, initial and final body composition were measured, from which energy retention was determined. Furthermore, faeces was collected for determining digestibility of protein, fat and carbohydrates. The design of this trial allowed for multiple regression analysis to determine the utilisation efficiency of the different digestible macronutrients for energy gain whilst separating the maintenance energy needs. By doing so, it was also possible to establish specific NE formulas for 30 and 90 gram rainbow trout.

Results
The results of this study showed first of all that both the utilisation efficiency of digestible nitrogen and energy intake for growth (kgDN and kgDE) were lower for the 90 gram fish (figure 1 & 2). However, it was only significant (P<0.05) for kgDE which decreased from 79% to 72% in the 90 gram fish indicating that these fish converted energy less efficient into energy gain. Secondly, differences were also found between size classes in the estimated NE formulas and the corresponding partial efficiencies of the digestible macronutrients for energy gain (kgNE,CP, kgNE,Fat and kgNE,Carb). The lower kgDE in the bigger fish seemed to be mainly related to a lower kgNE,Fat (P<0.05) even though kgNE,Carb did showed a tendency to increase (P<0.1). kgNE,CP on the other hand was not different (P>0.05) which corresponded with the lack of a size effect on kgDN.

Conclusion
The results of the current study demonstrate that energy utilisation in rainbow trout is affected by fish size and should therefore be taken into account when moving to a NE approach in feed evaluation for this species.

Introduction

Food security, specifically in water-scarce regions, is a local and global aim which requires innovative solutions. Assimilation based recirculating aquaculture systems (AsRAS) such as aquaponics, algaponics and bacterioponics can be such a sustainable solution. All AsRAS involve the integration of conventional recirculating aquaculture system (RAS) with assimilation based reactor in a symbiotic arrangement. In aquaponics for example, fish excretions are assimilated as a nutrient source for vegetable production (Zhu et al., 2022), where in algaponics and bacterioponics it would be replaced by macro or micro algae and bacteria respectively. As a result, the assimilation of the fish waste by plants or bacteria treat the water, and enables its recirculation back to the fish tank. This practice allows for extremely high efficiency in the use of water and nutrients, greatly limits the discharge of pollutants and recovers or saves a lot of energy (Yogev and Gross, 2019).

Methods

In recent years we have developed three different AsRAS that are operated on fresh or brackishwater in multi-loops near-zero waste setups. The systems include separate loops for fish production (RAS) and for the assimilation organism growth which facilitate optimal conditions for each crop. In addition, in some systems two separate treatment loops are used to treat the solid waste (e.g. from fish and inedible plant bits) by anaerobic digestion, producing nutrient-rich supernatant which is good for plant growth and energy via biogas.

Results

In all tested systems fish stocking density reached up to 80 kg/m³ with typical density of approximately 50 kg/m³. Feed (45% protein content) was applied daily at 2% of body weight. Typical fish performance was observed with a survival rate >95% and feed conversion ratio ranged between 1.1-1.4. Significant energy saving was demonstrated; from >80% in the aquaponics system and 50% in the bacterioponics/biobloc based RAS. Carbon sequestration was 1.4 higher than the feed carbon in the aquaponics system, which reduced the carbon footprint of typical RAS by 64% where similar or even higher reduction is expected for the algaponics-based AsRAS. Moreover in all of the studied AsRAS significant reduction of nitrous oxide was recorded when compared to traditional RAS.

These studies are among the first to demonstrate highly efficient AsRAS production with near-zero water and waste discharge and with significant energy recovery or savings. We postulate that AsRAS systems have a great potential to replace the traditional nitrification-denitrification based RAS.

Introduction
Mycotoxins are notorious contaminants of animal feed known to exert toxic effects in animals, including aquatic species. Fungi that produce mycotoxins infest crop plants in the field and agricultural products during storage. Therefore, the inclusion of plant-based feed ingredients in aquaculture feedstuffs can result in the introduction of mycotoxins. As mycotoxins are thermostable molecules that resist conditions applied during the feed production process, mycotoxins end up in compound feed. During storage of compound feed for aquaculture in moist and warm conditions, additional mycotoxins may be produced.

Our knowledge of mycotoxin prevalence and impact in the aquaculture sector lags behind what is known about these issues in the terrestrial livestock industry. Therefore, in this study, we investigated mycotoxin occurrence in feedstuffs destined for aquaculture species. To this end, we analyzed mycotoxin concentrations in 273 samples of aquaculture feedstuffs collected in Asia, Africa, Europe and South America.

Materials and Methods
We collected 273 samples of aquaculture feed from different countries in Asia, Africa, Europe and South America and analyzed concentrations of 51 mycotoxins and less-investigated fungal metabolites (“emerging mycotoxins”) using multi-analyte liquid chromatography-tandem mass spectrometry (LC-MS/MS) methods. Analytes included aflatoxins and other Aspergillus mycotoxins, Fusarium mycotoxins (e.g., deoxynivalenol, zearalenone, fumonisins), Penicillium toxins, ergot alkaloids and Alternaria toxins.

Results
In total, 46 mycotoxins and fungal metabolites were detected in aquaculture feed samples and 97% of the samples were contaminated with at least one mycotoxin/metabolite. We found that 36% of the samples were contaminated with the cancerogenic mycotoxin aflatoxin B1, and 5% of the samples exceeded the maximum level set for this mycotoxin in fish feed in the European Union (i.e., 10 µg/kg). Furthermore, Fusarium mycotoxins fumonisins, deoxynivalenol, and zearalenone were prevalent in aquaculture feed samples (detected in 63%, 59%, and 54%, respectively). In addition, less investigated fungal metabolites such as enniatin B1 (48%), beauvericin (38%), and alternariol (34%) were frequently detected. Co-contamination of aquaculture feed samples with multiple mycotoxins/metabolites was common. In total, 72% and 36% of the samples were co-contaminated with ≥5 and ≥10 mycotoxins/metabolites, respectively.

Discussion
Mycotoxins and other, less investigated fungal metabolites were almost ubiquitously present in aquaculture feedstuffs analyzed in this study. Mycotoxins are known to cause adverse effects in aquatic species such as reduced growth, impaired reproductive performance, increased mortality and immunosuppression. Furthermore, mycotoxins may accumulate in edible tissues. It is therefore necessary to closely monitor mycotoxin concentrations in aquaculture feed and take appropriate measures to minimize their negative impact.

Based on our results, co-contamination of feed with multiple mycotoxins is the rule rather than the exception. This finding is not surprising, as compound feed is a blend of a variety of raw materials, each of which has its own mycotoxin risk profile. Due to toxicological interactions, these “cocktails” of mycotoxins in feed can have stronger toxic effects than each individual mycotoxin would have on its own. Our findings underline the necessity to monitor the concentrations of multiple mycotoxins in aquaculture feed simultaneously and to investigate the combined toxicity of mycotoxins in aquaculture species.
BIOTECHNOLOGICAL TOOLS FOR THE RESEARCH AND CONTROL OF NODAVIRUS IN AQUACULTURE

Introduction.
Nodavirus (NNV) is the most threatening marine virus in the Mediterranean area, and it is spreading in the number and type of viral isolates and host fish species, either wild or culture. In our research group we have been studying the immune response of fish against NNV for 2 decades, focusing on gilthead seabream and European sea bass models. While European sea bass is highly susceptible to some classical NNV genotypes the gilthead seabream acts as a resistant and reservoir species. However, their potential vertical transmission, the emergence of new natural NNV recombinants, producing high mortalities to traditionally-resistant species such as gilthead seabream, the climate change and the aquaculture diversification might increase the deleterious effects of NNV infection in the aquaculture sector. Based on this, we are now increasing our knowledge about fish-NNV interactions in the following topics:

1. Generation of biotechnological tools to study NNV and the fish immune response. We have developed several fish cell lines (from seabream, sea bass, European eel or Senegalese sole) susceptible to NNV, antibodies for localization studies and transcriptomic databases, useful as research and diagnostic tools. These tools allow us to increase their applications to other host, marine viruses or, even, other fields.

2. Deepening of the antiviral immune response of fish. We are identifying and characterizing, among others, the involvement of antimicrobial peptides (AMPs) and cell-mediated cytotoxicity as two of the most important antiviral immune mechanisms. Thus, we are able to analyze levels of antibodies and AMPs, or the adaptive cellular cytotoxic activity in fish, novel techniques that are routinely applied in our laboratory.

3. Effect of culture conditions and welfare on susceptibility to NNV. We are characterizing the lethality and presence of the virus in survivors and its success on vertical transmission under different culture conditions, size, or sex of different species susceptible to NNV. We have evidence that survival is more dependent on size than on culture conditions, but the presence of the virus in survivors is not.

4. Design and generation of treatments against NNV. We have developed several effective NNV vaccines in previous projects. We are currently developing the application of sea bass AMPs as antiviral treatments in aquaculture. So far, we have already shown that 4 AMPs derived from sea bass can be applied both as preventive and therapeutics of the disease produced by NNV in sea bass fingerlings.

5. Study of the impact of emerging contaminants on the antiviral immune response. We have evaluated the possible effect that some contaminants, mainly nanoplastics, may have on the immune response of fish and their resistance to NNV infections.

Conclusions.
In short, our group aims to investigate the fish health status and well-being with interests for the aquaculture sector. We mainly focus on the prevention and improvement of the resistance against nodavirus infections. To this end, we have generated various very interesting biotechnological tools that are exploited through material transfer agreements with research centers and companies, which clearly and decisively adhere to the objectives of the ThinkInAzul program.

Introduction

It is well known that exercise promotes health in mammals (Pascoe et al., 2014). However, in farmed fish, the physiological effects of swimming activity are often overlooked. Swimming is a fundamental behavioral element that contributes to fitness in most fish species. In fact, reduced swimming performance has been associated with poor disease resistance and welfare (Castro et al., 2013). The current study aimed to address the lack of knowledge on swimming physiology by investigating the effects of induced swimming activity on immune parameters in European eel (*Anguilla anguilla*), a commercially important species for aquaculture in Europe (FAO, 2023).

Materials and Methods

Sixteen European eels (total length: 39.9 ± 0.7 cm; body weight: 108.8 ± 6.1 g) were equally distributed between two treatment groups: swimming and non-swimming (control). In the swimming group, fish were placed individually in acrylic tubes (length: 67.0 cm; width: 8.5 cm) and induced to swim at 0.3 BL s⁻¹ (n = 8) for 7 hours. In the control group, fish were also placed individually in acrylic tubes, but kept at minimal water flow (< 0.1 BL s⁻¹; n = 8). Immediately after the trial, fish were anaesthetised with MS-222 (0.1 g L⁻¹). The skin mucus was collected by carefully scraping the dorso-lateral surface of the fish with a cell scraper. The collected skin mucus was shaken vigorously, and centrifuged (2,000 × g, 10 min, 4 °C). Blood samples were collected immediately with heparinised syringes via the caudal puncture. The blood was centrifuged (2,000 × g, 10 min, 4 °C) to obtain plasma. Cortisol, glucose, and lactate levels were determined in plasma, while lysozyme, peroxidase, protease and antiprotease activities were measured in both plasma and skin mucus. Data were analyzed by unpaired t-test to determine differences between groups. The level of significance used was *P* < 0.05 for all statistical analysis.

Results and Discussion

Some studies have associated induced swimming, at moderate to high speeds, with an enhanced immune response in farmed fish (Liu et al., 2018; Hou et al., 2022). Although, the immune responses in fish plasma remained unchanged in the current study, the lysozyme, peroxidase and protease activities increased in the skin mucus in the swimming group. The skin mucus plays an important role in fish, as it acts as the first defence barrier, preventing pathogen attacks and contains several antimicrobial factors (Dash et al., 2018). In addition, fish skin mucus is an important factor in swimming performance as it reduces water resistance (Bernadsky et al., 1993). However, the possible effects of swimming activity on the structure and composition of skin mucus remain to be elucidated. The increased enzymatic activity observed in our study shows how skin mucus activity can be modulated by swimming. The European eel is a catadromous species, characterized by its endurance swimming performance, showing sustained and steady swimming during migration. While plasma glucose and lactate levels remained unchanged, cortisol levels were lower in the swimming group. Some studies have already shown that swimming can alleviate chronic stress by lowering circulating cortisol levels (McKenzie et al., 2021). Thus, swimming may contribute to optimize immune status in eel, as evidenced by the increased activity of immune-related enzymes in skin mucus.

(Continued on next page)
Conclusions

In this study, the results demonstrated that induced swimming caused an increase of immune-related enzymes in skin mucus. As migratory species, their efficient swimming abilities are essential to travel long distances and through different habitats, ensuring successful performances and development during migration. In aquaculture, understanding and optimizing swimming conditions is crucial for promoting growth and maintaining overall welfare, contributing to sustainable and profitable farming practices.

Introduction

In recent years, the aquaculture industry has focused on the use of agro-industrial by-products as a potential source of bioactive compounds, being some of the more interesting those produced after the distillation of aromatic plants. Although these residues present wide industrial applications as sources of polyphenols (Sánchez-Vioque et al., 2018), their potential use by the aquaculture industry is being only recently evaluated (Orso et al., 2022). However, optimal dosage of dietary polyphenols related to their biological responses requires an accurate estimation of their actual bioavailability, which is affected by a number of factors, such as the physical conditions used during feed preparation, the interactions with other components of the feed matrix and the biochemical transformations taking place within the gastrointestinal tract. One powerful tool frequently used to assess these aspects in humans and terrestrial animals are in vitro digestion models. In the case of aquatic organisms, models simulating the conditions existing within the gastrointestinal tract have been extensively used to assess bioavailability of key nutrients in wide range of feed ingredients, but to date they have been not applied in an equivalent form to study that of bioactive compounds (Martínez-Antequera et al., 2023). Considering this, the present study was aimed to evaluate the impact of different factors that may affect the digestive bioavailability of polyphenols present in the distillation by-products of Salvia lavandulifolia (Spanish sage) using an in vitro system simulating the digestive tract of gilthead seabream (Sparus aurata).

Materials and Methods

The sage polyphenolic extract was obtained from distillate dried leaves subjected to water extraction at 1:150 ratio (w/v). After filtering, the solution was lyophilized and the dried extract was added, at a proportion of 2.5%, into simplified feed matrix simulating a feed for seabream. Once prepared, different in vitro digestibility tests involving both stomach (acidic) and intestinal (alkaline) stages of digestion were carried out. For this purpose, membrane bioreactors similar to those described by Morales & Moyano (2010) were used. Each bioreactor consists of a digestion-leaching cell consisting of two chambers separated by semi-permeable membrane. Sea bream digestive enzyme extracts and substrates (feed matrix containing the plant extract) were added to the upper chamber and kept under continuous stirring by a magnetic stirrer. The products released during the reaction time that passed through the membrane into the lower chamber (digestates) were recovered in falcon tubes at different time intervals by a constant flow of the same alkaline buffer. These products were kept frozen (-80 °C) until extraction and subsequent analysis of the released for the qualitative and quantitative analysis of the polyphenolic profiles in both, the sage aqueous extract and the release phenolic compounds, a HPLC-DAD method previously described by Lozano-Perez et al. (2023) was applied.

Results and Discussion

A total of eleven compounds of different chemical nature were identified in the primary plant extract, which can be grouped into phenolic acids, flavonoids, and derivatives of these in their glycosylated forms. Among the identified compounds, rosmarinic acid and hesperidin stand out as the main phenolic and flavonoid compounds, representing a 52% and 23 % of the total identification, respectively. Other compounds corresponding to salvianic acid and luteolin-7-O-glucuronide were also identified reaching levels close to 10%. These results, at qualitative level, are in agreement with those reported by Lozano-Pérez et al. (2023) and Sánchez-Vioque et al., (2018). However, at quantitative level, differences in concentrations could be
related to the source of the sage by-products and even to the extraction method applied. Regarding the polyphenolic profile of the products recovered after in vitro digestion, a total of six polyphenolic compounds were quantified and they presented a quite different bioavailability under the changing pH conditions of the gastrointestinal phases and also depending on total digestion times. Luteolin-7-O-glucoronide is the higher release rate flavonoid 14.9% while the phenolic acids reach around an 8-10%. The results evidenced that potential bioavailability of ingested polyphenols is greatly depending on their chemical nature and on the different factors involved in their digestive processing within the digestive tract of aquatic organisms (Martínez-Antequera et al., 2023).

Conclusions
The methodology carried out has made it possible to confirm that, the use of in vitro digestive modelling together with high pressure liquid chromatography, are adequate tools for determining the bioavailability of polyphenols of a sage extract, along with the characterization of the compounds released under different gastrointestinal conditions in the simulated digestive tract of gilthead seabream. Thus, as a first approach, Salvia lavandulifolia water soluble extract could be proposed as a bioavailable feed additive in Sparus aurata diet. Deeper studies need to be developed in order to confirm this statement.

Introduction
The recent expansion of Atlantic blue crab (Callinectes sapidus) has generated great concern in the Mediterranean Sea because is considered a non-indigenous species which would represent one of the greatest biological issues (Marchessaux et al., 2023). In the field of aquaculture, the crustacean segment, encompassing approximately 8.7% (equivalent to 10.5 million tons) of the overall aquaculture harvest, assumes considerable significance. Crustaceans only have an innate immune system, which constitutes the humoral and cellular defence against pathogens or different situations (Bouallegui, 2021). These defences are activated in a cooperative way to initiate effective defensive actions and can be classified according to two main responses: i) a humoral-mediated response involving humoral factors produced and released by the immune cells; and ii) a cell-mediated response that requires a direct action of the cell itself, such as phagocytosis, initiating the cell death pathway mechanisms. Several authors have been studied how environmental factors (temperature, pH, salinity, etc.) affect molecular parameters and immune-related enzymes (e.g., phagocytic activity, phenoloxidase, etc.). For instance, immune response to several stress challenges (e.g., salinity and temperature) have been studied in relation to how family Portunidae modulate their responses under pathogen challenges (Lei et al., 2022). However, the study of the immune response of the family Portunidae is still limited. Therefore, the aim of the present study was to assess the impact of an abrupt change in temperature on the immune response of Atlantic blue crab to detect potential biomarkers of animal welfare to improve their integration into aquaculture.

Materials and Methods
Twenty specimens of Atlantic blue crab (343.66 ± 162.94 g body weight) were obtained from the fish market (San Pedro del Pinatar, Murcia, Spain) and carried to the Marine Facilities at University of Murcia (Spain). The crabs were randomly separated in two groups, each group (n=10) was introduced into a tank with individual compartments for a single crab each one with containing 30 L of water and 7 cm of sterile sand sharing water and filtration (rack system). The racks systems were previously adjusted to 20 ºC (unchallenged) and 30 ºC (challenged) and the samples collected at 3, 6, 12, 24 and 48 hours after challenge. As time zero, haemolymph samples were collected 48 hours prior to thermal challenge. At each experimental time, 2 mL of haemolymph were extracted and the total haemocyte count and the cell’s percentage populations were determined. Haemocyte lysate supernatant (HLS) was used to measure the total quantity of protein and several immune-related enzymes activities. Data were analysed by One-way ANOVA (p < 0.05).

Results and Discussion
The cells numbers in the haemolymph did no show variations between the experimental groups. However, the number of haemocytes increased at 30 min in giant river prawn (Macrobrachium rosenbergii) exposed to 34ºC for 2 h (Chang et al., 2015). The percentages of hyaline and semigranular cells showed no change between groups. Contrarily, the values of hyaline cells varied between experimental groups at 30 and 60 min in giant crayfish (M. rosenbergii) (Chang et al., 2015), although at 120 min the levels did not show variations in line with our findings. In the case of granular cells, the numbers decreased in the challenged group at 12 h of trial. Chang et al. reported differences in this type of cells at 30 and 60 min, however, is difficult to extrapolate these results since their experimental time was only 2 h. The amount of protein present at intracellularly and extracellularly levels no showed variations between experimental groups. Contrarily, Matozzo et al. (2011) observed variations in plasma protein concentrations in Mediterranean green crab (Carcinus aestuarii) exposed to an increase of temperature to 30ºC (2ºC per day, 7 days). Our results showed no variations in phenoloxidase activity between experimental groups. These outcomes align with the results obtained in Mediterranean green crab (C. aestuarii) which were challenge with an increase of water temperature to 30ºC (2ºC per day, 7 days). (Matozzo et al., 2011). These results could suggest that a sudden and progressive rise in temperature does not cause variations in the phenoloxidase concentration in HLS. In our study, no variations in cell-free haemolymph lysozyme levels were observed between the experimental groups. However, a thermal shock in Pacific white shrimp (L. vannameii) showed variations in the lysozyme values at 3 and 6

(Continued on next page)
hours, as well as a decrease at 12 h compared to time 0 (Peregrino-Uriarte et al., 2012). In the case of esterase, our results no reported variations between the experimental groups. The modulation of esterase activity mediated by some type of stress in crabs has not been studied until now. Finally, the antiproteases are molecules capable of neutralizing excess proteases which lyse proteins in the animal. In our study, variations between both experimental groups at 24 h were observed. Therefore, the activity of antiprotease under thermal challenge could provoke a modulation of the protease activity in the cell-free haemolymph of Atlantic blue crab. This may be due to the protection that these molecules provide to the proteins that at high temperatures can be affected by the action of endogenous proteases.

Conclusions
This study aimed to investigate how a thermal challenge could modulate the immune system of the Atlantic blue crab to found potential biomarkers of animal welfare to improve their integration into aquaculture. However, we could emphasize the relevance and the need to deepen the related studies in the field of crustacean immunology to solve certain challenges and improve the animal welfare of this group of invertebrates in the field of aquaculture.

Introduction

The accumulation of heavy metals that are absorbed in living organisms throughout the food chain can confer a hazardous impact on human health. In the case of fish, they can accumulate heavy metals such as lead (Pb) from the water and diet (Alsop et al., 2016). According to literature, even low concentrations of metals due to synergistic action can be toxic to organisms and can reduce or eliminate species from an ecosystem due to adverse effects on the immune system, decreased fecundity or mortality (Butrimavičienė et al., 2021). Therefore, the aim of this study was to evaluate the effects of Pb-diet evaluating haematological and biochemical parameters in order to demonstrate defense pathways in response to toxicity. In addition, several genes involved in detoxification and inflammation processes were evaluated as well as the organo-somatic indices in rainbow trout (*Oncorhynchus mykiss*).

Materials and methods

Seventy-two specimens (160 g +/- 10 g average weight) of rainbow trout, obtained from a local hatchery (Cuenca, Ecuador), were randomly divided into six (three groups in duplicate) experimental group tanks (12 fish in each tank, 750 L pool). Three experimental groups were established as follows: i) Unexposed group (control) fed diet with 0 mg of lead kg⁻¹; ii) Exposed to 120 mg of lead kg⁻¹; and iii) Exposed to 240 mg of lead kg⁻¹. The animals were fed at a rate of 3% during 21 days. The organ somatic indices (OSI) for liver and spleen were calculated. The number of red blood cells (RBCs) and white blood cells (WBCs), as well as the determination of haematocrit (Ht), and haemoglobin (Hb) were evaluated. The quantification of Glucose (GLU), Cholesterol (CHO), Bilirubin Total (BILT), Direct Bilirubin (BILD), Aspartate Aminotransferase (AST), Alanine Aminotransferase (ALT) were determined. For gene expression, RNA extraction was performed using the SV Total RNA Isolation System and revers transcribed using ipsogen® RT Handbook QIAGEN. Total RNA was treated with DNase I to remove genomic DNA, Real-time PCR reactions were conducted in a 96-well plate using the Applied Biosystems 7500. A factorial ANOVA analysis was conducted to compare the impact of lead exposure in diet at 15 and 21 days.

Results and discussion

The values of OSI did no show variations in liver and spleen of exposed fish. Our results showed variations in the values of RBC, Ht, Hb, MCH, MCV, and MCHC which progressively decreased as the concentration of Pb increased. Our results agree with previous data in several fish species, the number of WBC was increased in blood of fish exposed to 120 and 240 mg of Pb kg⁻¹ at 15 days. The levels found in the liver enzymes showed a disordered behavior compared to other studies. For instance, the ALT values showed decreased in correlation with the increase in Pb at 15 and 21 days of exposure. The values of AST increased, which is directly related to the increase in values of other biomarkers tested such as BILD, BILT and CHO, which increased as toxicity augmented to 120 and 240 mg of Pb kg⁻¹ at 15 and 21 days. These results could suggest that these enzymes are non-specifically altered in the liver after short-term exposure, damaging the tissue which would elicits a pathogenic response in liver enzyme activity. Variations in CHO concentration could be due to the hazardous effects of Pb on the cell membrane. Thus, the cholesterol levels could be good indicators of environmental stress in fish as has been previously reported (Heydarnejad et al., 2013). Exposure to higher concentration of Pb resulted in an increase in GLU values compared to the unexposed group at 15 days. However, at 21 days of exposure, the levels of GLU decreased in these group. The values of GLU showed a similar behavior compared to previous studies in rainbow trout where the decline in GLU is most likely a result of experimentation and the exhaustion of energy stores (Ricketts et al., 2015). Thus, rainbow trout exposed to Pb showed a peculiar behavior in terms of transaminase enzymes, increasing AST/TGO values, and decreasing ALT/TGP values. This fact could suggest that these variations could be used to determine the levels of damage in liver tissue and cell functions. In this study, the expression of mt-a, mt-b, cyp1a, cyp2k1, cyp2m1,
and cyp3a27 genes liver were inversely correlated with the increase in Pb and the exposure time. In this sense, Klaassen et al. (1999) commented that this could be due to metal-induced damage to metal transcription factor (MTF-1) alleles, resulting in the constitutive silencing, of MT-I and MT-II gene expression. In this study, the expression of cytokines such as Interleukin 21, TNF-alpha, Interferon 1, and Interleukin 6 were analyzed in the spleen, which showed an inverse correlation with the increase in Pb concentration and exposure time. The results obtained are in line with the results obtained by Zhang et al. (2020), where the expression of il-21 gene showed the ability to induce the expression of various cytokines, including ifn-γ, il-10, il-6, tnf-α and il-1β, indicating the pleiotropic effect of il-21 gene in immune response.

**Conclusions**

In conclusion, this study revealed that exposure to Pb in diet had significant effects on the hematological, biochemical, and molecular parameters of rainbow trout. More specifically, Pb exposure led to alterations in the RBC, Hb, and Ht levels. The toxicity level was directly proportional to the increase in values of AST, BILD, BILT, CHO, and GLU, while a decrease was observed in the values of ALT, indicating liver damage. Furthermore, Pb exposure activated detoxification genes such as mt-a, mt-b, cyp1a, cyp2k1, cyp2m1, and cyp3a27 in an inversely correlated manner. The inflammation-related genes, such as il-a21, ifn-α, inf 1, and il-6, showed both direct and inverse alterations in the spleen and head-kidney. Inflammatory processes were found to be severe after 15 and 21 days of exposure to this heavy metal. Our results suggest that testing protocols need to be established for rainbow trout to prevent contamination by heavy metals. This will contribute to promoting healthier food chains and restoring farms and hatcheries in the paradisiacal area of Cajas (Ecuador).

Introduction

Whole genome duplication (WGD) is widespread in eukaryotes, and has been linked to phenotypic diversification during evolution. The common ancestor of salmonids underwent a lineage-specific WGD event ~100 million years ago and a large proportion of the genome is retained in duplicate, offering an ideal vertebrate system to understand the role of WGD in genome evolution. The huge commercial importance of these species to aquaculture further demands improved understanding of genome function and regulation, which is still poorly understood. In the current study, we make extensive use of the functional annotation data generated through the European AQUA-FAANG project, including 0.6 billion ATAC-Seq and 4 billion ChIP-Seq reads, to investigate duplicated regulatory elements in the genomes of Atlantic salmon (Salmo salar) and rainbow trout (Oncorhynchus mykiss). The objective was to examine the conservation of regulatory element activity through ontogeny in both species.

Methods

Duplicate-aware whole genome alignments including Atlantic salmon and rainbow trout were generated with Cactus (Armstrong et al., 2020) to align the duplicated syntenic regions in both species. The genome was broken into syntenic blocks before alignment (Gundappa et al., 2022). Northern pike (Esox lucius) was included in the alignments as a closely related outgroup to the salmonid-specific WGD. High-confidence ATAC-Seq peaks (open chromatin regions) representing multiple stages of embryogenesis, and six adult tissues at two stages of sexual maturation, were overlapped with the Cactus alignments. The coupling of sequence and regulatory element conservation in open chromatin regions was established with respect to duplicated and orthologous regions.

Results

Our alignments captured a high proportion of duplicated and orthologous sequences across the genomes of Atlantic salmon, rainbow trout and northern pike, validating the robustness of our approach. After cross-referencing open chromatin regions with these alignments, we split the data into distinct categories according to their conservation between the two salmonid species (Fig. 1). The proportion of open chromatin regions overlapping both duplicated sequences retained from WGD increased across embryogenesis, being highest at the late somitogenesis stage, and was variable across adult tissue types, with brain showing the highest proportion (Fig. 1B). Reciprocally, we identified the lowest proportion of open chromatin regions in singleton sequences (i.e. where the other duplicated sequence was lost) at the equivalent stage of development and tissues (Fig. 1B).

(Continued on next page)
Discussion
Our results validate the use of genome alignment to understand the dynamics of regulatory element activity across the duplicated genomes of salmonids. Our results are broadly consistent with the hourglass model of development (Duboule, 1994), suggesting highest evolutionary constraints on gene regulation during the phylotypic stage, a pattern previously observed across species, but not in relation to WGD. We are currently overlaying chromatin state annotations generated by ChromHMM to understand the co-evolution of specific regulatory element classes (e.g. promoters/enhancers) and duplicated gene expression across different stages and tissues in both salmonid species. In addition, we are linking the open chromatin regions to conserved non-coding elements of different evolutionary ages. The results of this work, by revealing conserved regulatory elements linked to salmonid phenotypes, will support the uptake of functional genomic information into salmonid genetics and selective breeding approaches supporting sustainable and profitable salmonid aquaculture.

IMPACTS OF FEEDING REGIME VARIABILITY ON THE FILLET QUALITY AND HEALTH OF ATLANTIC SALMON (Salmo salar l.) FARmed IN NORTHERN NORWAY

Shruti Gupta1*, Martine Kjellså1, Silje Karlsen1, Ingrid Heggenes1 and Chris André Johnsen2

1LetSea AS, Sandnessjøen, Norway
2Faculty of Biosciences and Aquaculture, Nord University, Bodø, Norway
Email: shruti@letsea.no

Introduction
A challenge in any fish farming is to ensure that the feeding (meals) of the fish is optimized to ensure optimal growth. The feeding strategies of Atlantic salmon are plastic and determined by physical factors such as day length, temperature, and season variations. Although different approaches can help obtain satisfactory results, drawing bombastic conclusions in feeding studies with salmon can be very difficult. There is a limited understanding of the best feeding strategies for better performance, health, and welfare of post-smolt Atlantic salmon reared in sea cages. The objective of the present study was to establish whether different feeding regimes would be more effective in understanding the best feeding practices in the sea, supporting salmon health.

We tested the hypothesis that diverse feeding regimes (feeding frequencies and percent overfeeding) in different seasons will affect fish growth and welfare, resource utilization, and quantity of feed waste. Our approach was to avoid underfeeding (which inhibits growth) and excessive overfeeding (which increases feed waste) to achieve best practices for the feeding process in Atlantic salmon.

Material and Methods
The feeding trial was conducted for 41 weeks at LetSea’s R&D sea facility in Northern Norway between June 2022 and March 2023. Large smolts used for the trial were obtained from Kvarøy Smolt, Norway. At the start of the trial and with a mean weight of 700 g, the fish were randomly distributed amongst 12 marine net pens (5x5x5m; 125 m3) at an abundance of 150 fish per pen. The experiment was performed in triplicates, where all the cages were fed simultaneously with conventional industrial feed.

There were four study groups (3 replicate/group); fish of a particular group were fed with one of the following feeding strategies (FS): FS1 (2 meals a day + 0% overfeeding), FS2 (restrictive feeding; 1 meal a day + 0% overfeeding), FS3 (1 meal a day + 10% overfeeding) and the control group (CF) consisted of 2 meals and 10% overfeeding, with the purpose of investigating production efficiency, health, and quality parameters. Fish were fed using automatic feeders (Betten, Norway).

At the end of the experiment, all fish were weighed, and welfare scoring was performed. Fat and color, melanin/pigmentation, gaping, and texture of the end product were compared between the groups. Furthermore, muscle histology and product quality samples were also collected. Fat and color analysis were performed using Near-infrared spectroscopy (NIR- DS2500) and digital Salmofan.

Results and conclusions
Our study shows that all four explored feeding strategies were well accepted by the fish, which means the fish were eating well, indicating good growth. We did not observe any significant differences in weight gain, TGC, and feed efficiency (TGC values over 3 and FCR values below 1). Temperatures ranged between 11 and 9°C from late June and mid-November and between 7 and 4°C from late November to mid-February. Oxygen saturation was stable and sufficient with regard to season throughout the study. We did not observe any corresponding trend in the feeding responses with respect to changes in temperature and oxygen. Results of effects on the product quality will be presented at the Conference.

In summary, this study suggests a non-restricted feeding regime as an effective tool in obtaining a healthy Atlantic salmon of good quality and desirable growth during the 10 months period of a typical commercial production cycle. The study shows that a chosen feeding strategy can have an impact on several growth and quality parameters in Atlantic salmon. Further research is recommended in order to describe the mechanisms underlying these observations.
THE EFFECT OF DIFFERENT DRYING METHODS ON THE ANTIOXIDANT ACTIVITY, PHYCOCYANIN QUALITY AND DNA PROTECTION OF SPIRULINA (Arthrospira platensis)

Betül Güroy *, Derya Güroy, Serhan Mantoğlu, Onur Karadal and Sibel Bayıl Oğuzkan

* Yalova University
E mail: betulguroy@yahoo.com.tr

Introduction
Drying method can affect the amount of functional component of Spirulina. Spirulina culture, which was developed in different nutrient media prepared with geothermal water by producing Spirulina under greenhouse conditions with 420 L volume of geothermal water, was dried by different methods and analyzed.

Material and Methods
Wet biomass harvested at the end of the trial; It was dried in two different ways: spray drying (110°C) and conventional method in a fan oven (40°C). The resulting product was named “dry biomass” or “Spirulina flour”. In the products obtained, phycocyanin, antioxidant capacity, anti-radical activity, flavonoid and phenolic component content and DNA protection were determined.

Results
The best DNA protective activity was obtained according to the band appearance of A13: 50% Pear Geothermal (40 °C Traditional Drying) and A14: 50% Pear Geothermal (105 °C Spray Drying), which represents 50% Pear groups. The bands expressing the DNA protection of the products are presented in Figure 1.

The phycocyanin quality of Spirulina dried in 2 different ways is presented in Table 1. Total antioxidant level, total oxidant level and anti-radical activity level are presented in Table 2.

The correlation between total antioxidant level, total oxidant level and anti-radical activity level and nutritional elements of water is presented in Table 3.
OFF-THE-SHELF AI VISION TECHNOLOGY SUPPORTING SHRIMP BIOMASS ESTIMATION ACROSS THE ATLANTIC

Federal University of Rio Grande
guterres.bruna@furg.br

Introduction
The strict control of animal biomass and physico-chemical parameters within cultivation tanks plays a fundamental role in shrimp farming activities. Accurate biomass estimation is crucial for efficient feeding planning and reducing environmental impacts. Off-the-shelf AI solutions may be an important ally for biomass estimation within aquaculture applications. This can avoid time-consuming animal weighting activities, free up professionals for other activities and contribute to more sustainable and efficient production. This work presents a case study on the practical deployment and validation of an off-the-shelf AI vision solution for shrimp biomass estimation within the Atlantic Area. The main challenges and advantages are discussed from a user and technological perspective.

Materials and Methods
Description of the data Acquisition setup
The video footage is acquired inside the cultivation tanks with a high-definition wide-angle camera tied to two lighting units protected by a waterproofed acrylic cage (Figure 1). This device is fully immersed in the water and the camera is positioned at a distance of 10cm from a checkered background. The system has been designed to mitigate the impact of high turbidity on the image quality as follows: (a) it used a short distance between the camera and background, and (b) two lighting units to improve conditions.

Dataset Description
Sixteen video recordings were acquired at the IMTA lab, totalling 37 hours of video footage. We have extracted 9032 images of shrimps, out of which 6180 images were annotated with bounding boxes and pixel coordinates for a set of anatomical landmarks such as the shrimps’ eyes and the root of their tails.

Description of the data processing architecture
Our solution’s software architecture can be split into three modules. The first module consumes images and produces pixel coordinates of anatomical landmarks. It relies on a Region-based Convolutional Neural Network (R-CNN) as described by Kaiming He et al. (2017). The second module consumes the pixel coordinates of the detected landmarks to assess the average length of the shrimps by combining the distances between several pairs of landmarks. The third module consumes the estimated average size of the shrimps to assess their average weight. This module relies on a length/weight polynomial model fitted on ground truth data. Called sequentially, these three modules can give an estimate of the shrimp’s average length and weight from a stream of images. The choice of this architecture has been driven by the fact that the shrimps are rarely entirely visible within video footage. Working with body segments allows us to extract size information even if the animals are partially masked. A user feedback session is conducted after the first set of technology deployments in a relevant environment.

Fig. 1 - Setup for data acquisition

(Continued on next page)
Results and Discussions
The solution described above has been applied to estimate the animals’ weight and size in a cultivation tank. The models provided relative errors of 8% for the length and 17% for the weight. Some experiments are ongoing to investigate how model performance is affected by environmental conditions and animal size. The user feedback meeting aimed to discuss technology usefulness and weaknesses to best consider the application needs during technology development. The main weakness is the lack of control over the number of animals passing in front of the camera. It prevents the exploitation of two-thirds of the resulting video footage. We discussed two possible approaches to circumvent this issue: (1) attaching the camera to a feeding plate usually used by the IMTA lab within the cultivation tank; (2) using a smaller tank custom-made to have optimal recording conditions (no turbidity, controlled lighting, 100% of the tank fitting in the camera’s field of view). The second approach requires sampling shrimps from the cultivation tanks and temporarily moving them to the “data acquisition tank” to carry out the biomass estimation. The IMTA lab highlighted the usefulness of the AI vision technology for shrimp biomass estimation, even considering a more controlled data acquisition setup.

Conclusions
Our work highlights that computer vision and deep machine learning are useful tools to perform biomass estimation even when reliable data collection from cultivation tanks becomes challenging because of high level water turbidity.

E-mail: guterres.bruna@furg.br

Introduction
Measuring the total biomass of aquaculture production is a critical aspect of aquaculture management as it enables farmers to monitor the growth and development of their aquatic organisms, adjust feeding regimes for optimal growth, and plan harvest schedules (Chen et al., 2022). Although a common practice, manual assessment of biomass estimation at aquaculture farms is time-consuming and usually relies on weighing a sample percentage of animals which may be sensitive to physical disturbance (Khanjani, 2020). The present case study investigates a practical deployment of image-based computer vision systems to support urchin biomass estimation at an Integrated Multi Trophic Aquaculture (IMTA) farm in South Africa. It also discusses the main challenges, requirements and possible limitations to best support aquaculture applications.

The urchin Tripneustes Gratilla is not native to South Africa but is a commercially valuable species for the far Eastern export market. This is one of the new fast-growing, high-value species investigated at the ASTRAL South Africa IMTA laboratory at Viking Aquaculture’s Buffeljags aquaculture farm on the south coast of the Western Cape. The urchins are grown in open baskets placed in large seawater tanks (Figure 1) with active aeration and water circulation to simulate the dynamic inter-tidal conditions in which urchins occur naturally. The prototype developed estimates the diameter of individual urchins in the images using computer vision. The advantages of a computer vision system for urchin diameter estimation include standardization of the process, reduction of skilled operators, and reduced stress on the animal compared to manual measurement procedures. It is a non-invasive tool aligned with animal welfare principles for successful harvests and profitability. The laboratory aims to estimate urchin diameter with up to 10% relative error.

Methodology
Towards the development of automated measurements of sea urchin size using computer vision sensing, images of the growing urchins are captured monthly. For the development and calibration of the computer vision algorithm, the urchins are photographed underwater in a rigid basket designed to reduce background unevenness in the mesh, therefore providing a consistent reference for calculating scale. Each photographed urchin is measured for its corresponding diameter and mass. In the development phase, measurements for training and validation require that the urchins are removed from the water to measure their diameter using calipers and are placed on a small scale to be weighed. The removal of the urchins from the water is performed only in the development phase of the algorithm, as the computer vision system intends to avoid physical disturbance of the animals in an operational setting. The computer vision algorithms were developed using the Python programming language. Figure 2 illustrates the image processing block diagram.

The image processing step allows the animal diameter to be estimated based on the scale information provided by the crop basket screens/mesh. The HSV color space represents the images. A boundary operation delimits the pixels representing an urchin and allows the removal of the image background. Blur and morphological operators (erosion and dilation) remove noise from the image and improve the representation of the animal. Next the HoughCircles algorithm detects the urchin outlines. Then another step of the algorithm is performed to calculate the circumference of the urchin’s body without the spines. Figure 3 shows the step-by-step of the algorithm.

Results and Discussions
Table 1 presents the results obtained in the current version of the algorithm. The results were divided into two groups, one group comprises the images that do not have ulva over the urchins, and the other group has ulva over the urchins. Ulva is a type of sea lettuce used as food for the urchins and is therefore frequently present in their environment, often sticking to the urchin’s spines. The dataset of the current version contains 33 images. The Ulva make processing the images more difficult, resulting in lower accuracy in the diameter estimation.

(Continued on next page)
So far, improvements are being developed for estimating the diameter of the urchins; after obtaining a better accuracy in this estimate, the next step is to improve the algorithm for estimating biomass, which will have as input parameter the calculated diameter. The technology supports urchin biomass estimation avoiding time-consuming and manual processes. It may also contribute to animal welfare through a non-invasive image-based system.

Introduction

Monitoring key physico-chemical parameters is critically important to support the expanding aquaculture industry that provides a sustainable source of seafood for people worldwide. Uncontrolled conditions may lead to severe impacts on animal health and growth rate, compromising entire cultivation systems. Although a common practice, manual assessment of physico-chemical parameters is disadvantageous to aquaculture applications in which delayed actions to control water quality account for most of animal loss cases (Lafont, 2019). Using LPWAN (Low Power Wide Area Networks) technologies may become an ally for monitoring physical-chemical parameters. This technology enables communication between radiofrequency (RF) devices with low energy consumption. Among the existing LPWAN networks, LoRa technology is a promising alternative for aquaculture farms. The LoRaWAN network layer comprises a complete solution for managing and integrating sensors into the end-user application. This work investigates the system issues associated with the practical deployment of an end-to-end cloud-based system (a) coupled with long-range low-power communication protocol (b) intended to monitor key physico-chemical parameters within an Integrated Multi Trophic Aquaculture (IMTA) farm in Brazil.

System overview

The deployed system aims to monitor key physico-chemical parameters - Dissolved Oxigen (DO), Temperature, Salinity, Conductivity, Turbidity and Ph - within a multitrophic cultivation tank from an IMTA farming facility located in Rio Grande – RS, Brazil. The system architecture (Figure 1) consists of a LoRaWAN network. The system end-node comprises four sensors, a microcontroller, and a LoRa radio with enabled LoRaWAN protocol. The AC powered end-node collects sensor measurements every 5 minutes and sends the data to a central gateway through LoRaWAN radio communication. The LoRaWAN gateway directs the received LoRaWAN packet (sensor readings) to an AI Data Analytics platform (named AIDAP), which is a cloud-based platform that integrates different sensors, allowing easy data access and visualisation for early alarm systems.

Deployment Results and Discussions

The system has been deployed in the IMTA LAB Greenhouse 5 (tank 1). The sensors were strategically positioned 1 m from the aeration tubes and 70 cm deep. The LoRaWAN gateway has been installed 35 meters away from the tank. Once operational, the end-to-end cloud-based system could present the collected data in real-time through the end-user application interface. Before the technology deployment, the IMTA lab farmers used to carry out manual physico-chemical measurements twice a day. The LoRaWAN system provided 240 sensor readings per day, representing a significant contribution to best support aquaculture applications. The technology deployment enabled the end user to early detect and mitigate parameter variations through an integrated cloud platform, for instance, DO levels as presented in Figure 2. The deployed system and user validation have been key assets in the farming facility in avoiding production loss and impacts on animal welfare. A series of user feedback meetings guided the technology design and optimisations to better meet IMTA’s day-to-day needs. Upcoming optimisations include local data backup, self-powering capability and a customised alarm system.

(Continued on next page)
Conclusions
This case study addressed the feasibility of implementing a cloud-based end-to-end system and a LoRaWAN network architecture to support aquaculture day-to-day activities. The system monitors physicochemical parameters of the cultivation tanks in a representative IMTA facility in Brazil. The system delivered satisfactory results for quasi-real-time physico-chemical monitoring. It allowed early detection of parameter variations through a cloud-based platform. The immediate mitigation action played an important role in preventing impacts on aquaculture production and animal welfare. The end-to-end system optimised the data acquisition process, centralizing and standardizing the data collection. It also increased data acquisition frequency, best supporting aquaculture management. The user feedback provided valuable insights to guide technology optimization. A few system limitations could be established with this practical deployment, including areas of difficult access which can lead to data communication issues (e.g. packet loss). Such limitations will be addressed in future versions of the system.

Selective Breeding is the process of improving one or more desirable traits of a cultured species through the selection of superior parents for the next generation. A breeding program is the implementation of a selective breeding strategy and the set of tools needed to deliver the desired outcomes. The approach selected should be designed to maximize the economic return by balancing input costs and with the expected genetic and economic gains for a commercial aquaculture producer.

In this talk we will discuss the general concepts and common strategies for breeding program management, from the simplest requiring the least amount of investment to the more complex with more investment required but greater genetic gains delivered. The aim of the talk is to provide aquaculture producers with the key elements to enable the informed assessment of the options for new or improved breeding program designs, and how they can tailor their program and genetic gains to their needs. The three general options for enhanced selective breeding management are: 1) Mass Selection managing diversity and inbreeding, 2) Family based selection and 3) Genomic Selection. These management strategies should be used to build upon a good genetic foundation. It is recommended to assess the genetic base at the beginning, or before changing the strategy, of any breeding program.

Key to assessing genetic diversity and to more sophisticated breeding strategies are genomic tools. The recent development of industry-wide, single nucleotide polymorphism (SNP) genotyping panels from 200 to 50,000 SNPs provides access to such tools at a very reasonable cost. When jumping from the basic to the complex, investment can be expected to increase with the need for genotyping, tagging equipment and supplies, more complex data collection, organization, and analyses, in addition to the training of personnel. While it is possible to change from a mass selection program directly to a genomic selection program, or to transition to a family-based plan on the journey to increased genetic progress. In all cases, training of personnel, and staged build-up of infrastructure and capabilities will be part of the process.

In summary, there are multiple options for enhanced selective breeding program management, each requiring different inputs and investment with varying potential returns and gains. Key to the selection of a genetic improvement design is the consideration of individual program’s breeding goals, capacity, and available budget as well as the selection of the appropriate tools to support such a design.
EFFECTS OF TEMPERATURE, SALINITY AND DIET ON FATTY ACID COMPOSITION OF THE RAGWORM Hediste diversicolor (OF MÜLLER, 1776) (ANNELIDA: NEREIDAE)

Introduction
There is an urgent need in food and feed production to change from linear systems towards circular, recycling based solutions. Many wastes or rest raw materials from linear systems are in fact valuable side streams containing precious compounds. Sludge from land-based aquaculture is such a side stream which comprise faeces and uneaten pellets. A second readily available side stream is the solid phase remaining after biogas production commonly known as “solid biogas digestate” (SBD). Both are nutrient- and energy rich and require handling at the production site, hence the question arises if these side streams can be utilized in a more sustainable way. The common ragworm Hediste diversicolor is an omnivorous, burrowing polychaete showing potential as an extractive species in IMTA systems. Both SBD and aquaculture sludge have proven to be suitable feeds for polychaetes, but growth rates can be lower than for worms fed high quality diets such as formulated fish feed (Wang et al., 2019a). It has recently been shown that this species has the capacity for endogenous production of omega-3 long-chain polyunsaturated fatty acids (Kabeya, et al., 2020), however it is yet not understood how environmental cues affects this ability. We conducted two sets of experiments to assess the combined effects of diet, temperature and salinity on total body fatty acid composition in H. diversicolor juveniles.

Materials and Methods
Polychaetes (H. diversicolor) were collected at low tide at the mud flat of Leangen Bay, Trondheim, Norway (63°26'24.5"N, 10°28'27.7"E). To investigate the effects of diet and temperature on fatty acid (FA) composition of H. diversicolor, worms were fed mixes of solid biogas digestate (SBD) and salmon aquaculture sludge (SS) along a 4-step feed gradient ranging from pure SBD to pure SS, and a 5-step temperature gradient ranging from 5.8 to 17.1 °C, for 15 days, using fish feed (FF) as a control. A second experiment was conducted to investigate the effects of salinity and temperature on the same variables. Here, the worms were fed the diet which yielded the highest growth rates in the first experiment (33:66 % SS:SBD) along 5-step salinity- and temperature gradients ranging from 5 to 40 ppt and 7.7 to 17.9 °C, respectively, for a duration of 28 days. In both experiments, worms were fed isonitrogenous diets equalling 30 % of the worms’ total body nitrogen per day (Wang et al., 2019). Both experiments were conducted in a temperature

Figure 1: Principal Component Analysis (PCA) on total fatty acids composition of H. diversicolor fed different diets at different temperature visualized by (A) feed type (% AS in the diet or fish feed and (B) by the five different rearing temperatures (°C). PC1= 56%, PC2= 14%
gradient table modified after Thomas et al. (1963) using a 18h:6h light:dark cycle. Worms (n=7-8) were stocked in glass beakers (800 mL) containing an 8 cm thick layer of sand and filled with sand- and bag-filtered (1 µm) seawater from the Trondheim fjord collected at 60 m depth. The worms were allowed to evacuate their guts in clean seawater for minimum 4 hours before each sampling and weighing. Water exchange and feeding was conducted every second day. Data analyses were performed using the inbuilt statistical package of SigmaPlot v.14.5. Principal component analysis (PCA) on fatty acid composition of polychaetes was performed using PRIMER 5.2. Fatty acid levels were expressed as % of total fatty acids and were arcsine transformed before entering the PCA.

Results and Discussion
The main differences between the FF and side stream diets were the high concentrations of EPA and DHA in fish feed. EPA accounted for 15% of total fatty acids in FF, and about 1% in both, AS and SBD. DHA accounted for 8.5% of total fatty acids in FF, while it accounted for 2% in AS and 3.5% in SBD. Further, AS was richer in 16:0 (28% vs. 18% in SBD and 20% in FF), and it was also richer in 18:1n-9 (25% vs. 21% in SBD and 13% in FF). In sum, FF contained a lower percentage of saturated fatty acids (SFA) compared to AS and SBD (32% vs. 41%, respectively), and in turn a higher percentage of unsaturated fatty acids. No temperature- nor salinity-driven segregation patterns could be identified in the FA profiles of the polychaetes, however a clear diet-driven segregation was found between worms fed lipid-rich fish feed (control) and lipid-poor SS and SBD diets. The fatty acid composition of polychaetes fed side stream diets showed high concentrations of EPA (14–19%) comparable to the polychaetes fed fish feed (13%). Further, the percentage of PUFA was high in both (38–40%) also comparable to those fed fish feed (46%). However, DHA was higher in polychaetes fed fish feed (5%) than in polychaetes fed aquaculture sludge and SBD diets (1–2%). The pronounced differences in fatty acid composition found in the different feeds were not as pronounced in the polychaetes reared on these diets (Fig. 1). We here demonstrated that short-term (≤4 weeks) alterations of environmental parameters have negligible effects on the fatty acid profile in wild caught *H. diversicolor* juveniles. Hence, our results indicate that the major influence on fatty acid composition in *H. diversicolor* is diet.

Introduction
The aim of the project was to test aerobic digestion as a potential environmentally friendly and sustainable bioprocess for the treatment of solid organic waste from recirculating aquaculture systems (RAS) used for rearing of African catfish (Clarias gariepinus). A further aim was to optimize the conditions of this process to maximize the mineralization of organic matter for plant nutrition purposes. Thus, the outcome of the test would be to find the optimal conditions for aerobic digestion (pH, temperature, test duration, addition of external bioculture) and compare their effect on the progress and final degree of waste organic matter mineralization in fish farming. The concentrations of each element (N, P, Fe, K, Ca, Mg, Zn, Mn, Cu) in nutrient solution produced in this way were compared with the values at the inlet of the experiment.

Materials and Methods
The source of organic waste from the rearing of African catfish was an experimental RAS at the Department of Fisheries and Hydrobiology, Mendel University in Brno (Czech Republic). A self-made separator based on the principle of centrifugation and sedimentation of suspended solids in water (vortex) was installed to the already functional system. The raw sludge was dewatered using a hand press, thoroughly homogenized and preserved by lyophilization. Accurately weighed samples of freeze-dried faeces (10 g) were transferred into sterile glass containers and topped up with distilled water to a volume of 1 litre. These laboratory bioreactors were placed in a thermal incubator to maintain a constant temperature. An adequate oxygen supply was introduced into each bioreactor by aeration. Additionally, air bubbling ensured the mixing of the sample in water. Several factors were tested and evaluated. Temperature: three temperature constants of 20 °C, 25 °C and 30 °C were maintained, pH: pH values of 6 and 7 were maintained using a buffer. External bacteria: an external culture of micro-organisms for biological treatment of sewage sludge was added to one variant and their effect on the mineralisation efficiency was monitored. Time: the total duration of aerobic digestion was 21 days. For each temperature there was always a variant without buffer (control), without buffer + external bacteria, buffer pH 6 and buffer pH 7. Each variant was tested in triplicate. Water samples were collected regularly on days 1, 5, 9, 13, 17, and 21 of the experiment. The N-NH₄⁺, N-NO₂⁻ and N-NO₃⁻ contents were evaluated spectrophotometrically using a PhotoLab 6600 UV-VIS and other elements by ICP-OES method.

Results and discussion
N-NH₄⁺ production showed an increasing tendency over time for the pH 6 variants at all temperatures tested. The highest N-NH₄⁺ level (166 mg/l) was reached on day 21 of testing in the pH 6 variant at 25 °C. In all bioreactors without pH adjustment, N-NH₄⁺ production was several times lower than in the case of pH adjustment at 6 and 7. N-NO₃⁻ production was lowest in the variants with pH 6 at all temperatures tested, in contrast to N-NH₄⁺. The lowest nitrification was observed in the bioreactor at pH 6 and 20 °C. The highest N-NO₃⁻ value (101.27 mg/L) was obtained on day 17 of the experiment in the control bioreactor without pH adjustment and without external bacteria at 30 °C. However, at higher temperatures (25 and 30 °C), the N-NO₃⁻ content in the solution decreased gradually. In contrast, the increase in N-NO₃⁻ content was most evident for the pH 7 variants at all temperatures. The highest N-NO₃⁻ content at the end of the experiment was reached in the bioreactor with pH 7 at 30°C. Mineralization of phosphorus (P) was more efficient at higher temperatures. The highest P content (99.93 mg/L) was found at the end of the experiment in the control bioreactor without pH adjustment at 30 °C. Also in the case of the other macro-elements analysed, mineralization proceeded best under these conditions. When comparing the bioreactors with pH adjustment, metal mineralisation was more efficient at pH 6 than pH 7, however, the most efficient mineralisation of metals was achieved in the control bioreactor already mentioned. In all bioreactors, the elements Cd, Pb, Co, Cr and Ni were below the detection limit. Mineralization of organic solid waste without pH adjustment at 30 °C seems to be the most promising. This experiment will be extended in the future by comparing the resulting organic fertilizer with a selected commercial mineral fertilizer based on a hydroponic test. The growth of leaf lettuce (Lactuca sativa) seedlings would be tested in the Nutrient Film Technique (NFT) hydroponic system for 35 days.

Introduction
Atlantic salmon begin their lives in freshwater habitats before migrating to sea to grow and mature. To prepare for life at sea, salmon undergo behavioral, morphological, and physiological transformation, collectively known as smoltification. Key aspects of this life stage transition, such as remodeling of gill function, are well studied and known to be in part controlled by environmental queues like photoperiod (1). One key aspect of adaptation to life at sea is large-scale changes in lipid metabolism and energy homeostasis referred to as metabolic remodeling (2). Relatively little is known about this important seawater adaptation, specifically the timing of metabolic remodeling (pre-adaptation or reaction to life at sea), the impact of photoperiod on gene regulatory programs, and the role of epigenetic changes in smoltification of the liver.

To address these questions, we conducted a time course experiment where Atlantic salmon were exposed to either short- or long-day length, allowed to smoltify in freshwater, and transferred to seawater. We sampled the livers of fish at each key life-stage and measured changes in gene expression, DNA methylation, chromatin accessibility, and transcription factor binding. We test if photoperiodic history affects the smolt liver phenotype at the level of gene expression and use chromatin accessibility data to identify putative regulatory pathways and transcription factors (TFs) involved in life-stage associated changes in liver function from the juvenile stage in the freshwater environment to an adult fish in seawater.

Materials and methods
Atlantic salmon were reared on commercial diets throughout the experiment. Samples of liver were first taken 21 weeks after first feeding (week 1). Fish were then exposed to either “winter-like” (8 hours per day) or “summer-like” (24 hours per day) photoperiod for 10 weeks and sampled (week 10). Another sample was taken after smoltification in freshwater just before seawater transfer (week 19), and again after 6 weeks at sea (week 25). For each time point we performed RNA sequencing on four replicate fish. We also performed RRBS (DNA methylation) and ATAC-seq (chromatin accessibility) on two of the same individuals used for RNA-seq.

To identify gene expression patterns across smoltification we performed an ANOVA-like differential expression test between all four time points of fish exposed to artificial winter. We then generated expression clusters to identify sets of genes that are co-regulated across the smoltification gradient. To identify genes that respond to altered photoperiod, we performed an exact test across different photoperiod groups at weeks 10 and 19. To link DNA methylation status to gene expression during smoltification, we identified differentially methylated regions across the time course using an ANOVA-like analysis and correlated this to associated gene expression changes. To study genome wide transcription factor binding dynamics we identified dips in ATAC peak read depth at predicted TF binding sites (TF footprinting) across all time points.

Results
We find that metabolic remodeling is a preparatory adaptation to life at sea, as large-scale expression changes in metabolic genes occur primarily in freshwater smolts at week 19 before transfer to seawater. We observe a systematic reduction in expression level of genes with a metabolic function, such as lipid metabolism, and an increase in expression of energy related genes in pathways such as oxidative phosphorylation. We also find no impact of photoperiod history on smolt development in the liver in contrast to previous studies in gill. TF footprinting reveals key transcription factor binding dynamics and highlights ZNF682, KLFs, and NFY TFs as important for driving the metabolic shift in liver from parr-like to smolt-like. While genome-wide TF dynamics were highly correlated to observed smoltification related gene expression changes, we did not find a link between DNA methylation status and gene expression patterns.

(Continued on next page)
Discussion
We find that metabolic gene expression decreases in the liver of freshwater fish before transition to seawater. Given that the availability of polyunsaturated fatty acids is higher in seawater environments than freshwater, it is likely that this is a genetically programmed preadaptation to life at sea. This is the first report of smoltification associated DNA methylation and TF binding in liver of salmon during smoltification. Our observation that DNA methylation status is not linked to smoltification gene expression, but TF dynamics are highly correlated highlights the relative importance of chromatin accessibility and TF regulation in the smoltification process.

Introduction

Sustainable aquaculture is dependent on a variety of factors, including water quality and effective feed formulations. To increase sustainability in aquaculture maintaining fish health, alternative protein sources to replace fishmeal (FM) should be used. Insects represent a new world of sustainable and protein-rich sources for farmed fish diets. The yellow mealworm (Tenebrio molitor) is one of the most popular insect species used in aquafeeds. The larvae from this insect are an excellent substitute for FM (Chemello et al., 2020; Terova et al., 2021). While great research efforts have been made to evaluate feed formulations, focusing especially on the effects on fish gut microbiota, few studies have explored host-environment interactions. Here, we evaluated the effects of a T. molitor -based novel feed formulation on the microbiota at the water-fish interface, in an engineered ecosystem farming rainbow trout (Oncorhynchus mykiss).

Materials and methods

Rainbow trout of about 80 g mean initial weight were randomly distributed into 400 L tanks (3 tanks/diet, 21 fish/tank) and fed with either a control diet without insect meal (IM) (diet A), or diets B, C, and D formulated with T. molitor larvae meal at 5%, 10%, and 20% inclusion, respectively. Fish were fed twice a day (at 8 am and 3 pm), 6 days per week. Water samples and water tank biofilm samples were collected to quantify bacterial DNA load by using qPCR. For each water sample, total nitrogen, nitrites, nitrates, ammoniacal nitrogen, and phosphate were measured with a spectrophotometer. At the end of the trial, six fish/diet were sampled from the groups fed with diet A (without IM), and diet D (with 100% FM/IM replacement). The skin mucus microbiota was obtained by gentle scraping of the fish body with a cotton swab, whereas the gut autochthonous microbiota was obtained by scraping the mucosa of the entire intestine. Using 16S rRNA metabarcoding, we comprehensively analyzed the microbiota of water inlet, water, tank biofilm, fish mucus, fish cutis, and feed samples. Raw sequencing data was processed by QIIME2. The Kruskal-Wallis H test for all and pairwise tests were used to compare the groups. Statistical significance between groups was determined by the ADONIS (permutation-based ANOVA, PerMANOVA) test with 10000 permutation-based Bray-Curtis.

Results and Discussion

The microbiological and chemical analysis of water showed no significant differences due to different feeds consumed by fish, proving that FM/IM substitution does not affect water quality. Microbiota analysis revealed the presence of a highly reduced core microbiota, constituted by Aeromonas spp., for both the control group and the novel feed test group. Looking at tank biofilm, Acinetobacter, Pseudomonas, Rhodococcus, and Candidatus Amoebophilus were significantly more abundant in tanks in which diet A was administered. The skin microbial community composition of two dietary groups A and D displayed distinctive features. A decrease of Proteobacteria and specifically of the Deegfa genus in the skin mucus-associated microbiota was found in trout fed with IM. Similarly, at the gut mucosa level, the dietary T. molitor meal inclusion led to a significant reduction of gut Proteobacteria phylum, predominantly belonging to the Gammaproteobacteria class. Furthermore, with respect to the control fish group, feeding IM led to a lower abundance of Acinetobacter genus, another potential pathogen in aquaculture, commonly known as a microorganism transmitting antibiotic resistance genes. Therefore, altogether our findings on gut microbiota indicate that feeding trout with IM has a positive effect through inhibiting the growth of potential Gram pathogen bacteria. By network analysis, we showed that the major driver of microbial community structure was the sample source, with the main differences found between environmental vs host-associated samples. Network analysis indicated that samples clustered based on sample source.

(Continued on next page)
with no significant differences related to the feed formulation. Thus, different feed formulations seemed to not affect the environment (water and tank biofilm) and the fish (skin and mucus) microbiota. Trying to disentangle the contribution of feed at a finer scale, we performed a differential abundance analysis, and we observed differential enrichment/impoverishment in specific taxa, comparing the samples belonging to the control diet group and the insect-based diet group (Figure. 1).

Conclusions
Our results highlight a link between the environment and the fish, and subtle but significant differences due to feed formulation.

IN-SITU MEASUREMENTS OF PARTICLE DYNAMICS IN A RECIRCULATING AQUACULTURE SYSTEMS (RAS) FACILITY – A CASE STUDY

I. A. Henry a, *, R. Podduturi a

a AKVA group ASA
R&D Land Based
Ferjemansveien 10
N-7042 Trondheim (Norway)
Email: Ihenry@akvagroup.com

Introduction

The accumulation of suspended solids in recirculating aquaculture systems (RAS) is a major challenge, as they may affect the health of fish and rearing water quality negatively. In RAS, suspended solids are primarily introduced with the feed and consequently converted by biological processes, such as fish faeces excretion in the fish tank or by the microbiological processes i.e., the biofilters within the water treatment module. Commonly, suspended particles are reported as total suspended solids (TSS), given as dry mass concentration per volume (mg L⁻¹). In RAS, the TSS load strongly depends on the re-use rate, stocking density, fish species, feed quality and the treatment efficiency for solids removal [1]. At exchange rates below 10% per day, the majority of particles can be attributed to excreted faeces, uneaten feed and microbial growth, listed in decreasing order to the contribution to the total load [2]. However, TSS does not give any information on important physical parameters, such as the actual particle size distribution. To accurately determine the particle size distribution, an in-situ approach is necessary, as any sample handling will disrupt the fragile biogenic particles or floc together and thus bias the results.

Objectives

Despite the importance of limiting the concentration of suspended solids in RAS water, little is known about the actual particle size distribution (PSD), concentrations and/or dynamics found in large scale operated RAS facilities. This is important, as each RAS exhibits site-specific particle dynamics because the processes of settling, fragmentation and aggregation are influenced by the local flow conditions [1]. Thus, determining the site-specific PSD is important for optimizing the design of RAS, especially for effective solids removal.

Material and methods

This case study reports in-situ measured dynamics of particles in the range of 0.1 – 500µm in a RAS facility, measured by Laser In-situ Scattering and Transmissometry (LISST). PSD and associated volume concentrations were determined in a single RAS facility, operating two structurally identical RAS units, stocked with 81,000 and 85,000 kg Atlantic Salmon, and fed continuously for 24h with 360 kg and 352kg, respectively. The RAS water treatment module consisted of a drum filter with a mesh size of 60µm, up flow fixed bed biofilters, a CO₂-degasser and ozone treatment. Furthermore, the drum filter discharge was flushed to a plate separator for solids removal, while the effluent was led through an up-flow fixed bed denitrifying biofilter. LISST measurements were taken directly from the fish tank, before and after the drum filters, after the nitrifying and denitrifying biofilters, after the degasser, and at the effluent. However, the high-concentrated sludge discharge from the drum filters had to be diluted prior to LISST measurements. To estimate the mass concentrations of the volume concentration, water samples were taken in selected sites of both RAS and analysed for total suspended solids (TSS).

(Continued on next page)
Conclusions

Results of this case study provide an important first insight into the particle dynamics in RAS with identical construction and similar stocking/feeding loads, as well as daily operations. Results provide vital information for improving water and solids treatment design and understanding particle dynamics in RAS facilities.

Introduction

In the search for sustainable replacement of marine ingredients in aquafeed, relatively high levels of plant oils (PO) have been successfully included in the diet of freshwater and/or herbivorous fish species without affecting fish growth or health as long as requirements of n-3 long chain polyunsaturated fatty acids (LC-PUFA) were covered by the basal levels of marine ingredients (Sankian et al., 2019). The level of feasible inclusion is however lower in marine and/or carnivorous fish due to their inability to desaturate and elongate C18 PUFA, rendering them more prone to n-3 LC-PUFA deficiencies (Tocher, 2010). Below a certain dietary level of fish oil (FO), the fatty acid (FA) profile of the fish fillets produced are affected by the richness of PO in C18 FA and their deficiency in n-3 LC-PUFA. However, concomitantly to the ‘healthy’ FA, FO may also bring persistent organic pollutants. Because of the more sustainable and lower cost of PO and their low contaminant concentrations, it makes sense to increasingly use PO in aquafeeds (Belanger-Lamonde et al., 2018) but a strategy must be applied to recover the n-3 LC-PUFA rich FA profile of fish fillet, so important for human health. Such strategy involves the replacement of PO by marine ingredients in finishing diets some months before the fish commercialization. These ‘wash-out’ strategies have been tested in several fish species using oils rich in n-3 PUFA such as FO or microalgae (AO). The aim of the present study using such strategy in a marine carnivorous fish species of great economic importance in the Mediterranean region, the European sea bass (*Dicentrarchus labrax*), was to investigate if the potential drawbacks of long-term feeding with plant oil can be reverted by switching the fish to FO or AO diets for 11 weeks before reaching their commercial size.

Materials and Methods

Two microalgal species, *Nannochloropsis* sp. and *Schizochitrium* sp., were chosen for their richness in eicosapentaenoic acid (EPA, 4.5%) and docosahexanoic acid (DHA, 27.2%) respectively. The three experimental isonitrogenous (44.5%), isolipidic (17.5%) and isoenergetic (21.8MJ/kg) diets consisted in a control diet containing 9% FO and 6% rapeseed oil (RO) (FO diet), one diet containing 3% FO and 12% RO (PO diet) and a microalgae diet containing 7.2% *Nannochloropsis*, 3% *Schizochitrium*, 3% FO and 9% RO (AO diet). The microalgae mixture composition includes not only lipids but also high amount of proteins so the amount of soybean concentrate and wheat meal of this diet were reduced compared to that of the FO and PO diets. Diets were formulated and produced by extrusion at HCMR.

Continued on next page
European sea bass individuals of 198 g initial body weight were distributed in 12 nets of 0.84 m³ in 4 cement 5 m³ tanks in an open-flow system. Diets FO and AO were fed to triplicate nets while PO diet was supplied to 6 nets, all diets supplied twice daily to satiation over a period of 13 weeks. Thereafter, fish were allocated to new diets in duplicate nets for the washout phase of the trial which lasted for another 11 weeks (24 weeks in total). Fish fed FO or AO continued being fed the same diet while fish fed the PO diet were switched to FO or AO or maintained on PO. Feed consumed (g) was recorded daily. Fish were weighed individually at the beginning, intermediately and at the end of the experimental trial. The evaluation of the wash out strategy was done in terms of feed efficiency, fish growth and nutritional composition, FA profile recovery, digestive histology and immunology.

Results and discussion
The growth and feed utilization of the fish (Table 1) showed no significant difference between the different experimental groups at any sampling point, as all diets were well balanced and covered the basic needs of the fish. However, as expected, the FA profile of the fillets of all experimental groups mirrored the dietary profile. Indeed, after 24 weeks feeding with the PO-based diet, the FA profile was significantly affected with decreased levels of EPA and DHA to 69 and 62% compared to FO-fed fish respectively. The diet switch from PO to FO or AO diets 11 weeks before the end of the trial enabled the recovery of 93% and 83% omega-3 polyunsaturated fatty acids respectively.

The microalgae-based diet which may enable aquaculture professional to lower their dependence on fish oil and thus to lower the pressure on wild fish stocks, enabled partial recovery of the FA profile. Moreover, this AO diet increased the antibacterial activity of the fish sera with increased complement bactericidal activity in fish serum. Liver morphology was similar in all groups with slightly higher fat deposition in the PO group. Partial tissue recovery was observed in fish switched to fish oil or microalgae containing diets.

Introduction

The feeding practices in farmed salmon have traditionally relied on fishmeal and fish oil as primary protein and fatty acid sources due to their high bioavailability 1,2. However, the need for sustainability and the expansion of aquaculture necessitate the exploration of alternative resources to reduce dependence on marine ingredients and enhance feed efficiency and economic viability 3. To address this challenge, plant-based alternatives to marine ingredients have gained attention 4,5. In the salmon breeding industry, achieving high production of high-quality oocytes, embryos, and larvae is crucial, and the nutritional requirements of the broodstock play a fundamental role in this process 6,7. Nevertheless, the substitution of fishmeal and fish oil with vegetable ingredients, poses potential challenges to achieving optimal broodstock nutrition. Consequently, it is essential to assess the impact of dietary changes during gonadal recrudescence on reproductive efficiency and embryo quality in Atlantic salmon (Salmo salar) females, with the aim of optimizing the management of this species in freshwater environments.

Materials and methods

Four diets were employed in this study to assess their impact on the reproductive performance of Atlantic salmon (Salmo salar) during gonadal recrudescence. The diets included: marine ingredients diet (Diet 1); partial substitution diet where marine origin meals and oils were replaced by terrestrial animal and plant sources (Diet 2) and two commercially available Atlantic salmon broodstock diets used for comparison purposes (Diet 3 and 4). Each diet was administered to duplicate groups (circular tanks of 5,000 m³ each) of 15 female and 5 male S. salar for six months during gonadal recrudescence. Upon reaching the spawning stage, several zootechnical parameters and reproductive characteristics were evaluated. These included the measurement of weight, length, condition factor (K-factor), hepatosomatic index (HSI), and gonadosomatic index (GSI). Additionally, spawn mass, absolute and relative fecundity, oocyte quality (diameter and hydration percentage), fertilization rate, and blastomere symmetry were assessed. Furthermore, the survival and quality of embryonic development were evaluated by examining specific parameters such as microphthalmia, spinal malformations, siamese twins,

Among the various zootechnical parameters assessed, including weight, length, K-factor, and GSI, no significant statistical differences were observed between the diets (Table 2). However, a trend was observed where commercial diets tended to exhibit higher weight and length compared to the experimental diets. Furthermore, Diet 1, which was based on ingredients of marine origin, displayed a significantly higher HSI compared to the other diets.

Discussion and conclusion

In conclusion, the lower maturation rate and subsequent decrease in the number of spawned females observed in the groups fed commercial diets may be attributed to a potential nutrient imbalance. It is noteworthy that these diets had higher gross energy content compared to the other experimental diets. This finding aligns with existing knowledge that low protein diets in carnivorous fish can extend maturation time, reduce reproductive performance, and decrease ovulation frequency 8.

(Continued on next page)
The significance of nutrition in gonadal development is crucial and extends beyond its effects on maturation. It also plays a pivotal role in other biological responses, such as fecundity. Hence, the results underscore the importance of reevaluating diet formulations for Atlantic salmon broodstock, as it holds the potential to enhance reproductive efficiency in the industry by increasing the number of mature females and improving embryo production.

Consequently, further research is warranted to investigate the optimal inclusion levels of nutrients, particularly energy, or the incorporation of other additives that can enhance the utilization of these nutrients within diet formulations. Exploring these aspects will provide valuable insights for optimizing the nutrition of Atlantic salmon broodstock and improving their reproductive performance in aquaculture.

Introduction

Aquaculture is a main economic activity worldwide and specially in Chile, where the farm fish production is very intensive, which expose fishes to conditions that facilitates the attack of ectoparasites which produce skin lessions that constitute potential entry points for secondary pathogens, increasing the risk of diseases and stress, therefore affecting animal welfare and also production 1. In this context, tissue regeneration processes are fundamental and the use of natural compounds and extracts that could improve the animal regenerative capacity and immune system, is of great interest 2. In this work we evaluated the benefits of Aloe vera (Aloe barbadensis miller, AV) extracts diluted directly in the medium and included as a food additive in different formulations with a protein base of animal and vegetable origin 3. While is known that feeds with a vegetable protein base cause intestinal inflammation in several fish species 4 and that this effect can be reduced by AV 5,6, the impact of AV on tissue regeneration on wounds or other types of external insults, has not been investigated to date. To assess if AV administration improves the regenerative capacity on fish larvae, we applied a protocol to induce a wound and controlled tissue damage. To that end we took advantage of the zebrafish (Danio rerio) teleost model, and evaluated tissue regeneration, the cellular innate immune response and the transcriptional activity of genes implicated in these processes.

Material and methods

To quantify the impact of AV in tissue regeneration, a caudal fin and tail tip amputation protocol was used in zebrafish larvae exposed through immersion at 3 days post fertilization (dpf) and orally at 9 dpf. In the first instance, AV was administrated by immersion from 24 h before (pre AV) and until 3 days after (pre + post AV) amputation. Also 5 hours post amputation (hpa) the recruitment of phagocytic cells was quantified in the amputated area, and to further characterize the tissue response at the molecular level, we also evaluated transcriptional activity of genes implicated on immunity, regeneration, and oxidative stress by RT-qPCR. Finally, 5 days post amputation (dpa) the regenerated area was quantified.

On the other hand, for feeding experiments, two basal diets were used: one with protein of animal origin (FM) and other with vegetable origin (SBM). In these experiments the amputation protocol was established at 9 dpf with 4 days of previous feeding, and the regenerated area was measured at 16 dpf (12 days of total feeding). Additionally, immune cells recruitment was quantified at 5-6 hpa.

To achieve this a zebrafish transgenic reporter line expressing the red fluorescent protein (DsRed) under the control of the Lysozyme C gene promoter, Tg(lysC:DsRed) was used. This reporter line allowed us to see and track in vivo leukocyte cells (macrophages and neutrophils) in the amputated area, and therefore to evaluate in real time the cellular response of the innate immune system after injury.

(Continued on next page)
Results and conclusions

The results of AV in immersion experiments showed a greater leukocyte arrival to the amputated area in both groups previously incubated with AV, the same groups also showed a significant increase in the regenerated area at 5 dpa in relation to the control group. The molecular analysis showed that by 6 hpa the transcription of inflammatory genes was increased in the pre incubated groups, as were the genes that code for antioxidant enzymes, compared to the control group. At 24 hpa, genes involved in regeneration processes were significantly increased in the pre AV and pre + post AV groups, while transcription of the inflammatory and antioxidant genes remained elevated. To establish the protocol for diet trials, regeneration by 5 and 7 dpa was evaluated, obtaining significant differences between the basal diets FM and SBM at 7 dpa, where FM showed a greater regenerated area in the tail tip and caudal fin in relation to the SBM inflammatory diet. Later, the effects of a FM diet supplemented with AV (FM+AV) versus FM was evaluated, and results showed that regeneration is significantly higher in the FM+AV group. Similarly, a SBM diet supplemented with AV (SBM+AV) was evaluated, and we were able to detect that a greater recruitment of immune cells to the wound at 5 hpa, and a greater regenerated area in this group in comparison to the group fed with SBM diet. Our results suggest that AV, both dissolved in the medium and added to feed formulations, enhances the regenerative process in zebrafish larvae, and triggers a significant immunostimulatory effect that could explain this enhancement in cell proliferation and tissue repair. Trials with diets and immersion are still ongoing to reproduce and extend our results and solve questions about how AV is producing this effects and how this extracts can be optimally included in fish farm practices to improve animal health and specially wound recovery after skin damage.

Introduction

Intensive perch culture in recirculating aquaculture system (RAS) provides optimal culture conditions for rapid fish growth, high survival rate, shorter production cycle, reduction of fish stress and cannibalism. In order to ensure a high productivity and reduced production costs, several rearing conditions have to be optimized. Larvae of percid species are strongly phototactic therefore, the varied photoperiod is a factor that can significantly affect the efficiency of rearing. Current knowledge in this matter for Eurasian perch larvae is still very limited.

Material and methods

Larvae from wild Eurasian perch spawners were obtained followed reproductive protocol and reared up to 13 DPH according to standardized procedure described by Palińska-Żarska et al. (2020). Afterwards, 28 days experiment was set, where four variants of different photoperiod (L:D – light:dark) i.e. 24L:0D; 20L:4D; 16L:8D and 12L:12D were tested. Throughout the entire rearing period, the intensity of light, measured at the water surface was 900 lux. The sudden weaning procedure at 21 DPH was used, 7 days after photoperiod variants were established. At the end of the experiment 30 perch post-larvae from each group were euthanized, individually weighed, measured and relevant growth parameters were assessed: coefficients of body length variation \[ CV_L(%) = 100 \frac{SDL}{L} \times \frac{L}{100} \], where L is the mean body length and SDL is the standard deviation of body length; coefficients of body weight variation \[ CV_W(%) = 100 \frac{SDW}{W} \times \frac{W}{100} \], where W is the mean body weight and SDW is the standard deviation of body weight; Fulton’s condition factor \[ K = \frac{W}{L^3} \], where W is the mean body weight and L is the mean total length; specific growth rates \[ SGR(\% \text{ day}^{-1}) = 100 \times \frac{(\ln W_F - \ln W_I)}{t} \times 100 \], where W is the mean final body weight and WI is the mean initial body weight (g); t is 28 days. Moreover, cumulative mortality were calculated including the percentage of fish prey of cannibals. The data expressed in percentages were arcsin transformed before the statistical analysis. Data were compared using one-way ANOVA. A non-parametric Kruskal-Wallis’ test was used to evaluate the differences in analysed parameters (p<0.05). Analyses were performed using Statistica software (StatSoft).

Results

The analysis revealed no statistically significant differences (p<0.05) between groups for final length and weight of larvae, Fulton’s condition factor, SGR index, as well as in mortality (Table 1). On the other hand, such differences in the final values of coefficients of body weight and length variation were revealed with the smallest value recorded for the 20:4 photoperiodic regime.

Discussion

Lack of significant differences of perch larvae growth parameters reared under different photoperiod conditions suggest the limited influence of this abiotic factor on rearing efficiency. However, increased mortality of perch post-larvae after the change in the type of food and the violent transition from Artemia nauplii to artificial feed was confirmed. According to data Kestemont et al. (2015) perch larvae cultured under 24L:0D light conditions had significantly higher survival (56.2%) compared to those that had 12L:12D and 16L:8D photoperiod (45 and 49%), respectively, as well as on the final fish mean mass. It is likely that increased day length impacts the behaviour of both potential cannibals and potential prey. The day length did not significantly influence the survival of Eurasian perch but the proportion of mortality due to cannibalism was significantly reduced when day length was decreased from 24:0 LD to 8:16 (Kestemont et al. 2003; 2015) which was also reported in the present study.

ASSESSING THE PERFORMANCE OF WATERBORNE FEEDING SYSTEM IN A LAND-BASED POST-SMOLT FACILITY

I. Holm, H. Kjartansson and A.N Dale

Hofseth Aqua AS
Tafjordvegen 1385
NO-6213, Tafjord
inho@hofseth.no

Introduction
Waterborne feeding systems have gained significant attention in land-based aquaculture due to their potential to improve feed distribution flexibility, reducing microplastic emissions and energy consumption. This feeding system involves delivering feed pellets through water instead of traditional feeding methods such as airborne feeding. By replacing the transporting medium with water, the system is gentler on the feeding pipes and reduce the breakage of feed pellets. Less microplastics is released, thus reducing the environmental impact from the facility.

These systems rely on pumps, pipes, and spreaders to distribute feed throughout tanks, allowing for precise control over feeding rates and reducing feed waste. Waterborne feeding systems can be automated, allowing for more consistent feeding and freeing up labor resources. However, waterborne feeding systems require technical expertise and specialized knowledge to operate and maintain, and can be subject to malfunction, potentially affecting fish health and growth.

With capacities of up to 50 kg feed per minute from each line, the opportunity to schedule feed based on peaks and lows in appetite during the day is far greater. This allows the growth potential to increase and feed conversion rate (FCR) to reduce.

Method
At Hofseth Aquas facilities in Tafjord, Norway, we have a permission of raising 2,000 tons in biomass of rainbow trout ranging from 125g to 1000g. The post-smolt facility contains six tanks with a size of 18m x 4,85m (1234m³). Seawater from depths of 55m and 35m is treated with UV-filters which is used both in process and through the feeding-system. Water within tanks is renewed each hour using 80% new treated water, and 20% recirculated water using degassers.

Tests of waterborne feeding systems and adjusting numbers of feeding outlets to the tanks initiated in January and February. Two tanks had four feeding points installed, and two tanks had eight points installed. We observed visually and using submerged cameras how the fish behaved and how feed pellets were distributed from the feeding points.

To measure the effect of the feeding system, growth rate, feed conversion rate and energy consumption is compared to existing data from our facility which uses traditional feeding systems.

Results
One of the challenges with a waterborne feeding system has been its sensitivity to changes in water pressure. Malfunctions such as low water pressure can temporarily stop the system from operating and can result in lost opportunities for feeding and growth.

Distribution of feed through water has also been difficult compared to airborne distribution. The amount of feeding points in tanks had to be high enough to ensure a good distribution of the areal, while maintaining the water pressure for equal amounts of water and feed to reach each point. With fewer points of feeding, fish gathered in high density, creating empty areas in the tank. With more points of feeding, fish was distributed better in the tanks area, but feed pellet distribution was not satisfactory due to unequal water pressure.

A combination of a high amount of feeding points at different debts and reducing the pipe dimension to maintain optimal water pressure will be ready for testing in May, and results and further development will be presented at the conference alongside results of growth rate, FCR and energy consumption.
Paecilomyces variotii IN NOVEL FEEDS FOR ATLANTIC SALMON: EFFECTS ON PELLET QUALITY, GROWTH PERFORMANCE, NUTRIENT DIGESTIBILITY AND UTILIZATION, AND IMMUNE-RELATED BIOMARKERS IN THE DISTAL INTESTINE

*Department of Animal and Aquacultural Sciences, Faculty of Biosciences, Norwegian University of Life Sciences
P.O. Box 5003, NO-1432 Ås, Norway

*E-mail: jamie.marie.hooft@nmbu.no

Introduction
Filamentous fungi are promising microbial ingredients (MI) for use in aquaculture feeds due to their high protein content and bioactive components. Paecilomyces variotii (also known as PEKILO® mycoprotein) is a β-glucan- and nucleotide-rich MI with a crude protein content of about 60-70% (Bajpai, 2017). The objective of the current study was to evaluate the effects of P. variotii produced from sulfite stillage derived from forest by-products on pellet quality and growth performance, nutrient digestibility and utilization, and expression of immune-related biomarkers in the distal intestine of Atlantic salmon (Salmo salar) reared in freshwater.

Materials and methods
Four isonitrogenous, isolipidic, and isoenergetic diets were formulated. Diet 1 was a control diet formulated with fish meal, soy protein concentrate, and wheat gluten meal as protein ingredients. Diets 2, 3, and 4 were formulated so that P. variotii replaced 5, 10, and 20% of the crude protein content of the diets, respectively. Groups of 40 fish (initial average body weight of 24 g fish⁻¹) were fed the experimental diets ad libitum in triplicate tanks for a period of 9 weeks. Daily feed intake in each tank was quantified by collection of uneaten feed using wedge wire screens. Fish were batch weighed at the start and end of the experimental period. Following the 9-week period, six fish per tank were randomly sampled and a small section of the distal intestine closest to the anus was collected and secured in RNAlater for gene expression analysis. Moreover, a pooled sampled of 20 whole fish at the start of the experiment and five fish per tank at the end of the experiment were randomly sampled for chemical analysis. The remaining fish in each tank were carefully stripped for fecal collection from the posterior intestine for determination of nutrient digestibility.

Results and discussion
Increasing levels of P. variotii in the feeds was associated with changes in physical pellet quality, including significant linear and/or quadratic decreases in pellet length, pellet width, expansion, and durability. Conversely, significant linear and quadratic increases in water activity, bulk density, sinking velocity, and water stability index were associated with increasing dietary levels of P. variotii. The changes in physical pellet quality may be attributable to the high total fiber and β-glucan content of P. variotii. There were no significant differences in weight gain, growth rate or feed intake among fish fed the experimental diets, but a significant linear improvement in feed conversion ratio with increasing dietary inclusion level of P. variotii was observed (Table 1). The apparent digestibility coefficients for crude protein and gross energy of the experimental diets decreased linearly with increasing dietary levels of P. variotii. Similar results were observed for the essential and non-essential amino acids. Nonetheless, linear increases in nitrogen, energy, and mineral retention efficiencies were observed with an increasing inclusion level of P. variotii. This has also been reported in salmon fed other MI including bacterial meal and yeast (Overland et al., 2010; Overland and Skrede, 2017). Interestingly, dietary inclusion of P. variotii resulted in significant upregulation in the expression of several cytokines (tnfa, ifng, il10, and tgb), effector molecules (inos, arg1, sod), and transcription factors (irf4) in the distal intestine (Figure 1). These results suggest that P. variotii can induce the activation and control of the immune response through promoting pro- and anti-inflammatory responses, supporting immune homeostasis in the distal intestine, a mucosa-associated lymphoid tissue (MALT) (Morales-Lange et al., 2022).

Conclusion
Overall, replacement of up to 20% of the crude protein content of the feed with P. variotii improved feed conversion ratio and nutrient utilization efficiency of Atlantic salmon juveniles reared in freshwater. In addition, P. variotii also showed immunomodulatory effects in the distal intestine. P. variotii is a highly promising alternative ingredient for use in salmon feeds.

A SYNTHESIS – STARCH, AN ANTINUTRITIONAL FACTOR FOR YELLOWTAIL KINGFISH *Seriola lalandi*

**Kingfish Zeeland, The Kingfish Company, Kats, The Netherlands**  
**Aquaculture and Fisheries Group, Wageningen University and Research, Wageningen, The Netherlands**  
E-Mail: peter.horstmann@wur.nl

Introduction

Farming yellowtail kingfish (*Seriola lalandi*) in recirculating systems is challenging due to its instable and fine faecal particles, which hampers the faecal solid removal. Accumulation of total suspended solids potentially affect fish health, system performance and environmental eutrophication negatively (Reid et al., 2009). Feeding yellowtail kingfish with raw natural feed items resulted in distinct faecal pellets and short strings (Horstmann et al., 2023). When these natural feed items were included (freeze dried and ground) in pelleted diets containing 15% starch, faecal pelleting was absent. A study with juvenile white sturgeon (*Acipenser transmontanus*) by Hung et al. (1990) suggested that starch could negatively affect the reabsorption of water in the distal tract due to the high water binding capacity or lead to fermentation processes (indicated by production of volatile fatty acids (VFA)), thus negatively affecting faecal characteristics. Three studies were conducted with the focus of investigating the effect of dietary starch content on fish performance, faecal removal efficiency (both by settling and drum filtration) and digestion kinetics along the intestine.

Materials and Methods

Two diets varying in starch content were produced by either including 0% or 20% gelatinized wheat flour. Juvenile yellowtail kingfish were fed restrictively (study 1 and 2 on DM basis, study 3 on crude protein basis). Study 1 and 2 aimed to investigate the effect of starch level on faecal removal efficiency by settling and drum filtration, respectively. Study 3 aimed to investigate underlying mechanisms for observed differences throughout previous studies.

Results

**Study 1:** Low starch diet had a higher faeces removal efficiency by settling by 62% compared to the high starch diet (p < 0.001; Fig. 1a). Fish fed low starch diet excreted faecal pellets, while high starch diet resulted in poor faecal integrity (Fig. 1b).

**Study 2:** Faecal removal efficiency by drum filtration was not affected by dietary starch level (Fig. 2a). However, to achieve similar removal efficiencies at high starch systems, the drum filter frequency had to be on average 210% compared to low starch systems.

**Study 3:** Feed intake on crude protein and fat was equal among treatments, but fish fed high starch diets had a higher energy feed intake. High starch diets did not result in an improved growth, even high starch diet resulted in a numerically lower growth. High starch diets resulted in significantly higher chyme moisture content in the proximal and mid gut, but not in the distal gut. Butyric acid (VFA) was significantly higher at fish fed high starch diet.

Conclusion

Supplying additional energy in form of starch does not positively affect fish growth. High starch level induce a poor faecal integrity in yellowtail kingfish, hampering its removal by settling and drum filtration. Results study 3 suggests that this might be related to fermentation processes.

Introduction
Worldwide, aquaculture represents about 44% of the total fish production (FAO, 2022) and it is estimated that about 70% of aquaculture production is leaning on commercial feed sources. Fish meal contains high levels of dietary essential amino acids and essential fatty acids (ω6 and ω3 highly unsaturated fatty acids) that promote rapid growth. Nutritionally well-balanced diets/feeds play an important role to ensure high/optimal fish performance, maintaining good health and minimizing waste production. The objective of the study was to evaluate the shelf life of three different fish (i.e. gilthead sea bream, shaoor and Atlantic salmon) during refrigerated storage and to investigate the impact of conventional cooking in an oven on the composition and nutritional value of fish flesh. For farmed gilthead seabream, two alternative diets were also investigated, based on 45/12 or 43/16 protein/fat ratio, in order to evaluate the effect of fat content in diet on the nutritional value of farmed fish.

Materials and methods
Farmed gilthead seabream (Sparus aurata) was obtained from Tabuk Fisheries Co., wild shaoor (Lethrinus mahsena) and imported Atlantic salmon (Salmo salar) were purchased from the local marked (fish weight: 1 kg) and within 24 h samples were transported in polystyrene boxes with appropriate quantity of flake ice. For farmed gilthead seabream, two alternative diets were investigated, based on different protein/fat ratio, i.e. F1: 43/16 protein/fat ratio, F2: 45/12 protein/fat ratio, in order to evaluate the effect of FA composition of fish feed on the nutritional value of fish flesh. Conventional cooking in an oven for 45 min at 180°C was considered as a representative meal preparation for the evaluation of the nutritional value of the final product. The total nitrogen content was determined on 200 mg of sample using a micro system of Kjeldahl method. The profile of amino acids was determined by LC-MS/MS. The profile of amino acids was determined by GC/MS. For shelf life evaluation, fish was isothermally stored at 4°C. At predetermined times, a representative sample of 90 g of fish flesh were homogenized with 225 mL sterilized Ringer’s solution (Ringer tablets, Merck, Darmstadt, Germany) for 60 s with a Stomacher (BagMixer © interscience, France). Samples (0.1 mL) of 10-fold serial dilutions of fish homogenates were transferred into the appropriate media on Petri dishes for the enumeration of Total Viable Count (TVC) and Pseudomonas spp. TVC was enumerated on plate count agar (PCA, Merck, Darmstadt, Germany) after incubation at 25°C for 72 h. Pseudomonas spp. were enumerated on Cetrimide agar (CFC, Merck, Darmstadt, Germany) after incubation at 25°C for 48 h. The microbial growth was modelled using the Baranyi Growth Model (Baranyi and Roberts, 1995). For curve fitting the program DMFit (IFR, Institute of Food Research, Reading, UK) was used (available at http://www.combase.cc/index.php/en/). Kinetic parameters such as the rate (k) and lag phase (λ) of microbial growth were estimated.

(Continued on next page)
Results
The content and the composition of specific fatty acids in fish flesh are of high importance for assessing fish quality and nutritional value. Regarding ω3 fatty acids, EPA, DPA, ALA and DHA are essential fatty acids for human health that cannot be synthesized by the human body, so they have to be sourced from food. In the present study, sea bream contained important contents of ω3 fatty acids and especially fish fed the F2 diet (2400-2900 mg/100g sample). Trans fatty acids were not detected in any of the tested samples. The observed values of protein content are within the reported levels for fresh Mediterranean fish. For gilthead seabream fed the alternative diets, protein content was similar to the values reported in the literature for Sparus spp. fish (19.0-22.8%). Regarding the essential amino acids fraction, glutamic acid, aspartic acid were the most abundant, followed by methionine. In fact, fish contains high amounts of protein and balanced proportions of all amino acids relative to human requirements. No significant differences were observed in gilthead seabream fed the two alternative diets (i.e. F1 and F2). Pseudomonas spp. dominated spoilage in all aerobically stored samples. Based on the microbial growth data and considering a limit of acceptability as 10^7 cfu/g for total viable count, the shelf life of from gilthead seabream, shaooor and salmon at 4°C was estimated as 8, 8, 8 and 7 days, respectively (Tsironi et al., 2020). No statistically significant differences were observed in gilthead seabream fish fed the tested alternative diets (data not shown).

Discussion
The results of the study indicated that thermal processing did not affect the beneficial amino acids and unsaturated fats in fish tissues, thus conventional cooking in an oven for 45 min at 180°C retained the nutritional value of all the tested fish products.

References
Current estimates suggest over 2 billion people worldwide suffer from a micronutrient deficiency (MND). This figure is expected to increase with a growing global population unless existing food practices change. With limited agricultural land and increasing evidence that common farming practices negatively impact the environment and human health, there is an urgent need for novel farming techniques. In particular, the development of novel onshore aquaculture approaches, such as marine bivalve micronutrient fortification, offers considerable promise for easing these global challenges. This work explores the strong potential value bivalves present for food security. We first compare three bivalves, oyster, mussel, and clam nutrient profiles against top alternative protein nutrient profiles before laying the groundwork for developing optimised feeds for tailored micronutrient uplift in marine bivalves. This all in the setting of onshore bivalve aquaculture facilities holds a significant promise for addressing MNDs whilst mitigating the current human health risks associated with consumable bivalves.

### Bivalves as a Solution to Malnutrition

It is important that highly nutritious foods are farmed and produced at scale. Comparing the nutritional profile of ocean-based livestock (OBL): bivalves, salmon, and lobster, reveals bivalves are rich in protein, but also in micronutrients (MNs) that are consistently lacking within the global population. Furthermore, growing awareness of the environmental impact of meat and dairy farming has led to increasing interest in novel alternative protein sources (APs) to support food security. Nutritional profiling of bivalves compared to the five top alternative proteins: cricket meal, tofu, tempeh, Quorn, and meatless beef; show bivalves contain comparable levels of protein (Table 1) and generally much higher amounts of key micronutrients than other APs (Table 1).

As aquaculture feed is the main contributor of carbon emissions in aquaculture, we have also developed algal feeds as a nature-based solution to bivalve micronutrient fortification. Algae are the predominant source of food for bivalves in the ocean, and naturally contain various micronutrients. Optimised algal feeds show strong promise to reduce the carbon footprint of urban bivalve aquaculture and offer a more sustainable means of micronutrient support for deficient individuals within the human population.

Conclusion & Future Directions

The present work highlights the promising role of fresh, marine bivalves in addressing current population MNDs, as well as being a highly nutritious food source. The development of a novel urban marine bivalve aquaculture systems paired with non-GMO fortification not only sets the groundwork for its translational use towards addressing global food security, but also aids in addressing fundamental questions that are still unknown in bivalve mariculture, and MND reduction within the human population.

Future work will include optimizing bivalve growth, decreasing bivalve related health hazards, and expanding micronutrient fortification capabilities within an artificial setting. We believe elucidating these methods is a necessary step towards developing scalable technologies for onshore urban marine bivalve aquaculture, gaining consumer trust around bivalve consumption, and ultimately delivering the nutritional promises marine bivalves have to offer.
CONSCIOUSNESS INDICATORS AND CARDIAC RESPONSES OF EUROPEAN SEABBASS TO DIFFERENT SLAUGHTERING PROCESSES

Introduction
Harvesting and slaughter are the final steps in the production cycle for all farm animals used for human consumption. During the process, a large number of actions can affect fish welfare. The key point of humane slaughter is to ensure that the animals become unconscious rapidly and that this state lasts until death. Slaughter is generally a two-step process, stunning and killing. In industrial seabass and seabream aquaculture, the most commonly used slaughter method is suffocation and immersion in ice water (ice-slurry), where the animal remains conscious for a long period (several minutes) during which there are indicators of distress (inferred through physiological and behavioural responses) before death (EFSA 2009).

Regarding seabass, there are diverse studies comparing different stunning and killing methods, with a strong component on flesh quality assessment (e.g. Papaharisis et al. 2019; Simitzis et al. 2014; Zampacavallo et al. 2015; Acerete et al. 2009; Tulli et al. 2015). Most of these studies pointed towards the necessity to improve the knowledge of slaughtering methods to reduce stress and suffering of fish. Thus, the goal of this study was to assess levels of unconsciousness and cardiac response of seabass exposed to different slaughtering procedures.

Material and Methods
This study was carried out in the experimental facilities of IRTA located in La Ràpita (Spain). European seabass of about 1 kg in weight were randomly selected, and surgically implanted with bio-loggers capable to measure heart rates and internal temperature (DST milli HRT, 13 mm × 39.5 mm, 11.8 g, Star-Oddi®, Iceland, www.star-odd.com). For the surgery, we followed the steps developed by Mignucci et al. (2021). Right after the surgery the fish was placed in a quarantine tank and monitored until full recovery. All tagged fish were kept in rearing tanks for several weeks before the slaughtering experiment. The experimental approach consisted on a combination of pre-slaughtering procedures and slaughtering techniques in order to assess the cardiac response through heart rate variations before and after the slaughtering moment.

Results and Discussion
Observed indicators of consciousness differed among assessed slaughtering techniques. Individuals euthanized by ice-slurry took significantly longer to stop moving their fins and stop breathing than individuals euthanized by overdose of anaesthesia or ikejime. Regarding the bio-loggers, mean heart-rate values and patterns differed during the various combinations. The time until the heart rate signal becomes undetectable varies depending on the slaughter technique. Heart rate of seabass individuals slaughtered using ikejime showed a high peak instantly after slaughter, but heart rate dropped immediately, stopping after 30 minutes. For seabass slaughtered with anaesthesia, heart rate values decreased gradually to basal values, being undetectable after 35-40 minutes after slaughtering. Regarding seabass individuals slaughtered in ice-slurry, the heart rate dropped under basal value, but was detectable up to 45-50 minutes after the start of slaughtering.

It is worth to mention that in this latter case, the internal temperature of tagged seabass individuals decreased gradually (not immediately) when exposed to such cold conditions. If we add the effects of the pre-slaughter methods (fasting and crowding) on the cardiac response after slaughtering, it can be seen that the time when heart rate can be detected is reduced in both cases, being furthermore distinct at different seasons (winter and summer). Therefore, in this study we demonstrate the effects of the different slaughtering methods on the behavioural, mental and cardiac response of seabass, providing relevant information for the future development of more humane techniques.

Introduction

Artificial propagation is an essential source of sturgeon progeny for both commercial and conservation purposes. However, in culture settings sturgeons often spontaneously produce offspring with altered ploidy – mainly autotriploids having in somatic cells 1.5-fold more DNA than ‘normal’ fish. Autotriploidy can impact reproductive performance, the presence of autotriploid rather than normal individuals may thus decrease farm productivity or wild population recovery (Schreier et al., 2021). In this three-year study, we tested whether the temperature for holding female broodstock (female-holding temperature; FHT) and/or the temperature for fertilization of eggs and subsequent incubation of embryos (fertilization and incubation temperature; FIT) contribute to the incidence of spontaneous autotriploidy in sterlet (*Acipenser ruthenus*).

Material and methods

Due to the capacity for holding females at individual temperatures and the availability of ripe females, the study was performed in five experiments. Two experiments were designed to assess A) the effect of various FHTs (FHT-experiments), and three experiments to study B) the effect of various FHTs, various FITs, and potential FHTs to FITs relationships (FHT+FIT-experiments). The respective FHTs were reached several days before hormonal stimulation and kept until egg collection. In FHT-experiment 1 and FHT+FIT-experiment 1, we used several temperatures from the optimal range for spawning of females (11–17 °C, Detlaff et al., 1993), i.e. 12, 14, and 16 °C. In FHT-experiment 2 and FHT+FIT-experiment 2, FHT from the optimal range, 15 °C (preferred temperature at the authors’ workplace), and two above-optimal FHTs, 18 and 20 °C, were used. An additional experiment was conducted with FHT below the optimal range, 10 °C, and FHT 15 °C; FHT+FIT-experiment 3. In each experiment, the samples of eggs from three females at a given FHT were utilized, except for FHT 20 °C in FHT+FIT-experiment 2 with the eggs obtained from a single female only. Eggs were always collected within 2h post-ovulation and fertilized within 30 min using a common methodology (Gela et al., 2008). In FHT-experiments, the eggs of each female were fertilized individually (single female at a time) using water at 15 °C, the same temperature was used for subsequent incubation. In FHT+FIT-experiments, the eggs of the females at the same FHT were pooled, mixed properly and the resulting egg mixture was split into aliquots, each of them being subsequently fertilized and incubated at 12, 14, and 16 °C (FHT+FIT-experiment 1); 15, 18 and 20 °C (FHT+FIT-experiment 2); or 10 and 15 °C (FHT+FIT-experiment 3). Ploidy was analyzed using flow cytometry in 2-3d post-hatch prelarvae according to the methodology of Hubálek and Flajšhans (2021).

Results and discussion

Only low proportions of autotriploids (0–1.1%) were detected in the progeny of females held at 10, 12, 14 and 16 °C, which was the case also for females held at 15 °C. However, a considerable part of females from above-optimal temperatures – two out of three females at 20 °C and at least two out of six females at 18 °C – produced significantly higher proportions of autotriploids (FHT+FIT-experiment 2, FHT-experiment 2), with the highest proportion observed in a female held at 20 °C: 53.3% (FHT-experiment 2). We hypothesized in vivo egg ageing to be the most probable cause behind this observation. High temperatures can generally accelerate ageing in fish eggs and consequently reduce their developmental capacities (reviewed in Alix et al., 2020). Post-ovulatory ageing-associated changes in the cytoskeletal organization of the egg, which subsequently alter the fertilization mechanism and cause the failure of the second polar body extrusion and formation of autotriploid individual (Piferrer et al., 2009), may also appear sooner at higher temperatures. This theory is consistent with Aegerter and Jalabert’s (2004) study on rainbow trout (*Oncorhynchus mykiss*), as these authors suggested that autotriploid fry could frequently and spontaneously occur when broodfish are checked for ovulation at low frequency and/or are held at high temperatures.

(Continued on next page)
When each of the female-holding temperatures 12, 14 and 16 °C was combined with 12, 14 and 16 °C for fertilization and incubation (FHT+FIT-experiment 1), the holding temperatures 15, 18 and 20 °C were combined with 15, 18 and 20 °C (FHT+FIT-experiment 2), and holding temperatures 10 and 15 °C were combined with 10 and 15 °C (FHT+FIT-experiment 3) – the proportions of spontaneous autotriploids remained statistically unchanged. The exposition of eggs to certain species-specific temperatures after gamete activation can block the second polar body extrusion by disrupting the microtubules of the meiotic spindle, and effectively induce autotriploidy in sterlet (Fopp-Bayat et al., 2007; Flajšhans et al., 2020), but the temperatures used for fertilization and incubation in our experiments were probably too close to the physiological optimum (or directly within optimal range) to cause this phenomenon.

**Conclusion**

We conclude that the holding of sterlet female broodstock at temperatures of 18 °C or higher can often result in a remarkable occurrence of spontaneously autotriploid progeny, while the holding of females at 10–16 °C and/or using of water at 10–20 °C for fertilization and incubation do not seem to affect the incidence of autotriploidy.

Introduction

The ability of aquaculture to provide safe and nutritious fish products to consumers is highly dependent on the diets provided to cultivated fish, as aquafeeds are the principal operating cost of production. In times of climatic turbulence, rapid testing and deployment of novel aqua feeds that improve resilience and fish welfare are key. Moreover, the depletion of marine resources and numerous biotechnological innovations spur the inclusion of sustainable terrestrial sources in aquafeeds to replace traditional marine fish protein and fish oil. As wild salmonids are obligate carnivores, the concentration and quality of proteins present in salmon and trout pellets are crucial to their health and growth. Unfortunately, feed raw materials vary substantially in terms of protein digestibility and absorption, impacting the feed-conversion ratio. Previously applied to analyze the digestibility of ingredients, here we present a redeveloped version of SalmoSim-Digest for in-vitro testing of complete diets where we reveal the absorption of amino acids in-vitro and compare the in-vitro protein digestibility with in-vivo digestibility trial data.

Results and Discussion

The apparent digestibility coefficient values (Figure A) generated for each pelleted diet by The SalmoSim-Digest™ showed a highly significant correlation ($p = 0.04$) with the in-vivo digestibility coefficient values observed during a traditional feeding trial with rainbow trout (*Oncorhynchus mykiss*). Regression analysis ($R^2 = 0.83$) indicated SalmoSim-Digest has predictive power to estimate the digestibility of complete feed pellets containing protein from various sources. SalmoSim is being offered to producers of aquafeeds as an

Material and Methods

A total of seven diets based on commercially relevant protein raw materials with assumed contrasting effects on protein digestibility were formulated. The in-vivo study comprised a 5-week feeding trial using rainbow trout (start weight 55g). Fecal collection was conducted by stripping. SalmoSim-Digest is comprised of bioreactors where pH and temperature are maintained and cocktails of salmon bile and enzymes are added to mimic the digestive tracts (first stomach, then pyloric caecum, midgut and finally hindgut). Aquafeed pellets were characterized by nutritional composition, ground, sieved, and then applied to SalmoSim-Digest for simultaneous digestion and absorption of small molecular weight molecules. Each diet formulation was analysed by technical triplicate bioreactors (n=3). The amount of absorbed amino acids was quantified after each phase of in-vitro digestion using a phthalaldehyde assay (absorbance read at 340nm). The apparent digestibility coefficients were calculated by comparing crude protein content (as determined by the Kjeldahl approach) for both in-vivo and in-vitro assays.

Fig A: Comparison of in-vivo and SalmoSim-Digest crude protein ADC values in-vitro pre-screening test and promises to aid nutritional science in achieving the 3Rs (reduce, reuse and refine) the number of animals used in science. Moreover, SalmoSim-Digest presents an economically advantageous approach to evaluate the crude protein digestibility of novel feed pellet formulations.

This project has received funding from the European Union’s Horizon 2020 research and innovation program under grant agreement No 828835.

Fig B: Quantity of amino acids absorbed during in-vitro phases of digestion. Comparing each feed formulation regarding the amount of absorbed amino acids revealed significant differences at the pyloric caecum phase and midgut phase with the protein sources of fish meal and soya feather being significantly higher than the others (Figure B). SalmoSim-Digest in-vitro absorption allows repeated testing of individuals in a manner which would be unethical or impractical in in-vivo trials. Furthermore, the precise amino acid composition of the absorbed fraction can be readily ascertained to establish the bioavailability of the amino acids and optimise feed formulations where necessary.
EFFECT OF FEEDING TIME ON THE INTRADAY VARIATION OF AMMONIA EXCRETION RATE IN NILE TILAPIA Oreochromis niloticus

Introduction

Evolution has selected organisms that were able to anticipate fluctuations of their environment and adapt themselves accordingly (Dunlap et al., 2004). As a result, organisms have developed specific biological clocks that act as natural timing devices, regulating their metabolism according to the cyclic changes in conditions (Dunlap and Loros, 2017). These biological clocks respond to a broad range of parameters known as zeitgebers. Photoperiod and feeding time are some of the foremost zeitgebers controlling farmed-fish metabolism. The present study aims to investigate the variation of intraday rhythms of ammonia excretion in the commonly farmed Nile tilapia (Oreochromis niloticus) exposed to 3 different feeding protocols (ML group: fed during the middle of the light phase; MD group: fed during the middle of the dark phase; aleatory group: no fixed feeding time).

Materials and methods

A total of 189 fish were used in this study (8.87 ± 1.23 cm total length, and 9.39 ± 2.23 g total weight) equally distributed among the 3 different experimental groups. The 3 groups were exposed to the same 12:12 LD (light:dark) photoperiod. ML group was fed at ZT6, 6 hours after the beginning of the light phase, MD group fed at ZT18, 6 hours after the beginning of the dark phase, and the aleatory group were fed at a different time everyday).

After 3 weeks of treatment, the sampling took place. In order to measure ammonia excretion rate at a given time, 9 fish were selected per treatment and isolated in metabolic tanks. The ammonia concentration was measured in the metabolic tanks right before adding the fish, as well as 4 hours after the introduction of the fish. The differences in ammonia concentration allowed us to calculate ammonia excretion rates throughout these 4 hours. After 4 hours, the fish were sacrificed. The same methodology was consecutively repeated 7 times in total, allowing us to measure ammonia excretion rate throughout a period of 28 hours.

Additionally, in order to track ammonia excretion down to the molecular level, gills and liver samples were collected from the sacrificed fish. qPCR analyses were performed to measure the intraday variation of the expression of key genes involved in ammonia metabolism in fish (glsn and gludmit in the liver; ca, rhag, rhbg and rhcg in the gills).

Results and discussion

NB: qPCR results are not yet available, they should be released by the end of the month, so the current section will only cover ammonia excretion rate.

The data collected proved the rhythmic nature of ammonia metabolism in Nile tilapias. Statistical analysis (one-way ANOVA and its post-hoc Tukey test) have showed significant differences in the daily variation of ammonia excretion rate. Fish in the MD group had their highest ammonia excretion rate at ZT 20 (2 hours after their feeding time), ML group displayed its highest ammonia excretion rate at ZT 16 (10 hours after feeding time) and the aleatory group had its peak ammonia excretion rate at ZT 16 as well (17 hours after the last feeding time). Interestingly, this group is the only one that displayed a second minor peak of ammonia excretion at ZT 8. The experimental groups displayed different rhythmicity but the magnitude of their excretion rates were also significantly different (Student test, p<0.05), with the Aleatory group having the highest mean excretion rate (43.73g/kg/h) followed by MD (21.51g/kg/h), and ML (12.40g/kg/h).

(Continued on next page)
These preliminary results showed the strong endogenous nature of ammonia excretion in this species. Even though ML and MD had their feeding times shifted by 12 hours (ML was fed at ZT 6, MD was fed at ZT 18), their resulting peaks of ammonia excretion were only shifted by 4 hours. The aleatory group received its last meal at ZT 23 the day before the sampling began and displayed a peak of ammonia excretion at ZT16 the day of sampling. This group distinguishes itself from the others by having a second minor peak at ZT 8. When considering mean ammonia excretion rates, the aleatory group has the highest value, more than twice the value observed for MD and almost 4 times the mean ammonia excretion rate in ML. This difference may be the result of higher stress level in fish exposed to this aleatory feeding protocol, which would trigger a higher protein catabolism rate and consequently increase the amount of ammonia excreted.

When available, qPCR results will allow to follow daily variations of selected gene expression, and provide us an insight on the molecular mechanisms involved and their relation with photoperiod and feeding time. It is possible that some of these genes are sensible to light while others depend on feeding time, this would explain the strong endogenous nature of the results.

The main objective of this project is to gain knowledge on ammonia metabolism in order to control nitrogen cycles in aquaponic systems.

Many of us are unaware of how our daily actions affect the health of the ocean, its sustainability and many of the resources we depend on. In addition, most of us do not know about the global reach and importance of the sea and oceans in medical, economic, social, political and environmental terms. These aspects could be counterbalanced by providing or improving access to accurate and reliable education about the marine environment. Ocean Literacy’s main goal is understanding the ocean’s influence on humans and the influence of humans on the ocean. Lately, many international communities have assigned a large portion of their budgets and efforts to research and innovation programs, in order to reinforce science activity on different topics.

In this context, the All Atlantic Ocean Sustainable, Profitable and Resilient Aquaculture (ASTRAL) arises. ASTRAL is focused on Integrated Multi-Trophic Aquaculture (IMTA) farming, aiming to define, support, and promote sustainable aquaculture production across the Atlantic area. IMTA is the farming of species from different trophic levels in a way that allows one species’ uneaten feed and wastes to be used as inputs (fertilizers and feed) for another species. Sharing knowledge and capacity development are among ASTRAL priorities, as well as to build a collaborative ecosystem along the Atlantic Ocean with industrial partners, scientists, policymakers, social representatives, and other relevant stakeholders.

ASTRAL is committed to increasing the public acceptance and awareness of aquaculture by fostering public understanding of the value of aquaculture and especially IMTA, as a sustainable way to produce aquatic products. In Tierra del Fuego (Argentina), southernmost South America, we had to face the distrust of the local community on aquaculture as a production alternative due to a previous “no to salmon farming” campaign which was very popular. Therefore, several interviews in local radio and TV programs (at a local and national scale) were held in order to communicate and introduce society to other aquaculture systems. The project works with a multilayer stakeholder approach; therefore, we design different Ocean Literacy activities to be held in Tierra del Fuego, mainly in Ushuaia city and a nearby, small fishing village, Puerto Almanza to ensure that the message reaches all the sectors of interest. Some of the activities performed were oriented mainly to primary and secondary schools receiving kids and teachers at the research institution (CADIC-CONICET), organizing and participating in science fairs, giving lectures where we told stories, and we presented native species (that could be used in IMTA systems locally) through pictures and video images (Figure 1). Other activities include an apprenticeship program for early university students at CADIC-CONICET, workshops with local authorities, and training courses with technicians of the fisheries secretary, among others. It is worth mentioning an international course on the actual state of the art of aquaculture in Argentina that was held in Ushuaia on May 2023.

Up to the day, ASTRAL continues to interact with the local community by contributing to an educational project called “A window to the sea” (Una Ventana al mar), orientated to teachers for first educational levels, whose main goal is to teach Ocean Literacy, introduce native species and has a special chapter on sustainable and regenerative practices such as IMTA (Figure 2).

ASTRAL is a HORIZON 2020 project (GA 863034) financed under the Blue Growth program. Further information: www.astral-project.eu/
ELECTROLYZED WATER TREATMENT FOR THE CONTROL OF THE ZOONOTIC PATHOGEN Vibrio vulnificus AND ITS APPLICATIONS IN AQUACULTURE

Introduction

Vibrio vulnificus (Vv) is a septicemic zoonotic pathogen native to warm, brackish water ecosystems that is considered a biomarker of climate change. Recently, it has been shown that fish farms act as evolutionary drivers of this species by favoring the emergence of new pathogenic variants (Amaro et al., 2020). Establishing Vv control measures on farms would serve to reduce the risk of animal and human infection as well as the emergence of new variants that are dangerous to animal and public health. Saltwater electrolysis is an environmentally friendly control method that exhibits transient disinfectant properties due to the formation of hypochlorous acid (HOCl). HOCl attacks and destroys bacterial membranes and therefore has a bactericidal effect (Wang et al., 2020). In this work we explore this strategy to control the presence of Vv in water as a preventive measure or even treatment combined with antibiotic therapy.

Material and methods

Bacterial strains and culture. Representative strains of the five phylogenetic lineages of Vv were used in the study. The strains were grown in LB-1 (1% NaCl Luria Bertani broth) or on TSA-1 (1% NaCl Tryptic soy agar) plates at 28°C for 24 h. Bactericidal assay. An electric current was applied to a saltwater solution to obtain EW (electrolyzed water). Overnight cultures in LB-1 were inoculated (1:10 ratio) in freshly obtained EW (final volume of 100 ml) and bacterial viability at different times was tested by drop plate counting on TSA-1 plates. Different water salinities (0.5, 1.5 and 3%), chlorine concentration (5 to 125 ppm) and pH (3.5, 5, 6.5 and 7.5) were tested. All experiments were performed in triplicate.

Toxicity. European eels were exposed to different concentrations of chlorine (from 5 to 20 ppm) for 15 min to assess toxicity. EW conditions mimicked farm conditions (pH 6.5 and salinity 0.5%). For each test condition, 8-10 individuals with an average weight of 8 g were used.

Results and discussion

At concentrations of 125 ppm chlorine, EW was highly bactericidal for all strains tested, producing a 100% reduction of the bacterial population regardless of salinity and pH. In contrast, at concentrations of 20 and 25 ppm, the bactericidal effect depended on water salinity and/or pH. Thus, at intermediate salinity (1.5%) there was a 99.99% reduction in the population when water was acidic (pH 5, Fig. 1 and 2) and a 90-60% reduction when pH of water was around 7 (Fig. 2). At low salinity (0.5%) again, the bactericidal effect was high and independent of pH with a population reduction of 99.99% in all cases.

EW with chlorine 20 ppm resulted highly toxic for eels when treatment lasted 15 min but it was safe when chlorine concentration was up to 10 ppm. Animal trials are planned for short-term treatments.

Conclusions

Since EW was highly bactericidal against V. vulnificus, this technology could constitute a complementary and sustainable strategy to antibiotic treatment during vibriosis outbreaks in aquaculture facilities. Furthermore, EW could be used as a preventive measure during stressing periods to reduce the load of pathogenic bacteria in farm water.

**Introduction**

Proper nutrition is essential for immune system function, disease resistance, growth, and overall well-being of farmed fish. Alternative feeds in aquaculture can play a significant role in maintaining fish health and minimizing the environmental impact of fish farming. Although some potential benefits are already known, much work must be done to characterize their composition and the effect on the fish’s physiology and immune system. This study is part of the FISHEALTH project (financed by the Spanish Centre for the Development of Industrial Technology – CDTI), where 4 research institutions (ANFACO, AZTI, CETGA, and CTAQUA) are working together to develop tools and methods to diagnose, prevent and treat the primary infectious diseases that affect marine and continental Spanish aquaculture. In particular, this study aimed to include active ingredients from alternative sources that may enhance the fish’s immunity and improve the overall fish health status.

**Materials and Methods**

At the ANFACO-CECOPESCA aquaculture facility (recirculating aquaculture system, 6.5 m$^3$, 14°C), 20 fish per tank (8.34 cm and 6.71 g) were stocked at a 0.40 kg.m$^{-3}$ density. For 45 days, rainbow trout (*O. mykiss*) were fed 4 different diets (by triplicate) based on: (A) microalgae (the diatom *Phaeodactylum tricornutum*; 5.0% inclusion), (B) seaweed (the Pepper dulse, *Osmundea pinnatifida*; 5.0% inclusion), (C) fungi’s fermented fruits biomass (0.5% inclusion) versus a control diet (D). At the end of the experiment, 54 fish per diet were anesthetized and sacrificed by phenoxyethanol overdose and measured. Then, different target organs (liver, kidney, spleen, distal gut, and skin mucosa) were taken for ulterior analysis: antioxidant and immunomodulatory activities, differential gene expression (transcriptomic analysis), and gut microbiome composition.

**Results**

Different growth and performance indicators were measured at the end of the study, not showing any significant difference between the four treatments (growing at a specific rate of 4.36% and reaching a size of 15.95 cm and weight of 48.09 g, average) (Figure 1). A feed conversion ratio of 1.00.

Only Fulton’s condition factor (k) was different, being significantly higher for the fish under diet A (*Phaeodactylum*) (p = 0.049, ANOVA test; p <0.05, Tukey, LSD, and Bonferroni tests) compared to the control diet (Figure 2). Also, when the immunomodulatory activity expressed by the levels of inflammatory cytokines (Interleukin 6 (IL-6) and Tumour necrosis factor (TNF-α)) was measured, we found that the fish being fed with the *Phaeodactylum*-rich diet (A) also had significantly low levels of IL-6 in liver and spleen compared to the rest of the groups (p = 0.031, Kruskal-Walis test) (Figure 3).

ANFACO’s previous work evaluated the antioxidant activity of *P. tricornutum* bioactive compounds. Focusing on the levels of phenolic compounds, our results showed higher levels in diets containing algae biomass: A, *Phaeodactylum* (3.11 CFT, µg/mg sample) and B, *Osmundea* (3.46), compared to C (2.50) and D (2.65). Moreover, the analyzed microbiome in the fish’s gut fed with microalgae and seaweed was more diverse.

**Discussion and conclusions**

Although our results are still preliminary, we can already conclude that the tested alternative diets show, in general terms, good results in terms of growth and performance. Moreover, one of the diets, based on the diatom *Phaeodactylum tricornutum* at 5% inclusion, may contain natural active compounds related to the expression of some immunomodulatory molecules, such as IL-6.

Our next step is to identify the nature of these compounds, connect those results with the previous (phenolic compounds content and gut microbiome diversity), and add more information from the samples already collected (mucosal antioxidant activity and distal gut transcriptomic analysis). With all this information, we will be able to assess the suitability of this alternative source/s for aquaculture.

Introduction
The biological control of sea lice using cleaner fish including lumpfish (Cyclopterus lumpus) has become a feasible option due to the increased occurrence of resistance towards medical treatments in salmon lice, Lepeophtheirus salmonis. For lumpfish a significant individual differences in feed intake and preference for sea lice has been seen (Imsland et al., 2014a), and genetic influence has been suggested to be a possible factor (Imsland et al., 2021). A series of studies (called Phase I, II, III and IV) were conducted over a four-year period where distinctive lumpfish families have been established initially from wild caught mature fish and latterly from established breeding lines. The aim of this study was to evaluate whether sea lice grazing efficiency, behaviour, size variation and cataract development can be improved through selective breeding of lumpfish.

Material and methods
Four subsequent trials (called: Phase I-IV) with ten families of lumpfish (N = 480) with a mean (± SD) weight of 46.4 ± 9.4 g (Phase I), 54.8 ± 9.2 g (Phase II), 42.0 ± 7.4 g (Phase III) and 31.3 ± 2.4 g (Phase IV) were distributed among ten sea cages (5 × 5 × 5 m) during autumn 2018 to spring 2022, each stocked with 400-404 Atlantic salmon with an average initial mean (± SD) of 387 ± 9 g (Phase I), 621 ± 15 g (Phase II), 280 ± 16 g (Phase III) and 480 ± 66 g (Phase IV). All the ten cages were stocked with 48 lumpfish (12% stocking density). In all four phases sea lice grazing efficiency, behaviour, size variation and cataract development was monitored and compared.

Results
The increase in incidence of cataracts from start to end of each trial phase was significantly reduced from Phase I (16%) to Phase IV (2%) (Fig. 1A). In all phases there was a large inter-family variation of lice grazing of lumpfish of both L. salmonis and C. elongatus. When sea lice grazing was scaled in relation to sea lice infestation levels on the salmon the highest sea lice grazing activity was found in Phase IV (Fig. 1B) and in particular in families sired from farmed parents. There was a general trend for mean start weights and standard deviations to decrease as the phases continued. A significant increase was found in frequency of behaviour associated with feeding on natural food sources and grazing sea lice from salmon during each subsequent phase.

Discussion and conclusion
There were clear differences in sea lice grazing efficacy, size variation, behaviour and cataract prevalence between the families tested in the different phases of the study. Further, when sea lice grazing was scaled in relation to sea lice infestation levels in each experimental phase a trend of increased sea lice grazing in the 1G breed fish used in Phase IV. Juvenile lumpfish exhibit a limited palette of behaviour types (12-14 types) with the majority based on food location and/or feeding (Imsland et al. 2014b, 2021). These behaviour types were classified and grouped into “positive/cleaning”; “negative” and “normal” types for the purpose of this study. Positive behaviours are associated with feeding on natural food sources withing the cage environment, feeding on feed blocks and grazing sea lice from salmon. This behaviour type increased significantly during the subsequent Phases. One of the breeding targets of this study was to lower the incidence and development of cataract. This target was achieved as the increase in incidence of cataracts from start to end of each trial phase was reduced from Phase I (16% increase) to Phase IV (2% increase). Overall, present findings showed that sea lice grazing of both L. salmonis and C. elongatus, size variation, cataract prevalence and behaviour types can be enhanced through selection and targeted breeding programs.

Introduction
Farmed aquatic animals are subjected to numerous handling operations that can be challenging for their health and welfare. One such operation is crowding, where fish are subjected to reduced rearing volumes to facilitate handling, which is key in the rearing cycle. If fish are repeatedly crowded, there may be potential cumulative effects upon fish welfare and these effects can be detrimental (Espmark et al., 2015; Grøntvedt et al., 2015; Roth, 2016; Gismervik et al., 2017). Methodologies based on operational welfare indicators (OWIs), Laboratory-based welfare indicators (LABWIs), health indicators and new emerging technologies have been developed to monitor and audit the welfare of farmed animals, including fish (Noble et al., 2018). Its application can help audit, refine, and optimize crowding procedures. The main goal of this study was to quantify and audit fish behaviour during crowding operations in order to create automatic frameworks and protocols that can assist in documenting/optimising fish welfare during crowding operations.

Materials and Methods
The effect of four different crowding intensities on Atlantic salmon welfare was explored by the project Crowd Monitor (Norwegian Seafood Research Fund, pr. num. 901595) by means of 12 tanks of 3300 l, holding ca. 120 fish (>500g) within a clockwise water flow. Each crowding level was triplicated (4x3 design) and a GoPro hero4 black was installed over the tank to capture the entire water surface in the field of view. Each tank was recorded for ca. three hours: around half an hour before crowding, two hours during crowding and half an hour after crowding. One tank with intermediate crowding intensity was used for the present study. After observing the original video, both swimming structure impacted by crowding onset and its gradual increase during crowding were hypothesized. Hereafter, fish swimming behaviour was quantified through computer vision (Python 3.0, OpenCV library). Firstly, median frames were calculated for the 30-minute period before and after crowding. The 2h crowding period was split in four 30-minute periods and the median frames were also generated (Fig. 1A). Theoretically, a still and more structured fish swimming would be mirrored in median frames showing fish silhouettes oriented towards the water flow, whereas chaotic swimming and low swimming structure would render blurred median frames. Further metrics were quantified for median frames’ validation. Five frames of every 30-minute period were subsampled and the coordinates from heads, anterior dorsal fins and tail peduncles were extracted (ca. 50 fish per frame) to calculate a) individual swimming orientations and ii) swimming angles as proxies of swimming structure. Heart rate as a proxy of activity/stress to cross-validate mean frames, swimming orientation and swimming angle was obtained from intraperitoneal tags (n = 4 fish). Eventually, fish swimming behaviour was continuously quantified over the whole sample video by mean histogram values at three distinct levels, i.e., within the crowding area, rear- and front-zone of the crowding area. The fish abundance in the front and rear zone of the crowder were also calculated (Fig. 1B).

Results and discussion
The largest proportion of individuals swimming against the water flow was detected before crowding, followed by the post-crowding period. The crowding period showed the largest variability in swimming orientation and swimming angle. Overall, and consistent with median frames observation, the mean histogram colour unveiled a gradual increase in fish abundance in the front of the crowder, in contrast to the rear zone (Fig. 1B). This is consistent with the visual analysis of median frames, revealing clearer fish silhouettes swimming against the water flow in the crowd front, and avoidance of the rear zone. Both the largest shift in the number of fish swimming against the water flow and a decreasing heart rate coincided one hour after the crowding onset. This could be linked to a decrease in activity/stress during crowding. Overall, the current behavioural approach detected fish gradually coping with crowding conditions by structuring swimming and avoiding the rear zone of the crowding area. Uncontrolled factors such as chaotic swimming and/or interactions with the crowder might jeopardize fish welfare status. Therefore, further research could focus on the optimal thresholds of duration, repetition and/or the speed of crowding activities regarding welfare status.

(Continued on next page)
Figure 1. A) Fish activity based on median frames. Activity in the rear versus the front zone of the crowding area is represented in the left and right column respectively, whereas the first 30 minutes of the two-hour crowding period versus the last 30 minutes correspond, respectively, to the top and bottom row. B) fish activity depicted by mean histogram values over time (0 = black, 255 = white). White arrows in A) indicate an empty area in the back of the crowd (bottom-left) and an example of a fish silhouette swimming against the water flow (bottom-right).

Introduction
Pathogen surveillance and diagnostic methods are constantly evolving. Sequencing can provide critical information to diagnose diseases and inform control and mitigation strategies by identifying genetically distinct pathogen variants that may have different host reservoir species or geographic distributions.

During the last decade, with the development of high throughput sequencing methods, reference laboratories and research groups studying marine mollusc diseases have advanced considerably in sequencing-based analyses. However, data management is still unconventional as the community lacks dedicated databases and tools, despite a considerable increase in data volume.

Material and methods
We therefore developed a user-friendly web-platform, called MoPSeq-DB, which references curated genomic data related to mollusc pathogens. It gives users opportunities to navigate through data, interactively visualise genomic structure and variation, provide integrated analysis tools, and allow to download data in various file formats. Since marine bivalve molluscs can be affected by viral, bacterial and eukaryotic pathogens, MoPSeq-DB is designed to be used with a large panel of genome particularities (e.g. size, architecture).

Results
MoPSeq-DB, is an open-source tool based on the Python web-framework Django enabling convenient and fast sequencing data exploration and visualisation in an intuitive and user-friendly way, particularly for non-bioinformaticians. It has minimal hardware requirements and is easy to install, host, and update.

While MoPSeq-DB folder structure enforces systematic yet flexible storage of genomic data of bivalve mollusc pathogens, including associated metadata, the platform could easily be declined to pathogens of any other organisms. The application can be deployed using a Docker container, and runs on all modern browser engines (Firefox, Chrome, Safari).

Availability
Source code and documentation are available at https://gitlab.ifremer.fr/bioinfo/mopseq-db.

A public web server will be online at: https://mopseq-db.ifremer.fr by end 2023.
MISLABELLING OF STURGEON CAVIAR – A DRAWBACK FOR LEGAL TRADE AND SPECIES CONSERVATION

J. Jahrl
WWF Austria
Ottakringer Str. 114-116
1160 Vienna, Austria
E-Mail: jutta.jahrl@wwf.at

Introduction

In response to dramatic declines in many sturgeon populations globally – in large parts due to overharvesting – and with the aim of ensuring that the trade in sturgeon products is sustainable, all 27 species of Acipenseriformes have been listed in the Appendices of CITES\(^1\) and international trade is strictly regulated. In 2000, a universal labelling system for caviar was introduced to allow the identification of the source. The system has been revised and updated on a number of occasions since then. The labelling system\(^2\) should be implemented for all types of caviar – both wild-sourced and derived from aquaculture – for both international and domestic trade. Labels must be non-reusable, i.e. they cannot be removed undamaged or transferred to another container, and they must seal the container, or if not, the packaging should permit other visual evidence of any opening. They must provide a minimum amount of information, in a defined code of letters and numbers: the species or hybrid of origin, the source code of the caviar (“W” for sturgeon harvested from the wild, “C” for captive-bred sturgeon etc.), the country of origin, etc.

Despite these trade regulations and legal protection of recent years and despite the large increase of caviar from aquaculture, the decline of critically endangered sturgeons in the wild continues, and poaching and illegal trade have been reported in many sturgeon range countries globally.

Materials and methods

Information on illegal trade in sturgeon and the reasons for it (e.g. incorrect caviar labelling) was collected from own research, published literature, seizure reports, investigations of experts and journalists, etc. to understand and address deficiencies in labelling implementation and enforcement and close entry points for illegal activities.

Results

Market survey

A large-scale market survey – including wildlife forensic analysis to determine species and source of sturgeon meat and caviar – demonstrates the widespread occurrence of caviar mislabelling and sturgeon tracking in the Lower Danube Region (Bulgaria, Romania, Serbia and Ukraine)\(^3\).

Apart from 27 samples (19% of all samples) that originated from wild-caught sturgeons, 17 samples (12% of all samples and 29% of all caviar samples) were caviar sold in violation of CITES regulations. Of these, 2 caviar samples were illegally imported into the country, 4 caviar samples were sold without mandatory CITES labels in EU Member States (where CITES caviar labelling is legally required both on the international and on the domestic market), and 11 mislabelled caviar samples were sold in EU Member States:

- 7 of these were determined (with genetic analysis) to have a wrong species code,
- 3 were determined (with isotope analysis) to have a wrong code for the country of origin,
- 1 had a wrong code for species and country of origin.

On 10 of the caviar samples which were found to provide wrong information in their CITES codes, all labels also failed to meet mandatory CITES requirements (not sealing or providing visual evidence of opening).

In many instances, consumers were misled by e.g. products from lower-priced sturgeon species being misrepresented as coming from higher-priced ones or caviar from hybrids as deriving from pure species, but also vice versa.

(Continued on next page)
Other findings of caviar mislabelling

Official investigations, seizures, court cases, trade suspension, market surveys, journalist investigations, etc. revealed several cases of incorrectly labelled or mislabelled caviar, e.g.:

- According to a presentation by a German CITES representative in 2006, falsified marks and labels for over 3000 kg of caviar were seized, and smuggled caviar had been sold to different traders – including reliable companies – all over Europe.
- In an organised crime investigation in Germany, a witness stated that Russian caviar was smuggled into the EU and commercialized as Bulgarian farmed caviar. Isotope analysis of samples taken in 2009 supported this claim and found caviar labelled as coming from a registered Bulgarian aquaculture operation actually to originate from the Caspian Sea. The extensive evidence showed that more than 100 kg of illegally obtained Beluga caviar were sold to several top restaurants in the course of a year.
- In 2009, the UK Border Agency seized twenty tins – in total two kilograms – of Beluga caviar after suspicions based on poor labelling.
- Between December 2017 and January 2018, French enforcement authorities led 32 inspections aiming to control trade in sturgeon caviar. 17 controls detected non-compliance to the caviar labelling provisions, e.g. CITES labels being removable undamaged. 329 primary containers corresponding to 9,750 kg of caviar, for a value of approximately 15,000 €, were seized. The caviar had come from processing plants in France and China, repackaging plants were located in France, Germany, and Spain.
- Published in 2015, journalist investigations found that a company in Lithuania sold caviar with counterfeit CITES labels from a registered Bulgarian aquaculture operation to EU Member States such as Germany. Isotope analysis of three caviar samples with CITES labels and country code BG for Bulgaria showed that one sample ordered directly from Lithuania and one bought from a German repacker did not derive from Bulgaria but likely from the Caspian Sea region.

Discussion

Nearly a third of all caviar samples tested in targeted market research did not meet CITES requirements and were therefore illegal. All these samples were from farmed sturgeons. However, misdeclarations are a breach of CITES regulations and undermine the aim to ensure that the international trade in sturgeons does not threaten their survival in the wild. Furthermore, any misuse or incorrect implementation of the labelling is a drawback for the confidence in the labelling and for all legally operating facilities.

Current CITES regulations are not sufficient or not adequately enforced to detect and stop illegal trade. Some national CITES Management Authorities accept labels that do not fulfil all CITES labelling requirements or do not control sufficiently the implementation by caviar processing and repackaging companies and, in general, law enforcement authorities do not further investigate labelled caviar containers unless with initial suspicion (most seizures are of un- or mislabelled tins or due to infringements of the personal or household effects exemption).

CITES caviar labelling requirements must be correctly applied, including on domestic markets, and improved (considering new technologies such as QR codes). Furthermore, effective and secure traceability systems throughout the trade chain are needed (including database systems such as blockchain). To this respect, e.g. a feasibility study is currently underway to determine if individual analytical signatures can be identified to reliably trace sturgeon products in trade back to the aquaculture facility of origin.

Strengthened enforcement measures are indispensable and need to include inter-agency and cross-border cooperation, and controls have to cover the whole trade chain and include forensic analysis of samples. Effective combating of illegal activities also fundamentally requires the cooperation of the sturgeon industry (aquaculture producers and traders).

Department of Separation Science, LUT School of Engineering Science, LUT University
Sammonkatu 12, FI-50130, Mikkeli, Finland

Parul.jakhwal@lut.fi

Introduction
Recirculating aquaculture system (RAS) has advantages compared to flow, and semi-flow-through systems, such as reusing treated wastewater and requiring lower water volume. Despite these advantages, nitrate accumulation is a significant problem of RAS wastewater (RASWW). The nitrate accumulation can be toxic to fish in the RAS system and cause eutrophication (1). Therefore, microalgae can be introduced as it can utilize nutrients from RASWW, and harvested biomass can be used as fish feed.

Materials and methods
*Nannochloropsis oculata* and *Chlorella vulgaris*, were ordered from Norwegian Institute for Water Research (NIVA) culture collection, inoculated in a 2 L photobioreactor containing 0.5 L medium at 23 ± 2 ºC. Light irradiance source was white neon tube LED with light intensity of 115 μmol/m²s and photoperiod of 12:12 (otherwise stated). Microalgal growth was measured by filtering a specific volume of microalgal culture on to filter paper followed by drying at 60 ºC in a hot air oven. The microalgal dry cell weight (g/L) was measured calculating the difference between the empty filter paper before and after filtration. The microalgal dry cell weight (g/L) was measured by ion chromatography (Shimazu). The concentration of nitrate (NO$_3^-$) and phosphate (PO$_4^{3-}$) was measured by TOC/TN Analyzer (multi-N/C 2100S). The nutrient removal efficiency was calculated by equation 1, where $C_i$ is the initial and $C_f$ is the final concentration of respective nutrients.

$$ R\% = \frac{(C_i - C_f)}{C_i} \times 100 \quad (1) $$

Experimental design

Experiment 1: Screening of different strains (*N. oculata* and *C. vulgaris*) and RAS wastewater (RASWW 2 ppt and 14 ppt) for optimum biomass.

Experiment 2: Effect of different photoperiods (light:dark period, L:D) (8L:16D, 24L:0D, 0L:24D) and light wavelengths (red, blue, white) on microalgal growth.

Experiment 3: Effect of autoclaved and non-autoclaved RASWW on microalgal biomass accumulation.

Experiment 5: Effect of different salinity (14, 20, 25, and 34 ppt) for microalgal growth.

Experiment 6: Effect of optimized condition (*N. oculata* in RASWW 14 ppt, with 24-hour white light, 25ppt salinity and with NPR of 20:1) based on the experiment 1-5.

Results and discussion

Experiment 1: *N. oculata* is a marine microalga so it preferred 14ppt over 2ppt RASWW and 14ppt RASWW over commercial media f/2 possibly due to its nutrient composition.

Experiment 2: White light resulted in optimum growth as it is composed of all light spectra essential for microalgal growth. Previous studies have also shown the optimum growth of some microalgae species obtained in white light and 24 h photoperiod (2).

Experiment 3: The dry cell weight accumulation showed a similar pattern in RASWW with and without sterilization. Therefore, nonsterile RASWW was chosen as it is economically favorable.

Experiment 4: The optimal nutrient ratio required for biomass accumulation and nutrient uptake can be depicted by microalgal cell’s elementary composition (C$_{106}$H$_{263}$O$_{110}$N$_{16}$P). In this regard, previous studies have also shown the important role of NPR in microalgal growth (3). In the current study the optimal biomass was accumulated with NPR of 20N:P.

Experiment 5: Salt concentration is required at an optimum level otherwise it might disrupt the osmoregulatory mechanism of microalgal cells. In the current study salinity of 25 ppt provided optimum biomass accumulation.

In experiments 1-5, The dry cell weight ranged from 0.55 g/L to 0.62 g/L. The highest dry cell weight obtained was 0.62g/L, in salinity experiment at 25 ppt salinity.

(Continued on next page)
Experiment 6: This study was based on the optimum dry cell weight obtained in experiments 1-5. The maximum dry cell weight of 0.81g/L was obtained, which had significant increase of 30.64% than that in the highest biomass obtained in the experimental variations. The nutrient removal profile on day 11 consisted of total nitrogen removal of 54.1%, dissolved organic carbon removal of 15.76%, nitrate removal of 76.65%, and total phosphate removal of 100%.

Conclusion

*N. oculata* can remove nutrients and organic carbon from RASWW and produced algal biomass can be used as fish feed. Thus, microalgae can be introduced as a carbon-neutral option for achieving a circular bioeconomy to solve the issue of nutrient accumulation in RASWW.

**Introduction**
Aquaculture is crucial for global seafood production as it addresses the growing demand resulting from population growth. Developing robust and efficient autonomous solutions such as unmanned underwater vehicles (UUVs) is vital for a safe and cost-effective aquaculture industry \([1]\). However, unsuitable technologies or underdeveloped automation can lead to unexpected negative consequences. Among important aspects, vehicle design plays an essential role to ensure fish welfare. In other words, understanding fish-UUV interactions is essential for designing UUVs that do not scare or hurt fish. This study explores the application of computer vision and stereo vision tools to study such interactions, to examine the behavior of Atlantic salmon (Salmo salar) in industry-scale fish farms. Specifically, the study aims to analyze how fish respond to static structures, seeking to determine the distances that fish maintain from these structures.

This work was carried out in collaboration with SINTEF Ocean, specifically SINTEF ACE-Robotic Lab and the CHANGE project \([2]\).

**Materials and methods**
To collect the data, a structure of varying shape and color was fitted with two Lucid TRI032S-CC GigE vision cameras and two BlueRobotics Ping360 echo sounders before being lowered into the water. The structure was maneuvered around before being secured, and data was captured for 12 minutes. This procedure was executed six times for each structure variation in two distinct cages at depths of 8 and 12 meters, respectively. Additionally, stereo calibration videos featuring a moving chessboard in front of the structure were captured in order to enable 3D position estimation from the resulting trial videos. The data were derived from computer vision techniques to estimate the distance from the fish and monitor its behavior.

The employed method extracts frames from a video and performs object detection in the left image frames utilizing YOLOv8, a state-of-the-art object detection model \([3]\). SuperGlue \([4]\) is subsequently employed for feature extraction and matching, with the resulting point matches being used to associate detections in the left frame with objects in the right frame. To maintain tracking of individual fish across multiple image frames, object tracking capabilities are incorporated through StrongSORT \([5]\). Lastly, the 3D positions and distances relative to the camera are determined through triangulation, using the positions and disparities of the corresponding left and right objects and the calibration data.

![Figure 1 Distance distribution of detected fish per frame. Most fish keep one to three meters distance.](image-url)

*(Continued on next page)*
Results

The distribution of distances for detected fish in a video with a white cube structure is shown in Figure 1. In ideal conditions like this scenario, most fish maintain a distance of one to three meters from the structure. However, when current and water pollution increase, the estimation quality declines, leading to many unrealistic distance estimations. This degradation can be attributed to inconsistent epipolar geometry when the structure moves due to current or challenges in correcting distortion with increased suspended particles in the water.

Figure 2 instead illustrates the estimated 3D X-Y movement and corresponding distance to the camera for a single fish. The position and distance estimations depend on disparity, which can vary between frames based on detection and feature matching performance, resulting in fluctuations in raw estimations. In challenging conditions, these fluctuations become more pronounced. Consequently, raw estimations are smoothed to reveal movement trends, represented by the blue lines in Figure 2. The fish’s movement in the video aligns with the trajectory shown in the left graph. Additionally, the fish initially swims away from the camera, then turns toward it, and finally swims away again, as depicted in the right graph, demonstrating that the method accurately captures the movement trend.

Conclusion and future work

The results show that under ideal conditions most fish maintain a distance of one to three meters from the structure. However, in challenging situations with increased current and water pollution, the quality of the estimations deteriorates due to inconsistent epipolar geometry and challenges in correcting distortion. Despite this, by smoothing the raw estimations, the method proves capable of capturing movement trends. Future efforts should focus on mitigating the impact of adverse conditions and ultimately using the method to analyze fish behavior in response to various structures. Gaining such insights will contribute to the development of innovative autonomous tools that can further advance the aquaculture industry.

REAL-TIME OPTIMIZATION IN RECIRCULATING AQUACULTURE SYSTEMS

Jamal, A.

Introduction:
The aquaculture industry is rapidly growing and has become a crucial part of global food production. Land-based recirculating aquaculture systems (RAS) are increasingly important due to their efficient water use, stable conditions, solids removal, and effluent treatment (Spiliotopoulou et al., 2018). Efficient management and optimization of RAS protocols are essential to achieve optimal growth outcomes (Seginer 2016). Optimizing various factors that impact the process, including feeding, heating, and oxidation, is necessary to achieve optimal growth. However, most existing RAS management methods are based on pre-determined solutions that may not be optimal for specific cases. Furthermore, existing solutions are yet to be applicable, as they fail to incorporate a proper description of the processes in the system such as water quality and fish growth processes (Chahid et al., 2021).

Materials and Methods:
In this study, I propose a novel decision support system (DSS) that provides optimal decisions regarding the feeding rate, temperature, and oxygen for maximizing profits in RAS. The proposed method utilizes a simulation-optimization framework that ensures reliable application in real-time (Jamal et al., 2018). A holistic simulation is developed by integrating fish growth simulations as well as water quality simulations. The fish growth simulations are based on bioenergetics models in which the fish growth is estimated by the metabolism rate with time as a function of current weight and the water quality of un-ionized ammonia, temperature, and dissolved oxygen (Ursen 1967). The water quality is simulated to describe the dynamics of the water quality with time while accounting for the impacts of the feeding, temperature, pH and bio-filtration. The relation between these factors and the water quality factors are well-known in the literature (Ebeling and Timmons, 2010). The coupled simulations of fish growth and water quality are used as a simulation for the processes that occur in RAS. The accuracy of the simulation is enhanced through a closed loop based on observations for oxygen, temperature, ammonia and weight. The simulation is coupled with the optimization algorithm (e.g. genetic algorithm) to estimate the value of several decisions (several levels of feeding rate, temperature and oxygen) within a simulated forecast period to the future. The decision that comes with the optimal expected profit in the forecast period is the optimal decision which is applied for the current time step. The process is repeated on a daily basis. Overall, this approach provides a reliable and customized solution for RAS management, enabling efficient decision-making to maximize profits. Figure 1 describes the overall framework.

Figure 1: the overall flowchart.

(Continued on next page)
Case Study:
A case study of Tilapia for feeding optimization for maximizing profits was conducted. The oxygen and temperatures were not optimized and remained constant throughout the growing cycle. The optimized results were compared to a conventional feeding schedule based on proportions (between 1% to 5%) of the current weight of the fish. The bioenergetics model parameters were used from Yi (1998).

Details:
Tank volume: 6 cubic meter; Number of fishes: 3000; Initial weight: 7 gr; Temperature: 28 C; Fish price: 1.5 $/kg; Oxygen price: 0.016 $/kg; Oxygen level: 0.6 mg/l; Bio-filter surface area: 500 ; pH level: 7.

Results:
Although lower revenue was obtained using the optimization method, the profits (the objective) was higher due to the saving in the feeding.

AquaVitae is a four and a half year H2020 EU funded project which started in 2019. It has 35 partners from all around the Atlantic, focusing on Europe, Brazil and South Africa. The project has two main aims. The first is to increase the production from low trophic value chains across the Atlantic. The second is to contribute to the All Atlantic Ocean Community, particularly in regards to the sustainable production of food from the Atlantic.

The project focuses on 5 value chains selected for their potential for sustainable production and their significant impacts, specifically:

- Macroalgae production; New species, offshore production, and post-harvest processes
- Integrated Multi-Trophic Aquaculture (IMTA); land-based and sea-based, biofloc systems
- New echinoderm species: Sea urchins and sea cucumbers
- Existing shellfish species: Oysters and mussels
- Optimised production of selected existing finfish species; freshwater and marine

These value chains are implemented through 13 case studies (including two cross cutting case studies) where practical, hands-on innovation and exploitation work has been carried out by industry and research participants. In addition, a significant part of the research activities in AquaVitae have focussed on cross-cutting issues applicable to many of the CSs. This includes research on: biosensors, Internet of Things and data management, product characteristics, consumer attitudes and market potential, sustainability, circular economy, environmental monitoring and risk assessment, and value chain analysis, profitability and socio-economic aspects. Issues related to policy and governance are essential and AquaVitae has contributed to various policy dialogues and produced EU policy briefs.

Knowledge, network-building, training, and communication is crucial when it comes to ensuring project impact both inside and outside the consortium. In AquaVitae this includes the development of relevant stakeholder platforms, exchange programs as well as a Massive Open Online Courses (MOOC) in low trophic aquaculture. The knowledge and Capacity Building activities will be the focus of this presentation together with their impact on Europe and the wide Atlantic Ocean Community.
DEVELOPING USES FOR SEA URCHIN BIMASS REMOVED FROM AREAS TO REINSTATE MACROALAGE FORESTS

There are many places around the world where there are issues with overpopulation of both endemic and invasive sea urchin species. Generally, this leads to large mono populations of sea urchins that are known as ‘sea urchin barrens’. These areas have reduced diversity, overall ecosystem production and reduced ecosystem services. There are many initiatives to remove the sea urchins and re-establish the macroalgae forest in the place of the sea urchin barrens. Along with developments in harvest technology and the possibility of ‘enhancement’ of some of the extracted sea urchins there are initiatives to find a productive and economically viable use for the sea urchin biomass extracted from sea urchin barrens. In addition, there are approximately 700,000t of sea urchins harvested and processed every year around the world. The byproduct of this processing could also be used in various forms.

This presentation will summarise the results from three trials which have investigated various uses for sea urchin biomass. The first of these is to make a hydrolysis of the biomass to extract marine based protein powder. This trial identified some basic processes and chemical characteristics of the hydrolysis from sea urchin crush. The results are published and will be presented.

The second was a Master student project investigating the use of sea urchin crush as a nutrient source for macroalgae seedlings. This proved challenging, primarily in respect to bioavailability of nutrients to the seedlings. The results of this trial will be presented.

Finally, the third was to develop and use sea urchin crush as an agricultural bio stimulant for agricultural production. This involved two harvesting events from 4 sites close to Tromsø in northern Norway to characterize the biochemical content of the sea urchin crush and any changes that occur because of harvesting from different sites and at different times of the year. Additionally, a plant trial has measured the efficacy of the sea urchin crush as a natural bio stimulant. The results from these trials will be presented.

The work in this presentation was funded by the InEVAl Project, funded through the Blue Bio Era Net call.
Introduction

Today, there are various questions to address – from how to tackle global challenges such as climate change, biodiversity loss, resource depletion, water scarcity, waste, and pollution to how to build a resilient model, good for business, people, and the planet. The circular economy model helps to address these stakes, by applying three principles: reduce waste, circulate products, and regenerate nature.

Circular economy

Symrise Aqua Feed employs a circular model to bring marine co-products to their highest value. This helps the industry to tackle challenges for more sustainable aquafeed. Our solutions can create value to the aquaculture industry. (Figure 1)

100% co-product raw materials

Symrise Aqua Feed collects raw materials such as shrimp heads, tuna viscera, tilapia heads and bones or other marine by-products, which are not used for human consumption. These are usually waste by-products from fish and shrimp processing plants, that contain many precious proteins.

These sites are located next to the plants where fish and shrimp are processed, guaranteeing the freshness of the raw material. The locations also help to optimise the logistic and minimise the carbon footprint of the raw material transport.

The process, optimisation of nature.

Consequently, there is the processing and transformation to increase the functional value of the by-products. We master enzymatic hydrolysis, aiming at highly standardised hydrolysates in liquid and powder form, with multiple benefits such as nutrition, palatability, health.

We also pay attention to our own organic waste. We try to valorise left-over materials in the feed chain as much as possible, with the further processing into fish or shrimp meals. When the process into meal is not the best option, other alternative solutions come into play, such as composting with anaerobic digestion. Overall, it is always seeking to find the highest value of fish and shrimp by-products.
Combined benefits on palatability, nutrition, and health in the aquafeed.

The ingredients use in aquafeeds help to substitute fish meal, enhance feed palatability, standardise fish and feed performance by reducing deviation, enhance fish health status and fish resistance to environmental and pathogen challenges. With better digestibility and better absorption, the ingredients help to reduce “fish in” while maximise “fish out” ratios (FIFO)

Sustainable aquafeed for sustainable farming.

The zootechnical performance of Symrise Aqua Feed’s ingredients are proven in Aqualis: performance measurement centres, by scientific partners and in aquaculture farms. While guaranteeing high performance, the ingredients also help to reduce the environmental impacts in aquaculture. With high palatability, the company ensures high feed consumption while reducing feed wastes. With good nutrition, they improve the whole feed digestibility to reduce the release of non-digested feed in the environment and improve FIFO. With health benefit thanks to bioactive compounds, they enhance resistance to stressful events, improve gut health, increase survival, and help to reduce synthetic inputs.

Conclusion

Using this circular model, Symrise Aqua Feed produces alternative ingredients with a low carbon footprint and high positive social impact.
ENHANCING AQUACULTURE WITH AN OPTICAL AND ARTIFICIAL INTELLIGENCE BASED SYSTEM FOR MICROPLASTIC DETECTION

Introduction
The presence of microplastics (MPs) in marine water is one of the main contamination sources nowadays, becoming a significant threat to marine ecosystems [1]. MPs detection and removal methods are essential to control water quality and implement measures to ensure the preservation of the environment. This paper proposes a work developed within the frame of ASTRAL European project and based on the design and development of an optical MP sensor capable of identifying these particles, differentiating them from other natural particles present in seawater. The technology will address some of the issues and limitations of current commercial alternatives [2], such as low flow rate or high cost, by combining fast off-the-shelf industrial cameras, tunable optics, image processing and deep learning models.

ASTRAL is a European project that aims at developing and providing innovative techniques and species combination to improve Integrated Multi-Trophic Aquaculture (IMTA). Within ASTRAL, a circularity assessment is being carried out to provide evidence-based metrics to evaluate how the new aquaculture systems performs in the context of the circular economy. Particularly, for the specific case study in Scotland, focused on the cultivation of seaweed and bivalves, we have identified the major drivers to increase the circularity in infrastructure.

Microplastic Sensor
The designed device can inspect a continuous water flow to search for microscopically-sized polymer particles, or MPs, and differentiate them from other natural particles (e.g., sand, algae) that may be present in marine water. The sensor’s operation consists of a pump circulating water through a pipe which, in a stretch, passes through an optical detection system based on a laser light and a photo-diode. If the water contains a particle, the photo-diode stops receiving the laser beam, allowing the image acquisition system to take multiple images with different focus configurations. The collected images are analyzed to identify the detected element and determine its nature: a MP, a grain of sand, a bubble in the water, etc. The design and development of the microplastic sensor intends to achieve several objectives:

• Reliable MP detection. The optical system must properly detect particles so that they can be subsequently analyzed, allowing the sensor to provide helpful information about water quality. The image acquisition system must capture high-sharpness focused images to detect the particles and distinguish MPs from other common elements in water (e.g. sand, algae) using image processing algorithms.

• Efficient operation. The design must ease the deployment in marine environments, achieving low-power operation, robustness, and effective protection against hazardous environmental conditions (corrosion, water inflows, humidity, etc.)

• Automatic and manual control. The manual control allows to configure, test, and validate the operation in offline mode, and the automatic control allows the sensor to operate without continuous supervision and online after the deployment. A dedicated house is designed to ensure portability and long-term operation without continuous supervision or maintenance. The design is based on commercial components to create an affordable sensor but capable of analyzing a permanent water flow and uploading results to a cloud database with low latency. The conducted validation reports a promising efficiency for the identification of MPs, which must be confirmed after the final deployment in a real location.
Results
A partial validation of the microplastic sensor prototype has been achieved at LEITAT laboratory by using synthetic samples based on the most common polymers (microplastics) located in sea water (such as polystyrene, propylene, etc). Furthermore, samples gathered nearby Norway (NORCE) and Scotland (Scottish Association for Marine Science), has enriched image datasets to assist LEITAT in the development. First results have shown that the microplastic sensor is capable of detecting samples from 350µm and upwards, with the current lenses and AI configuration.

Conclusions
Preliminary validation of an optical microplastic sensor, combined with artificial intelligence (deep learning) models and algorithms has been conducted in order to identify microplastic particles (from to 350µm and upwards) and to differentiate them from other particles located in seawater, at laboratory. Final validation in a real environment is planned to be performed in the upcoming months.

THE EFFECTS OF WOODCHIP BIOMEDIA AND DIFFERENT CARBON SOURCES IN DENITRIFICATION SYSTEMS COUPLED WITH SHRIMP RAS

Mark E. Johannemann*, Leo J. Fleckenstein, Andrew J. Ray

Center for Aquaculture and Aquatic Sciences
Kentucky State University
Frankfort, Kentucky, USA
mark.johannemann@kysu.edu

Nitrate continually accumulates in most RAS and has been shown to reduce production in high concentrations, thereby limiting long-term water reuse. Denitrification, a process in which facultative anaerobic microbes reduce nitrate to harmless dinitrogen gas, may allow for greater water reuse. Many denitrification filters are media based and may be unsuitable for systems with high solids concentrations such as biofloc-style techniques. Reactors relying on heterotrophic microbes also require organic carbon additions to fuel microbial activity, which increases costs for producers. In addition, some media types can be expensive. Low-cost alternatives such as wood chips for media and utilizing endogenous solid waste for carbon may lower costs while maintaining high rates of denitrification. The purpose of this study was to evaluate the potential for using no media versus woodchips in in-line denitrification bioreactors as well as to evaluate carbon sources, including fermented sludge supernatant, ethanol, and no added carbon.

The study consisted of six treatments with four replicates each and lasted 90 days. Each system included a 1 m$^3$ shrimp tank stocked at 250 shrimp m$^{-3}$. Water from each shrimp tank was pumped through a 3 L foam fractionator, an 18 L settling chamber, an 18 L moving bed biofilter, and a 28.7 L denitrification column. Sludge was collected from the settling chambers and allowed to ferment for a week prior to additions. Ethanol was added to maintain a 3:1 C:N ratio based on the daily nitrogen additions through feed. The concentrations of TAN, nitrite, nitrate, phosphate, alkalinity, turbidity, and TSS/VSS were measured weekly. Temperature, DO, pH, salinity and ORP were each measured twice daily.

Results indicate that nitrate was significantly lower in the WC treatments than in the NM treatments and in the ethanol treatments than in the no-C and sludge treatment. Shrimp survival and average weight were greater in the no media treatment than in the woodchip treatment. The ethanol treatment had greater average weight but lower survival than both the no added carbon and the sludge treatments. This experiment indicates that there can be a range of implications based on media and carbon types in denitrification reactors. Some factors seem to benefit water quality, but may have negative effects on shrimp. Such considerations are important for producers who wish to balance nitrate remediation while optimizing shrimp production.

Introduction

Lumpfish (*Cyclopterus lumpus* L.) is used in the salmon farming industry to combat sea lice. The numbers produced and used have increased from 10 million in 2010 to 51 million in 2020. However, the ethical use of these animals in the salmon net pens is an ongoing discussion, and concerns on how they are being handled during production has been extensively reported. The health and welfare of lumpfish must be improved if continuation of using lumpfish for biological control of sea lice in salmon farming should proceed. This includes a better understanding of lumpfish biology, insights into the physiological responses of cleaner fish to stressors, and development of tools for a better accuracy of assessing lumpfish health. At least 40% of the cleaner fish used in Norwegian farms die during production. This mortality is mainly linked to delousing operations, injury during transport, or release of poor-quality fish. Stress and damage through these events increase disease susceptibility and high mortalities can follow. Despite their robust appearance, lumpfish are very susceptible to skin damage and incidence is increased by their habit of adhering to substrates from which they are at times forcefully removed. Fish skin provides protection against external stimuli, has a high capacity for healing and regeneration and its structural changes may offer insights into the quality of the production environment. In this study we have studied lumpfish skin to characterize it’s features comparatively in pre-adult and adult fish, we have used the sample-sets to develop digital histomorphometry algorithm, and we have used this algorithm to study the effects of handling and delousing on lumpfish skin.

Material and methods

Lumpfish were collected from three different sources: Preadult lumpfish from a land-based hatchery, adult lumpfish from a salmon farm, and adult lumpfish before and after a delousing procedure using HydroLicer in a salmon farm. Skin samples were analysed histologically from five different regions in the two first sampling sets to characterize lumpfish skin: dorsal (1), anterior (2), posterior (3), tail (4), and suction disc (5). A digital histomorphometry algorithm was developed using Aiforia® and tested on all skin regions and on the sample set from the delousing event. The algorithm included basic layers typical for fish skin, like the epidermis, the dermis, and mucous cells. In addition, features specific for lumpfish skin were added, e.g. goblet cells and bone plates. 52 AB/PAS-stained histological skin sections were used to build the Lumpfish skin algorithm (AI Lumpfish skin). In these, there were 1403 training regions, with 12730 mucous cells and 6089 goblet cells identified. Samples sets were run in the AI and results manually inspected to verify the algorithm.

Results and discussion

Results showed that regions 1-4 had similar features in the adult and pre-adult lumpfish, with epidermis, dermis, and the bone plates. In the dermis, mucus cells, goblet cells and keratocytes were found. However, several features differed between adult and pre-adult lumpfish. One markable difference was the thickness of the dermis. Preadult fish have a thin layer of dermis, whilst adult fish had an extensive dermis layer in all regions except for the tail region. The dermis layer increased at both stages in regions with bone plates and fins. The dense connective tissue is also more pronounced in adult fish compared to the pre-adults. Furthermore, the mucous cells are more numerous in adult fish, reflected by a higher mucous cell: epidermis ratio, while the ratio goblet cell: epidermis is higher in the pre-adult fish. Lumpfish has no scales, but instead the skin is strengthened through numerous smaller and larger bone plates. The bone plates are located between the epidermis and the dermis. In adult fish, the epidermis makes a thin layer, consisting of one or two cell layers, surrounding the bone plates. In preadults, the epidermis covering these bone plates are thicker, with several cell layers. Lumpfish skin has few, but evenly scattered sensory cells in the skin, with increasing numbers in the head/mouth region.

The analyses of lumpfish from untreated and treated (deloused) lumpfish showed an increase in fin and skin damage up to 14 days after treatment in the treated groups. Skin damage will leave the fish more vulnerable to infections. Aiforia based analyses showed significant increase in dark pigment and in mucus cells in treated fish 14 days after treatment, both indicative of a stress response, as earlier shown in Atlantic cod, Polar cod and Atlantic salmon. Opposite, the amount of

(Continued on next page)
goblet cells was significantly reduced. Goblet cells are known from other species to be responsive to stress and as first line of defence against pathogens. They have been shown to be responsive to environmental factors and production related stress like handling and transport, however the specific response to stressors might vary between species. Three weeks after delousing the mortality of treated lumpfish was increased and the fish were diagnosed with crater disease caused by *Tenacibaculum* sp. Indications are that effects from the handling and delousing treatment of the lumpfish made them more vulnerable to disease.

**Conclusion**

An algorithm based histological analyses for lumpfish skin has been developed and has been successfully used to describe the lumpfish skin architecture of pre-adult and adult fish. It has furthermore been tested on field samples from lumpfish subjected to delousing. Results show that delousing operations contribute to skin- and fin damage and increase responses in the skin known to be connected to production related stress and handling. Indications are that the effects of delousing on the lumpfish make them more susceptible to pathogens.
DIVING INTO ZEBRAFISH STRESS: SKIN MUCUS CORTISOL AS A STRESS BIOMARKER

S. Jorge, L. Félix, B. Costas, and A. M. Valentim

Introduction

Zebrafish are often used to study cortisol mediated responses, particularly acute or chronic stress responses. However, to extract cortisol researchers have been relying on the zebrafish trunk, which is terminal, inhibiting the possibility of new cortisol measurements (Midttun et al., 2022) or re-using the animals for other purposes. Skin mucus offers a non-terminal and minimally invasive option (Franco-Martinez et al., 2022). However, no study has demonstrated its usefulness for identifying changes in cortisol levels in stressed zebrafish. Here, we evaluated the ability of zebrafish skin mucus to quantify cortisol in acute and chronic stressful situations.

Materials and methods

Adult AB wild-type zebrafish (sex ratio 1:1; 24 animals/group) were exposed to no-stress (control), acute (5 min net chasing + 30 sec air exposure), or a two-week unpredictable chronic stress protocol (2 stressors/day; a total of 7 stressors). The animals were euthanized by rapid cooling (0-4ºC) either immediately (control), 20 min after acute stress or approximately 20h after the last chronic stressor. Alterations on physiological levels were evaluated through cortisol (trunk and skin mucus) and oxidative stress markers (brain and liver homogenates). The sample (n=8), consisting of a trunk or a pool of 3 fish (skin mucus, brains, or livers) was considered the experimental unit. Data was analyzed using the IBM SPSS Statistics 27.0 computer program and plotted in GraphPad Prism 7 for Windows. Data normality and variances homogeneity were evaluated using the Shapiro-Wilk and Levene tests, respectively. For the cortisol data, the Independent Samples t-test and Mann-Whitney U-test were used to assess differences between groups. The oxidative stress markers in the liver and the brain were compared across groups using the one-way ANOVA or the Kruskal-Wallis test. The significance level was set at \( p < 0.05 \).

Results and Discussion

As previously seen in other tissues, acute stress significantly increased (\( p < 0.05 \)) ROS (e.g., Monteiro et al. (2021)) and AChE levels in the brain. However, no differences were observed in the liver. This could be due to the liver’s robust antioxidant activity compared to the brain (Song et al., 2006). Results also showed that skin mucus cortisol strongly responds to acute stress, identically to the trunk cortisol (\( p = 0.002 \) and \( p < 0.001 \), respectively).

Oxidative stress parameters were not altered by chronic stress, probably due to the animals’ adaptation to this stress, which is also supported by the lack of alterations in the trunk’s cortisol. Nevertheless, the cortisol levels in zebrafish skin were heightened after prolonged stress exposure compared to non-stress animals (\( p = 0.043 \)), which is interesting since skin mucus is traditionally viewed as an acute stress biomarker (e.g., Fernández-Alacid et al., 2019; Guardiola et al., 2016). It is possible that changes in skin composition were induced during exposure to chronic stress (see Carbajal et al., 2019), and that alterations in cortisol levels could have been masked by the cortisol distribution in the zebrafish trunk. However, due to the data variability and \( p \) near 0.05, these results require further confirmation.

Conclusion

Overall, the data suggested that skin mucus cortisol is an acceptable biomarker for acute stress in adult zebrafish. However, its role as chronic stress biomarker requires further studies.

Introducing the Red King Crab

Biofluorescence in decapods has been reported for several taxa. However, few studies have carried out a detailed examination under controlled conditions to describe fluorescence patterns and how it varies between individuals and under different conditions. Red king crabs *Paralithodes camtschaticus* (RKC) are an introduced species to Norway in the 1960s (Lorentzen et al. 2018) that are routinely kept in long-term holding facilities prior to live shipping (Mota et al., 2021). The aim of this study was to evaluate whether *P. camtschaticus* biofluoresces and to document the dynamics of fluorescence in the species under controlled conditions. The specific objectives for this study are to determine whether detectable changes in fluorescence levels occur in either the hemolymph or exoskeleton of *P. camtschaticus*.

**Methods**

The study of biofluorescence in male RKC was divided into two groups: hemolymph and exoskeleton. RKC (N=19) were sampled for hemolymph before and after they were transported and stored overnight in 20-liter styrofoam boxes. Each RKC had ~1.5 mL of hemolymph sampled and analyzed with a Duetta fluorescence and absorbance spectrometer. Fluorescence emissions were recorded in the EZ Spec Software. Each sample was recorded with excitation wavelengths from 250 to 350 nm with a 5 nm interval and emission wavelengths from 400 to 800 nm with a 0.5 nm spectral resolution.

The exoskeleton analysis scanned RKC (N=10 juvenile, 8 adults) on a conveyor belt illuminated with ultraviolet (~400 nm) and royal blue (~445 nm) LED lighting. After hyperspectral scanning, the crabs were placed overnight for post shipping recovery in an aerated 1000-liter holding tank at 6°C overnight. All hyperspectral images were taken with the HySpex VNIR-1800 hyperspectral camera. Raw data files collected with hyperspectral scanning were radiometrically calibrated with HySpex Rad v2.5 to produce radiance values in units of . The radiometrically calibrated data was uploaded for analysis in Breeze hyperspectral imaging software and inspected visually for fluorescence signals.

![Figure 1](image.png)

**Fig 1.** (A) Adult male king crab hemolymph fluorescing under 250, 300, 320, and 350 nm excitation light at 0 hours and 12 hours. The end point (blue line) of the experiment shows elevated fluorescence levels. (B) Fluorescence in the eye stalks of juveniles (left) and adults (right) during simulated shipping (start) and subsequent recovery (12 hours) in 6°C seawater overnight.
Results
Biofluorescence was recorded in both the exoskeleton and the hemolymph in the species. We found that RKC show great variability in biofluorescence and that most displayed a green biofluorescence in their exoskeleton (~500 nm), with the greatest intensity occurring in the eye stalks and the cervical groove of the carapace. The arthrodial joints between the limbs fluoresced in red (~680 nm). Hyperspectral analysis detected both green and red fluorescence in juvenile (N=10) and adult (N=8) crabs. A decrease in fluorescence occurred in the eye stalks after a post transportation recovery period while the cervical groove remained constant (Figure 1B). After applying a live transport simulation to a second RKC group (n=19), we found a significant increase (Anova; p = 0.008) in the hemolymph fluorescence of animals tested before and after out of water transport (Figure 1A).

Conclusions
As both physiological parameters such as stress hormones and tools available for empirically documenting physiological changes in crabs remain less advanced compared to higher order aquaculture species, it is difficult to ascertain whether this change in fluorescence can be categorized as an indicator for specific levels of stress. A recent study exposing adult RKC to low oxygen levels documented anoxic stress in hemolymph through an increased concentration of lactic acid (Mota et. al., 2021). Imagery-based estimates of changing fluorescence, like the one demonstrated in this study, should be linked with such empirical approaches in future studies to further explore the utility of non-invasive techniques for assessing RKC welfare. These findings indicate that biofluorescence in RKC is dynamic and further investigation may reveal whether such fluorescence could be used to monitor the welfare of decapods in captivity.

Introduction

Atlantic salmon, *Salmo salar*, is a key aquacultural species, with Norway, Chile and the United Kingdom as the largest producers. There has been progressive uptake of land-based systems, ranging from flow-through to fully closed recirculating aquacultural systems (RAS). Scotland, that dominates salmon production within the UK, is the exception and there is still large-scale use of floating net-pens in freshwater lochs up to smoltification (Bergheim et al., 2009). In line with other countries, in Scotland there is now increased interest in the adoption of RAS as it allows greater husbandry control, mitigates environmental impacts, as well as providing flexibility in farm design and location, among others benefits (Clark and Bostock, 2017; Bostock et al., 2018). However, given the environmental differences in RAS compared to loch systems, it is necessary to assess the relative performance of selected stocks across the two environments. We therefore aimed to investigate the genetic architecture of growth traits as well as quantify genotype environment interactions (GxE) of salmon smolts when reared in each environment. Our findings will potentially help inform possible future breeding and husbandry choices.

Materials and Methods

~250,000 eggs from MOWI commercial stock were transferred to RAS in the northwest of Scotland. The population was co-reared for 9 months, undergoing vaccination and 10% cull. After this time half the population was transferred to a freshwater loch system. After 8 weeks of separate rearing 1,000 fish were sampled per environment, with weight length and condition factor recorded. Fish were genotyped to 50K SNP by Identigene Ltd, along with parental genotypes, were made available for analysis. Duplicated and unaligned SNPs were removed, with the remaining filtered by removing individuals missing >10% of SNPs, SNPs missing in >10% of individuals, SNPs that failed HWE at $p=10^{-6}$ and SNPs with minor allele frequency <0.005. Variance components (residual ($V_r$) and additive genetic ($V_g$) variance) and narrow sense heritability ($h^2$, calculated as $V_g / V_p$) were estimated using univariate animal model via implementation of a REML approach. GxE was quantified as the genetic correlation between a given trait measured in each environment, estimated by fitting a bi-variant model (Mulder et al., 2006; Sae-Lim et al., 2016). All models were fit with H matrix and performed in BLUPF90 software (Misztal et al., 2002).

(Continued on next page)
Results and Discussion

55,357 and 65,774 SNPs were returned for parental and offspring genotypes, respectively. After filtering 45,751 SNPs, which were common to both, were used for analysis. Pedigree reconstruction identified 72 sires and 139 dams, as well as 141 full-sib families, of which 134 were shared between environments. The greatest difference was seen in body weight and length, which were both greater in the loch compared to RAS population. However, though smaller the RAS population showed low estimates of variability as well as marginally greater condition factor (table 1). Differences between the populations reared in each freshwater environment were also seen in the genetic architecture of each trait, whereby the RAS population had comparatively greater heritability estimates.

Estimated GxE ranged from moderate to low. Specifically, the genetic correlation for body weight was 0.624 (s.e. 0.14), for length 0.778 (s.e. 0.15) and for condition factor 0.853 (s.e. 0.17). These values indicate that GxE may be of concern for weight as the genetic correlation fell below the break-even correlation, suggested in fish as < 0.7 (Mulder et al., 2006; Sae-Lim et al., 2016). This indicates that, if employment of RAS continues to increase in the UK, the performance of current commercial populations may be below what could be achieved if environment specific breeding programs were established. However, such conclusions are only based on statistical results and further investigation in use of RAS for current populations is necessary.

Changes in water temperature are one of the most important environmental factors that directly affect the physiology and behavior of ectothermic fish. In order for fish to adapt to a wide range of seasonal temperature changes, corresponding changes in physiology and gene expression are required. In previous studies, myosin, lactate dehydrogenase, Δ3-desaturase, and warm temperature acclimation related 65kDa protein (wap65) were reported as genes regulated to adapt to temperature changes. Wap65 is known as hemopexin (hpx) in vertebrates. Hpx is a glycoprotein that binds to heme with high affinity and transports it to hepatocytes. It has been reported to prevent free heme-mediated cell damage in plasma. In fish, Hpx (Wap65) consists of two isoforms. In this study, to infer the function of Hpxs in fish, we analyzed the gene expression pattern of the hpxs in zebrafish by temperature and immune stimulation.

Whole mount in situ hybridization analysis showed that hpxa and hpxb are primarily expressed in the liver of 2, 3, and 5 dpf embryos. Specifically, hpxb expression was observed in the liver at 2 dpf, while hpxa expression was not. In 5 dpf embryos, hpxa and hpxb expression was strongly maintained in the left lobe of the liver; however, compared with the overall expression of hpxb, hpxa was observed as a single spot on the limited hepatic region. Although hpxa and hpxb distribution differed in adult tissues, they were most strongly expressed in the liver, while the lowest levels were detected in the heart. When temperature stimulation was applied, it was confirmed that the expression of hpxa decreased and the expression of hpxb increased in low temperature. During artificial infection with Edwardsiella piscicida (E. piscicida), a major bacterial pathogen in fish, and viral hemorrhagic septicemia virus (VHSV), a viral pathogen, expression of hpxa decreased, while that of hpxb increased. Thus, zebrafish hpxa and hpxb may have important roles in E. piscicida and VHSV infection; however, are likely controlled by different regulatory mechanisms. The higher expression of zebrafish hpxa and hpxb in important immune-associated organs, as well as their significantly regulated expression in response to immune challenge and temperature stimulations, warrant a more detailed in vivo analysis of the immune-related role played by zebrafish Hpxa and Hpxb. The findings of the current study provide novel insights that may help elucidate the immunological role of Hpxa and Hpxb in fish.
AVOIDING FISH ESCAPES IN OFFSHORE AQUACULTURE THROUGH THE DIGITALIZATION OF MOORING SYSTEMS AND THE CONTROL OF THE SEA CAGE BEHAVIORS

A. Jurado-McAllister*, I. Felis, R. Martinez, J.C. Sanz and M. Navarro

CTN-Marine Technology Center
Parque Tecnológico de Fuente Álamo
Ctra El Estrecho-Lobosillo km 2
30320 Fuente Alamo (Spain)
Email: amaliajurado@ctnaval.com

One of the main problems that offshore aquaculture is facing are losses and fish escapes caused by breaks in the sea cages. This problem arises mainly from failures in the mooring and the integrity of the system produced by storms, deficiencies in infrastructure supervision and maintenance, and lack of prediction of the sea cage behavior. In addition, sea cage ruptures have been intensified due to climate change.

This poster presents a pilot deployed in a meagre offshore fish farm in the Region of Murcia (Spain) within the project DigiSafeCage. The aim of the pilot is to take a first step towards a digital transformation in aquaculture production processes through monitorization and sensorization of infrastructure parameters such as deformations and tensions in the mooring lines, and oceanographic parameters such as waves and currents. Moreover, advanced statistical techniques and Artificial Intelligence analysis have been developed to predict sea cage movements under climate change scenarios.

Aim:
The aim of the project is to minimize the economic, environmental and social impact derived from sea cage escapes, caused by failures and breaks in the infrastructures. This poster presents a new digital system for the supervision of the offshore infrastructure that has been designed and, it is currently being tested to decrease the risk of ruptures based on the implementation of the sea cage digital twin.

Material and Methods:
To study the sea cage movements, sensors for monitoring the net deformations have been deployed (Figure 1 left) and load cells (Figure 1 right) have been installed in each mooring line. Wave parameters and currents data (direction and speed) have been correlated with the net movements and the tension of the mooring lines. The data analysis was done using the CRISP-DM (Cross-Industry Standard Process for Data Mining) methodology.

Results:
The load cell number shows an average value of 1507 kg and a minimum value of 593 kg (Figure 2).

The net sensors number 46 (Figure 3). “Pitch”; in green backwards movements and in red forwards movements (Figure 3 top). “Roll”, refers to side-to-side movements; in grey movements to the right and in blue movements to the left (Figure 3 bottom movements).

Conclusions:
Wave moments do not play a significant role in the sea cage net movement. Besides, there is a negative correlation between the net sensor’s movements and the speed of the current. These results mean that the speed of the current determines the movement of the sea cage net in one direction or another, in many cases regardless of the direction. Therefore, a continuous control of the currents in the location where the sea cage is placed would help to further understand the net behavior.

Regarding the load cell number 1, it shows values within the limits the mooring lines can hold, meaning that there is no risk of ruptures if the values are maintained as monitored. Nevertheless, these values were collected during the summer season without any storms. Loading cells should be deployed during winter season to understand the load the mooring lines are holding under adverse conditions to arrive to solid conclusions.

Introduction
The limitations surrounding oral vaccines for aquaculture species pose challenges to both animal welfare and production efficiencies. Insufficient understanding of delivery matrices and histological effects further compounds these challenges. Immersion and injective immunization methods come with drawbacks, underscoring the potential of effective oral vaccines to confer lasting protection while reducing costs. Encouraging outcomes from experimental trials employing oral vaccines have been reported (Adelmann et al., 2008; Ballesteros et al., 2015). Overcoming existing obstacles necessitates the development of biocompatible matrices and defense mechanisms during administration. Notably, alginate and polyethylene glycol have demonstrated successful protection of vaccine components; however, comprehensive insights into the impact on fish intestinal histology are lacking (Mohapatra et al., 2019; Weber et al., 2006). The conducted study aims to assess the influence of polyethylene glycol and alginate on the digestive tract and systemic response of juvenile rainbow trout (*Oncorhynchus mykiss*). The findings provide valuable insights into the suitability of these compounds as secure and effective delivery matrices for bioactive substances, including oral vaccines.

Materials and Methods
Conducted at the Center for Aquaculture Research (ZAF) of the Alfred-Wegener-Institute Helmholtz-Center for Marine and Polar Research, Bremerhaven, the trial involved 240 juvenile rainbow trout (18.7 ± 0.1 g) acclimated to a temperature of 15°C for 14 days before the 22-day feeding trial commenced. The fish were randomly allocated to 16 rearing tanks within a recirculating aquaculture system (RAS). The four treatment groups were tested in quadruplicates:
- Treatment 1 – Commercial pellet with 5% alginate inclusion
- Treatment 2 – Commercial pellet with 18% polyethylene glycol inclusion
- Treatment 3 – Commercial pellet with 17% polyethylene glycol and 5% alginate inclusion
- Treatment 4 – Commercial pellet (control)

The effects of the test substances were evaluated through histomorphological analysis of different intestinal sections and the quantification of inflammatory gene expressions including TNF-α, IL-1β, and IL-8.

Results and Discussion
Following the 22-day trial period, fish receiving the experimental diet with polyethylene glycol inclusion exhibited alterations in the intestine, notably a reduction in villus height and bioactive intestinal surface. Alginate inclusion resulted in a decrease in mucus-secreting goblet cells. Despite observable intestinal changes, analysis of inflammatory gene markers did not reveal significant systemic impairments. While negative intestinal effects were observed, their potential adjuvant impact on the immune response following oral vaccination, particularly for bioactive components such as oral vaccines, remains to be defined (Just et al., 2023).

Conclusion
Based on the outcomes of this study, all test substances showed immunocompetence and can be considered safe for the encapsulation and application of bioactive substances, including oral vaccines. These findings hold promise for advancing the development of effective and efficient oral vaccination strategies in aquaculture, contributing to improved animal health, welfare, and overall production outcomes.

Introduction:
The worldwide increase in the production of organic wastes has increased the need for treating and using them as manures, fertilizers, nutritive feeds or energy substrates. Integrated multitrophic aquaculture (IMTA) systems along with wastewater treatment techniques is a novel area of research which in future can be established as a cutting-edge technology in the field of agriculture and aquaculture. The sediment microbial fuel cell (SMFC) assisted wastewater treatment system has the potential of simultaneous agriculture/livestock/synthetic wastewater and aquacultural wastewater treatment along with promising power production for powering different low-energy up-taking sensors such as water quality or environmental sensors. Activated aquacultural biochar catalysts can be prepared from aquacultural wastes, which can potentially improve the performance of SMFC acting as cathode catalyst. Biochar-based catalysts are made of naturally available sources, mainly wastes which makes them a better sustainable alternative to metallic catalysts making them more cost-effective for large-scale applications. Waste minimization, wastewater treatment, water utilization and renewable energy production are the primary advantages of SMFC-assisted aquacultural systems.

Materials and methods:
A sediment microbial fuel cell (SMFC) reactor with carbon felt as the electrode was designed and fabricated for wastewater treatment and power generation studies (Fig. 1). After filling up the pond sediment and aquacultural wastewater, an anode electrode (carbon felt of dimension 18cm ×3cm ×0.5 cm) was placed at the bottom attached to the pond sediment and a cathode electrode (three carbon felt each of 6cm ×3cm × 0.5cm) which was stacked parallelly, was placed in the overlying water. The water quality parameters of the aquacultural pond water sample were analyzed and synthetic wastewater was prepared considering the maximum COD range that can occur in an integrated poultry-fish system for more accurate studies. The SMFC reactor was operated and monitored for more than 50 days (10 experimental cycles).

A novel activated aquacultural biochar catalyst was synthesized from aquacultural wastes and used as a cathode catalyst for improving the performance of SMFC. Material and electrochemical characterization studies were carried out in order to analyze the property of aquacultural biochar catalyst. Polarization studies were carried out by varying external resistance from 10 kΩ to 10 Ω to compare the performance of SMFC reactor with and without activated aquacultural biochar-based cathode catalyst in treating aquacultural and synthetic wastewater (poultry-fish based). A detailed design of an intensive poultry fish culture system assisted with SMFC-based wastewater treatment was proposed after validating the data from the experimental SMFC reactor’s performance.

Results:
SMFC started producing an open circuit voltage (OCV) of 772 mV and an operating circuit current of 0.4 mA on the first day after its acclimatization phase. The stable operating voltage was generated until the COD value reached the optimal range and hydraulic retention time (HRT) was determined to be 4 days. An average COD removal efficiency of 86.31% was obtained over the 10 experimental cycles. SMFC generated a maximum operating voltage of 0.422 V when connected to an external resistance of 975 Ω on the 21st day of operation. The characterization studies of the synthesized aquacultural biochar catalyst such as cyclic voltammetry (CV), and electrochemical impedance spectroscopy (EIS) exhibit the synthesized aquacultural biochar catalyst is an active electrocatalyst which can help in faster oxygen reduction reaction (ORR) rate which ultimately leads to higher power output and overall efficiency of the cell. Raman spectroscopy and X-ray diffraction (XRD) analysis suggest that the biochar shows good electrochemical activity and catalytic properties.

(Continued on next page)
The SMFC with aquacultural waste-based biochar cathode catalyst treating the synthetic wastewater showed the highest maximum power density (MPD) with a range of 101.63 mW m$^{-2}$ (1693.83 mW m$^{-3}$) and lowest internal resistance (49.34 $\Omega$) which depicts the improved performance of the SMFC by the use of cathode catalyst. The results validate the reliability of using SMFC in actual aquacultural systems, thus proposing a system design of SMFC reactor-assisted small-scale integrated poultry fish culture system. SMFC used for the design study was proposed for the aquacultural fish tank of inner dimensions of 1.75 m $\times$ 2.1 m with a tank depth of 1.2 m. The design specifications for the integrated poultry fish culture are proposed in such a way that the poultry cage set-up should be installed on the top of the fish tank to easily pass the poultry droppings into the fish tank (Fig. 2). The poultry chickens will be kept inside the cages and the fish will be reared in the same fish tank where SMFC has been developed. SMFC equipped inside the fish tank will treat the wastewater and maintain the aquaculture water quality with simultaneous power production.

**Conclusion:**
This study represents the experimentation, analysis and validation of incorporating wastewater treatment techniques such as SMFC into IMTAs including integrated poultry-fish culture. The operating parameters such as pH, DO, temperature, SMFC reactor design, electrode material, and stocking density of fish and chicken are to be considered before incorporating SMFC into an integrated poultry-fish culture. SMFCs can be integrated into aquacultural systems, such to provide a complementary source of energy and improve water quality reducing the risk of disease outbreaks in aquacultural systems. SMFCs have the potential to act as power generators for different water quality and environmental sensors which in fact provides multiple advantages of assisting this reactor with the IMTA system. SMFC using aquacultural waste-based biochar catalysts can effectively be incorporated into IMTA systems resulting in a potentially valuable technology for sustainable IMTA systems. SMFC-based IMTA systems improve water quality, generate renewable energy, improve fish growth and survival and maintain sustainability.
STOICHIOMETRIC IMBALANCES OF AVAILABLE NUTRIENTS DRIVE CENTRAL EUROPEAN FISHPONDS—A REVISION OF CURRENT POND MANAGEMENT IS NEEDED

Introduction
Fishponds, artificial ecosystems built exclusively for fish production, had been integral parts of the European landscape for centuries. The current fishponds have become less predictable regarding production processes, hence, also less cost-efficient, more stochastic, and greatly unstable systems. While human activities purposefully eutrophicated fishponds in the last century to increase their productivity, little is known about stoichiometric shifts of macronutrients available for planktonic food webs in these shallow ecosystems. Understanding the complex interactions between nutrient stoichiometry and ecosystem dynamics in fishponds is crucial for effective management and conservation efforts aimed at preserving these vital aquatic ecosystems while keeping them as protein-production units. We hypothesized that (a) the nutrient regime might vary both on regional and seasonal scales and (b) fishery management interventions might enforce stoichiometric imbalances. The long-term excessive nutrient loading may thus lead to stoichiometric imbalances and further worsen the bad nutrient state of fishponds yet affected by a region and a period of the vegetative season.

Material and methods
We surveyed 31 fishponds from lowland to highland regions of Czechia (altitudinal range from 170 to 730 m a.s.l.). All fishponds are polymictic, eutrophic to hypertrophic waterbodies (area 0.23–449 ha) with controlled fish stock. The fishponds under study were used for rearing ongrowing common carp exclusively. They were sampled monthly over a vegetative season from April to September (Apr–Sep). Data spanning the vegetative seasons were taken as observation units, herein referred to as pond-year, resulting in 150 pond-year cases. Dissolved inorganic N to total P ratio (DIN:TP) was used as an indicator for inferring in situ N versus P limitation of primary production from chemical data. DIN was calculated in-silico: DIN = NO₃-N + NH₄-N. We analyzed the data using generalized linear mixed models (GLMMs) with Gaussian distribution and log10 and log10+1 transformations to explore the drivers of chlorophyll-α and DIN:TP concentrations in water.

![Graph A](image1.png) ![Graph B](image2.png)

Fig. 1. Predicted effects of supplementary feeding (A) and altitude (B) during the season as identified by the most parsimonious model. Non-focal continuous values are fixed at the mean value in the dataset. Symbols: individual data, Colours: different months; lines and ribbons denote GLM model predictions with 95% confidence intervals.

(Continued on next page)
Results
We surveyed the seasonal trends of chlorophyll-a and the dynamic of available nutrients to the planktonic food web in 31 ponds used exclusively for fish production. Results of data compiled over various temporal and spatial scales suggested that fishponds might be stressed by seasonal and regional stochiometric imbalances of available macronutrients that could drive the concentration of chlorophyll-a (Fig. 1).

Discussion
Pond aquaculture is becoming progressively more marginal and challenged by many factors, such as prices, sustainability, environmental concerns, and resource utilization. Besides altitude, supplementary feeding (e.g., cereals and triticale; rich in phytate P) seems to be connected to the DIN:TP shift. The dynamics of available nutrients changed over the vegetative season with the cumulative input of supplemental feed. Most of the feed (65%) is fed in the second part of the growing season, at the time when the natural prey is over-grazed. We suggest that the current pond management practices deserve a revision, as warranted by changing nutrient status, stoichiometry, and climate.
INFLUENCE OF Artemisia Arborescens AS A FEED SUPPLEMENT ON PHYSIOLOGICAL AND IMMUNE RESPONSES OF GILTHEAD SEA BREAM (Sparus Aurata)

Introduction
Fish infectious diseases are one of the main constraints of the aquaculture sector, representing a serious economic, social, and environmental challenge for the industry. Sea bream (Sparus aurata) is a teleost fish found in the Mediterranean Sea. It is economically important and natural stocks are subject to intensive exploitation raising future conservation and management issues. Due to its importance as high-quality food, many studies are focusing on enhancing its immune defense mechanisms, in order to improve its health in farming conditions. The use of medicinal plants as aquafeed additives provide a sustainable way of fish protection using safe, eco-friendly compounds in a cost effective way compared to antibiotics and chemical compounds currently used. Several studies have proved that medicinal plants have extensive antimicrobial, immunostimulant, antioxidant, anti-stress, and growth-promoting properties [Awad et al., 2017; Firmino et al., 2021].

Aim of the present study was the assessment of Artemisia arborescens feed supplementation effects on sea bream (Sparus aurata) physiological and immune responses in both lab-based experimental and field feeding trials.

Materials and methods
Two experimental diets containing different amounts of Artemisia arborescens (AA) essential oil extract (0.25 % AA and 0.50 % AA) and a positive control diet (commercial diet without AA) were used. Sea bream were assigned to experimental tanks and each diet was allocated in triplicate groups. The feeding trial was continued over a period of two months. At the end of the feeding trial, fish mucus was isolated, followed by measurement of fish weight and length. Blood was drawn by the caudal vein of fish and serum was isolated by centrifugation. Spleen tissues were removed aseptically and stored at –80 °C. All animal handling and sampling procedures were conducted in accordance with Greek and EU laws and regulations.

Mucus and serum samples were used for biochemistry and immunological parameters assessment, according to well established protocols. Non-specific immune parameters (i.e. nitric oxide, lysozyme, myeloperoxidase, complement C3, proteases and anti-proteases), antibody responses (total antibodies, immunoglobulin M, anti-microcotyle and anti-T. maritimum antibodies), oxidative stress (CYP1A1, metallothionine (MTT)) and metabolism markers (glucose, alkaline phosphatase (ALP) were determined. Total RNA was extracted from fish spleen and real-time PCR assays were carried out to analyze the expression levels of genes related to antioxidants (SOD1, GPx1), cytokines (Il-10, TGFb1, Il-1b, TNFa), anti-bacterial peptide (Hepcidin) and heat shock protein (GRP75).

Results and Discussion
Fish weight, length and splenosomatic indexes showed no significant differences in tested diet groups. The total protein amounts in serum and mucus were significantly lower when the experimental diets were compared to control diet. Glucose and alkaline phosphatase levels weren’t significantly altered by the experimental diets in serum, however the ALP mucus levels were decreased. Non-specific immune responses were assessed in fish serum and mucus by measuring the levels of nitrite ions, lysozyme, complement C3, myeloperoxidase, as well as protease and anti-protease activities. No significant differences were found in serum nitric oxide; however, mucus nitric oxide levels were significantly lower in experimental diets. Lysozyme and C3 levels were relatively stable in all groups. The myeloperoxidase levels were also not altered by the experimental diets. The remaining parameters (proteases and anti-proteases activities) were not affected by any of the experimental diets. The total antibody levels remained stably low, however the IgM levels was significantly increased with experimental diet 0.25% AA compared to the control diet. The cytochrome 1A1 was significantly lowered in 0.50% AA diet, while metallothionine was not affected by experimental diets. Those results indicate a mild modulation of oxidative stress by A. arborescens.

(Continued on next page)
Gene expression profile was analyzed to evaluate the modulation of immune-, oxidative stress- and metabolism-related genes in sea bream fed with the two experimental diets. The studied genes in sea bream spleen were related to cytokines (IL-1b, IL10, TGFb1, and TNFa), oxidative stress (SOD-1 and GPx1) and metabolism (hepcidin and GRP-75). All analyzed genes were differentially expressed to some extent but gene expression differences were not statistically significant for any of the tested groups. However, the 0.50% AA group appear to have increased expression of the immune and oxidative stress markers compared with control and 0.25% AA groups.

The 0.25% AA diet was also tested in a field feeding trial and it was found that the experimental and control groups had no statistically differences in any of the tested parameters, which were described above.

Concluding, serum and mucus tested parameters revealed that *A. arborensis* influences *S. aurata* immune and oxidative stress profile. The gene expression levels increased in diets with high extract concentration. The suitability of *A. arborescens* as efficient food supplement for immune status improvement was investigated and the results indicated that it could be used as dietary additive since it appears to have considerable potential as natural immunostimulant.

INTRODUCTION

Marine larval feed technology has greatly advanced and provides microdiets that cover the nutritional needs of newly hatched larvae, have high acceptability and palatability, water stability and low nutrient leaching (Hardy and Barrows, 2002). In the hatchery practice of gilthead seabream *Sparus aurata*, red seabream *Pagrus major* and European seabass *Dicentrarchus labrax*, dry feed is progressively introduced to fish larvae not earlier than 15-25 days post hatching (dph) with the concomitant use of live feeds (rotifers, *Artemia*) until weaning. However, compared to live feed, dry feeds appropriately manufactured (i.e. physical and nutritional properties) are expected to better provide for all nutritional needs of altricial fish species. Although the exclusive use of dry feeds is still inefficient, it is widely accepted that the longer the co-feeding period of live and dry feeds, the better the larvae performance at weaning (e.g. Cañavate and Fernández-Díaz, 1999; Khoa et al., 2020). In cooperation with commercial hatcheries, we previously investigated the introduction of dry feed, together with live feed, as soon as the onset of the exogenous feeding in gilthead seabream, red seabream, and European seabass larvae (Karakatsouli et al., 2019, 2021a, 2021b, 2022). The aim of the present study is to overview results obtained and present comparative data regarding three of the most important intensively reared fish species of Mediterranean aquaculture.

MATERIALS AND METHODS

Three experimental trials were conducted, one for each species. The experimental design included two stages: Stage 1, Hatchery rearing (Hr), was performed in a commercial marine fish hatchery. It is in this stage that the experimental treatments were imposed. Specifically, dry feed was introduced either on the first day of exogenous feeding (Experimental Feeding Protocol, EFP) or on the dph (days post hatching) that the specific hatchery protocol used (Typical Feeding Protocol, TFP). The trial was performed under actual production conditions and each treatment was duplicated. In all experimental tanks, the larvae were fed equal amounts of live feed according to the hatchery protocol. Samples were regularly taken, from hatching up to weaning, to monitor larvae growth and functional development of the digestive system (digestive enzymes analyses). Skeletal deformities were also evaluated. Stage 2, Laboratory rearing (Lr), was performed in a laboratory recirculating seawater system. It is in this stage that post-larvae growth performance (pre-growing) was evaluated by rearing larvae produced from Stage 1 under common and controlled conditions. The trial was decided to be performed under laboratory conditions, since, under production conditions, it is not feasible to keep together and separately a specific hatchery batch due to frequent gradings. Post-larvae growth performance was monitored for about two months.

Figure 1. Summary of obtained results when larvae were co-fed live and dry feed from the onset of exogenous feeding (EFP) compared to TFP. Arrows indicate significant higher or lower values; equals indicate not significant differences; DF: dry feed.

(Continued on next page)
Results and discussion

For gilthead and red seabream the EFP promoted larvae and post-larvae performance (Figure 1). It is noted that growth enhancement in red seabream was highly remarkable. In the case of European seabass, no growth differences were observed between the two feeding protocols (EFP vs TFP). In all three species, survival of larvae co-fed live and dry feed from the onset of exogenous feeding was similar to those that followed the TFP, while no differences were observed regarding the percentage of larvae without swim bladder. Moreover, the functional development of the digestive system was normal in both treatments; in the case of EFP larvae digestive function (i.e. trypsin, chymotrypsin, amylase, lipase specific activities) was responsive to dry feed intake, especially during the first feeding days. In all three species, a common observation was the development of fewer skeletal deformities in the EFP.

Overall, present results suggest that the introduction of dry feed together with live feed in first-feeding gilthead seabream, red seabream and European seabass larvae does not compromise larvae and post-larvae growth performance and functional development of the digestive system. The incidence of fewer deformities in all species tested support the hypothesis that the ingestion and digestion of an appropriate dry feed may provide larvae with the necessary nutrients to form a healthy skeletal system. Nevertheless, species-specific differences are indicated, red seabream being the most responsive species while European seabass the least. However, in the latter case, there is a great variability of applied feeding protocols in commercial hatcheries, while in this study, only one of them was examined. In conclusion, co-feeding dry and live feed in first-feeding gilthead seabream, red seabream and European seabass larvae can be considered as a viable feeding protocol producing healthy fish with fewer deformities.

THE EFFECT OF A SLOW-RELEASE AMINO ACIDS MIXTURE IN EUROPEAN SEABASS DIET ON FISH GROWTH PERFORMANCE AND AMINO ACIDS DIGESTIBILITY

Introduction
The increasingly challenged fishmeal market together with sustainability concerns strongly dictate the constant search for alternative protein sources for aquafeeds. The product examined in the present study (NatuPro, Devenish Nutrition) is an alternative, nutritionally enhanced protein that due to a sugar-based carrier allows for a slow release of amino acids during the digestion phase resulting in a more efficient absorption and utilisation of amino acids by the animal. The product has been tested in growing pigs improving nitrogen retention and utilisation and reducing total and urinary nitrogen output (Kasserly et al. 2005). To our knowledge no literature data have been reported regarding its use in the diets of intensively reared fish species. The aim of the present study is to evaluate the inclusion of NatuPro in European seabass Dicentrarchus labrax diets on juvenile fish growth performance and amino acids digestibility. The evaluation was performed under the general scope of reducing the currently used dietary protein content by sparing high protein raw materials, fishmeal in particular.

Materials and methods
A feeding trial was designed that included three experimental diets: (a) a diet formulated according to current commercial diets for European seabass (Control diet, crude protein 46.9 %, fishmeal 15 %), (b) a negative control diet, i.e. a diet with 1 % lower crude protein level by 1.5 % lower fish meal level (C1, crude protein 45.7 %, fishmeal 13.5 %), and (c) a C1 diet with NatuPro included at 2 % (C1-N2, crude protein 46.0 %, fishmeal 13.5 %). Experimental diets were fed, for 140 days, to tetraplicated fish groups (mean initial body weight ± s.e.: 38.3 ± 0.08 g; fourteen fish per group; recirculating seawater system). Fish were fed a restricted ration according to body weight and water temperature. After the completion of the main rearing period and growth performance assessment, fish were fed the same diets including chromic oxide (1.0%) as a marker, once daily to satiation. Faeces were collected by stripping every two days. At the end of the digestibility trial all fish were sacrificed; liver and carcass were weighted to calculate hepato-somatic index (% body weight) and carcass yield (% body weight). Diets and lyophilized faeces were analyzed for chromium, protein and amino acid content. Data were analyzed by one-way ANOVA and tank was the experimental unit (n=4).

Results and discussion
No significant differences were detected among experimental diets for growth performance (i.e. final body weight, condition factor, specific growth rate, thermal growth coefficient, weight gain) and feed efficiency (i.e. feed conversion ratio, protein efficiency ratio, economic conversion ratio). Also, experimental diets did not affect hepato-somatic index and carcass yield. Protein digestibility was similar among experimental diets. However, values obtained were rather low probably due to the stripping method of faeces collection (Spyridakis et al. 1989; Shomorin et al. 2019) and the low water temperature (19.3 ± 0.6 °C) during the digestibility trial (Peres and Oliva-Teles 1999). Lysine (Lys) digestibility was significantly higher in C1-N2 diet compared to C1 and control diets (Table 1). Methionine (Met), glutamic acid (Glu) and glycine (Gly) digestibility was significantly reduced in C1 diet compared to Control diet; the inclusion of NatuPro (C1-N2 diet) highly improved Met and Glu digestibility in higher levels than those observed in Control diet, while Gly digestibility was back at Control diet levels.

Obtained results indicate that the inclusion of NatuPro in European seabass diets does not compromise fish performance and feed efficiency. The improvement of some essential and non-essential amino acids digestibility suggests the product’s potential use in fish diets and agrees with previously reported results on other productive animals (Casserly et al. 2005). With the continuously increasing prices and scarcity of fishmeal, NatuPro is indicated as an interesting alternative protein source. However, since present experiment was conducted under lower than expected water temperature for the growth of European seabass, further research will be needed to better understand the mode of action under different rearing conditions, especially under the optimum water temperature range for the species (Yilmaz et al. 2020).

Introduction
Given their high nutritional value and low environmental impact, microalgal biomass can serve for the partial replacement of dietary fishmeal (Glencross et al. 2020) towards more sustainable aquafeeds. Chlorella vulgaris is the most common commercial microalgal protein that has been successfully used for fishmeal replacement in aquafeeds (Karapanagiotidis et al. 2022). However, its rigid cell wall lowers its digestibility and nutrient availability to fish (Tibbetts et al. 2017). Chlorella sorokiniana is also a unicellular alga that can contain high levels of crude proteins and essential amino acids (Liu et al. 2022) and thus could also be a promising fishmeal substitute. However, studies on the use of C. sorokiniana meal for fishmeal replacement in aquafeeds are extremely limited. Thus, the aim of this study was to evaluate the dietary fishmeal replacement by graded levels of a C. sorokiniana meal on the growth performance and feed utilization of an important Mediterranean farmed species, the gilthead seabream (Sparus aurata).

Materials and Methods
A total number of 360 S. aurata juveniles of 2.6 g initial mean weight were obtained from a commercial fish hatchery, transferred to the aquaculture facilities of University of Thessaly and stocked at 12 tanks (125L) in a closed seawater recirculation system. Fish in triplicate groups (30 fish/tank, 3 tanks/dietary group) were fed to satiety, twice a day, four isonitrogenous (46%) and isoenergetic (21 MJ/Kg) diets differing in the source and the inclusion level of C. sorokiniana (CS) meal. CS0 diet used as the control one and contained fishmeal at an inclusion level of 200 g/Kg and zero levels of CS. A second diet (CS020) was used containing a CS meal that was produced in the open ponds of University of Thessaly under photoautotrophic conditions, replacing the fishmeal protein of the CS0 diet at 20% corresponding to 54 g/Kg dietary inclusion level. The protein content of this CS meal was 48.8% (N to protein factor 4.95). In diets, CS20 and CS30 fishmeal protein of the control diet was replaced at 20% and 30%, respectively by a commercial CS meal corresponding to 70 g/Kg and 104 g/Kg dietary inclusion levels, respectively. The commercial CS meal was produced in closed photobioreactors (PBR) with a protein content of 37.7%. After 60 days of feeding, fish were weighted to measure growth and feed utilization parameters. Data were analysed using one-way ANOVA and differences between means were determined by Tukey’s multiple-range test (P=0.05).

Results and Discussion
Survival was high and similar (P>0.05) among the groups (Table 1). All groups of fish promptly accepted the respective diets and feed intake was similar (P>0.05) among the groups, though it was a trend for higher consumption in fish fed the commercial CS meal-based diets. The latter two groups had higher, though not significantly (P>0.05), final weight, weight gain, specific growth rate (SGR), feed efficiency and protein efficiency ratio (PER) compared to the control group. Fish fed the CS meal produced in open ponds (CS020 group) had also similar growth and feed utilization parameters compared to the control group, but their performance was significantly inferior compared to the fish that were fed with the commercial C. sorokiniana product. This performance differentiation maybe due to C. sorokiniana strain-specific nutritional features or to a possible higher biological contamination level of the CS biomass produced in open systems vs PBR. These results indicate that both C. sorokiniana meals can successfully replace part of fishmeal protein without impairing fish growth performance and feed utilization.

(Continued on next page)
Studies on the use of *C. sorokiniana* meal for fishmeal replacement in aquafeeds are extremely limited. In *Oncorhynchus mykiss*, Chen et al. (2022) using a 5% dietary inclusion of CS meal, replacing fishmeal, significantly increased the feed intake by 19.3% and weight gain by 17.3% without impairing feed efficiency, while also improved the antioxidant capacity and immunity of fish. In the same species, Liu et al. (2022) reported a higher feed intake, growth performance and feed efficiency of fish fed a diet where fishmeal was totally replaced by CS. The authors attributed this to the higher digestibility and feed palatability of the used CS meal, its similar amino acid profile with fishmeal and the *Chlorella* growth factor that provides several bioactive compounds to fish nutrition. The present findings could help the aquaculture of gilthead seabream to further decrease dietary fishmeal levels by *C. sorokiniana* meal towards more sustainable aquafeeds.

Introduction
A bottleneck to the growth of the aquaculture industry is disease outbreak. The most recent disease outbreak in shrimp farming systems, known as Acute Hepatopancreatic Necrosis Disease (AHPND), occurred in 2009 and resulted in enormous economic losses across the globe (FAO, 2022; Sarker et al., 2021; Mishra et al., 2017). The opportunistic pathogenic bacterium \textit{Vibrio parahaemolyticus} (VP) produces plasmid encoded (pVA1) binary toxins pirA\textsuperscript{VP}/pirB\textsuperscript{VP}. The toxins cause up to 100% mortality by degenerating the epithelial cells of the hepatopancreases during the early stages of shrimp stocking (Lightner et al., 2012; Lai et al., 2015). Bacillus strains have been used widely in combating diseases in aquaculture. There is also evidence that Bacillus treatment improve brine shrimp survival against \textit{V. parahaemolyticus} (Nguyen et al., 2021). Interestingly, the protection mechanism is still not clear. In this study, eight distinct Bacillus strains as potential AHPND disease controlling or mitigating agents were examined in vitro for their ability to degrade AHPND toxins and other phenotypes potentially contributing to their probiotic nature.

Materials and Methods:
Eight Bacillus strains have been used for the study. The Bacillus were collected from BCCM/LMG and DSMZ collection centre. The recombinant binary toxins (rPirAB\textsuperscript{VP}) were purified using His Spintrap column (Cytiva 28-4013-53, USA). In vitro degradation (over a period of 48h by 10\textsuperscript{7} CFU/ml) of recombinant AHPND toxins were detected using SDS-PAGE followed by Western Blot techniques. Strains were tested for their capacity to degrade quorum sensing molecules (only acyl homoserine lactons; AHL) in an LB background over a period of 24 h. The flow cytometer was used to test their capacity to bind four fluorescently (FITC) labeled lectins (from plant origin). Biolog GENIII microplate (BOLOG, Hayward) assays were used for metabolic profiling analyses and data were processed by PCA analysis. Extracellular proteins harvested from concentrated Bacillus culture were separated by SDS-PAGE and analysed using the BioNumerics 7 software (setting: 1% optimization of band migration) (Applied Maths, Kortrijk, Belgium).

Results and discussions:
Bacillus strain LMG9300, DSM1668 & DSM8785 exhibited strong AHL-degrading properties. Apart from AHL-degrading capacity, LMG9300 also showed significant rPirB toxin degradation overtime (Fig. 1). Each Bacillus strain produced different secreted proteins and dendrograms of secretome profiles from all Bacillus strains were constructed based on two strategies (namely based on presence/absence of bands or band intensity) (Fig.2). In both cases, 2 main clusters of strains could be observed, harboring the same Bacillus species. Yet, in the band based approach of clustering, LMG9300 was singled out. All Bacillus strains bind predominantly either the lectin WGA or the lectin ConA (Fig. 2). The grouping of the secreted protein profiles correlated to a large extent with the capacity to bind either the WGA or ConA. Metabolic profiles for carbon sources of each strain were examined using Biolog GENIII plates. The metabolic data were processed using heatmap and principal component analysis (PCA). Generally, three clusters were detected by heat map analysis. The heat map analysis for amino acids and peptides was not significantly different from heatmap analysis of carbon sources. Finally, the tested in vitro phenotypes (in vitro AHPND toxins degradation, secretome profile, metabolic profile and lectin binding profile) will be correlated with their in vivo capacity to control AHPND, hopefully facilitating establishing links with their in-vivo functionality.

Introduction
Feed is an essential part of aquaculture. Firstly, as the nutritional benefits and the general health and robustness of fish depends mainly on the nutrients supplied through aquafeeds. Secondly, as feed is the most expensive part of fish aquaculture and availability of a cost-effective feed remains as one of the bottlenecks to achieve an adequate aquaculture sector development. The feed attributes to around 60-70% of the production cost. Due to fluctuations in supply and prices of traditionally used marine ingredients such as fish meal (FM) and fish oil (FO), the aquaculture industry has inclined towards plant-based feeds. However, plant-based diets may result in deficient and imbalanced supply of essential nutrients, due to negative effects on palatability, and the presence of anti-nutritional factors on nutrient availability, which may also have other negative effects on fish health. Hence, to cover the nutritional requirements of fish, without compromising its health, and at the same time utilizing aquafeeds ingredients effectively, it is important to produce feeds with functional raw materials that could enhance the bioavailability and utilization of nutrients, which would lead to enhanced fish health and performance. In addition, it would enable the industry to save costs by improving feed efficiency. One such functional and sustainable marine ingredient is krill meal. The present trial was conducted to test the effect of krill meal inclusion towards enhancing the feed utilization and enhancing growth and nutritional in gilthead seabream (Sparus aurata) juveniles.

Methods
Juvenile gilthead seabream (8.4±0.04 g), were fed a practical diet with either a 15% FM/5.5%FO level of inclusion (KM0; control diet) or the same diet replacing FM by 20% (KM3; 30 g KM/kg diet), 33% (KM5; 50 g KM/kg diet) or 50% (KM7; 70 g KM/kg diet) Antarctic krill meal (KM) for 12 weeks in triplicates. At the end of the feeding trial, growth performance and feed efficiency were evaluated, and fish were subjected to a stress-challenge by confinement for 7 days. The omega-3 index (EPA+DHA% in RBC, which is used as an indicator of EPA+DHA% in the different tissues) was measured at day 0, 24 hours and after 7 days post stress.

Figure 1. (A) Growth performance and (B) feed utilization of gilthead sea bream (Sparus aurata) juveniles fed diets with graded KM levels along the feeding trial. Values expressed in mean ± SD. Specific growth rate (SGR) = [(In final weight - ln initial weight)/number of days] x 100; Feed conversion ratio (FCR) = (total feed fed/total weight gained). KM = control diet; KM3 = krill meal 30 g/kg diet; KM5 = krill meal 50 g/kg diet; KM7 = krill meal 70 g/kg diet.

(Continued on next page)
Results
Fish fed with KM5 and KM7 presented an improvement in FCR when compared to fish fed on conventional control diet with FM and FO (15% FM/5.5% FO). In particular fish fed KM7 and KM5 diets presented an improvement in FCR by a 6.5% and 4%, respectively when compared to control group. Besides, a relatively higher growth performance (3.5%) was observed in fish fed with KM7 diet in comparison to control group (Fig. 1). Further, the lipid efficiency ratio (LER) was significantly enhanced with all the 3 doses of krill meal (9% higher LER for KM3 and KM5 and 15% higher LER for KM7, respectively, in comparison to control diet) and protein efficiency ratio (PER) was enhanced for KM5 and KM7 (3% and 7% higher PER for KM5 and KM7 diets, respectively) in comparison to control group. Omega-3 index was increased in all the three krill diets (4.3% increase in KM3, 4.7% increase in KM5 and 3.6% increase in KM7, respectively) in comparison to control group (1.2% increase) after 7 days post stress, indicating that nutrients in KM have the potential to possibly prevent the oxidation of vital polyunsaturated fatty acids, such as EPA and DHA and hence maintain the nutritional value of fish. These results demonstrate that krill meal inclusion leads to better utilization and retention of nutrients (fat and protein) in feed, and hence could significantly optimize feed efficiency, which provides economic benefits to farmers. Further, the inclusion or krill meal could enhance the nutritional value of fish as indicated through higher increase in EPA+DHA% (omega-3 index), and possible prevention of oxidation of EPA and DHA after oxidative stress, which would be beneficial for the consumers.
THE EFFECT OF SILVER NANOPARTICLES ON THE MORPHOLOGY AND PHYSIOLOGY OF THE DIGESTIVE SYSTEM OF THE BUTTERFLY SPLITFIN (Ameca splendens)

Kawalski K.*, Wiechetek W., Szudrowicz H., Martynow J., Adamek-Urbańska D., Łosiewicz B., Bujarski P., Kamaszewski M.

Department of Ichthyology and Biotechnology in Aquaculture, Warsaw University of Life Sciences (Poland)

Introduction
The aim of this study was to investigate the effects of silver nanoparticles (AgNP) on liver and intestine of butterfly splitfin (Ameca splendens), a potential model species. The focus was on analyzing the activity of digestive enzymes in the intestine and markers of oxidative stress in the liver and intestine. In addition, changes in the morphology of these two organs were demonstrated.

Materials and methods
This work was supported by the National Science Center, Poland Grant No. 2015/19/D/NZ8/03871. Fish of both sexes aged about 5 months were exposed to aqueous solutions of silver nanoparticles at concentrations of 0.01 mg/l, 0.1 mg/l and 1.0 mg/l for 42 days. Fish from the control group were maintained in water without AgNPs. Each experimental group was conducted in 3 replicates. On the last day of the experiment, the fish were euthanized, and their livers and anterior intestines were dissected. For enzyme activity analysis livers and intestines were frozen in liquid nitrogen. Then enzymatic analyses were performed to evaluate the enzymatic activity of the following enzymes in livers: alkaline phosphatase (ALP), acid phosphatase (ACP), superoxide dismutase (SOD) and glutathione peroxidase (GPX). In anterior intestine, the activities of alkaline phosphatase (ALP), acid phosphatase (ACP), amylase, trypsin, lipase, chymotrypsin and leucine aminopeptidase (LAP) were measured. Additionally, the intestines and livers underwent standard histological processing (H-E staining). Their morphology was then analyzed and the height of the intestinal folds, the height of the enterocytes, the supranuclear height of the enterocytes and the area of hepatocytes in the livers were measured.

Results
During the experiment, there was no mortality in any of the experimental groups and the control group. On the last day of the experiment, there were also no statistically significant differences in body weight, body length or Fulton’s fitness index. Enzyme analyses showed that the tested nanoxenobiotic increased the activity of ACP, ALP and SOD in the livers of fish exposed to AgNP, while GPX activity was not statistically significantly different between groups. Exposure of butterfly splitfin to the tested nanoxenobiotic did not statistically significantly alter the activity of digestive enzymes in the anterior intestine (Table 1).

Analysis of anterior intestinal morphology showed that the histological structure of the anterior intestine revealed no significant histopathological changes. The AgNP 1.0 mg/l group showed the longest intestinal folds compared to the other groups. In addition, infiltrative cells (lymphocytes) and inflammatory cells were deposited in the intestinal submucosa in all groups exposed to AgNP solutions.

Table 1. Activity of digestive enzymes in liver and anterior intestine.

(Continued on next page)
Analysis of the liver parenchyma showed the formation of foci of increased accumulation of fatty vacuoles in the cytoplasm of hepatocytes. In fish from the control group, the level of steatosis was lower compared to fish from the AgNP-exposed groups. In the hepatocytes of fish from the control group, steatosis dominated in the form of single large fat vacuoles. The dominant type of steatosis was microvesicular steatosis, with some individuals in the group of fish exposed to AgNP 1.0 mg/L also showing white adipose tissue in the exocrine pancreatic parenchyma adjacent to the liver. Histomorphometric analysis showed that hepatocytes in the AgNP 1.0 mg/L group had the largest surface area; however, there were no statistically significant differences in the value of this parameter between the groups.

**Conclusion**
The results indicate that exposure to AgNP can lead to disruption of liver homeostasis. Changes associated with hepatocyte vacuolization and the appearance of lymphoid cells in the liver have also been observed by other authors in zebrafish exposed to silver nanoparticles (Szudrowicz et al., 2022). In fish exposed to silver nanoparticles, increased activity of antioxidant enzymes in the liver was observed. Histopathological changes were found in the anterior intestine in groups exposed to AgNP. Similarly, necrosis of the intestinal folds was observed in the intestines of carp exposed to AgNP by Kakakhel et. al. (2021). On the other hand, no effect of the tested xenobiotic on the activity of digestive enzymes was observed in the studied fish.

BEHAVIOURAL MONITORING OF ATLANTIC SALMON (Salmo salar) REARRED IN EXPERIMENTAL TANKS USING DEEP LEARNING MODELS

S. K. Kumaran*, D. Izquierdo Gomez, L.E. Solberg, A. Espmark and C. Noble

Nofima, The Food Research Institute, Norway
* E-mail: santhosh.kumaran@nofima.no

Introduction
In aquaculture, the monitoring and analysis of fish behaviour hold crucial insights into various aspects of fish welfare. Notably, operational welfare indicators (OWIs) and laboratory-based welfare indicators (LABWIs) have emerged as promising tools for welfare auditing, as highlighted by Noble et al. (2018). Recent advances in computer vision technology have opened up possibilities to improve the monitoring of fish behaviour, rendering it an invaluable resource for welfare evaluation. Such technology allows for non-invasive inspection in a variety of applications as it offers methods across diverse applications. Despite notable progress in computer vision particularly in object detection (Wen et al. 2021) a persistent challenge remains in high-density scenarios. This study explored the potential of using pose estimation (Jocher et al. 2023) in Atlantic salmon aquaculture to automatically assess swimming behaviour during feeding events in tanks.

Material and Methods
The video recordings captured using GoPro Hero4 Black cameras were used in this study to investigate the behaviour of Atlantic salmon (Salmo salar) reared in hexagonal tanks of 3300 litres, each holding approximately 90 fish (> 500g). The water current in the tanks was clockwise. Fig 1. gives an overview of the method. A key point annotation scheme, as shown in Fig. 1(a), was used to annotate the fish’s snout, dorsal fin, and tail base. The training dataset was prepared by subsampling videos of four tanks using the CVAT annotation tool (CVAT 2023) in COCO key point format. Fig. 1(c) depicts the overall pipeline of the employed method. The annotations from COCO key points were converted into YOLOv8 format to train the pose model. The experimental/test videos were used to predict the fish pose. The predicted key points were used to calculate the orientation flows. The orientation flow is the angle of the fish’s heading in relation to the opposite direction of the water current, as shown in Fig. 1(b). It is calculated by finding the angle between the tangential vector at the dorsal fin and the vector from the dorsal fin to the fish snout. As shown in Fig. 1(d), a spatio-temporal analysis is performed by visualizing the orientation flow over time. Our common observation is that the fish tend to swim facing the water current unless disturbed by some events. Finally, the results are obtained in the form of an orientation score, which is defined as the absolute value of the mean of the orientation flows over time, reflecting the spread of the distribution. The YOLOv8 pose model was trained on a workstation with an Intel(R) Core(TM) i9-10885H CPU with 64.0 GB RAM and an NVIDIA GPU Quadro RTC 4000 using python 3.9.

Fig. 1 Workflow overview: a) Annotation scheme. b) Calculation of swimming orientation based on key points and water current direction. c) AI Pipeline steps: pose model training with annotated frames, fish pose estimation in sampled videos for metric’s extraction and metrics calculation and d) An example of a feeding event happening in a 60-second video clip. Top figure: most of the fish swim against the water as their anterior body forms an angle around 0° with regards to the water flow direction. Bottom figure: violin plot showing irregular group swimming orientation caused by feeding, as the fish to start chasing pellets in random directions (encircled in red colour).

(Continued on next page)
Results and discussion

A few results from analyses are presented here to illustrate the relevance of the tool for documenting and understanding behaviour. Fig. 2(a) shows the pose model evaluation metrics. A snapshot of the predicted key points is shown in Fig. 2(b). Fig. 2(c) demonstrates the orientation scores during two key events, feeding and disturbance by the presence of persons around the tanks. The study demonstrates that the proposed method can interpret the dispersion of fish using swimming orientation, and this can be a potential tool in welfare auditing in experimental studies. The results demonstrate that the tool has the potential to explore behaviour in different scenarios and settings. We intend to explore this aspect by applying it in different contexts and developing the tool further and auditing its utility for welfare documentation.

**Introduction**

Mixes of free amino acids (MFAA) obtained from extensive hydrolysis of full protein chains are interesting candidates for aquaculture feeds. In addition to their specific amino acids profile, their low molecular weight ensure a fast and high level of assimilation with synergetic effects during the first development stages. Previous investigations on shrimp (*L. vannamei*) underline MFAA positive effects on zootechnical performances (Le Reste et al., 2019) and survival in case of bacteriological and viral challenges (Kersanté et al., 2021). The results presented here have been obtained from a study conducted in three different phases to investigate the effects of a mix of 17 amino acids obtained from extensive hydrolysis of poultry keratin, on plasma protein (PP), oxyhemocyanin (OxyHc), minute till surgical anesthesia for low salinity and dissolved oxygen stress test and their PP and OxyHc at surgical anesthesia, growth performance (GP), size variation (SV), feed conversion ratio (FCR), molting frequency (MF), survival rate (SR), ions and chitin in cuticle and cuticular structure of *L. vannamei*.

**Protocol**

To understand the specific consumed period of MFAA supplementary feed with 38.5% protein to sufficiently maintenance for *L. vannamei* physiology in terms of PP and OxyHc, shrimp were fed three feeds (control; two concentrations of MFAA as 5g/kg of feed (MFAA 0.5%) and 10g/kg of feed (MFAA 1%) for 16 days with three replications. The healthy *L. vannamei* juvenile with 14.12±0.35 g and 11.67±0.22 cm in size were held in 15 ppt medium at 100 ind/m² using 250L rectangular plastic tanks for 16 days. They were fed 4 times daily with 5% body wet weight. 

**Exp I:** Experimental shrimp at Do molt stage were collected the hemolymph for examining OxyHc and PP of day 4, 8, 12, 16.

**Exp II:** It was operated as same at Exp I until 16 days of feeding prior to apply stress test with low dissolved oxygen (LO) and freshwater (FW). Both test checking the minute till surgical anesthesia (MA) the hemolymph of individual anesthetized shrimp for determination of OxyHc and PP was suddenly collected then transferred to 15 ppt aquaria with well oxygenation to recover and record the number of survivors.

**Exp III:** The two feeds as control and MFAA 1% supplementary feed were operated. Specifications of experimental shrimp and tank including culturing methodology were identical to Exp. I with five replications for 60 days to determined GP, FCR, SR, MF and SV. After termination, shrimp carapace at Do molt stage was individually sampled for examining ions, cuticular thickness (CT) and number of layers (NL) and chitin content using Electron Microscopy and Energy Dispersive System.

**Results**

The results of Exp I found that shrimp raised with MFAA supplementary feed with both dosages for 16 days showed significant increase of OxyHc and PP. The results of Exp II for low dissolved oxygen stress test showed the significant longest period for shrimp fed with MFAA 1% supplementation (p<0.05) until the beginning time to surgical anesthesia (BTSA) (58.3 min) with the significant lowest concentration of OxyHc (1.93 mg/l) (p<0.05) versus with control (2.61 mg/l). In the same manner, PP values of MFAA 1.0% group (330.8 mg/ml) was significantly (p<0.05) lower than that of control (347.5 mg/ml). For freshwater stress test, shrimp fed on MFAA 1% feed showed the significant (p<0.05) longest period at BTSA (86.5 min) with the significant lowest (p<0.05) PP values (342.9 mg/ml) while OxyHc values among groups were not significantly different (p>0.05).

The results of Exp III showed higher significant % of weight gain, average daily gain and specific growth rate gain of MFAA 1% group (p<0.05) than those of control and FCR of MFAA 1% group was significantly lower (p<0.05) than that of control. % SR, MF, % CV of length and weight were not significantly (p<0.05) different between groups.

(Continued on next page)
Interestingly, the CT and NL of Do cuticle of MFAA 1% group was significantly higher than those of control ($p<0.05$). The cuticle architecture of MFAA 1% and control are shown in Fig 1. The endocuticle layer structure of MFAA 1% group was magnified.

The percentages of Ca and Mg of Do cuticle of MFAA 1% group were significantly higher than those of control ($p<0.05$) versus %Na and %Cl of control were significantly higher those of MFAA 1% ($p<0.05$). The chitin content of MFAA 1% group showed higher rate ($p<0.05$) than that of control. (+19.4%).

**Discussion**

This study underlined some particularly interesting effects of MFAA when applied on juvenile whiteleg shrimp, *Litopenaeus vannamei*. Firstly, regarding growth parameters with positive effects on biomass and feed utilization. Interestingly, we underlined strong influence of MFAA on hemolymph composition in term of oxyhemocyanin and plasma protein after the 16 days of feeding supplementation inducing better resistance to low dissolved oxygen and freshwater stress conditions. Monitoring of oxyhemocyanin and plasma protein in hemolymph at surgical anesthesia also disclosed the interest of MFAA as direct source of energy to balance the osmoregulation during freshwater stress and maintain life under shortage of oxygen. After 60 days of feeding period, the cuticule thickness and structure was also magnified in relation with higher examined concentrations of chitin, but also of calcium (Ca) and magnesium (Mg) linked with Ca and Mg carbonate crystals to construct the cuticle and positively influence the molting. These results confirm the interest of MFAA as a sustainable protein source converted into an efficient functional ingredient for shrimp nutrition.

Department of Animal Sciences and Aquatic Ecology

Introduction
In shrimp farms, probiotics have been showed to promote growth, improve the efficiency of feed utilization, modulate the intestinal microbiota, and protect the host from disease by stimulating the immune system. In recent years, diseases caused by Vibrio spp. became the most serious threat to shrimp production, among them acute hepatopancreatic necrosis disease (AHPND) caused by V. parahaemolyticus, that affects shrimp in their early post-larvae growth stage. Among probiotic species, Lactic Acid Bacteria from different genera including Lactobacillus, Enterococcus and Pediococcus; and bacteria from Bacillus genus are commonly used for shrimp feed supplementation.

To elucidate the mode of action of a 4-species mixed probiotic product (AquaStar®, DSM Nutritional Products Ltd.) consisting of Lactic Acid Bacteria and Bacillus subtilis, the 4-species-mix as well as two individual components and their 2-strain mixture were fed to vannamei shrimp post-larvae in order to assess growth performance and resilience to V. parahaemolyticus challenge.

Material and Methods
Whiteleg shrimp (Litopenaeus vannamei) were imported as postlarvae (PL10) from Shrimp Improvement Systems (Florida, USA) and acclimated to lab conditions over one week. These shrimps are certified to be specific pathogen-free for the following pathogens: WSSV, YHV/GAV/LOV, TSV, IHHNV, BP, MBV, BMN, IMN, Microsporidians, Haplosporidians and NHP bacteria. The shrimp were randomly allocated to 30L tanks (100 PL/tank) equipped with individual biofilters and fed five different treatments in 5 replicates each: Lactobacillus reuteri (LR), Bacillus subtilis viable cells (BS), 2-strain mix LR+BS, 4-strain mix (B. subtilis, E. faecium, P. acidilactici, L. reuteri in equal proportions, AS), no probiotic control (CC). Shrimp were fed commercial crumbled diets with treatments at 1 x 10^7 cfu/g. Control feed was mock-treated with RO water. Growth was assessed by group weighing after 3 weeks. Shrimp were challenged after 3 weeks feeding (PL41) by immersion with 10^6 cfu/ml Vibrio parahaemolyticus MO904.

Results
Significant >20% improvements in final weight, body weight gain and specific growth rate were observed by treatments LR and AS (table 1). LR treated shrimp PLs had a significantly 22% reduced feed conversion ratio. PLs receiving BS had numeric improvements in final weight and a significant 17% improvement in specific growth rate. The survival rate during the feeding trial was above 90% in all tanks without any clear observable trend. A numeric improvement in survival to V. parahaemolyticus challenge was observed in shrimp treated with LR and the 4-strain mixed probiotic AS.

Discussion
The results obtained with shrimp post-larvae confirm previous experiences (Kesselring et al. 2019, Gruber et al 2023) with this 4-strain mixed probiotic product (AS; AquaStar® DSM ANH) in adult shrimp. Bacillus subtilis (BS) alone significantly improved the specific growth rate and led to numeric improvements of body weight gain and feed conversion ratio. A longer feeding period may have allowed the shrimp to reach a sufficient immune-competence to respond favorably to a potential B. subtilis related stimulation of their immune response as well as the nutritional effects of this strains’ extracellular enzymes.

Lactobacillus reuteri (LR) supplementation led to significant improvements in final weight, body weight gain, feed conversion ratio and specific growth rate. LR supplemented shrimp PLs had numerically improved survival probability 48h after V. parahaemolyticus immersion challenge. This strain of L. reuteri has previously been described to have a pronounced ability to attach to gut epithelium in vitro, thereby preventing the attachment and invasion by pathogenic bacteria (Pillinger et al. 2022). It is indeed imaginable that these properties led to a more efficient energy use. Generally, bigger shrimp have a better defense against any type of challenge than smaller individuals.

(Continued on next page)
Conclusions

Probiotics with a high inclusion of different lactic acid bacteria demonstrated significant benefits over a *Bacillus subtilis* only supplementation in an early stage of shrimp production. The single component *Lactobacillus reuteri* was shown to be particularly effective in shrimp post-larvae due to its strength in competitive exclusion. The combination *L. reuteri* with *B. subtilis* could not realize the full potential of the single components, pointing out the adjuvant role of the *Enterococcus* and *Pediococcus* in the 4-species mix. This experiment presents an interesting pilot study furthering our understanding of probiotic efficacy in shrimp post-larvae.

Table 1: Zootechnical growth performance of *L. vannamei* fed individual probiotic strains and a 4-strain probiotic mix similar to the commercial product AquaStar® (DSM Nutritional Products Ltd.) for three weeks. Mean and standard deviations are shown. Superscript letters indicate significant differences.

EFFECT OF DIETARY TALL OIL FATTY ACIDS (TOFA) ON PERFORMANCE, IMMUNOLOGICAL STATUS AND PATHOGEN (Aeromonas SPP.) LOAD OF JUVENILE ASIAN SEABASS (Lates calcarifer)

Introduction

Tall oil fatty acids with 9% natural coniferous resin acids (TOFA) is a novel feed ingredient which improves the production performance and intestinal microbiota of farm animals (e.g. Vienola et al., 2018, Uddin et al., 2021). Resin acids are anti-inflammatory and antibacterial secondary metabolites of coniferous trees (San Feliciano et al., 1993). The present study investigated the effects of dietary TOFA on the performance, immunological status and load of the pathogenic bacterium Aeromonas spp. in the intestinal tract and liver of juvenile Asian seabass (Lates calcarifer) in Thailand.

Materials and methods

Juvenile Asian sea bass were allocated into 20 freshwater cages of 2 m³, 15 fish/cage, at a site with a known background challenge of Aeromonas histolytica. The water was aerated to maintain DO >5 mg/l. Feed was of commercial-type, with main ingredients of fishmeal, poultry meal, soybean meal and tapioca, and it was amended with 0 (Control), 0.35, 0.7, or 1.0 kg/ton of TOFA (Progres®, AB Vista, UK) for treatments T1-T4, respectively. The fish were fed 3 times/day at 3-5% of body weight for 16 weeks. Fish weight, weight gain, feed intake and feed conversion ratio (FCR) were determined every 2 wk, and the survival rate every 4 wk. Two fish/replicate were sampled for blood at 8- and 16-wk time points for determining the red blood cell (RBC) count, white blood cell (WBC) count, hemoglobin and haematocrit, and the concentrations of total serum protein and immunoglobulin M (IgM). The same fish were sampled for liver and intestinal contents for determining the number of Aeromonas spp. by plate culturing, using Aeromonas-selective media. The study design was completely randomized. Data was analysed with one-way ANOVA, followed by Duncan’s Multiple Range Test, using P<0.05 as a limit for statistical significance.

Results

Mean weight of the fish was 54.6 g, 111.8 g, and 170.0 g for wks 0, 2, and 4, respectively, without a significant difference between treatments. Dietary TOFA supplementation dose-dependently improved fish weight and weight gain from the 6-wk time point onwards (p<0.05). Table 1 presents fish weight on wks 8 and 16, and FCR for wks 0-8 and 0-16. Feed intake and fish survival rate was not affected by the treatments. At the end of the study, the survival rate was 89.3%, 92.0%, 93.3% and 96.0% for T1-T4, respectively. The treatments significantly affected FCR for the following time periods: wks 0-6, 0-8, 0-10, and 0-12 (p<0.001), with the best performance in T4.

Parameters analysed from blood and tissue samples are reported in Table 1. The TOFA supplementation significantly increased haematocrit (wk 8) and IgM (wks 8 and 16), and decreased Aeromonas spp. density in the liver and intestinal tract (wk 16).

Discussion and conclusions

In the present study, supplementing the diet of juvenile Asian seabass with TOFA promoted the growth performance, feed conversion and immunity of the fish, and at the same time improved their ability to control the growth of Aeromonas spp. in the liver and intestinal tract. Increased haematocrit and the trend towards higher serum protein levels in TOFA-supplemented groups may indicate positive effects on the physiological status of the fish. The effects were dose-dependent, and the treatment with TOFA at 1.0 kg/ton gave the highest responses. The results were in line with previous observations from studies with poultry and swine, in which dietary TOFA had positive effects on performance, gastrointestinal microbiota and disease resistance of animals (Vienola et al., 2018; Uddin et al., 2021). In conclusion, TOFA may function as a dietary strategy to improve the production performance and disease resistance of Asian seabass.

EFFECTS OF DIETARY TALL OIL FATTY ACIDS WITH RESIN ACIDS ON THE PERFORMANCE AND IMMUNITY OF JUVENILE WHITE SHRIMP (*Litopenaeus vannamei*) WITH AND WITHOUT AN INTENTIONAL *Vibrio parahemolyticus* CHALLENGE

Introduction

Tall oil fatty acids with 9% natural coniferous resin acids (TOFA) is used as a feed ingredient for poultry and swine for improved production performance and beneficial effects on intestinal condition, but its potential for aquatic species has remained unexplored. The present experiment studied the effect of dietary TOFA on performance, immunity and disease resistance of white shrimp (*Litopenaeus vannamei*) in an experimental model which included an 8-week period without intentional challenge factor, followed by a 1-week period with *Vibrio parahemolyticus* (*V. p.*) challenge.

Materials and methods

The experiment was carried out in 30 aquariums with 120 liters of 15 ppt saline water. Juvenile white shrimp were stocked at 200 shrimp/m³, 25 individual/aquarium. The water in each aquarium was aerated to maintain DO >5 mg/l, and 20% of water was changed every 3 days. Commercial-type shrimp feed, based on soybean meal, wheat flour, fishmeal, poultry meal and corn gluten was amended with TOFA (Progres®, AB Vista, UK) at 0, 0.5, and 1.0 kg/ton for the dietary treatments T1-T3, respectively. Feed was applied to the shrimp 3 times/day at 3-5% of body weight. Uneaten feed was siphoned out 1 hour after feeding, dried in hot air and weighed. Shrimp weight, weight gain, feed intake and feed conversion ratio (FCR) were recorded every 2 weeks and survival rate every 4 weeks. At the 8-wk time point, 6 shrimp/tr. were sampled for haemolymph, hepatopancreas and intestinal contents. The experiment continued by allocating 3 replicate aquariums/tr. into a 7-day challenge period which started by a subcutaneous injection of the virulent EMS strain of *V. p.* (6.9*10⁷ cfu/ml) to each shrimp. The survival rate was monitored daily. On day 7 post-challenge, the shrimps were sampled as described earlier. Haemolymph samples were analysed for parameters relating to immunity and oxidative status. Density of *Vibrio* spp. in samples was determined by plate culturing. The study was conducted in a completely randomize design. Data was analysed with one-way ANOVA, followed by Duncan’s Multiple Range Test, using *p*<0.05 as a limit for statistical significance.

Results

Results are summarized in Table 1. On day 1, the mean shrimp weight was 2.46 g, with no difference between treatments. Compared to T1 (control) treatment, shrimp weight, weight gain and FCR were improved by T2 and T3 from the 4-wk time point onwards (*p* <0.05). Post-challenge survival rate was increased from 32.5% in the control group to 55.0 and 65.0% in T2 and T3, respectively (*p* <0.05). Compared to T1, the haemocyte count, phenoloxidase activity, lysozyme activity, superoxide dismutase activity and glutathione concentration in haemolymph were all significantly higher, while the density of *Vibrio* spp. in tissues was lower for T2 and T3 both before and after the challenge. Haemolymph protein was increased by TOFA only post-challenge.

Discussion and Conclusions

In the present study, dietary TOFA at 0.5 and 1.0 kg/ton improved the performance and survival rate of juvenile white shrimp, suggesting a better production potential for TOFA-fed shrimps, in comparison to the control group. The decreased *Vibrio* load in the tissues and the parameters analysed from haemolymph indicate that TOFA positively affected several immunological and antioxidative functions and the disease resistance of the shrimp. Previously, in-feed resin acids have been shown to reduce intestinal inflammatory processes (Aguirre *et al.* 2019) and to positively modulate gut microbiota (Vienola *et al.*, 2018) in chicken. In conclusion, TOFA may become a dietary strategy for supporting the performance, immunity and disease resistance of white shrimp.

GENETIC PARAMETERS FOR EARLY SEXUAL MATURATION IN ATLANTIC COD

A. Kettunen1*, V. Puvanendran2, Ø.J. Hansen2 and M.L. Aslam1

Introduction
Sexual maturation before farmed Atlantic cod reaches the harvest size is coupled with economic losses and potential ecological concerns. Reduced appetite and allocation of energy from somatic growth into gonads starts prior to and continues throughout the spawning season causing a significant, up to 50%, loss in body weight. Investment in gonadal growth and significant loss in body weight translate into resource wastage in terms of feed costs. Additionally, spawning and spread of fertilized eggs from sea-cages poses a threat of genetic introgression from domesticated cod into the wild.

Earlier genetic studies on early sexual maturation in cod have been either conducted in the infancy of cod aquaculture (Kolstad et al., 2006) or struggled with maturation frequencies suitable for genetic studies (Drangsholt et al., 2014). Kolstad et al. (2006) estimated low to moderate heritability for sexual maturation registered at 2 years in two geographical locations: 0.16-0.29. Drangsholt et al. (2014) reported non-significant heritability for sexual maturation at 2 years from the same genetic material as presented here.

The assessment of selection potential against early sexual maturation in the National Cod Breeding Program after 5 generations of growth selection was prompted by the re-vitalisation of the Norwegian cod aquaculture.

Material and methods
Individually tagged Atlantic cod representing 104 full-sib families of the National Cod Breeding Program were tested for early sexual maturation at LetSea Research facilities (Dønna, Norway). Experiment was run on a semi-commercial scale from 29th of January 2020 until 23rd of March 2021 following standard production protocols, except from light manipulation regimes to avoid sexual maturation. At the end of the experiment, fish were euthanized and individually registered for round weight (WT), length (LENGTH), liver and gonads weight, and sex (male/female) and the status of sexual maturation (MAT, mature/immature) were determined by visual inspection after dissection. Gutted weight (GWT) was calculated by subtracting weights of liver and gonads from WT. Tissue samples were collected and 1272 individuals representing 67 families were genotyped with a newly developed 21K SNP-array (Illumina Infinium™ Array). Additionally, harvest weight (HWT) was recorded for 2011 sibs from 173 families in November 2021. Heritability for MAT was estimated with univariate sire-dam model both on the observed and underlying liability scale using ASReml (pedigree relationships) (Gilmour et al., 2015), and with GCTA (genomic relationships, GWAS) (Yang et al., 2011). Bivariate animal model was used for estimation of phenotypic and genetic correlations between growth traits (WT, GWT, LENGTH, HWT) and MAT.

Results and discussion
Out of the 1680 registered individuals, 814 were females and 866 males, and 87.4% of the fish were classified as sexually mature. The frequency of sexually mature females was 83.7% whereas maturation frequency in males was 90.9%. Mature (and female) fish were significantly heavier than immature (and male) fish. These differences in round body weight were mainly due to differences in gonad and liver weight; there was only 30g and 20g difference in GWT between mature and immature fish and between females and males, respectively.

(Continued on next page)
Estimated heritability for MAT using pedigree relationships was moderate to high: 0.33±0.06 on the observed scale and 0.51±0.10 on the underlying liability scale. Estimated heritability utilizing genomic relationships from a subsample of the material was somewhat lower: 0.23±0.04. Genetic correlations between MAT and growth traits were negative (favourable) and connected with high standard errors (Table 1), indicating that selection for rapid growth has not affected the frequency of sexually mature fish at 2-years of age. GWAS detected a suggestive QTL for early sexual maturation at chromosome 23 where a single SNP crossed chromosome-wide threshold. Additionally, earlier detected QTL for sex was validated in our breeding population.

The significant additive genetic variation, and insignificant genetic interrelationships with growth traits, indicate that selective breeding has potential as a part of a solution to solve problems connected with sexual maturation in Atlantic cod without adversely affecting the genetic gain in growth. The suggestive QTL for MAT should be confirmed from a larger data set.

HOW SECONDARY EDUCATION CAN HELP TO REDUCE THE SHORTAGE OF AQUACULTURE PROFESSIONALS?

Anikó Khademi-Vidra1*, Izabella Bakos1, Zoltán Bokor2, Julianna Kobolák2 and Béla Urbányi2

1 MATE, Institute of Rural Development and Sustainable Economy, Department of Humanities and Vocational Education, Gödöllő, Hungary

Introduction

In Hungary, the aquaculture sector is characterised by two main segments: pond fish farming and intensive (precision) fish production. The Hungarian aquaculture sector employs 1,462 permanent workers, of whom 645 have primary education, 598 have secondary education and 219 have tertiary education (AKI, 2022). During peak periods, casual workers help to carry out the tasks, worked 22,254 days in the sector (AKI, 2022).

Over the last 20 years, the aquaculture sector has evolved significantly: changes in methods, procedures, and technologies have created major challenges for workers and employers alike. In addition to this technological development, the working environment has also changed, but in this area, thanks to the close-to-nature production, it is only possible to improve working conditions in small steps. It is partly these factors that fundamentally determine a young person’s career orientation and choice.

It is a sad fact that marine and freshwater aquaculture and fisheries, like other segments of agriculture, find it difficult to compete with the job opportunities and working conditions offered by other sectors of agriculture. In addition, the steadily increasing demand for aquaculture products requires enterprises in the sector to meet market needs by producing products tailored to consumer demands, but this requires skilled workers at all levels. However, it is important for companies to be able to define their expectations towards workers, which fundamentally determine the quality and depth of training they need (Padrós et al., 2023).

Basic training has disappeared from the palette of the Hungarian aquaculture sector’s professional training for 5 years. The physical work is mainly done by semi-skilled workers who have little technical knowledge of the sector’s work processes. The development of a National Aquaculture Training Strategy is a sectoral need, one of the first steps of which is to define the possibilities offered by different levels of education.

The basis for the supply of professionals at the secondary and tertiary level is the training in natural sciences and biology in secondary schools, which, integrated into the national educational framework, provides knowledge to students with this interest. The framework includes a so-called ‘faculty’, which provides students with an increased number of hours of study and learning in this area of science.

Materials and methods

A questionnaire survey was carried out to investigate the attitudes of teachers and the available infrastructure towards aquaculture in secondary schools (mainly high schools) with faculties offering natural science and biology courses.

Results

It can be concluded that the teachers working in these institutions responded positively to the sector’s inquiry and were willing to fill out the questionnaire in a higher proportion than expected. However, it can also be said that the rigid system of education provides few opportunities to broaden knowledge of a particular agricultural sector, in this case aquaculture. On the other hand, there was a strong demand for practical training courses and study trips, and this is an area where the sector has the greatest potential for improvement.

The questionnaire also confirmed the earlier finding that one of the breakout and development areas of the Hungarian aquaculture sector is education and the development of the teaching methodology (Urbányi et al., 2023).

A CRUSTACEAN OOCYTES DELIVERY TOOL FOR LARGE-SCALE GENE SILENCING

Isam Khalaila, Shany Cohen, Mahde Hasan

Avram and Stella Goldstein–Goren Department of Biotechnology Engineering
National Institute for Biotechnology in the Negev
Ben-Gurion University of the Negev
84105 Beer Sheva, Israel

Oviparous animals are characterized by an elaborated yolk production process and packaging in the oocytes before egg-laying. The major yolk protein (vitellin) is usually produced as vitellogenin outside the egg (Vg) and internalized into oocytes by receptor-mediated endocytosis (RME). Like many other crustacean species, *M. rosenbergii* vitellogenin is expressed in the hepatopancreas. *M. rosenbergii* vitellogenin possesses 2537 amino acids and shares at least 33% identity with other decapod crustacean vitellogenin, such as shrimps, crabs, and crayfishes. Vg contains several domains, including the lipid-binding domain involved in yolk-lipid vesicle formulation. Upon arrival at the oocytes, the Vg-receptor (VgR) extracellular domain interacts with a distinct amino acid sequence of the Vg and internalizes it to form yolk droplets. One distinctive characteristic of the VgR family is their role in the massive internalization and accumulation of lipoproteins. Vitellogenesis is recognized by an immense accumulation of the Vg in the oocyte that will serve the embryo’s metabolic needs for development and growth. For that reason, we predicted that Vg endocytosis could be used as a valuable tool for oligonucleotides’ high throughput delivery into the oocyte. Indeed, a specific Vg-derived peptide sequence (Vg24) was found capable of oocytes’ specific entry by *in vitro* and *in vivo* means. However, a peptide with the same amino acid composition but scrambled order (scVg24) could not enter the oocytes. Vg24 synthesized with nine Lysine-Histidine repeats successfully induced dsRNA electrostatic interaction and piggybacked the bound dsRNA into *M. rosenbergii* oocytes. When *PAX6* (eye development transcription factor) dsRNA was piggybacked, that led to eye development retardation in embryos of the treated mothers. Alignment analysis of the *M. rosenbergii* Vg24 shared 85% identity with the corresponding Vg peptide sequences from other decapod species. The peptide similarity proposes cross-reactivity between the *M. rosenbergii* peptide and the VgR of other decapod species. The developed tool might serve to deliver other than dsRNA molecules into crustacean oocytes and might be a powerful asset for large-scale silencing or editing aquaculture-relevant genes of crustacea.
EXPLORING A NOVEL INSECT MEAL FOR THE DIET OF PACIFIC WHITE LEG SHRIMP
(Litopenaeus vannamei)

³ AgroParisTech, 75000 Paris, France
⁴ Halieutica, Aquaculture Nutrition, 49000 Angers, France

Introduction
Pacific white leg shrimp, Litopenaeus vannamei, is one of the most productive species in aquaculture (FAO, 2022). This species has high dietary protein demands, with a significant portion being fulfilled by fish meal (FM). The increased demand for feed supply necessitates the exploration of new protein sources. In recent times, insect meals, particularly black soldier fly larvae meal (BSFLM), have emerged as an alternative to FM due to its high protein levels and adequate essential amino acids profile (Richardson et al. 2021). In this context, the objective of this study was to determine the effect of a novel insect meal (NIM) on the diet of Pacific white leg shrimp. The insects used were obtained from a biocontrol production, with the surplus potentially being used for aquaculture feed purposes.

Materials and methods
Shrimps were initially acclimated for a period of five weeks in Halieutica research facilities (Angers, France). A total of 195 shrimps were distributed across 15 aquariums with a density of thirteen shrimps per aquariums (40l). Shrimps were reared in triplicate and fed at 5% of their body weight for a period of four weeks. A control diet (CTRL; 7% FM and 37.3% protein content) served as the basis of comparison for four additional experimental diets, in which 10% and 20% of the control diet were replaced by NIM or BSFLM. The experimental diets containing 10% and 20% of BSFLM were also used as a reference diet to evaluate the efficacy of NIM as an insect meal. A non-parametric Kruskal Wallis test was used to compare the mean growth performance of each treatment.

Results and discussion
Weight gains (WGs) and Feed conversion ratios (FCRs) did not exhibit significant differences among the treatments (Figure 1).

The comparable growth performance of the shrimps shows that NIM is a promising new alternative ingredient for replacing FM. Furthermore, since insect-based feeds (BSFLM and NIM) were directly integrated into the CTRL feed, there is still potential for enhanced performance through formulation refinement and adjustments to all raw materials to accommodate the inclusion of insect meal. In addition, a more comprehensive understanding of the feed’s efficacy would require further investigations into aspects such as immunology and intestinal microbiota (Chen et al., 2021).

Figure 1. Comparison of WGs and FCRs among treatments.

(Continued on next page)
Conclusion
The growth performance results achieved with NIM are promising. Furthermore, the cost-effective production of this insect could potentially position it as a competitive alternative to other insect meals and fish meals.

COMPARISON OF MUCOSAL IMMUNE TRANSCRIPT RESPONSE IN RAINBOW TROUT 
(Oncorhynchus mykiss) IN FRESH WATER AND SEA WATER AFTER VACCINATION

Ali Reza Khansari*, Nicklas Wallbom, Henrik Sundh and Elisabeth Jönsson

Department of Biological and Environmental Sciences
University of Gothenburg, Sweden
Email: ali.khansari@bioenv.gu.se

Introduction:
Vaccination is known as the most efficient and adequate method to induce immune activation and thus protecting fish against pathogens since fishes live in an antigen-enriched environment (Tafalla et al., 2013). Beside the importance of the systemic immune system to protect fish against pathogens in the environment, mucosal-associated lymphoid tissues (MALTs) are also implicated in protection and play a crucial role in maintaining homeostasis (Parra et al., 2015; Khansari et al., 2018). There is also an extensive communication between the neuroendocrine and immune system where activation of neuroendocrine system elicits immune activation, thus either suppressing or enhancing the immune response. Most of our knowledge on the effect of vaccination in rainbow trout comes from studies in freshwater, but transfer of the fish to seawater after vaccination can be hypothesized to be a challenge for the fish that influences the immune response. In the present study, we aimed to compare how the mucosal immune system after long-term vaccination is affected by stress in both fresh- and seawater acclimated fish.

Material and Method:
Juvenile rainbow trout weighing on average 70 g was obtained from a local hatchery (Väneåns fish farm AB, Knäred, Sweden). The fish were held in recirculating tanks at ca 10°C and fed daily with ±2% of body weight. At the start of experiment, fish were immunized with Alpha Ject 3000 or injected with saline as controls. Starting 12 days post injection (dpi), salinity was gradually increased to 31 ppt over 10 days for half of the vaccinated and control fish, while the other half (vaccinated and non-vaccinated) remained in fresh water. To stress fish, they were chased for 5 min and after 48 hours of recovery, all fish were euthanized, length and weight measured, and skin mucus, blood and tissues skin, gills and gut were collected for further analysis.

Results and discussion:
Our results show an overall significant interaction between salinity groups (FW and SW) and treatments. The cortisol level in skin mucus were significantly higher in the stress and in vaccine+stress fish in both fresh water (FW) and sea water fish (SW) groups (Figure 1). In addition, cortisol was augmented in the vaccine+stress group in SW versus FW (Figure 1). This reflects a general stress response of animals to external stimuli that results in activation of the hypothalamic-pituitary-interrenal axis (HPI) axis to secretes cortisol by head kidney interrenal cells (Schreck and Tort, 2016). It is not yet clear if cortisol secretion at mucosal levels is delivered by the circulation or is secreted by local cells since cortisol secretion by interrenal axis (HPI) axis to secretes cortisol by head kidney interrenal cells (Schreck and Tort, 2016). It is not yet clear if cortisol secretion at mucosal levels is delivered by the circulation or is secreted by local cells since cortisol secretion by immune cells has also been demonstrated. However, previous results showed that abiotic and biotic stressors are capable of inducing cortisol release in both systemic and mucosal system (Khansari et al., 2018; Ordóñez-Grande et al., 2020) and therefore cortisol has proven to be a reliable stress indicator.

Genes transcriptions were also analysed, and they were classified in three groups including stress related genes (gr1, gr2, mr, β-ar, hsp70), innate immune related genes (il1β, il6, tnfα, il10, tgfβ1, nadph oxidase, c3, enolase and lysozyme) and adaptive immune related genes (igm, igt and cd8). In the gills of FW fish, stress and vaccine+stress enhanced the transcription level of il1β. The il1β transcript expression in stress and vaccine+stress was significantly lower in SW versus FW. In the skin, FW (stress and vaccine+stress) and SW (vaccine) fish, the mRNA level of il1β was decreased, whereas a significant increase was observed for the vaccine+stress group in SW. There was a significantly higher il1β expression in the skin of the stress and vaccine+stress groups in SW compared with FW. In the intestine, vaccine and vaccine+stress was found to induce il1β gene expression in FW while no alteration was registered in SW. The same expression pattern as gills was observed in intestine; a suppression of il1β transcript expression in the vaccine and vaccine+stress groups in SW (Figure 1). The results support that an inflammatory response was induced by the vaccine and stress in the peripheral tissues that is characterized by a first wave of expression of proinflammatory cytokines such as il1β, mainly produced by activated macrophages, that plays a crucial role in host defence (Stolte et al. 2008).

Overall, our results show that mucosal immune response at cellular level is triggered by intraperitoneal vaccine injection. Furthermore, the cellular immune response induced by vaccine/stress is significantly suppressed by salinity in rainbow trout. Thus, more studies should be devoted to investigating the effect of salinity on immune response elicited by vaccine in order how to mitigate the negative effect of hypersalinity within smoltification stage.

Introduction

The emerging prominence of spotted wolffish (*Anarhichas minor*) as a potential candidate for cold water marine aquaculture in Norway and the Arctic region has garnered attention due to its promising attributes, including non-aggressive behavior, disease resistance, high fillet yield, and high market value (Moksness, 1994; Foss et al., 2004). Through the past 30 years of research and development, there has been notable progress in understanding and managing various fundamental aspects of spotted wolffish aquaculture and currently one fish farm in Norway is commercially producing spotted wolffish since 2013. However, scaling up the spotted wolffish production requires further studies and research. These include investigating reliable reproduction methods, comprehending nutritional needs across life stages for species-specific feed development, exploring sustainable feed options, conducting genetic studies and selective breeding for desired traits, and ensuring optimal health and welfare management in captive settings.

In this study, blue mussel meal was chosen as a potential alternative ingredient to assess its effects on the growth, health, and welfare of spotted wolffish. Blue mussel meal contains high protein and an amino acid profile similar to FM (Berge & Austreng, 1989) and been investigated as fishmeal replacement in the diet of poultry (Jönsson & Elwinger, 2009), rainbow trout (Árnason et al., 2015) and turbot (Weiss & Buck, 2017) with some promising positive results. The blue mussels used in meal production are derived from the waste stream of food production and are typically smaller than 5cm in size (Berge & Austreng, 1989). In mussel meal production, the shell is usually removed through deshelling process, which is both energy-intensive and costly. Consequently, processing the entire mussel, including the shell, is a more sustainable approach, despite the resulting higher ash content. For spotted wolffish, incorporating mussel meal with shells could be advantageous, given their natural diet of bottom-dwelling creatures like echinoderms, mollusks, and crustaceans (Albikovskaya, 1982, Foss et al., 2004). This study aims to understand how incorporating blue mussel meal, both with and without shells, into spotted wolffish diets affects their growth performance, stress biomarkers, plasma biochemistry and the occurrence of nephrocalcinosis (calcareous deposit) in kidney.

Materials and methods

The spotted wolffish (*Anarhichas minor*) were provided by Aminor AS (Halsa, Norway) and the feeding trial was conducted at Nord University research station, Mørkvedbukta (Bodø, Norway). 180 juveniles of approximately 500–800g (877.05g ± 18.88) were randomly distributed into six tanks with a total of 30 fish per tank. Two iso-calorific, iso-nitrogenous and iso-lipophilic diets were formulated and each was provided to three tanks of fish. The control diet contains mussel meal (CNT) and the experimental diet contains mussel meal with added shell (BMS). The experiment lasted 12 weeks and at week 0, 6 and 12, weight and length of the individual fish were measured for the calculation of weight gain (WG), specific growth rate (SGR) and condition factor (CF). At the end of the experiment, six fish from each tank were randomly chosen and sacrificed for sampling. Blood sample for analysis of plasma parameters was collected with a heparinized syringe (7.5g lithium heparin / 1ml Millipore water) from the caudal vein. Rest of the six fish from each tank were stored as whole body for identification of nephrocalcinosis through CT scan.

Results

In general, the growth parameters of juvenile spotted wolffish, including body weight, condition factor (CF), weight gain (WG), and specific growth rate (SGR), displayed notably higher values in the group of fish that were fed a diet containing shelled blue mussel meal (BMS), in contrast to those fed the control diet (CNT). At the 6-week mark (W6), the CF of the fish in the BMS group exhibited a significantly higher level compared to that of the fish in the control group (p < 0.05). Similarly, at the 12-week mark (W12), both WG and SGR of the fish were markedly higher in the BMS group than in the control group, and these differences were statistically significant (p < 0.05).

(Continued on next page)
Regarding plasma stress biomarkers, such as glucose, lactate, and cortisol levels, there were no significant differences observed between the fish groups fed diet CNT and diet BMS. The same lack of significant difference was observed for plasma osmolality, acid-base balance, and ion concentrations.

Furthermore, the incidence of nephrocalcinosis demonstrated a similar frequency of occurrence in both groups, with a ratio of 0.22% - equivalent to four out of the 18 fish observed in each group. The severity of nephrocalcinosis observed in both groups was characterized as minor in grade, and no significant differences were detected between the two groups.

Introduction

Choline is one of the essential micronutrients for aquatic animals and plays an important role as a methyl donor and component of lecithin. This study was conducted to evaluate the effects of dietary different choline levels with or without on the growth, nonspecific immune response, antioxidant capacity and ammonia stress resistance of Pacific white shrimp *Litopenaeus vannamei*.

Material and methods

Experimental diets were prepared to contain choline levels of 2000, 4000, 6000 and 8000 mg/kg without lecithin supplementation (designated as C2000, C4000, C6000, C8000, respectively) and with lecithin of 2500 mg/kg (designated as CL2000, CL4000, CL6000 and CL8000 respectively). Juvenile shrimp (0.20 ± 0.00 g) were randomly distributed in acrylic tanks (240 L) with 25 shrimp per tank. Triplicate groups of shrimp were fed one of the experiment diets four times daily for 56 days. For the ammonia stress test, after the feeding trial, 18 shrimp per tank were randomly selected and distributed into 24 tanks (120 L) in triplicate groups per diet. The concentration of ammonia (NH₃) in tanks were kept 2.5 mg/L with ammonium Chloride (NH₄Cl). The mortality was monitored for 60 h.

Results

Growth performance results were significantly higher in shrimp fed diets containing over C4000 with or without lecithin than those in C2000 and CL2000 groups. Phenoloxidase, superoxide dismutase activity, glutathione peroxidase activity and catalase activity were significantly lower in shrimp fed C2000 and CL2000 diets compared to those of shrimp fed other diets. Digestive enzyme activity (trypsin, chymotrypsin, lipase and amylase) were significantly improved in shrimp fed diets containing over C4000 with or without lecithin than those of shrimp fed C2000 and CL2000 diets. Similar trends were found in relative expression of the insulin like growth factor-1, insulin like growth factor-binding protein, prophenoloxidase and heat shock protein 70 genes. During the ammonia stress challenge, C2000 and CL2000 groups showed the lowest survival than other groups. However, the two-way ANOVA showed that the supplementation of lecithin could increase the ammonia resistance of the shrimp.

Conclusion

Choline deficiency (≤2000 mg choline/kg diet) could resulted in negative effects on the growth performance, nonspecific immune responses, antioxidant capacity, digestive enzyme activity and ammonia stress resistance in *L. vannamei*. Supplementation of lecithin in diet for *L. vannamei* had no effect on the determination of choline requirement from a growth performance. Broken-line regression analyses of weight gain indicated that the optimum dietary level of choline is 4609 without lecithine and 4594 mg/kg with lecithin supplementation in diet for *L. vannamei*.

Introduction

World aquaculture production has broken the all-time production record with a total of 214 million tons, of which 178 million tons are aquatic organisms and 36 million tons are algae. Human consumption of seafood products has increased from 9.9 kg in the 1960s to 20.2 kg today. Considering the world population growth rate, aquaculture products contribute to human food as a great source of protein. Especially with increasing post-harvest food processes, income growth, urbanization, climate crises and changes in dietary trends, the average per capita consumption is expected to be 21.4 kg in 2030 (FAO 2022). Fish farming in Turkey was 79,031 tons in 2000, this amount reached 421,411 tons in 2020, an increase of more than 5 times. In Türkiye, 69.6% of this production, i.e. 293,175 tons, takes place as gilthead seabream (S. aurata) and European seabass (D. labrax) production. While the number of gilthead sea bream and European sea bass fry in Türkiye was 29 million in 2000, this figure was approximately 450-480 million fry of gilthead sea bream and European sea bass in 2022. Today, there are 265 licensed net cage enterprises engaged in marine fish farming in Türkiye. The number of enterprises with a capacity of 1000 tons is 93 (BSGM 2023).

The rapidly growing aquaculture sector in the world and in Türkiye has led to an increased awareness of environmental problems and fish welfare (Çoban et. al., 2020). Although there are many scientific studies on environmental problems, studies on animal welfare and fish suffering are very few. Although some improvements to fish welfare during harvesting are gradually being made, the vast majority of the world’s farmed fish are currently harvested using inhumane methods. More welfare-friendly alternatives exist for some species, but much work remains to be done before they are widely adopted in the industry. Humane slaughter methods for other fish species are still under development and research should be prioritized. A report prepared for the European Commission in 2017 stated that member states are not fully complying with various directives on fish slaughter. The report also highlighted a major problem that stunning systems are not formally assessed and controlled in practice.

Percussive stunning or electric stunning is recommended for some species. These systems are important as long as they do not kill the fish. These systems should be followed by an appropriate killing method, such as gill cutting, decapitation or destruction of the brain, the important thing here is to ensure that the fish is killed before it regains consciousness (OIE, 2010).

Figure 1. Electric stunning systems (ESS) in the harvest.

(Continued on next page)
Retailers and consumers are undoubtedly the most important influencing forces in promoting and investing in fish welfare. Therefore, the present study examines producers’ awareness and perspectives on fish welfare in Türkiye, the second-largest fish producer in continental Europe and the largest producer of gilthead sea bream and European sea bass in the world.

Material and Methods

In the study, a face-to-face/online survey was conducted with fish producers. The questionnaire consists of about 50 questions in two parts including production methods and approach to animal welfare. The survey questions were open-ended or based on a 4-point Likert scale. In the study, producer companies corresponding to 75% of the total production capacity were interviewed. The SPSS package program was used to evaluate the data.

Conclusion

All of the producer companies participating in the study attach importance to fish welfare and declared that they carry out studies (training, meetings, etc.) on this subject. They reported that they apply the most important elements of fish welfare such as stock density, feeding time and amount, cage maintenance etc. according to the fish species and geographical location. So much so that the survival rate during aquaculture in all net cages is between 10-15% and the FCR varies between 1:1 and 1:1.5 depending on the cultured fish species. The companies use either the ice slurry method or electric stunning systems (ESS) for the harvesting of gilthead sea bream, European sea bass and rainbow trout. All of the companies have an ESS (Figure 1). However, in line with the demand from the market, the preference for using ESS during harvesting varies. However, they also reported that the selling price of fish harvested using ESS is not higher than other harvesting methods both in the domestic and foreign markets. Of the companies using this impacting machine, 40% prefer domestic production. They stated that spare parts, maintenance-repair, etc. cannot be done in imported machines or that this process takes a lot of time. They reported that the most important problem faced by the companies during the ESS was the installation of this machine on the harvesting boat. Likewise, they also reported that when the wave height is high, sufficient amounts of fish from the fish pump cannot reach the electric impactor system sufficiently.

Introduction
Atlantic salmon farming industry in Norway is engaged in carefully crafting feed formulations and employing innovative technologies to address the sustainability concerns. However, the evolution has been associated with challenges linked to welfare issues. To maintain a sustainable growth trajectory and to preserve the health of farmed fish, the industry must rely on feed ingredients that have beneficial implications beyond their intended growth promoting effects. Microalgae varieties are among the new ingredient sources being evaluated for salmon feeds. In the present study, we assessed the effects of meals from three differently processed microalgae on the growth, feed performance and intestinal health of Atlantic salmon reared in sea cages under commercial farming conditions.

Materials and Methods
Atlantic salmon of average weight 1.8 kg were employed in a 32-week feeding trial conducted at the pilot-scale farm site of Gildeskål Forskningsstasjon (GIFAS), Norway. The fish were fed one of the following five test feeds: control feed based on plant ingredients and 15% fishmeal and four other feeds containing 10% fish meal and different microalgal biomass – 7.5% of defatted Desmodesmus sp., extruded Nannochloropsis oceanica, bead milled Phaeodactylum tricornutum, and unprocessed P. tricornutum. Growth of salmon, feed conversion ratio, and histomorphological features of the distal intestine of the fish were compared at the end of the feeding term.

Results and Discussion
After 32 weeks in the sea cages, the fish had gained more than two times their initial body weight, reaching 4.09 kg on an average. Inclusion of different algal biomass in the feeds did not reveal any significant difference in weight gain. Nevertheless, the condition factor of fish on the Desmodesmus feed was significantly lower compared to those fed the control and the Nannochloropsis feeds. Feed conversion ratio for the latter fish group did not differ from that of the fish on the control feed, though the values of the other algal-fed groups were significantly lower compared to the control group. Furthermore, the fish on the Nannochloropsis feed had significantly higher values for villi height, submucosa thickness, muscle layer thickness, villi width, and height of enterocytes compared to the control and bead milled Phaeodactylum fed groups. The control group had wider lamina propria compared to the fish fed unprocessed Phaeodactylum. The latter fish group had fewer mucous cells compared to the control fish and those that received Desmodesmus and Nannochloropsis feeds. The fish fed Desmodesmus had more intraepithelial lymphocytes compared to the control fish and those fed Phaeodactylum (both types). The Nannochloropsis fed group had significantly higher number of supranuclear vacuoles in the enterocytes compared to the control fish and those fed Desmodesmus.

The principal component analysis of the distal intestine histomorphometry-based parameters pointed to the better gut health of the fish fed Nannochloropsis compared to the other diet groups, based on improved height and width of villi, and height of enterocytes. The bead milled Phaeodactylum negatively affected the villi features compared to those fed the unprocessed biomass.

(Continued on next page)
Conclusion
The studied microalgae affected the intestinal micromorphology differently; while the *Desmodesmus* sp. stimulated the barrier defence features, *N. oceanica* improved the villi features in the intestine of Atlantic salmon. Processed *Phaeodactylum* biomass was not effective in maintaining the normal morphological features of the intestine. Taken together, the microalgal products examined here can be considered as potential ingredients for salmon feeds, especially the biomass of *Nannochloropsis*.

Introduction
Under in vitro conditions, isolated fish ovarian follicles retain the ability to resume meiosis and progress through the last stages of oogenesis when exposed to maturation-promoting stimuli. Assessing the dynamic response of follicles during in vitro maturation (IVM) can help estimate the reproductive state of the broodstock and gamete quality. To maintain viability and induce follicle development in culture, it is necessary to consider both effective hormonal stimulation and optimal media composition. In fish, gonadotropins and maturation-inducing hormones, such as 17α,20β-dihydroxy-4-pregnen-3-one (DHP), are commonly used to induce maturation of isolated ovarian follicles. Furthermore, both amino-acid rich culture media and additional incorporation of protein and lipid sources—such as serums and bovine serum albumin (BSA)—were found beneficial for maintaining follicular cell and oocyte viability, as well as promoting maturation and ovulation.

In pikeperch (Sander lucioperca), IVM was used to predict the maturational competence and latency time of female breeders (Ljubobratović et al., 2023). The aim of this study was to further optimize the established IVM protocol for immature, postvitellogenic ovarian follicles of this species. This was done by testing different culture media types and supplementation, as well as the effect of maturation-promoting hormones in a range of concentrations.

Materials and methods
Adult pikeperch females (TL: 37 ± 2 cm; W: 424 ± 63 g; GSI: 12 ± 1%) were sampled during the chilling period of the photo-thermal spawning induction (6 °C, 8 h light/16 h dark cycle at sampling moment), prior to any hormonal stimulation. Intact fully grown ovarian follicles were isolated manually and subsequently placed in culture media consisting either of 90% Leibovitz L-15 medium or full strength Cortland’s medium. Both media types were supplemented with antibiotics and 15 mM HEPES, with pH adjusted to 7.5. Furthermore, the effect of additional culture media supplementation in the form of BSA (0-1%) or fetal bovine serum (FBS; 0-20%) was tested. Maturation was induced by adding either DHP (1-1000 ng/ml), human chorionic gonadotropin (hCG; 1-20 IU/ml) or a combination of the two, after which the follicles were incubated at 12 °C, under gentle agitation for 6 days. Resumption of meiosis and maturation progress was evaluated regularly, by scoring the percentage of follicles that underwent germinal vesicle breakdown (GVBD), ooplasm clearing and lipid droplet coalescence, compared to the control group with no hormonal stimulation. In addition, ovulation was monitored by checking the integrity of the follicular layer under light and fluorescent stereo microscope, after staining the follicular cells with SYBR Green.

Results and discussion
At the time of sampling, most of the fish contained follicles in postvitellogenic stage of development that have attained maturational competence (Ø 898 ± 15 µm). Both media types successfully maintained the viability and responsiveness of follicles throughout treatments; however, the rate of GVBD a 4-day stimulation with 100 ng/ml DHP was higher in Leibovitz L-15 medium (83 ± 11%), compared to ones in Cortland’s medium (67 ± 9). The rate and speed of maturation were dependent on the concentration of DHP used. Furthermore, a high percentage of maturing follicles had issues with lipid droplet fragmentation. Treatment with only hCG resulted in comparable final GVBD rates (85 ± 13%); however, the length of incubation notably increased (up to 6 days), regardless of hormone concentration. Slower response during hCG stimulation enabled gradual and synchronized nuclear and cytoplasmic events, resulting in proper lipid droplet coalescence in all mature follicles, as well as evident hydration – increase in diameter was 33 ± 10 µm at the time of GVBD, as opposed to 14 ± 8 µm in the DHP-groups. The rate of ovulation was low after both DHP- (10 ± 8%) and hCG-induced maturation (9 ± 8%), with the majority of non-ovulated mature oocytes showing signs of activation and cell cleavage with longer incubation times. In hCG-groups, higher ovulation rates were achieved by subsequently including DHP (10-100 ng/ml) to the ongoing treatment, shortly before the follicles reached GVBD. Incorporation of supplements in the form of BSA (0.1-0.5%) and FBS (2-10%) to the 90% L-15 medium improved the hormone-induced GVBD of pikeperch follicles in

(Continued on next page)
culture. Moreover, it was noted that FBS in concentrations higher than 10% promotes maturation (>32 ± 6%), even with no additional stimulation with DHP or hCG. This outcome might be due to the complex biomolecular composition of FBS, which can include hormones and growth factors that can influence follicle development and induce oocyte maturation. However, although favorable for nuclear maturation, high concentrations of both BSA (≥1%) and FBS (≥15%) seemingly affected the lipid metabolism and cytoplasmic maturation of the oocyte, most often leading to disruption in the lipid droplet formation.

Conclusions
An in vitro maturation protocol was successfully developed for fully grown, postvitellogenic pikeperch ovarian follicles. The culture media consisting of 90% Leibovitz L-15 media (pH 7.5) with the addition of 0.5% BSA or 5% FBS maintains viability and responsiveness of follicles to hormones. The highest quality and rate of maturation was obtained after treatment with 2-5 IU/ml hCG after 6 days of incubation at 12 °C. Subsequent addition of DHP (10 ng/ml) to the culture media during an ongoing hCG treatment improves ovulation rates of matured oocytes, without notable changes in the GVBD rate and lipid droplet morphology. The protocol detailed here presents a useful tool for refining pikeperch spawning practices in the future, as it enables an in vitro assessment of the maturational competence of individual fish, as well as the prospective outcome of hormone-induced ovulation during artificial spawning.

Introduction

In recent years, aquaculture become one of the fastest developing food sectors of the world with an effect on environment. An increase of phosphorus rich effluents from culture system creates consequences on environment sustainability. Phosphorus (P) is present in fish diets, which are the essential source of P in aquaculture. Importance of P nutrition on bone development and energy kinetics in the cells are well studied (Strauch et al., 2018). Although, it is considered as biologically important for fish, it is as well established that excess phosphorus in fish feed can promote eutrophication of aquatic environments (Antony Jesu Prabhu et al., 2016).

The excretion of indigestible P leads to an accumulation of P in closed water systems, like recirculation aquaculture systems (RAS). Previous studies show that freshwater tilapia species can absorb P from the water through the gills and gastrointestinal tract (Al-Kholy et al., 1970) and in other species, it has even been shown that the accumulation of this mineral in water can be beneficial for growth and normal skeletal development (Strauch et al., 2019; Van Bussel, C et al., 2013). Normal developing skeleton is a prerequisite for sustainable production and animal welfare, but vertebral column deformities are a persistent concern for farmed Atlantic salmon (Fjelldal et al., 2012a).

The major objective of this study is to understand and quantify the differential impact of water-borne phosphorus and dietary phosphorus content on P retention juvenile Atlantic salmon. The final goal is to find an equivalence ratio between P-water and P-feed to reduce the dietary phosphorus content by recycling the P accumulated in water. Differences will be assessed by quantifying fish growth, P-accumulation in the whole body and opercula and comparing the skeletal development and the total fat content.

Materials and method

Atlantic salmon juveniles weighing on average 2.71 g were reared in this trial. This experiment includes three identical RAS systems with 48 freshwater tanks (each 50L). Three water treatments with different phosphorus level were applied in these systems: no phosphorus addition; supplemented to 30 mg P/litre and supplemented to 60 mg P/litre. Mono sodium phosphate was used to maintain phosphorus level in water. 8 different diets were tested in this experiment with different phosphorus levels in feed: 0.00%, 0.21%, 0.42%, 0.63%, 1.25%, 1.88%, 2.50% and 3.13%. Each diet was tested in triplicate groups at 120°C in freshwater. Growth performance of each tank was measured after 8 weeks. At the end of the trial, phosphorus content in whole body and opercula was analysed and skeletal changes were assessed.

Results

Growth performance was significantly impacted by P-water and P-diet. High water-P depressed growth performance. At the end of 8 weeks, phosphorus content in opercula and whole-body of fish has been analyzed. Analyses of skeletal abnormalities will support chemical analyses. A recommendation will be given how far water-borne P can replace dietary P in a sustainable manner.

INTRODUCTION TO THE NEW RECIRCULATING AQUAPONICS SYSTEMS AT LEIBNIZ INSTITUTE OF FRESHWATER ECOLOGY AND INLAND FISHERIES – WITH SPECIAL FOCUS ON COST EFFECTIVE DESIGN

L. Klatt*; C. Shaw; S.M. Strauch; Prof. Dr. W. Kloas

Department of Fish Biology, Fisheries and Aquaculture
Leibniz Institute of Freshwater Ecology and Inland Fisheries
Müggelseedamm 310
12587 Berlin, Germany
E-Mail: laura.klatt@igb-berlin.de

Aim

In RAS and aquaponics, optimum system design is key to assure best results, defined by key performance indicators (e.g. removal of solid wastes, nitrification, NO$_2$ and CO$_2$ removal and O$_2$-supply). In this respect, a better understanding of the principles and performance of different functional components can improve robustness and performance of RAS.

The aquaponics team of Leibniz Institute of Freshwater Ecology and Inland Fisheries (IGB) has developed a modular, Recirculating Aquaponics System.

The aim of this presentation is, to show how to calculate, design and build a robust and price effective RAS for aquaculture and aquaponics.

Materials and Methods

The system set-up includes 16 identical RAS specifically designed for aquaponic research trials. Each system is equipped with one fish tank a polyethylene sedimentation tanks, moving-bed nitrification bioreactor and pH stabilization. The modular approach of the design allows for high flexibility, e.g., by “by-pass” to synchronize bio filters flow rate, feces collection and valves for fresh- and wastewater usage, if needed. Furthermore, it is possible to adapt the system design towards altering research questions (figure 1). New water use was 10% per day. pH was adjusted with NaOH by means of a medical drip applicator when needed and was kept at 7.8 ± 0.27 during the trial.

Furthermore, it is possible to customize the system for every new trial, if necessary. An outline of the system as it is in use at the moment can be seen in figure 1.

Results

Robustness and performance of the system was demonstrated during first year of operation. During this time, different research trials were carried out, with main focus on development of aquaponics feeds for different fish species [1, 2]. These studies demonstrated that physico-chemical parameters (e.g. oxygen concentrations, temperature, pH, and levels of ammonium and nitrite), were within suitable ranges for fish tested.

During the trials oxygen and temperature could be kept constant in the defined limits of 7.11 ± 0.23 mg and 27.0 ± 0.3 °C. The values were measured once a day before feeding and water exchange. Solids were removed on a daily basis from each RAS from the sedimentation tanks.

Discussion and Conclusions

The authors believe, that the use of a low-budget but well-planned research system presents a chance to create something that opens up new possibilities for your future research and should be exploited more often. Through the above-mentioned study, it was possible to show that by controlled removal of waste water and aquaculture sludge the closing of nutrient streams between aquaculture and hydroponic can be supported. The ongoing development of aquaponics and the reuse of system-internal waste streams is becoming increasingly important.

We share our personal experiences on the design process -the planning, assembly, performance assessment and design improvement.

Introduction

The profitability of small and medium-sized fisheries in the inner and outer coastal waters of Mecklenburg-Western Pomerania is being made more and more difficult by the limitation of fish resources and regulatory measures such as catch quotas, seasonal fishing bans and area closures. In order to continuously ensure the regional demand for fresh fish in the face of declining yields, marine aquaculture is an alternative solution. The herewith presented project aims at three main points that currently still significantly restrict the spread of mariculture systems in Europe and especially in Germany:

1. The management of mariculture systems is significantly more complex than systems on land.
2. The animal welfare rating of the cultured fish is difficult to determine. Non-invasive evaluation is necessary for both ethical reasons and to increase yield.
3. The approval of new systems often fails because of bureaucratic hurdles and skepticism about risks of water pollution and negative environmental effects.

On the basis of data acquisition with comprehensive sensors - from e.g. image and video material, weather satellites, hydrodynamics (currents, waves), water temperature, salinity, pH, dissolved oxygen (O$_2$), redox potential (ORP) - the concept of a digital management tool for the aquaculture facility including its spatial environment, should be addressed via the project. By using methods from the field of artificial intelligence (AI) to evaluate the sensor data, a monitoring system for aquaculture systems with intelligent sensors is to be created. Digitalization in the form of mapping the value chain through real-time monitoring and the associated option for remote maintenance can greatly reduce the effort involved in managing a mariculture facility.

Material and Methods
For implemented studies, an offshore mariculture system in the Baltic Sea off Warnemünde/Rostock was chosen. Within the circular net cage (Vol. 70 m³, PE) rainbow trout, *Oncorhynchus mykiss* were farmed within season of 2022. Real-time monitoring of animal welfare, animal behaviour and environmental parameters was done by comprehensive sensor technology and a camera system. Obtained video and photo material was processed and analysed using artificial intelligence. Additionally, health status of the fish was examined by means of parasitological and bacteriological investigations, following standardised methods (Bush et al. 1997, Unger & Palm 2021, Fuentes et al. 2023).

Results
For AI detection by software, fish keypoints and zones were defined on the rainbow trout, which are helpful in analysing fish behaviour (see Figure 1). For example, the relationship between the maximum height and length of individual fish can be used to determine the nutritional status. In addition, external injuries can provide clues to husbandry conditions and diseases, since these are mostly induced by stress and/or stocking density (Weirup et al. 2022). In addition, open wounds represent potential entry points for parasites and pathogens.

AI-assisted detection of damage to gill cover (operculum) and damage state of the caudal fin was successfully established for the trained video sequences. Statistical analysis and specifications of these markers are planned for season 2023.

The parasite fauna of rainbow trout was studied in April and November 2022. In April, only one specimen of eye fluke (*Diplostomum* sp.) parasite was found in the studied rainbow trout, originating from the freshwater hatchery. In November sample, beside these parasites, moderate prevalence of digenean parasite, *Brachyphallus crenatus* were obtained, which were transferred from the Baltic Sea environment, via intermediate hosts (see tab. 1).

Discussion and conclusion
The aim of the presented project is to develop a real-time monitoring system for improving the welfare and management of aquaculture systems. This is done by setting up digital image, which includes various animal welfare, animal behavior and environmental parameters. In addition, parasite and microbiome studies are used in this project to evaluate aspects of fish health and to be able to make comparisons between fish in aquaculture and fish outside of the net cage. With establishing the first markers and keypoints in the first season of project work, increasing the robustness of detection and a detection of the dietary status of the fish is in focus of the upcoming project work. This may include a test of our monitoring system and a comparison of different farming systems and conditions. Possibly enabling a wider field of application.

Introduction

Pacific white shrimp (*P. vannamei*) is one of the most important species of shrimp in aquaculture with a global production of over 5 million tons per year. Vitamin C is an essential nutrient to maintain and enhance growth performance, immunity and antioxidant capacity of fish and shrimp. This study was conducted to determine the optimal level of vitamin C supplementation in diet for Pacific white shrimp.

Materials and methods

A vitamin C-free basal diet (C0) was formulated as a control to contain 200 g kg⁻¹ fish meal, 360 g kg⁻¹ soybean meal and 50 g kg⁻¹ squid liver powder as main protein sources. Five other diets were prepared by adding vitamin C (L-ascorbic acid-2-phosphate, Stay C® 35) to the basal diet at 30, 60, 90, 120 and 150 mg kg⁻¹ (designated as C30, C60, C90, C120 and C150, respectively). The vitamin C concentration in the experimental diets were determined to 5.99, 34.3, 63.1, 87.9, 131 and 158 mg kg⁻¹, respectively, for C0, C30, C60, C90, C120 and C150. Total 480 shrimp (0.70±0.00 g) were stocked into 24 acrylic tanks (120 L) in quadruplicates per dietary treatment.

Results

The survival of the shrimp was not significantly different among all the groups even though it was the lowest (93.8%) in C0 group. Final mean body weight was significantly higher in C90, C120 and C150 groups compared to that of C0 group. Phagocytic activity was significantly higher in shrimp fed C90 diet than in shrimp fed C0 diet. Phenoloxidase activity was significantly improved in shrimp fed C90 and C150 diets, while antiprotease and lysozyme activity were significantly increased in the vitamin C-supplemented groups than in shrimp fed C0 diet. Superoxide dismutase activity was significantly increased in C60, C90 and C120 groups in hemolymph, and significantly higher in C60, C90, C120 and C150 groups in hepatopancreas compared to that in C0 group. Catalase activity and total-antioxidant capacity were significantly increased in shrimp fed C90 diet compared to that of C0 group. Hepatopancreas ascorbic acid and, muscle hydroxyproline and collagen concentrations gradually increased with increasing dietary vitamin C levels (up to 63.1 mg/kg). Vitamin C supplemented groups had increased mRNA expression of hepatopancreas insulin-like growth factor-binding protein (C90, C120 and C150 groups), prophenoloxidase (C90, C120 and C150 groups), crustin (C30, C60, C120 and C150 groups) and HSP70 (C60, C90, C120 and C150 groups).

Table 1. Growth performance, feed utilization and insulin-like growth factors binding protein gene expression of *P. vannamei* fed the experimental diets for 49 days.

Conclusion

This study demonstrates that supplementation of vitamin C in diet for *L. vannamei* can enhance the antioxidant enzyme activity, which may contribute to improving their health and performance. Vitamin C supplementation in *L. vannamei* diet positively affects shrimp growth by increasing hydroxyproline and collagen synthesis. A broken-line regression analysis based on the growth of *L. vannamei* showed that the optimal dietary vitamin C requirement was 87.1 mg/kg.

![Graph showing the relationship between dietary vitamin C level and final mean body weight of *L. vannamei*](image)

Introduction

Common carp is reared in man-made ponds, mostly under semi-intensive management in Central Europe, especially Czechia. Most of the ponds were built several centuries ago, spread freely in the landscape and resemble natural lakes, pools, and wetlands. Such ponds fulfil other important ecological and non-productive functions. This is the reason for never-ending public discussions about the present role of ponds and common carp culture. Fishery practices are often criticised as destructive to biodiversity and water quality (Pechar, 2000). There are no doubts about the effect of common carp stocks on pond ecosystems, but many other factors co-share the water quality in ponds. Still, when looking at the system of common carp culture in Czechia as on the animal production cycle, it is hard to find another comparable concerning the welfare of animals and carbon footprint (Roy et al., 2020). From a fish farmer’s point of view, it is essential for the rentability of the common carp farming to maximize the fish mass yield per water area unit. The simultaneous study showed that carp stocks with higher performance potential better utilize the pond ecosystem productivity (Kocour et al., 2022). Here, we focused on relationships between production parameters, type of supplemental feed used and basic parameters of water quality to evaluate the level of possible negative effects of higher carp production in ponds on the environment.

Materials and methods

During 2019–2022, there were altogether 60 ponds (water area ranging from 0.8 – 11.7 ha) monitored for basic water quality parameters: Ammonia nitrogen (N-NH4+), Nitrate nitrogen (N-NO3-), Total inorganic nitrogen (TIN), Total phosphorus (TP), Chemical (CODMn) and Biochemical (BOD5) oxygen demand. The water samplings were performed once per month from May to September (i.e. during the main growing season) close to the pond outlet and in the tributary (if any). Mean values of water quality parameters for each pond and year were calculated from the five values. Balances between water quality parameters from outlet and tributaries were calculated where applicable. Ponds were stocked with different age categories (AC) of common carp, with two mirror carp stocks of different performance potential (assigned as M2 and M2 x AL) and a scaly control group (for evaluating pond conditions). Fish were fed with two types of supplemental food (wheat grain or meal and a plant granule fodder). At harvest, the number and mean weight of the mirror and scaly carp survivals were recorded, and final carp mass and mass yields of the mirror and scaly carp stocks per 1 ha of pond water area were calculated. Amount of spent food and other factors (winter period, presence of wild ducks, excessive quantity of unwanted fish) were also considered. After excluding incorrect data, information from 41 ponds was included in the statistical analyses (one-way and multifactorial ANOVA, non-parametric Mann-Whitney U test, ANCOVA, multiple correlation matrix, PCA).

Results

Data showed significantly higher weight gain (WG) in M2 x AL stock in some age categories compared to M2. During the third growing season, the difference in WG was up to 33.6 % based on the type of analysis. Even survival was usually better in M2 x AL stocks, but the difference was statistically insignificant. It was also shown that unified mass yield (MY) and carp mass (CM) of M2 x AL stocks were higher than in M2 stocks, even if insignificantly. However, the share of M2 x AL stocks on total carp MY was significantly higher compared to M2 stocks. Unified carp MY in ponds ranged from 203 kg*ha⁻¹ to 1246 kg*ha⁻¹. Statistical analyses did not reveal powerful relationships between water quality and carp production parameters (MY, CM, the type of carp stock used, amount of supplemented food used and relative food conversion ratio). On the other hand, relationships among some water quality parameters were significant and moderate to high. Balances between quality of incoming and outgoing water indicated that the pond ecosystem did not change the water quality significantly, even if parameters of organic pollution may be moderately changed in relation to carp mass in ponds.

(Continued on next page)
Discussion and conclusion

It is supposed that ponds with higher CM have higher levels of TP, TIN, COD and BOD₅ in the water. In presented study, CM in ponds varied quite a lot, but no correlations of the CM with these parameters, except a moderate but significant correlation with COD, was observed. It seems that there may be more important factors responsible for the ecological status of the ponds than CM common in ponds of Czechia. Comparison of historical data and our observations for the level of TP in ponds of Czechia (Pechar, 2000) showed that from 1990' there has been no increase in the level of this main nutrient responsible for water eutrophication. Balances of water quality parameters in the tributary and outlet parts of ponds clearly showed that ponds in our study decreased in average the content of TIN (by 1.91 mg*L⁻¹), practically did not change the content of TP (-0.003 mg*L⁻¹) and only slightly increased the COD (2.95 mg*L⁻¹) and BOD₅ (5.21 mg*L⁻¹). Concerning organic pollution, the positive of ponds may be seen at least in the fact that they increased the ratio of organic matter that may be easily biologically mineralized (by 2.26 mg*L⁻¹). Moreover, the results indicate that the share of CM in the pond on the organic pollution increase is rather low. Based on the results, it can be concluded that a certain increase in average CM in ponds, an essential condition for implementing a selective breeding program, should not dramatically affect the basic water quality parameters.

Introduction

Gilthead sea bream (Sparus aurata) farming is of great importance to European finfish mariculture accounting for 13% of its production value. A bottleneck to further increasing this species production is Sparicotyle chrysophrii, a gill-attaching blood-sucking monogenean, which is currently the most serious pathogen for gilthead seabream farming. To date, formalin bath treatments are the primary measure to battle sparicotylosis, however, bath applications in large cages are associated with several drawbacks.

Praziquantel (PZQ) is an anthelmintic drug widely used in veterinary medicine to control Platyhelminthes. The efficacy of the drug against a wide range of parasitic helminths in numerous farmed fish species has been recently reviewed (Bader et al. 2019; Norbury et al. 2022). Admittedly, drug pharmacokinetics (PKs) in the targeted organisms provide useful information optimizing treatment schedules. Nevertheless, to our knowledge, there is no literature examining the PKs of PZQ in gilthead seabream, thus, the present study attempts to investigate the kinetic profile and bioavailability (F) of dietary-administered PZQ in this species.

Materials and methods

Three hundred healthy gilthead seabream (52±3.7 g) were equally randomized in 3 groups of tanks; Low and High groups received an experimental diet supplemented with PZQ 75 mg/kg and 150 mg/kg, respectively, while the intravenous group received intravenously (i.v) the PZQ dosing of 75 mg/kg fish dissolved in DMSO (0.5 mL/kg BW). During the experimental procedure, fish were hand-fed once a day, assuring that the feed was consumed. Water temperature was maintained at 21±1°C. Ten fish/group were anesthetized (MS-222, 150 ppm) and blood samples were collected at 1, 2, 4, 6, 8, 12, 24, 48, 72, and 96 h post-treatment. Plasma was separated from blood by centrifugation (3000 g for 10 min at 4°C). Fish were then killed by an overdose of anaesthetic and gill samples were also collected. PZQ levels were analyzed after extraction by an HPLC-UV chromatographic apparatus.

Results and Discussion

Plasma PZQ concentrations after oral and i.v administration are shown in Figure 1. As expected, the double dosing resulted in significantly higher PZQ plasma levels although only an approximately 22% increase in Cmax (6.7 μg/mL for the low group vs 8.2 μg/mL for the high group) was observed. PZQ elimination from fish circulation following dietary administrations was found to be relatively sharp for both examined dosing regimens albeit distinguished profiles were evident. Particularly, the elimination half-life (t1/2β) was shorter at high compared to the low PZQ dosing, revealing values of 14.4 and 25.7 h, respectively. The F of PZQ was calculated to be 49%, confirming a high absorption in fish circulation. In agreement with this, a high F of PZQ (51%) has also been reported in yellowtail kingfish (S. lalandi) (Tubbs & Tingle 2006).

Gill PZQ concentrations in gilthead seabream after two single oral doses are shown in Figure 2. The maximum concentrations of PZQ in fish fed 75 and 150 mg/kg were found 20.7 and 39.1 μg/g, respectively, 4 h post-feeding. Additionally, a dose-dependent effect in relative exposure to PZQ was observed. Furthermore, the t1/2β of PZQ in fish fed the low dose was found at 8.9 h while in the high-dose group, the corresponding value was calculated to be 11.7 h, indicating faster elimination for the low dosing. The aforementioned results clearly indicate that among examined tissues, distinct kinetic profiles of PZQ exist. Since a route of xenobiotics elimination may be via the gills (Hansen et al. 2001), the discrepancies in drug PKs between plasma and gills found herein could be attributed to this assumption.

(Continued on next page)
Conclusions
Based on the information obtained from the PZQ analysis in the gilthead seabream body compartment, the 150 mg/kg dosing regimen is superior to the 75 mg/kg, as confirmed by the significantly higher drug levels in all tested tissues. Since PZQ concentration trends to decrease sharply and the elimination time of the drug in plasma was shorter in fish that received the 150 mg/kg dosing regimen, the daily dosing should be divided into two medicated meals, to ensure adequate drug circulatory levels during treatments. The efficacy of the proposed medicated scheme remains to be evaluated in field trials against *S. chrysophrii*.

ORGANIC MINERALS SUPPLEMENTATION AFFECT FILLET QUALITY OF FARmed GILTHEAD SEABREAM (Sparus aurata)

D. Kogiannou*, A. Vasilaki, M. Kotsiri, Ch. Nikoloudaki, K. Grigorakis, I. Nengas
Institute of Marine Biology, Biotechnology and Aquaculture
Hellenic Centre for Marine Research
46.7 km Athens-Sounion, Greece
E-mail: dkogiannou@hcmr.gr

Introduction
Over the last decade, due to the continuous growth of the aquaculture sector, marine-origin ingredients, i.e. fish meal (FM) and fish oil (FO), have been partly substituted with sustainably produced plant raw materials. The aforementioned changes in fish feeds composition affect the micronutrients balance resulting into lower levels of bioavailable minerals in aquatic feeds compared to fish natural diet, thus inorganic mineral supplements are commonly used to meet fish requirements.

Gilthead sea bream (Sparus aurata) farming is of great importance to European finfish mariculture accounting for the 13% of its production value. This species is marketed mainly as whole fish and more recently as fillets. Unfortunately, gilthead seabream fillets suffer from gaping, a texture deterioration phenomenon which leads to economic loss, because of the rejection by consumers due to its unappealing appearance. Factors that have proven to be strongly associated with the fish propensity to gap, include the species, harvest or slaughter history, temperature during storage (Lavety et al., 1988; Sheehan et al., 1996; Robb et al., 2000) and diet (Kousoulaki et al., 2016).

Taking all the aforementioned into account, this study aimed to evaluate the impact of organic mineral feed inclusion on growth performance and fillet quality in terms of gaping occurrence, in gilthead seabream.

Materials and methods
Three isoproteic, isolipidic and isoenergetic diets were formulated: a control diet (Diet1) containing high FM (30%), a plant-based diet (Diet2) containing low FM (12.5%) and a plant-based diet supplemented with organic minerals (0.18%) (Diet3). These finishing diets were fed to triplicate groups of gilthead seabream (253g initial body weight) for a 92-day period. Water temperature maintained at 19°C in an open flow water system. Fish were fed by hand to apparent satiation with the three diets. At the end of the trial, fish were slaughtered by the commercial method (ice-killing), individually weighted, packed with ice (0°C), and shipped to a commercial fish processing unit. After mechanical scale removal by drum, fish were machine filleted, weighted, ice-packed and transferred (within two hours) to the Hellenic Centre for Marine Research (HCMR). Individual fillets were assessed for their gaping according to a recently published gaping scale for Mediterranean fish species (Kogiannou et al., 2022), pH, water holding capacity (WHC), total composition, fatty acid profile, chemical freshness (K value), and total and soluble collagen content. The SPSS version 26.0 was used for the statistical analysis. Growth, physical and chemical parameters are presented as mean±st.dev. and comparisons among means were made using one-way analysis of variance (ANOVA). The non-parametric χ² test was applied to find statistical differences in the frequency of gap occurrence between the diets. Differences were considered significant at the level of P<0.05.

Results
Fish growth parameters and feed intake were similar for all treatments, while organic minerals inclusion had beneficial effect on fish fillet quality. Specifically, as shown in Figure 1, distribution of gaping scores frequencies were found to be statistically different among diets. In both Diet1 and 2, increased high gaping scores incidence were observed while flesh integrity remained quite intact in fish received Diet3. Additionally, fish fillet liquid losses and pH were not different in gilthead seabream fed the organic minerals supplemented diet compared to Diet1 and 2. No statistically significant differences were found also in the fillet composition of the fish fed the experimental diets however, increased levels of n6 fatty acids were observed in both plant-based diets (Diet2 and 3). Finally, the total collagen content and collagen solubility in gilthead seabream muscle, calculated based on the hydroxyproline content, were found to be significantly affected by the diet composition and the organic mineral supplementation.

(Continued on next page)
**Conclusions**
Dietary organic minerals included in low fishmeal diet for gilthead seabream significantly improved fillet quality in terms of achieving lower gaping incidence probably due to changes occurred in collagen content and solubility. The exact mechanism responsible for these observations remains to be identified.

DIETARY NON-STARCH POLYSACCHARIDES AND ENZYME ADDITION AFFECT THE MICROBIOTA COMPOSITION AND METABOLITES IN THE GUT OF NILE TILAPIA

R. Maas, F. Kokou*, M. Verdegem, J. W. Schrama

Aquaculture and Fisheries Group
Wageningen University
Wageningen, The Netherlands
E-Mail: fotini.kokou@wur.nl

Introduction
With the current aquafeed formulations including high levels of plant-based ingredients, there is a higher carbohydrate inclusion, including non-starch polysaccharides (NSP), which are less digestible by fish (Kokou and Fountoulaki, 2018). To improve the NSP digestibility and thus feed efficiency, exogenous enzymes of microbial origin such as xylanases can be added (Maas et al., 2021). When such enzymes are included in the feeds, they can assist in the degradation of the NSP into less polymerised compounds, making them more available for fermentation by microbiota, resulting in the production of volatile fatty acids. Understanding how the dietary NSP levels and the enzyme addition may affect microbial composition and metabolite production in the gut, and how this relates to nutrient digestibility can assist in optimization of dietary formulations with aim to enhance fish performance and digestibility, especially when raw materials high in NSP are used. In this study, we explored the impact of two different non-starch polysaccharide and enzyme levels on the microbial composition and microbial metabolites in the gut of Nile tilapia (Oreochromis niloticus). Nile tilapia has omnivorous dietary habits and the potential for fibre fermentation (Amirkolaie et al., 2005), thus making it an interesting species to understand non-starch polysaccharide effects on the gut microbiota.

Materials and Methods
A 2 x 2 factorial design was used to test the effect of enzymes and dietary NSP levels. The enzyme supplementation included phytase (1000 FTU/kg, Danisco Animal Nutrition) and xylanase (6000 U/kg, Danisco Animal Nutrition). The NSP levels were included at 122 g NSP/kg DM diet (moderate) and at 311 g NSP/kg DM diet (high). The feeding trial lasted 6 weeks, with four replicate tanks per diet. At the end of the trial, digesta samples were analyzed for microbiota composition, volatile fatty acid and NSP content. For the microbiota analysis, DNA was extracted with commercial kits and the V4 variable region of the 16S rRNA gene was sequenced, using Illumina MiSeq. Taxonomic composition was analyzed according to Kokou et al., 2020. For diversity analysis, the ‘microeco’ R package was used. Volatile fatty acid concentrations were measured as described in Maas et al. (2021). The NSP content were measured as described by Blakeney et al. (1983). Network analysis using sparcc as correlation method was performed to explore associations between the different microbial taxa, including the environmental variables (nutrient digestibility, NSP content, VFA) as explanatory variables (Kurtz et al., 2015).

Results
The results showed that both NSP level and enzyme inclusion can affect the gut microbiota composition. An increased microbial richness and diversity was observed with high NSP or no enzyme addition compared to the enzyme addition in lower NSP levels. Such changes were attributes to a change of the Fusobacteria (Figure 1A), and specifically an increase in the abundance of Cetobacterium, in the gut of Nile tilapia, fed with the MEDENZ diets. This was in accordance with an increase in VFA content in the gut, which was higher in the specific diet (Figure 1B). The digesta VFA content and the nutrient digestibility could explain the variation in the microbiota composition, as indicated by redundancy analysis. Network analysis indicated that NSP levels and enzyme addition may interfere with microbial associations, by altering the clustering co-efficiency. Our previous study showed that enzyme addition to high NSP diets may enhance the microbial associations in the distal gut of Nile tilapia, by increasing the network complexity (clustering co-efficiency and density), which was hypothesized to benefit the gut microbiota homeostasis (Maas et al., 2021).

Conclusion
These findings suggest that both NSP level and enzyme addition can have a significant effect on the gut microbiota diversity and composition, with the latter being the major factor in this study. Volatile fatty acid content and composition were consistently altered by the enzyme addition in the diets. The interpretation of such results is important in order to better understand the microbial dynamics in the gut and how such dynamics may be altered by dietary formulations such as the presence of NSP or by enzyme addition, ensuring an optimal fish performance.

ARE THE EFFECTS OF DEOXYNIVALENOL (DON) ON PERFORMANCE, LIVER AND GASTROINTESTINAL TRACT HEALTH OF RAINBOW TROUT (*Oncorhynchus mykiss*) INFLUENCED BY DIETARY COMPOSITION?

Introduction

Ever since mycotoxins have been described as emerging feed contaminants for European aquaculture, it has become evident that deoxynivalenol (DON) is the most prevalent mycotoxin in aquafeeds (Koletsi et al., 2021). Different fish species display different sensitivities to DON. Compared to other fish species, rainbow trout (*Oncorhynchus mykiss*) is very sensitive to DON (Hooft et al., 2011; Koletsi et al., 2021). Experimentally, studies on the effects of DON have generally targeted the concentration of the mycotoxin instead of focusing on the composition of the diet. Studies with DON in carnivorous fish have hitherto been performed against a background of optimal quality marine-based diets. Yet, as argued above, ingredient composition of aquafeeds has diversified rapidly to include more plant-based ingredients. This not only introduces the risk of feeding mycotoxin contaminated ingredients but also introduces a risk that the negative effects of DON can be amplified by sub-optimal diets. Information on the interaction between DON and diet composition is generally lacking. Therefore, this study investigated if dietary composition influences the effects of DON on the health and performance of rainbow trout (*Oncorhynchus mykiss*).

Material and methods

Four experimental diets (2x2 factorial design) were formulated which differed in 1) the type of protein source; fishmeal (FM) versus soybean meal-based (SBM) and 2) the DON content of wheat; clean versus naturally contaminated wheat. Triplicate groups of n=30 fish were assigned to each diet: (1) CON-FM; DON= 0 µg/kg feed; (2) DON-FM; DON=1200 µg/kg feed; (3) CON-SBM; DON= 46 µg/kg feed; (4) DON-SBM; DON= 1300 µg/kg feed. The 8 week experiment was divided into two feeding periods: after 6 weeks of restrictive feeding, fish were fed *ad libitum* for 2 weeks. **Influences on performance were evaluated by determining growth**, protein and energy gain metrics, and on health parameters through the determination of histopathological changes in the liver and gastrointestinal tract (GIT).

Results

Restrictive feeding showed negative effects of DON and dietary composition on performance but did not show an interaction between DON and diet composition. Similarly, subsequent *ad libitum* feeding showed effects of DON and/or diet composition on growth, feed efficiency and body biometrics, but no interaction effects. These data confirmed the challenging nature of the SBM-based diet and confirm previously noted negative effects of DON on performance. Neither DON, nor diet composition indicated significant effects on liver health, nor was there an interaction effect. We discuss that the combination of DON and a sub-optimal diet based on SBM could accentuate the effects of DON, in particular concerning GIT functioning. Indeed, the histopathological assessment of mucosal fold width, enterocyte width and goblet cell density indicated significant interaction effects between DON and diet composition in the midgut. Yet, the differences were generally small and interaction effects were restricted to the midgut. Overall, this study suggests that DON is harmful to rainbow trout regardless of diet quality.

(Continued on next page)
Figure 1. Interaction effects between dietary DON (CON versus DON) and diet quality (FM versus SBM) on mucosal fold width (p≤0.05), enterocyte width (p≤0.05) and goblet cell density (p≤0.05) in the midgut of rainbow trout fed the experimental diets: CON-FM, DON-FM, CONSBM and DON-SBM restrictively for 6 days (week 1) and 40 days (week 6) and ad libitum exposure for 15 days (week 8). *Goblet cell density was calculated as the number of cells per μm fold height. Error bars indicate standard error of means. Treatments lacking a common letter are statistically different (p≤0.05) according to Tukey’s multiple comparison test.
COMPARISONS OF METHODS FOR ASSESSING FIN CONDITIONS

J. Konrad*, C. Pietsch

School of Agricultural, Forest and Food Sciences (HAFL)
Bern University of Applied Science (BFH)
3052 Zollikofen, Switzerland
E-Mail: jonathan.konrad@bfh.ch

Introduction

Fin condition is one of the most frequently used welfare parameter for farmed fish. Several methods for actually evaluating and calculating fin conditions have been used in the past like the Kindschi index which correlate the longest fin ray vs. the body length of a fish. For this study a new method is presented which uses the calculation of the area index (AI) and relating this to the total body length or the standard body length (improved AI). In order to compare the suitability of the methods mentioned below, the present study thus investigated the fish indices based on different methods for two different species - rainbow trout (*Oncorhynchus mykiss*) and common carp (*Cyprinus carpio L.*), aiming at recommending the most useful fin condition assessment method for fish farming.

Material and methods

Data from 4 different fish farms in Switzerland (2x trout, 2x carp) have been collected for more than 19 months. At each sampling up to 15 fish have been sampled belonging to maximum three size classes (<100g, 100-250g, >250g). Different fin lengths and area were determined in Adobe Photoshop CS. For the estimation of the fin condition a visual classification of the fin appearance by using 5 different categories was done. The following parameters have been calculated from the fin measurements and were compared to the visual estimation of the fin condition:

- longest fin ray vs. total / standard body length (Kindschi 1987, Ellis et al. 2009)
- fin basis (wide) vs. fin length
- longest fin ray vs. length of caudal fin (Good et al. 2011)
- fin area vs. total / standard body length

Results and discussion

The two trout farms show the same pattern of correlations of the fin indices with the visual fin scoring. Moreover, the correlations can be strong. This clearly shows that fin index assessment is a reliable parameter for this fish species, and especially the area-based calculation and Kindschi methods result in highly significant correlations with the visual fin scoring method. With the Kindschi method, care must be taken that even with very badly damaged fins the longest fin ray may be intact. This could falsify the result, especially in the case of fin damage from aggressive encounters between fishes.
THE EFFECT OF INCREASING CONCENTRATIONS OF A NOVEL ULTRA-HIGH PROTEIN SOYA AND REGULAR HIGH PROTEIN SOYA MEAL ON THE PERFORMANCE OF GILTHEAD SEABREAM (*Sparus aurata*)

Wolfgang Koppe¹, David AH Sutter², Alessio Bonaldo³, Hannah Lucas⁴

¹Simplyfish AS, Balders gate 12, 4011, Stavanger, Norway

³Department of Veterinary Medical Sciences, University of Bologna, 40064 Ozzano Emilia, Italy
⁴Benson Hill Inc., 1001 North Warson Rd, St. Louis, MO 63132, USA

Introduction:
Soybean meal is widely used in aquafeeds and, due to the favourable amino acid profile and competitive pricing, usually one of the main ingredients of fish feeds. However, high inclusion rates of soybean meal have been reported to have adverse effect on fish performance and to result in soy-induced enteritis (Knudsen et al., 2008). This has been attributed to different antinutritional factors present in soybeans, such as saponins and oligosaccharides (Krogdahl et al., 2010). Whereas to date most of the work studying the impact of soybean meal on fish performance has been carried out in Atlantic salmon, there is indication that high inclusion rates of regular soybean meal may also affect the performance and gut histology of other species, such as the gilthead seabream (*Sparus aurata*, Perera and Yúfera, 2017). Novel soy-products, containing very high amounts of protein (UHP-soya) and low amounts of oligosaccharide (Roe et al., 2019), could, therefore, offer significant advantages over the use of regular soybean meal when formulating feeds for Mediterranean species such as the gilthead sea bream. The present study sets out to compare the effect of increasing concentrations of regular soybean meal and UHP-soya on the growth and performance of gilthead seabream. By gradually replacing the protein fraction of a soy-free reference diet with regular high-protein soya (Hipro-soya) and UHP-soya, the present trial determines the effect of increasing concentrations of soy and different soy-products on the performance of gilthead seabream.

Materials and Methods:
The five experimental diets were formulated be iso-proteic and iso-energetic and to average a crude protein content of 48% and a level of digestible energy of 18 MJ/kg. The reference diet contained 15% of fish meal and corn gluten, wheat gluten, feather meal and poultry meal as main protein sources. With the exception of fish meal, which was kept constantly at a level of 15%, other raw materials were replaced by two substitution rates of either UHP-soya and Hipro-soya. The relative contribution of protein by both soybean meal was kept constant, resulting in total substitution rates of 15 and 30% for diets containing regular soybean meal and 13.1 and 26.3% for diets containing UHP-soya. This design should allow to assess the true protein value of both soybean meal in an experimental setup using a raw material basket representative for current commercial formulations for Mediterranean species.

The experiment was carried out at the Laboratory of Aquaculture, Department of Veterinary Medical Sciences of the University of Bologna, Cesenatico, Italy. Gilthead seabream juveniles were obtained from an Italian hatchery. At the beginning of the trial, 50 fish (initial average weight approx 40 g) per tank were randomly distributed into 18 square tanks with a capacity of 800 L. Each diet was administered to triplicate groups, with random assignment. Tanks were provided with natural seawater and connected to a closed recirculation system (overall water volume: 20 m³). The rearing system consisted of a mechanical sand filter (PTK 1200, Astralpool, Barcelona, Spain), ultraviolet lights (PE 25 mJ/cm²: 32 m² h⁻¹, Blaufish, Barcelona, Spain) and a biofilter (PTK 1200, Astralpool, Barcelona, Spain). The water exchange rate was 100% every hour, while the overall water renewal amount in the system was 5% daily. During the trial, the temperature was kept at 24 ± 0.5 °C and the photoperiod was maintained at 12 h light and 12 h dark through artificial light. The oxygen level was kept constant (8.0 ± 1.0 mg L⁻¹) by means of a liquid oxygen system regulated by a software programme (B&G Sinergia snc, Chioggia, Italy). Each day, ammonia (total ammonia nitrogen ≤0.1 mg L⁻¹) and nitrite (≤ 0.2 mg L⁻¹) were monitored by spectrophotometer (Spectroquant Nova 60, Mereck, Lab business, Darmstadt, Germany) and salinity (25 g L⁻¹) was measured by a refractometer (106 ATC, Giorgio Bormac S.r.l., Carpi, Italy). Sodium bicarbonate was added if needed to keep pH constant at 7.8–8.0. Animals were fed to satiation with automatic feeders, twice a day, six days a week, set to release pellets gradually for one and a half hours. The uneaten pellets of each tank were collected, dried overnight at 105 °C, and weighed for feed intake (FI) calculation.

(Continued on next page)
At the beginning and at the end of the experiment, all animals in each tank were anaesthetised by MS222 at 100 mg L\(^{-1}\) and weighed. Specific growth rate (SGR) and feed conversion rate (FCR) were calculated. Proximate composition of the carcasses was determined on a pooled sample of 10 fish per tank at the beginning and on a pooled sample of 5 fish per tank at the end of the trial.

**Results:**
The present study performed a detailed analysis on performance of gilthead seabream in response to increasing concentrations of UHP- and Hipro-soya. Growth performance, feed efficiency, carcass composition as well as gut histological parameters were affected by the treatments. The results of the study show a differential response of *Sparus aurata* to increasing concentrations of UHP-soya and Hipro-soybean meal.

Introduction
Variation in nutrient digestibility is among the most critical points of variation in feed quality and constitutes a key parameter when evaluating new feed raw materials for fish. Nutrient digestibility is traditionally assessed in vivo by animal feeding trials, but recent EU obligations to put the 3Rs concept into practice have facilitated research initiatives to develop complementary in vitro methods. One of the current project initiatives addressing this topic is the H2020-FETOPEN project Fish-AI, which aims to develop an in vitro screening platform based on rainbow trout (Oncorhynchus mykiss) digestive enzymes and intestinal cells to evaluate nutritional and health values of novel aquafeeds. As part of this project, we have developed a static in vitro digestion (IVD) model for simulating the in vivo feed digestion in rainbow trout. In the present study, the performance of the Fish-AI IVD model was assessed by comparisons with two independent in vivo feeding trials using juvenile rainbow trout and mink (Neovison vison) as experimental animals. In addition, the Fish-AI model was compared against the standardised human in vitro model INFOGEST.

Materials and methods
A total of seven diets based on commercially relevant protein raw materials with assumed contrasting effects on protein digestibility were formulated. Six test feeds contained the challenging raw materials guar meal and soybean meal at relatively high inclusion levels, feather meal at low and high inclusions, and the combinations guar/feather and soybean/feather. A diet high in fish meal was included as a reference. The study in rainbow trout comprised a 5-week feeding trial using fish with an average start weight of 55 grams. Fish were fed the seven experimental feeds in duplicate tanks each. Fecal collection was conducted by stripping. The mink trial was carried out using adult male mink with a mean body weight of 2.8 kg. Four healthy mink were assigned for each of the seven experimental diets. The animals were kept in individual cages equipped for controlled feeding and quantitative faecal collection. The experiment lasted for 14 days. Feed and faeces samples were analyzed by established procedures. The Fish-AI IVD procedure was based on the static INFOGEST model with several modifications, including the use of enzyme extracts and bile obtained from rainbow trout, whereas the INFOGEST protocol was performed as described elsewhere. The IVD products from both in vitro procedures were analyzed using size exclusion chromatography (SEC) and quantification of soluble nitrogen with Dumas for estimation of the proportion of small soluble peptides potentially available for uptake. Difference among diet groups was analyzed for statistical significance using a one-way ANOVA followed by Fischer’s LSD test. The level of significance was set to p<0.05.

Results and discussion
Figure 1 illustrates the results regarding apparent protein digestibility for the seven experimental diets as tested in the four separate model systems. Significant effects of diet were evident. Rainbow trout fed either the control, guar-high, or soya-high diet generally showed high (>95%) protein digestibilities, whereas inclusion of feather meal in the diet, singly or in combination with guar or soya, clearly reduced protein digestibility. The results obtained with mink were in overall accordance with the results obtained from the study in rainbow trout and strengthen the observation that the biological value of the feather meal protein was low. The results from the two in vitro model systems displayed relatively similar protein digestibility profiles among the experimental diets as the two in vivo models, thus demonstrating that the low protein value of the diets containing feather meal also could be detected in vitro. The absolute values of protein digestibility were higher for the INFOGEST than for the Fish-AI IVD procedure (70-86 vs. 43-62%) and indicate that there is still room for improving the Fish-AI IVD efficiency. These studies are currently ongoing and will be presented and discussed.

EVALUATION OF TOXICITY OF PRAZIQUANTEL AGAINST FISH CELL LINE AND NON-TARGET MARINE ORGANISMS

Introduction
Praziquantel (PZQ) is a synthetic broad-spectrum anthelmintic, widely used in veterinary and human helminthiasis. In farmed fish, PZQ has been demonstrated to be highly effective against a range of internal and external parasites. Thus, PZQ constitutes a good candidate substance based on its proven efficacy against flatworms such as Sparicotyle chrysophrii, a microcotylid blood-sucking monogenean, which is currently the most serious pathogen for gilthead sea bream (Sitjà-Bobadilla et al., 2010, Rigos et al., 2021). PZQ is generally considered safe in treated animals (Norbury et al., 2022). Little work has been done examining the effects of PZQ in the surrounding marine environment, albeit assessment of the effects on non-target organisms is one of the most important components of environmental risk assessment. Therefore, the objective of this study is the evaluation of the toxicity of PZQ on cell culture and selected non-target marine organisms.

Materials and methods
Amphibalanus amphitrite toxicity assay: The barnacle-rearing method was carried out according to Kotsiri et al. (2018). Assays were conducted by adding 10 nauplii into individual wells of a 24-well plate with 2 ml of artificial seawater (25‰) and various concentrations of PZQ. Nauplii have incubated for 48 h in the presence of PZQ at 25°C and the plates were examined after 24 and 48 h. Each animal was inspected under a stereomicroscope and its condition was recorded. The LC50 was determined as the concentration of PZQ that resulted in 50% mortality of the nauplii.

Marine bacteria growth assay: The ability of PZQ to inhibit the growth of the bacteria Vibrio. alginolyticus was assessed by the disk diffusion test. Sterile filter paper discs (4 mm) were loaded with samples of serial dilutions of PZQ, allowed to dry at room temperature and then were placed on agar plates, which were seeded with the strain of bacteria. Plates were incubated for 24 h at 35°C. Marine bacteria growth inhibition was determined by measuring the zone of inhibition in mm around the filter paper disc. As a positive and negative control, standard discs were loaded with 0.5 M penicillin G or solvent, respectively.

Cytotoxicity assays: The cellular toxicity of PZQ was evaluated in epithelial cell line cultures, RTgill-W1. The cytotoxicity of PZQ was evaluated in 96 well plate cultures applying the neutral red (NR) assay to assess the ability of viable cells to incorporate and bind the supravital dye neutral red in the lysosomes. In a flat bottom plate, 5×10^4 cells ml^-1 were placed and incubated at 19°C for 24 h until adherence. Next, the medium was changed and PZQ was added to the culture in different concentrations. After 24 h, NR medium was added, the plate was incubated, washed, the dye was extracted and the absorbance was measured at 540 nm.

Statistical analysis: For statistical comparisons between groups, one-way ANOVA followed by Dunnett’s multiple comparisons test at P<0.05 was used where appropriate using GraphPad Prism v.9. For LC50 all data were fitted to a three-parameter logistic curve according to the following model: (Y=Bottom + (Top – Bottom)/(1+10^((X – LogIC50))).

Results & Discussion
Based on ecotoxicity tests against A. amphitrite (24 h: LC50 = 47.5 mg/L), also confirmed by marine bacteria growth assays, PZQ induced no effect on the growth of the tested bacterial strain, the toxicity of PZQ was found to be low (Fig. 1a, c). This conclusion is in agreement with previous findings in acute and long-term experiments (Cioli et al., 2003; Norbury et al., 2022). Also, the results indicated that very low and low concentrations (≤ 1 mg/L) of PZQ induced no effect on RTgill-W1 cells viability after 24 h of exposure, while medium and high concentrations of PZQ exerted cytotoxic effects (Fig. 1b).

(Continued on next page)
While the environmental concentrations are likely dependent upon dose and stocking density, there is no evidence that high concentrations of PZQ are being discharged into the environment after a treatment regimen. Data from a previous study have shown that PZQ was detected in very small concentrations (0.003 mg/L) in water during PZQ administration and was not detected in the sediment (Ido et al., 2019).

In agreement with existing limited knowledge, this trial suggests that PZQ use in aquaculture is relatively safe for the treated animal and the environment. Nevertheless, there is a need to investigate the fate of this anthelminthic in aquaculture systems in order to more accurately assess concerns about ecological impacts.

EVALUATION OF FERMENTED SOYBEAN MEAL AS A SUSTAINABLE REPLACER OF FISHMEAL IN THE DIETS OF EUROPEAN SEA BASS JUVENILES (*Dicentrarchus labrax*): EFFECTS ON GROWTH PERFORMANCE

**Introduction**

Aquaculture production relies heavily on the availability of sustainable and viable compound feeds. For many decades fishmeal has been considered a superior ingredient and the primary protein source of choice for the aquafeed industry due to its desirable nutritional characteristics. However, due to the increasingly limited supply of fishmeal, sustainable alternatives need to be thoroughly evaluated for the production of aquafeeds. Fermented soybean meal (FSBM) has gained much attention over the past decades due to its improved nutritional value, lower ANFs content, increased digestibility, and health benefits (Kumar et al., 2020; Kari et al. 2022). Thus, the aim of this study was to investigate the potential of FSBM to replace fishmeal as measured by growth performance, feed utilization, and health of European seabass (*Dicentrarchus labrax*).

**Materials and Methods**

A 12-week feeding trial was conducted to compare different inclusions of fermented soybean meal (FSBM, SOYAMAX BIO PLUS, INOLASA, COSTA RICA) as fishmeal (FM) replacements in the diets of European sea bass juveniles (*Dicentrarchus labrax*) in terms of growth performance. Six isonitrogenous (46.5% crude protein) and isolipidic (16% crude lipid) diets were formulated: a fish meal-based diet containing 30% FM which was served as a control diet and five experimental diets replacing FM by 15, 30, 50, 70, and 80% with FSBM. The formulation strategy aimed to replace the 30% FM (67% protein content) with the FSBM (48.5% protein content) while keeping concurrently similar nutrient levels. A reasonable amount of wheat flour was added to the control diet which was reduced gradually in the rest of the diets. Simultaneously, the blood meal and corn gluten dietary inclusion levels were slightly increased to compensate for the lower crude protein level in the FSBM relative to the FM. SPC levels were kept to a minimum in all diets. The corresponding replacement of FM protein with FSBM protein in the different diets was 11, 21, 36, 50, and 57%, respectively. All diets (3.5 mm pellets) were produced by cooking extrusion.

European sea bass juveniles were obtained from a commercial fish farm located in Agios Serafim (Phthiotis region) owned by PHILOSOFISH SA and transferred to the Hellenic Center for Marine Research (HCMR) facility located in the campus of Agricultural University of Athens, Greece. The fish were distributed among 18 cylindroconical experimental tanks of 1,000L, 35 fish per tank, with 3 replicates for each feed. The average sea bass initial weight among the tanks was 30.48 ± 0.14g (SD). Fish were hand-fed to apparent satiation, twice per day, and uneaten dry feed that was collected in each tank’s waste collection system was monitored and taken into account before calculating the daily feed consumption. Similarly, feces were also collected and stored at -20 °C pending digestibility analysis. The average seawater temperature was 20.2 ± 5.6 °C.

**Results**

Our findings revealed that sea bass consuming the FSBM 15% and FSBM 30% diets exhibited the highest overall growth performance and better feed utilization, showing a numerically higher average final body weight (75.11 g and 73.24 g, respectively) compared to the other groups (71.92 g, 70.96 g and 69.92 for Control, FSBM 50%, and FSBM 80%, respectively). However, those differences were not statistically significant (P>0.05). The final body weight on the FSBM 70% (67.8 g) was significantly lower compared to the FSBM 15% diet (P<0.05). However, no significant differences were found compared to other dietary groups. The same trend was observed in weight gain (WG), thermal growth coefficient (TGC), daily growth index (DGI), and protein efficiency ratio (PER) for FSBM 15% and FSBM 30% in comparison to the fish fed the other diets. Furthermore, the replacement of FM by FSBM did not affect the palatability of the diets since no significant differences were recorded in feed intake among the dietary treatments (P>0.05). Feed conversion (FCR) was also similar among the diets (P>0.05) except for the observed significant lower value for fish on the FSBM 70%. The replacement of FM by FSBM had no effect on the somatometric indices in either of these dietary treatments.

(Continued on next page)
Overall, this study demonstrated that the tested FSBM allowed at least a replacement of up to 50% of FM in the diets of European sea bass without impairing growth performance and diet utilization, provided fish nutrient requirements are met. The results clearly demonstrate the high nutritional value of FSBM for European sea bass. Depending on the potential economic considerations, higher replacements of FM by FSBM (70-80%) are possible and may be considered. Additional analyses should demonstrate the physiological basis for the potential of FSBM to replace FM.

Introduction
Skeletal abnormalities develop frequently in aquaculture and laboratory fish. They consist of either post-metamorphic deviations of initially normally developed bones (e.g., Printzi et al., 2022), or deviations from the species developmental pattern (e.g., Kourkouta et al., 2022; Printzi et al., 2021, 2023). A variety of biotic and abiotic factors, including feeding practices and nutrition, has been shown as critical for fish skeletal development (Boglione et al., 2013; Printzi et al., 2021, 2023). In addition to serving as an important quality index, skeletal abnormalities are also considered a valuable welfare indicator that reflects how well fish husbandry conditions align with fish preferences (Printzi et al., 2021). In the present study we examined whether different feeding practices during the larval stage affect the development of skeletal deformities in zebrafish.

Materials and Methods
Larval rearing was performed under five different feeding regimes, following the results of Printzi et al. (2021), using Artemia nauplii and dry microdiet. The control group (A) was based on a long period of co-feeding, while the rest of the regimes included less frequent meals (group B), abrupt shift from live to inert feed (group C), application of two-days fasting period (group D), or exclusive feeding on dry feed (group E) (Fig. 1).

Embryos were obtained from a common broodstock (AB strain), under standard for the species conditions. Random samples of individuals were double stained with Alizarin Red and Alcian Blue for the skeletal analysis at the end of the trials. Experiments were performed in three independent replicates.

Results and Discussion
Detected abnormalities consisted mainly of irregularly ossified vertebral centra (Fig. 2a, 2b), hemirays separation (Fig. 2c), bending of the neural processes (Fig. 2d) and the branchiostegal rays. Less frequent abnormalities included fin deformities, pre-haemal kyphosis, and caudal-peduncle scoliosis.

Feeding practices during the larval period had a significant effect on the rates of skeletal abnormalities (p<0.05, G-test). Compared with the control group (A), groups B, C and E presented significantly higher abnormality rates (Fig. 2e). In agreement with the results of Printzi et al. (2021), decreased usage of Artemia nauplii (groups C and E) resulted in a general increase of the abnormality rates (Fig. 2e). The decrease in the number of daily feedings (group B) resulted in comparatively increased rates of bended neural processes, and to a less extent of vertebral ossification irregularities and branchiostegal deformities. Finally, the effects of fasting (group D) were limited to a significant elevation of the rate of abnormal hemirays (Fig. 2e).

![Fig. 1. Applied rearing practices. A, control group with both *Artemia* and dry feed; B, as in control group, but with fewer daily feedings (2); C, abrupt transition from *Artemia* to dry microdiet; D, as in control group, but with two fasting periods (*) of two days each; E, exclusive provision of dry feed. In all except B groups, feed was provided to the larvae five times daily.](image-url)
Our results demonstrate elevated rates of deformities at the conditions with a relatively higher use of dry feed. Although more research is needed to support these findings in respect to the causative factors, gene expression analysis of specific genes related to skeletogenesis, could provide some basic insights. An interesting approach would be to test a possibly altered osteoblast-osteoclast balance as a potential cause of osteoporotic conditions (Bergen et al., 2019).

Introduction
The aquaculture industry is significantly concerned about skeletal abnormalities, which mainly occur during the larval and early juvenile stages due to various factors (Boglione et al., 2013). To minimize their negative impacts on fish quality and welfare, these abnormalities are culled from the reared populations before the on-growing period. Recent studies suggest that some types of abnormalities, such as haemal lordosis, have a high recovery potential during fish growth in net pens (Fragkoulis et al., 2019; 2022). This raises questions about the early cull off practice’s appropriateness. In this study, we examined the recovery potential of jaw abnormalities (two types of pugheadness and the shortening of the lower jaw) in Gilthead seabream.

Material and Methods
At 162 dph (ca 14.7±3.7 g W) 158 fish with short upper jaw, 94 fish with short lower jaw and 275 normal fish were anaesthetized, weighted, individually photographed and pit-tagged (FDX-B, Trovan Ltd., USA). They were then transferred to an experimental net-pen for on-growing. At 514 dph (ca 351±56 g) all fish were anesthetized, photographed, and tag-identified for further morphological examination and geometric morphometric analysis (as described in Fragkoulis et al., 2019). All fish originated from a common larval population that was reared under standard conditions.

Results & Discussion
Short-upper jaw abnormalities were categorized as type-I (Par) or type-II (Kub) based on the absence or presence, respectively, of gross malformations on the premaxillary and maxillary bones (Fig. 1). At the end of the trial, 40% of the initially pit-tagged fish were not found due to mortality or tag loss. The group with the short lower jaw presented a significantly higher rate of tag non-recovery than the normal fish (p<0.05, G-test) (Fig. 1).

Given that the tag was always implanted in the same area, differences in the frequency of unidentified fish should be ascribed to differences in the mortality rates between LoJ and the rest phenotypic groups.

Fig. 1. Tag-loss and mortality rates of the different phenotypic categories during the on-growing period. Frequencies marked with different letters are significantly different (p<0.05, G-test). Nor, normal. Kub, type II upper jaw abnormality. Par, type I upper jaw abnormality. LoJ, short lower jaw.

(Continued on next page)
Following fish morphological examination, 30% (14 out of 46) of the initially Par fish presented a normal phenotype by the end of the on-growing period (514 dph). In contrary, no recovery from LoJ or Kub abnormality was found. The partial recovery from Par abnormality was furthermore supported by the results of geometric morphometric analysis, with the recovered individuals presenting no significant differences in skull shape from the normal fish (p>0.05, Canonical Variate Analysis, Fig. 2). Together with the haemal lordosis (Fragkoulis et al., 2019; 2022), vertebral fusions (Witten et al., 2006) and light gill-cover abnormalities (Beraldo & Canavese, 2011; Amoroso et al., 2016), this is the fourth abnormality type that recovers during the on-growing period.

**Funding.** This study was financially supported by EU (European Maritime and Fisheries Fund, EMFF) and national (Greek) funds (NSRF 2014–2020, Novelty in Aquaculture, Project No. 5010952) of the Ministry of Rural Development and Food, Greece.

Introduction

Feed cost is one of the highest expenses in aquaculture production, mainly due to the provision of sufficient protein content. Nowadays, protein supply is covered by fish meal among others, although fish meal production is gradually decreasing while its price is increasing. Several studies have been performed to investigate different alternative protein sources; however, most of them revealed inadequate growth performance in fish with alternative protein feeds. Nevertheless, better economic indexes could be achieved in some fish species with positive selection for feed utilization. African catfish is an important species in aquaculture production in numerous African, Asian, and some European countries. Our objective was to investigate the growth performance of F3 and F4 generations of an African catfish (Clarias gariepinus, Burchell, 1822) line selected for utilisation of low fish meal feed in a half-industrial experiment and to test feeding with alternative protein sources. We also tested the early growth performance of a Vietnamese line as a possible alternative genotype of our lines.

Materials and methods

African catfish was selected for efficient utilisation of low fish meal feed through three generations. Two performance tests were conducted on the F3 and three in the F4 generations. The selection, fish rearing, and investigations were performed on a half-industrial scale in a flow-through system using 2 m³ tanks at the Bajcshal Ltd. site, with a water temperature of 23-24°C. All generations were produced with 4 multifactorial crosses of 5 male and 5 female individuals. To avoid indirect selection in the control group (CG), the big and the small specimens were used for crossing, and reared on the control diet (CD) containing 8.1% fish meal. Parallel with that, positively selected groups were created in triplicates (PS1-PS3) by crossing the biggest individuals fed with the experimental diet (ED) containing only 6% fish meal. All fish were fed with the same pellet size according to their age and size and all feed had the same crude protein (42%) and row fat (12%) content. During selection fish were reared until market size and body weight (g) was measured in the F1-F3 generations (F1 n=1683; F2 n=1783, F3 n= 2983). In the F3 generation the control group was created from the group previously fed with the control feed and two experimental groups were created from two of the positively selected groups (PS1, PS2), then all groups were divided into two subgroups and fed with the experimental and the control diet to accomplish a performance test in flow-through and RAS system. In the F4 generation, the control and all three positively selected groups were used in flow-through and RAS systems for performance tests with the same conditions as in F3, while an additional test was performed in flow-through using a 5% microchloropsis algae-containing diet (AD). The feed contained a low amount of fish meal (6%), 22% soybean meal and 5% extruded soybean meal, 42% crude protein, and 12% raw fat, while the control diet (AC) contained 24% soybean meal and 8% extruded soybean meal. The tests performed on the F4 generation lasted for 6 weeks.

An additional larvae-rearing test was performed to analyse the early growth rate of a Vietnamese African catfish line. The larvae were reared in RAS, for 30 days at 25°C, using CD feed from 0.5mm to 1.5mm. The Data analysis was performed in Excel with a p<0.05 significance level.

Results

The selected lines showed a higher growth rate compared with the control genotype with both diets in the flow-through system. The direct selection gain for the body mass was 11% in the F3 and 21% in the F4 generations fed with the experimental diet (ED) and 14% and 26% fed with the control diet (CD). While in RAS the average selection gain was 32% and 33% in F3 and F4 fed with the experimental diet (ED), and 12% fed with the control diet (CD) in both generations, respectively. There was no significant difference between the CD and ED diets. In the RAS system, a feed-specific selection gain of 21% was also present in both F3 and F4 generations. In this case, the feed-specific differences were significant. Using algae-containing feed the selection gain was 21.3 and 19.3 % in the case of AD and AC feeds. Algae complementation had a minimal effect on the meat colour in the yellow range. In the case of larvae rearing the Vietnamese line’s specific growth rate was the highest (14.5%).

(Continued on next page)
Discussion and conclusion
We can conclude that the selected lines (PS1-PS3) performed better with all tests conducted on the F3 and F4 generations than the control genotype (CG). However, the effect of selection for low fish meal feed could be detected only in the RAS system in both F3 and F4 generations. All groups fed with microchloropsis algae-containing feed had higher growth rates. The average body weight was 5.3% higher than the control.

The effect of the selection for feed could not be detected in both the F3 and F4 generations, thus the effect of selection for higher body mass was significant, suggesting that there is a good potential for achieving better performance by selection in African catfish. However, finding out if the Vietnamese genotypes can be used in long-term breeding programs requires further investigation.

Introduction

Sturgeon caviar is an incredibly profitable product, making females more valuable in aquaculture. However, the application of sex control has not been widely implemented. All species of sturgeons are gonochoristic, but none of them exhibit clear external sexual dimorphism, nor do they possess heterochromatic sex chromosomes (Wuertz et al., 2006). Identification of females in current practice can only be achieved through examination of differentiated gonads, typically at the age of 3-5 years, depending on the species. Consequently, males can only be removed from production after an extended rearing period (Keyvanshokooh & Gharaei, 2010). This has prompted the search for early sex identification and methods for sex control in sturgeons (Havelka & Arai, 2018). Currently, this involves rather costly and cumbersome hormone level measurements or ultrasound examinations, which are still uncertain during the early stages of development. However, a recently isolated sex-specific genetic marker shows a new potential of use (Kuhl et al., 2021), though it has not been widely tested in practice yet. In this study, our goal is to initially assess the practical functionality of the sex marker on the ex-situ sterlet broodstock of Hungarian University of Agriculture and Life Sciences (MATE), Institute of Aquaculture and Environmental Safety (AKI), Research Center of Fisheries and Aquaculture (HAKI).

Materials and methods

Sterlets used in this study are part of the Live Sturgeon Gene Bank of MATE AKI HAKI. This sterlet stock consists of 202 matured individuals and approximately 600 juveniles. All matured fish in the broodstock are tagged with Passive Integrated Transponder and their sex is known through experience from reproductions. We collected fin clip samples from the broodstock which were preserved in 96% ethanol until the DNA isolation process. DNA isolation was performed using the E.Z.N.A.® Tissue DNA Kit (Omega Bio-tek, Inc.) following the producer’s instructions. The DNA were qualified and quantified by NanoDropTM 2000 spectrophotometer (Thermo Scientific™). Based on the DNA concentrations, the extracted DNA was diluted to 100 ng/µl. During this study, we used the AllWSex2 sex-specific marker (Kuhl et al., 2021), which was amplified by a PCR from the diluted template DNA. The final volume of the reactions was 15 µl thereof, 1.5 µl of 10X DreamTaq Buffer (Thermo Scientific™), 0.3 µl of dNTP (10mM, Thermo Scientific™), 7.7 mM of each primer, 1 u of DreamTaq DNA polymerase (Thermo Scientific™), 100 ng µl of template DNA and 10.5 µl of nuclease-free water. The first step of the PCR (Kyratec SuperCycler Trinity Revision 2.0.0) was a 2 min. denaturation at 95°C, followed by 45 cycles of 1 min. at 94°C, 45 sec. at 56°C and 45 sec. at 72°C, and final extension 5-min. at 72°C. PCR products were inspected on 1.5% agarose gel in TBE buffer for 45 min at 70V. The phenotypic sex was determined based on obtained gametes or by biopsy.

Results

The samples involved in this study were sourced from 119 females, 72 males and 11 hermaphrodite breeding individuals. Among the 119 females, we identified 106 genetically positive females (89,1%), while 13 individuals (10,9%) produced negative PCR results even after being tested three times. From the group of 72 males, we detected 60 as genetically males (83,3%) and 12 were identified as genetically females (16,7%). The sex distribution among hermaphrodites unfolded as follows: 7 individuals were genetically determined as females (63,6%) and 4 individuals were found to be genetically males (36,4%).

(Continued on next page)
Discussion and conclusion

Overall, it can be concluded that the AllWSex2 female-specific marker performs very well in sex determination, even in cases of a large sample size. We have identified 13 naturally feminized individuals in the female group where the female specific marker could not be detected. We have found 12 naturally masculinized individuals among the male specimens that are genetically females. From these 12 males, 4 produced large quantity and high-quality sperm during the artificial propagations in recent years. The misallocated results could stem by natural sex reversal or mutation on the binding site of the used sex specific primers. To investigate these phenomena, further studies are required in genetic verification of sex by applying other appropriate sex marker(s) or examining the effects of possible mutations on sex development as well as the genetic background of intersex individuals.

The crustacean ectoparasite *L. salmonis* is the biggest problem in Atlantic salmon commercial aquaculture. In addition to financial losses, it severely affects fish welfare and public perception of the industry. The available antiparasitic measures are costly, stressful and traumatic for the fish and do not provide a satisfactory solution to the problem. A large-scale international project funded by the Norwegian Seafood Research Fund (FHF) is working to elucidate mechanisms underlying host resistance to the parasite. This work is expected to contribute to the development of effective antiparasite measures. Susceptibility to the parasite is markedly different between species in the *Salmo* vs. *Oncorhynchus* genera. The project is using state-of-the-art methods to study differences in chemical signaling, molecular and cellular responses in differentially susceptible salmon species. The use of CRISPR Cas gene silencing provides a powerful experimental approach to the search for genes responsible for lice resistance.

The success of lice infestation is determined by the ability of free-swimming copepodid stages to find and contact salmon, attach themselves and resist immune and cellular responses directed against the parasite. The project investigates both phases of parasite-host interactions: before and after attachment. Here we present chemical signaling research. Chemical cues (semiochemicals or kairomones) play a key role in host detection. Water conditioned with Atlantic salmon but not with non-salmonid sea fish species attracts copepods. Given that lice attracting kairomones are not produced by the majority of fish species, blocking their biosynthesis is unlikely to cause any negative effect. The identification of genes involved in this pathway may open a practical way to improve resistance to the parasite. Semiochemical studies include three parts: water chemistry, lice behavior assays, and genomics. Water conditioned with Atlantic salmon, Pacific salmon and other marine species was collected from several farms and research stations in Norway and Canada, processed with solid phase extraction (SPE), and analyzed by GC-MS and LC-MS. Putative semiochemical compounds were selected for testing on the free-swimming life stages of the parasite. Lice behavior studies use two complementary approaches. The immediate response is assessed by observing and recording directional movement towards the stimulus in an arena chamber. Another method evaluates response to a light flash following exposure to water containing test material. Lice copepods consistently show strong reactions to Atlantic salmon conditioned water but not to water conditioned with non-salmonid fish species. Comparison of lice behavioral responses to water conditioned with Atlantic and three Pacific salmon species is underway. Filtration through SPE columns removes semiochemicals and the response of lice to various sorbents has been evaluated. Recovery of the chemical stimuli in eluates from the columns was confirmed. A suite of putative semiochemicals was selected and tests of the lice behavioral response to them are underway.

The most ambitious goal of the project is termination of semiochemical production by gene silencing. It is important to find out in which tissues semiochemicals are produced and how they are released into water. The directional assay suggests that skin is a stronger attractant than other tissues and biological materials (blood plasma, mucus, and feces). Another assay indicates a dose-dependent effect of skin extract and the possible presence of semiochemicals in other tissues and mucus. In search for candidate genes, priority was given to cytochromes P450 (CYP). These enzymes play the key part in various pathways of secondary metabolism. In addition to the conserved CYP present in all vertebrates, some genes are specific to certain taxonomic groups. Their substrate specificity and physiological roles are unknown. Comparison of the genomes of salmon and other marine fish species has found several salmon-specific *cyp* with high expression in the skin. CRISPR Cas silencing of *cyp2m1* was performed in Atlantic salmon.

Studies conducted by scientists from five countries combined parasitology and fish health, marine biology and invertebrate behavior, chemistry, genomics, and molecular biology. Research is ongoing and has reached a level where synergy is expected from pooled competency.
HEART FOR AQUACULTURE – SPONTANEOUS CONTRACTING HEART CELL CULTURES AS A TOOL FOR MEASURING THE EFFECT OF VIRUSES AND ENVIRONMENTAL POLLUTANTS IN VITRO

Introduction:
Circulatory disorders in the heart are an increasing challenge to the sustainable development of salmonid aquaculture worldwide. The main pathogens causing these problems are piscine orthoreoviruses (PRVs), which often cause Heart and Skeletal Muscle Inflammation (HSMI). In addition to pathogens, acute or chronic toxic exposures to nano- and micrometre-sized plastics and oil spills are a significant risk to aquatic life. The aim of the present study was to develop novel cardiac cell cultures from salmonids to reduce and replace the use of animals to investigate the effects of viral and environmental stressors on cardiac cells. In addition, gene expression signatures in these cardiac primary cultures of salmonids (SCPCs) after infection with PRV-1, PRV-3, piscine myocarditis virus (PMCV) and salmonid alphavirus 3 (SAV-3) were investigated to determine whether innate immune responses could be used as markers to confirm virus replication.

Materials and methods:
A novel method was used to culture SCPCs, which are constantly beating for up to eight weeks. Three-week-old SCPCs from Atlantic salmon, brown trout and rainbow trout were infected with the viruses and then cultured at 8°C and 15°C for a further four weeks. The virus-infected cultures were sampled immediately after infection and at 3, 7, 14, 21 and 28 days post infection. In addition, SCPCs and salmonid larvae were exposed to nano- and microplastics or crude oil. The number of contractions of the cultures was counted and samples of the cells were taken. Cell and media samples were used for virus detection, and cell samples were used to measure 10 genes involved in antiviral and pro-inflammatory responses by RT-qPCR.

Results:
The heart cell cultures were more sensitive to the effects of environmental stressors than heart in vivo. While the in vivo studies did not show any change in heart rate, the in vitro studies showed an increase in the number of contractions after exposure. Preliminary results from the virus exposures show that antiviral genes were upregulated when cardiac cells were actively replicating viruses and that these genes are likely to play an important role in the cardiac immune response.

Conclusion:
SCPCs may therefore be a valuable tool for monitoring host-pathogen or host-environment interactions involving cardiac cells of fish species used in aquaculture.

Introduction:
Viral haemorrhagic septicemia virus (VHSV) is a highly contagious pathogen affecting salmonid fish populations. Recent evidence suggests that host genetics play a key role in susceptibility to the virus, with differences in innate antiviral immune responses underlying VHSV resistance in rainbow trout strains. The aim of the present study was to investigate gene expression signatures in a VHSV-resistant local German rainbow trout strain (R7) under VHSV infection and to compare them with expression signatures in a highly susceptible commercial strain (R9).

Materials and methods:
Fin, gill, gut, kidney and spleen tissues were collected from susceptible and resistant adult rainbow trout at 2 and 4 days post infection with VHSV. RNA-seq was performed from kidney samples at 2 dpi. In addition, gene expression of 27 selected genes was determined by RT-qPCR in all samples collected. The results were compared with gene expression in primary cell cultures from fins, scales and kidneys of fish of the same strains infected with native and inactivated virus.

Results:
It was found that the genes involved in the interferon response of rainbow trout showed clear differences in gene expression levels between the two origins. Especially on day 2 after infection with VHSV, a large number of genes differed significantly (p < 0.05), especially in spleen and kidney. Particularly striking were the gene expressions of pro-inflammatory cytokines and type II interferons. While gene expression in tissues of resistant origin increased steadily over the observation period, there was a rapid increase (day 2) followed by a decrease in gene expression (day 4) in samples of susceptible origin. The in vitro experiments confirmed the in vivo results that VHSV induces a stronger immune response in cells derived from the R9 strain.

Conclusions:
Our results could not confirm that an increased antiviral response is the main factor for increased resistance. Furthermore, it can be concluded that trout from the susceptible R9 origin died because of a dysregulated inflammatory response and cytokine storm.

Introduction

Infectious diseases represent a major threat to farmed animals, having a large impact on animal health and welfare, production, and compromising human food security. Genetic disease control strategies that focus on enhancing host response to infectious pathogens have gained attention in recent years. Disease resilience, the ability of an animal to cope and survive an infectious disease, has emerged as a desirable breeding goal. However, resilience is a complex trait that involves various underlying mechanisms, including host resistance, endurance and infectivity, which are not easily disentangled.

In this study, we used whole-genome sequencing and imputation to genotype all the genetic variants, including structural variants, in a turbot breeding population challenged with the parasite *Philasterides dicentrarchi*, a ciliate that causes scuticociliatosis resulting in high mortality in farmed flatfish. The design of this challenge allows disentangling the different components of resilience, and the goal of this study is to evaluate whether whole-genome sequencing combined with genome functional annotation might i) improve our ability to accurately measure these traits, ii) reveal their genetic architecture and iii) increase the accuracy of selection.

Materials and methods

The turbot population consisted of ~1,400 animals from 36 full-sib families, challenged with *P. dicentrarchi* using a complex semi-factorial design involving donor and recipient families (full design in Anacleto et al. 2019), to enable decomposing the resilience trait into resistance (propensity to become infected), endurance (propensity to survive the infection) and infectivity (propensity to transmit the disease). For this project, we sequenced the whole genome of the 54 turbot parents of the challenged families using a Novaseq 6000 150 PE sequencing. After quality control, filtered reads were aligned with BWA-MEM to the new turbot chromosome level genome assembly of a group frequently showing limited sex chromosome differentiation and high SD evolutionary turnover. Turbot (Scophthalmus maximus (GCA_013347765.1). Single nucleotide polymorphisms (SNPs) were called with BCFtools and structural variants with Smoove, following a custom pipeline but remain challenging to accurately type and are hence poorly characterized in most species. We present an approach for reliable SV discovery in non-model species using whole genome sequencing and report 15,483 high-confidence SVs in 492 Atlantic salmon (Salmo salar L.. The genotypes of the 54 whole-genome sequenced (WGS) parents were used as the reference population to impute the 2b-RAD SNPs sequenced genotypes of their offspring using FImpute v.3. After quality control, the resulting imputed dataset was used to estimate genetic parameters of resilience traits with ASREML v.4.2, and conduct genome-wide association study (GWAS) for each trait using GCTA v.1.24.7. The functional annotation of the genome including regulatory regions, obtained from the AQUA-FAANG project, was intersected with the genetic variants, and used to test if their prioritization led to improved accuracy of genomic selection using BayesRCA.

(Continued on next page)
Results

The average sequencing coverage across the 54 whole genome sequenced samples was ~14 ± 8.6. After quality control, 2,825,587 SNPs and 8,722 high-confidence SVs remained for imputation. There were 10,301 common SNPs between the WGS and the 2b-RAD of the offspring, which were used as anchorage for imputation of the whole population to whole-genome genotypes. After imputation, 1,100,299 SNPs and 1,390 offspring passed filtering and quality control. The heritability estimate for the composite resilience trait time to death was 0.15 ± 0.04, similar to that previously reported\(^4\). Disease resilience, the ability of a host to survive or cope with infectious challenge, has become a highly desirable breeding goal. However, resilience is a complex trait composed of two different host defence mechanisms, namely resistance (the ability of a host to avoid becoming infected or diseased, and GWAS using the imputed data identified a polygenic genetic architecture of the trait, with no major SNP surpassing the genome-wide significance threshold (Fig.1).

We are now estimating the genetic parameters and performing GWAS for resistance, endurance and infectivity to understand the genetic makeup of resilience to *P. dicentrarchi* in this turbot population. The study also aims to investigate the accuracy of genomic prediction using preselected variants integrating genome annotation information from the AQUA-FAANG project to enrich the dataset with functional information and improve the predictive performance of the models. The incorporation of biological knowledge into genomic prediction models can provide insights into the underlying biological processes of disease-related traits and be useful for future functional studies.

BIOAEROSOLS AS A POTENTIAL TRANSMITTER OF FISH PATHOGENS IN AN ATLANTIC SALMON (Salmo salar) RECIRCULATED AQUACULTURE SYSTEM (RAS) SMOLT FARM

Dhiraj Krishna1,2*, Petra Elisabeth Petersen1, Maria Marjunardóttir Dahl1, Nicolina Vest1, Debes Hammershaimb Christiansen1

1National Reference Laboratory for Fish and Animal Diseases, Faroese Food and Veterinary Authority
Faro Islands
2Department of Veterinary and Animal Sciences, University of Copenhagen, Denmark
Email: dkr@hfs.fo

Introduction
Pathogen transmission in aquaculture is mainly through two modes, vertically via eggs and horizontally via water (Oidtmann et al., 2013). Aerosols represent another potential mode of transmission. Although it is indisputable that human and animal pathogens are disseminated frequently via aerosols, there is little knowledge of aerosol transmission in aquaculture (Wang et al. 2021). The Faroe Islands are known for their high-quality Atlantic Salmon produced in closed containment systems called Recirculated Aquaculture Systems (RAS), wherein the water gets constantly cycled through various compartments. The system also involves the constant import of large volumes of air for degassing purposes, and recent studies have shown that indoor systems generate pathogen-laden aerosols from water (Roberts-Thomson et al., 2006, Gołaś et al., 2022). The sea surface microlayer (SML) has been identified as a source of aerosols that could transmit bacteria and viruses that can stay infective and transmit through long distances (Sharoni et al. 2015, Reche et al. 2018). In our study, we will focus on the aerosolization potential of five fish pathogens in a commercial Atlantic Salmon RAS smolt farm: Salmon Gill Pox Virus (SGPV), Infectious Salmon Anaemia Virus (ISAV), Infectious Pancreatic Necrosis Virus (IPNV), Piscine Orthoreo Virus (PRV), and Flavobacterium psychrophilum.

Materials and Methods
Aerosol samples were collected using the Coriolis Micro and Coriolis Compact (Bertin Instruments, France) wet and dry impaction-based cyclonic air samplers, respectively. The Coriolis Micro has a variable flow rate of 50-300L/min, while the Compact has a fixed rate of 50L/min. The location choice for the sample collection included targeted areas of high aerosol formation burden based on preliminary results from a pilot study using the Coriolis Compact. Coriolis Micro employed sampling cones containing 15ml 1X PBS (Corning, USA) with 0.1% Ecosurf (Dow Inc.) surfactant in the sampling cone, while 1ml of 1X PBS+0.1% Ecosurf reconstituted the samples from the Compact. Aliquots of 1ml of the neat samples were made for viral propagation in cell lines and bacteriological cultures and stored at -80°C. Due to the higher sample volume of about 15ml obtained from the Coriolis micro, Amicon Ultra 50kDa will concentrate samples to attain better detection limits. Simultaneous sampling of fish and water was also done to assess the infection dynamics of the pathogens in the RAS tanks. All the samples were stored at -20°C until further processing. RNA extraction was performed using the Kingfisher semiautomated nucleic acid extraction machine per the manufacturer’s instructions under standard laboratory conditions. The extracted RNA samples will be screened for the above five pathogens using RT-qPCR on a Quantstudio RT-qPCR system (Applied Biosciences, USA)

Results
Preliminary results from the pilot study have demonstrated the presence of all the pathogens of interest, SGPV, ISAV, IPNV, PRV, and F. psychrophilum in the aerosol at varying Ct-values between 26-36. An interesting observation from the RT-qPCR results indicates differential pathogen levels in the air and varied over the sampling period, with higher Ct during peak infection. The pathogen levels in the water seem to influence the levels in the air directly; however, significantly lower.

Conclusions
Based on the pilot study, the pathogens get aerosolized at differential rates depending on their load in the water. Several other factors, such as the location of sampling, proximity to air vents, and machinery, influence the aerosolization of the circulating water. This underlines the importance of a high biosecurity level in closed containment systems (CCS) to prevent the uncontrolled spread of pathogens between different RAS systems in a smolt farm. The results derived from the fish and water samples will help determine the aerosolization potential of the pathogens.

Introduction

Information on how domestication affects early life stages in fishes is limited. One of the recent studies showed that domestication has an impact on the digestive capacity of Eurasian perch larvae that coincided with a higher growth rate recorded for domesticated ones (Palińska-Żarska et al. 2020). Weaning is a critical step for cultured percid species as the transition from live food to commercial feed often results in high mortality. Further studies are required for the optimization of the weaning protocol at the earliest possible stage of perch larvae e.g., is full substitution of live food by commercial diet should be preceded by co-feeding period or not? (Król and Zieliński 2015). Therefore, the aim of the study was to determine the effect of a different weaning strategy (sudden switch vs co-feeding) of perch larvae originated from domesticated or wild spawners on the results of their subsequent rearing parameters.

Material and methods

Eurasian perch larvae from wild and domesticated spawners were obtained followed by separate reproductive protocols described by Żarski et al. (2019). Incubation of eggs and larvae rearing procedures, except feeding scheme, were the same for domesticated and wild stocks and conducted according to standardized protocols described by Palińska-Żarska et al. (2020). Four experimental groups (in triplicate each), differed by origin of the larvae (domesticated or wild) and two weaning strategies (sudden switch or co-feeding), were reared in RAS system during subsequent 34 days. From 4 dph until 17 dph, two groups of larvae (domesticated and wild) were fed exclusively by *Artemia* nauplii and the others two groups (also domesticated and wild) were co-fed using *Artemia* nauplii and commercial diet. Afterwards, fish were switched entirely to commercial feed. At the end of the experiment all survivors (34 dph) per tank were counted, weighed, and measured. Other rearing parameters were assessed according to the scheme described by Król and Zieliński (2015). A two-way ANOVA was used to test the effects of origin of the perch larvae (domesticated or wild), weaning strategy (sudden switch or co-feeding) and the interactions of both these factors on subsequent rearing parameters of perch larvae. Differences were considered significant at P<0.05.

Results

At the end of experiment, domesticated and co-fed (*Artemia* nauplii and commercial feed) perch larvae characterized by better growth, lower mortality caused by type II cannibalism and final bigger biomass, whereas these wild perch larvae which were fed only by *Artemia* nauplii, until were switched entirely to commercial feed, had better final survival, lower mortality other than cannibalism and final bigger biomass. Based on two-way ANOVA, origin of perch larvae (domesticated or wild) affected individual body weight, mortality caused by type II cannibalism and mortality other than cannibalism. Weaning strategy significantly effected on individual body weight, mortality caused by type I cannibalism and final survival of the fish. None of the factors had a significant impact on the final fish biomass. However, significant interactions between origin of the larvae and the weaning strategy were found in all tested rearing parameters (Table 1).

Discussion and conclusion

Our study supports the hypothesis that the type of food is the main challenging factor in intensive Eurasian perch larviculture conditions affecting its final efficiency. Recent study suggested that the production of digestive enzymes does not matter when easily digestible high-quality food, such as *Artemia*, is offered, although digestion capability was higher in wild than in domesticated perch larvae (Palińska-Żarska et al. 2020). However, in the presented study, significant changes in growth between perch larvae originated from wild and domesticated spawners were observed even before *Artemia* was completely replaced with commercial feed using co-feeding scheme. This suggests that other processes than only the production and activity of digestive enzymes are modified by progressive domestication. In conclusion, our results indicate, that choice of the weaning strategy in Eurasian perch larvae may depend on the domestication level of their parents and could significantly affect their subsequent rearing parameters.

Introduction
Several parameters influence the establishment of a BFT system and farmed animals’ performance. One of these parameters is light, which is an abiotic factor of paramount importance for organisms that live in the aquatic environment. Aquaculture production systems with shrimp exposed to plenty of natural light may perform better than systems with low light levels due to the growth of photosynthetic microorganisms. Added to this, the presence of light also positively influences the abundance of microorganisms, reflecting in the better performance of *Litopenaeus vannamei*. This research aimed to assess the impact of various green light photoperiods from green LED lamps on water quality, microorganism community, antioxidant capacity (ACAP), lipid peroxidation (TBARS), and growth performance of the Pacific white shrimp *L. vannamei* in the BFT system.

Material and Methods
The study was conducted in the Shrimp Production Laboratory of the Institute of Oceanography of the Federal University of Rio Grande – FURG, Brazil. Trial was performed in 150L indoors tanks, using *L. vannamei* larvae with an initial weight of 0.48 g at a stocking density of 500 shrimp m⁻³. The experiment lasting 61 days. The experiment was designed with four treatments and four replicates each, with different photoperiods using LED green light: 1) 16h LI/8h DA, 2) 12h LI/12h DA (control), 3) 8h LI/16h DA and 4) 4h LI/20h DA.

Results
No significant differences were found in the water quality parameters following the completion of the trial (p >0.05). However, there were significant differences in the bacterial abundance of free coccoids, free filamentous, attached filamentous, vibrios, and bacilli (p >0.05) and in protozoa, such as flagellates, ciliates, rotifers, nematodes, and amoebae (p <0.05, Fig 1). There were also significant differences in lipid peroxidation (TBARS) with lower lipid peroxidation in the 12h LI/12h DA, 8h LI/16h DA, and 4h LI/20h DA treatments and higher antioxidant capacity (ACAP) in the hepatopancreas and muscle tissues in the 8h LI/16h treatment DA (p <0.05). In addition, shrimp from treatment 8h LI/16h DA showed a higher final weight than the control treatment 12h LI/12h DA (p <0.05).

Conclusion
Using green LED light in different photoperiods positively influenced the antioxidant capacity and oxidative damage (lipid peroxidation) of *L. vannamei* and zootechnical performance. Therefore, results suggest that the photoperiod of 8 hours of green light and 16 hours of darkness can be recommended for rearing *L. vannamei* in biofloc system.

A DECISION SUPPORT TOOL FOR ECOSYSTEM-BASED MANAGEMENT AND BIODIVERSITY CONSERVATION IN TRADITIONAL CENTRAL AND EASTERN EUROPEAN CARP FISHPOND SYSTEMS USING ECOPATH WITH ECOSIM

*Institute of Aquaculture, University of Stirling, Scotland, Stirling, United Kingdom

Introduction
Promotion of ecologically beneficial forms of aquaculture has emerged as a policy priority in recent years (European Commission, 2021), with promotion of culture techniques that closely resemble natural systems. While still managed, traditional carp ponds in Central and Eastern Europe are an example of a sustainable aquaculture technique that has been shown to contribute to the biodiversity and maintain regulatory functions of ecosystems, comparable to natural wetlands (Popp et al., 2019). However, there may be varying management practices between farms, with differing intensities of production. Traditional carp ponds are thus complex socio-ecological systems, and to make sure they are sustainably managed and regulated, environmental interactions must be understood. Ecological assessments for regulatory and management use should be simple, practicable in terms of farming operations, and cost-effective, in addition to making sure that human benefits from the system are not heavily compromised. The goal of this study was thus to develop a rapid decision support tool to determine the ecological outcomes of different management intensities.

Materials and methods
Aquatic biodiversity data of selected taxonomic groups (Amphibia, Gastropoda, Bivalvia, Insecta, Aves) and aquatic vegetation was sampled from 6 carp ponds of varying management practices from June – September 2023. Environmental parameters were also recorded. Species abundance data was used in biodiversity analyses, including the calculation of multiple diversity indices expressed through Renyi diversity profiles, and multivariate analyses of ecological community composition. Collected biomass data was used to parametrise an Ecopath with Ecosim (EwE) model for each production intensity. EwE models were used to determine ecosystem health indicators through ecological network analysis (Aubin et al., 2019).

Results and Discussion
The preliminary biodiversity analyses showed differences in biodiversity between different pond management regimes are evident, with more intensively managed systems varying more from the natural state. Diversity profiles showed that the natural pond had the highest biodiversity across all indices, whereas semi-intensively managed ponds showed higher species richness but lower Shannon-Weiner, Simpsons and Berger-Parker diversity than intensively managed ponds. Non-metric multi-dimensional scaling showed that semi-intensively managed and natural ponds tend to be more similar in terms of community composition. Further analysis of data collected in September 2023 is ingoing and will be included in further multivariate analyses to determine the interactions of environmental variables and community composition and to carry out the ecological network analysis with EwE.

Introduction
Pikeperch is successfully used for the diversification of inland aquaculture due to its high-quality flesh, fast growth, and overall market profitability (Overton et al., 2015). Fully grown and marketable sized pikeperch is highly demanded by gastronomy industry and angling community. During the last decade this species was subjected to an intense scientific study in both Central and Western Europe. To establish pikeperch as a permanent part of European inland intensive aquaculture, the formulation of new feed is necessary to adequately address the specific nutritional needs of pikeperch. This issue was not yet solved. Also, the characteristics of the pellets itself, whether they float on the surface or sink to the bottom, may influence the growing rate and nutrient utilization of cultured and fed juveniles. The present study is focused to determine the influence of the different pellets characteristics on the efficiency of pikeperch intensive production in RAS (Recirculating Aquaculture System) during grow out phase.

Material and methods
Experimental fish were stocked into 8 experimental tanks (1.5 m³ each) in one production RAS of Faculty of Fisheries and Protection of the Waters in Vodňany, Czech Republic. Juveniles in number of 8000 individuals (1000 juveniles per tank, mean IBW (Initial Body Weight) 21.38 ± 7.32 g, biomass of 13.42 kg. m⁻³, were cultured) for 112 days with control period of 28 days. After 14 days of adaptation experimental fish under new conditions, the experiment was started. Fish were fed during 16 hours per day using two commercial dry feed diets set at DFR (Daily Feeding Ratio) 1.2 % of fish biomass. The first group was fed with floating pellets Skretting Europa 15F (3.5 and 5mm). The second group was fed with sinking pellets Biomar Effico Sigma (3 and 4.5mm) Both types of pellets contain the same level of protein (55%) and of fat (16%). At the beginning and the end of experiment, 50 randomly selected experimental fish from each tank were measured. These fish were anesthetized in solution of clove oil (0.04 ml.l⁻¹). From this data following production markers were determined - IBW= Initial Body Weight; FBW= Final Body Weight, WG= Weight Gain, SGR= Specific Growth Ratio, TL= Total Length; FCR= Food Conversion Ration, CF= Condition Factor. Also, the growth heterogeneity was assessed.

Results and discussion
An achieved final body weight of 80 g was observed in the more rapidly growing group fed by sinking feed, compared to 72 g in the group fed by floating feed. Group fed by sinking feed also exhibited significantly higher WG and TL indicating higher growth of fish fed by sinking feed. Higher feed utilization was found in group fed by sinking feed as well as evidenced by lower FCR of 0.88 g.g⁻¹ and a higher SGR of 1.24 %.d⁻¹ compared to group fed by floating pellets which managed to reach FCR 0.93 g.g⁻¹ and SGR 1.13 %.d⁻¹. Both groups exhibited no statistical difference in survival rate (92.13 and 94.45 %). These results would suggest that sinking feed is a preferable choice. However, there were different results in growth heterogeneity and Condition Factor. Group fed by floating pellets reached statistically higher CF (1.16) compared to the other group (1.09) probably because of increased physiological exercise resulting from periodical surfacing for floating pellets. Additionally, group fed by floating pellets showed lower growth heterogeneity with fewer cases of cannibalistic and growth deprived individuals.

Introduction
One of the cornerstones of closed intensive pikeperch farming is the production of habituated high quality juveniles (Ljubobratovic 2015). In the case of pikeperch larvae, lighting is one of the environmental factors that can have a major impact on the success of rearing. The relationship between larval rearing efficiency and light intensity levels has been studied (Tielmann et al. 2017), but the effects of other aspects of lighting on larval rearing are less well understood. In our experiment, the effects of overhead and submerged light sources on survival, growth and larval quality were investigated.

Materials and methods
Fertilized egg originated from broodstock reared in a recirculating aquaculture system were used for the experiment (number of fertilized eggs: 10,000). The hatched larvae were distributed by volume into 6 250L conical bottom upwelling larval rearing tank (1600 larvae per tank). Three tanks were illuminated from above with warm white diffused light, three tanks were illuminated with insulated LED strips emitting warm white light submerged in water (16h light 8h dark). The fish were fed exclusively with artemia (300 nauplius/larvae/day) for two weeks from the beginning of exogenous feeding, and then supplemented with dry feed (10g food/tank/day 0.3-0.5mm Essence Coppens) until the end of the experiment, which lasted 24 days after hatching.

Results and discussion
The fish grew evenly in both treatments. The growth rate was slightly higher in the tanks with submerged light, while the survival rate was higher in the tanks illuminated from above, with a poorer swim bladder inflation in percentage. However, the differences in neither growth nor in survival were not significant (p>0.05 t-test).

Experience from the current study suggests that submerged light sources may have a positive effect on larval quality, but further studies are needed to determine the optimal light intensity and duration.

SINGLE-STEP GENOMIC PREDICTION IN GROWTH AND SEXUAL MATURITY TRAITS IN FINNISH RAINBOW TROUT (*Oncorhynchus mykiss*)

A.A. Kudinov1*, A. Nousiainen2, H. Koskinen2, A. Kause1

Introduction
Genomic selection in aquaculture species has been regarded especially useful for hard-to-record-traits, such as disease resistance, product quality and traits that need to be improved in multiple production environments. In the Finnish national breeding programme for rainbow trout, family tanks are used at the initial phase of growth which allows to maintain a pedigree for a large number of fish, and breeding value evaluation is based on this pedigree (PBLUP) (Kause et al. 2022). Genotyping of a portion of the fish accompanied with a single-step genomic evaluation (ssGBLUP) would maintain high selection intensity and simultaneously make use of possibilities of genomic selection. ssGBLUP has been shown as one of the optimal tools, especially when genotyped population is relatively small (Christensen et al., 2012). The combination of pedigree (A) and genomic (G) relationship matrix improves pedigree recording errors and helps utilize sib information more efficiently. The aim of the current study was 1) to implement ssGBLUP approach for routine evaluation, and 2) to use a validation method to demonstrate the added value of this approach, when breeding for growth and maturity age in two production environments.

Materials and methods
Data from Finnish national breeding programme was obtained from individually tagged fish reared in freshwater (nucleus) and sea stations. Pedigree included 600,409 individuals and 6,234 families made from 3,418 sires and 3,446 dams. Phenotyped fish were born between 1992-2019. Three body weight traits recorded at ages of 2 and 3 years at the nucleus (Weight2, Weight3) or at age 2 at a sea farm (Sea Weight2) and three binary maturation traits (1=early maturity, 0 = late maturity age) were recorded for males and females at the nucleus (MaturityMale, MaturityFemale) or at sea (Sea MaturityMale) (Table 1). Genomic data was available on 4,573 fish born in 2014, 2018, and 2019. Generations 2018 and 2019 were both established from generation 2014, and they had 8,525 and 9,241 tagged fish of which 16% and 28% were genotyped. Samples were genotyped using 57K SNP Axiom™ Trout Genotyping Array. After quality control and imputation 40,374 markers remain for further analysis

Genetic and genomic prediction was performed using mixed-model equations as shown in Kause et al. (2022). Pedigree BLUP was upgraded to ssGBLUP by replacing $A^{-1}$ matrix with $H^{-1}$ computed as:

$$H^{-1} = A^{-1} + \begin{pmatrix} 0 & 0 \\ 0 & (s_t (1 - w) G_{05} + w A_{22})^{-1} - A_{22}^{-1} \end{pmatrix},$$

where $G_{05}$ is a G matrix constructed with assumption that allele frequency of all markers was equal to 0.5, $A_{22}$ is a part of A matrix for genotyped fish, $w$ is residual polygenic effect equal to 5%, and $s_t$ is a scaling factor equals to $\frac{\text{trace}(A_{22})}{\text{trace}(G_{05})}$

To test for the predictive ability of PBLUP and ssGBLUP, partial data set was created by removing phenotypes collected in generation 2019 (Table 1). Validation of the model fit was done by linear regression of breeding values computed from full ([G]EBV) and partial ([G]EBV) data using formulae (Legarra & Reverter, 2018). Model $R^2$ was assumed as validation reliability.

(Continued on next page)
Results and Discussion
Average validation reliability ($R^2$, Table 2) in ssGBLUP was on 47% (0.18 reliability units) higher than PBLUP implying more accurate prediction. This resulted even though our validation design was strict - validation group did not share any full-sibs. Sea weight and sea male maturity trait gave lower $R^2$ than freshwater traits due to the lower number of records.

[$G$]EBVs of validation fish were overestimated ($b_0 > 1$) in PBLUP and underestimated in ssGBLUP ($b_0 < 1$). Dispersion ($b_1$) results in PBLUP (<1) and ssGBLUP (>1) showed respective under- and overprediction of the [G]EBVs. Low $b_0$ and high $b_1$ in ssGBLUP may be explained by a suboptimal validation design. Removing full year 2019 makes training population small. In such a case n-fold cross-validation might be a better option to use.

| Table 2. Validation bias ($b_0$), dispersion ($b_1$), and correlation squared ($R^2$) in PBLUP and ssGBLUP models. |
|-------------------|-----|-----|-----|-----|-----|-----|
| Trait             | $b_0$ | $b_1$ | $R^2$ | $b_0$ | $b_1$ | $R^2$ |
| Weight2           | 46   | 0.83 | 0.39 | -26  | 1.18 | 0.57 |
| Weight3           | 57   | 0.87 | 0.56 | -37  | 1.13 | 0.66 |
| Sea WeightMale    | 49   | 0.82 | 0.33 | -48  | 1.25 | 0.56 |
| MaturityMale      | -0.02| 0.61 | 0.69 | 0.01 | 0.95 | 0.80 |
| MaturityFemale    | -0.02| 0.93 | 0.48 | 0.02 | 1.12 | 0.67 |
| Sea MaturityMale  | -0.01| 0.85 | 0.32 | 0.01 | 1.09 | 0.61 |

Conclusions
A single-step genomic evaluation was successfully implemented in the Finnish national rainbow trout breeding programme. Genotyping of 16-28% tagged fish in the pedigree increased selection accuracy of body weight and maturity age traits.

The Norwegian salmon aquaculture industry is regulated to control sea lice levels and prevent disease outbreaks.

Limited research has explored how the regional location of farms and the mutual positioning of farms within a region affect productivity in the industry. This study aims to estimate the productivity of salmon aquaculture companies while considering factors such as the location of production sites. The hypothesis is that some companies are more productive due to owning well-located or differently-located production sites.

By examining the factors behind differences in productivity and the impact of current regulation on the industry’s sustainability, this study contributes to a better understanding of how governance processes can adapt to promote the sustainable transformation of the industry.

Introduction
Moving fish production from sea to land is gaining popularity due to the ability to control physico-chemical environmental parameters like temperature, salinity, and illumination, as well as to avoid parasitic infestations or harmful algae blooms. To achieve a sustainable production with low water and other resource consumption, recirculating aquaculture systems (RAS) have evolved rapidly in the recent past. RAS facilities do however come with their own challenges of maintaining water quality parameters including different nitrogen compounds, carbon dioxide or in a worst-case scenario hydrogen sulphide concentration as real-time sensors for these parameters are typically missing or not even available for industrial scale operations. A change of these water quality parameters can impact the fish welfare and, in worst case, cause a total loss of biomass in a few hours.

Materials and method
We present a system based on stereo vision for 3D tracking of each detected individual fish, utilizing a modified version of Stereo R-CNN (Li et al, 2019) for stereo detection and Norfair (Alori et al, 2023) for tracking of fish in a RAS facility (Figure 1). Using the 3D trajectory data, in x, y, z [mm], three fish behaviour parameters were be calculated, (i) swimming velocity, (ii) swimming pattern and (iii) fish synchronization. These values can be used to describe the general fish welfare and indicate physico-chemical water quality changes, e.g., an increase in carbon dioxide will impact the swimming velocity of the fish.

The method was validated via an experiment conducted in an experimental RAS facility at LetSea (Sandnessjøen, Norway), the experimental setup consisted of an 800 L tank stocked with a density of 10 kg/m³ (~70 fish) with a submerged stereo camera filming horizontally. The fish was exposed to H₂S to induce a stress reaction and dissolved H₂S, O₂ and CO₂ was monitored using the Aquasense system (SeaRAS, Bergen, Norway). The experiment was approved by the Norwegian Food and Safety Authority (FOTS id. 29143).

Results
During the H₂S exposure an increase in the average swimming velocity was detected (Figure 2, subplot 2), and the fish showed a more erratic swimming pattern (Figure 2, subplot 3) as well as loss of schooling behaviour (Figure 2, subplot 4).

Figure 1. A frame grab from the stereo camera system with image from the left camera (left) and right camera (right), illustrating detections (black bounding boxes) and the 3D swimming trajectory (multicolour) with the detection ID and x-, y- and z coordinates in millimetres (green).

(Continued on next page)
Figure 2. A plot illustrating the stress response of the fish (2nd, 3rd and 4th subplot) in relation to the dissolved H$_2$S concentration (1st subplot).

Conclusions
Using H2S as a stressor with high relevance for fish production in RAS facilities, the here described system showed its potential to serve as a real-time and cost-effective 24/7 surveillance system, that can automatically notify the operator when abnormal fish behaviour is occurring. The operator could then investigate the problem and initiate counteractions before long term damage to the biomass is sustained. Compressing the video streams down to only three essential parameters will ensure that the operator will not get overwhelmed by too much data during normal operation. The here demonstrated proof-of-concept represents a first step for optimizing land-based fish production in the next generation of digital RAS facilities, where fish welfare is in focus.

Introduction

Estimating the growth of fish in real-time comes with many benefits for indoor aquaculture farms, such as saving labor time and costs, reducing water pollution during starvation, improving feeding activity, and supporting harvesting.

This study aimed to develop a visual-information-based, real-time method for measuring olive flounder (*Paralichthys olivaceus*) lengths in indoor aquaculture farms in order to efficiently manage fish stocks through accurate growth tracking. This study first compared the actual lengths of olive flounders with the lengths obtained using an image processing algorithm to analyze the morphological characteristics of fish within their rearing environment. Then, estimating the length-weight relationship allowed body weight to be determined based on the estimated length.

[Image of the process for estimating fish growth]

**Fig. 1.** The process for estimating fish growth. First, the image is captured on the grid. The area of the fish image is calculated by counting the number of pixels, then the area can be converted from pixels to cm² based on the relationship between the pixel and the centimeter unit for the grid. The longest length of detected extreme points can be equal to the length of the fish.

(Continued on next page)
Materials and methods
We could estimate the body weight of olive flounders based on the generated length-weight relationship. A 5×5 cm grid paper was placed at the bottom of the water tank for measuring the fish length along with two single RGB cameras. The pixel unit from the fish length in the captured image was converted to millimeters (mm) based on the pixel-mm relationship of the pre-built dataset. A total of 180 lengths were calculated using images captured by the left- and right-side cameras, which have fixed positions above the surface of the water tank. The average length of each fish acquired from both cameras was calculated separately, and Lagrange’s interpolating polynomial algorithm was implemented to calculate the overall length of each fish.

Results
