Our system estimated the length of olive flounders with a simple, low-cost device comprising two mobile phones as cameras. A 5×5 cm grid paper was used to generate the learning environment as a reference object to convert from pixels to cm. Lagrange’s interpolating polynomial algorithm was applied to calculate the length of fish in cm after calculating the pixel length of fish with extreme points. The difference between the actual and computed lengths was minimal, with a high degree of accuracy ($R^2 = 0.994$).

Conclusion
This method was able to reduce the computational complexity, allowing results to be obtained more rapidly and in a user-friendly environment. The power model generated the length-weight relationship, which allowed us to estimate the body weight of each olive flounder based on the length.
COUPLED AEROBIC AND ANAEROBIC GAS FERMENTATION PROCESS FOR CARBON-NEUTRAL SINGLE CELL PROTEIN (SCP)

The food sector produces ¼ of anthropogenic climate impact. Low-carbon and carbon-neutral feed, particularly for aquacultures, can hence have a very strong impact for climate change mitigation. The methanotrophic strains *Methylomonas methanophilus V1* and *Methylococcus novellus V8* were used to obtain single cell protein (SCP) in continuous fermentation with CH$_4$ as sole carbon and energy source in an aerobic process. The maximum growth rate was 3.75 g/(l*h of biomass) (dry cell weight). Using CO$_2$ and H$_2$, experiments were carried out in a second anaerobic fermenter with *Thermoanaerobacter kivui* to make acetate. Process coupling is achieved via water electrolysis to H$_2$ and O$_2$, and fermenting the metabolic CO$_2$. This work demonstrated at the 30l + 30l scale that by coupling 2 gas fermentation processes, bacterial SCP and value-added side products can be obtained in a CO$_2$-neutral mode. The SCP has a crude protein content of 51-72%.
RELATIONSHIP BETWEEN BEHAVIOUR TRAITS AND RESISTANCES TO ACUTE HYPERTERMIA AND HYPOXIA IN RAINBOW TROUT

Email: henri.lagarde@inrae.fr

Introduction
A significant potential for genetic improvement of resistances to acute hypertermia and acute hypoxia was demonstrated in rainbow trout (Oncorhynchus mykiss) through selection (Perry et al., 2005; Lagarde et al., 2022; Prchal et al., 2023). However, the physiological mechanisms underlying these resistances are still under debate. It is therefore necessary to understand what makes a genotype resistant by identifying the mechanisms underlying these resistances. In previous experiments (Lagarde et al., 2022; Prchal et al., 2023), we observed expression of a large behavioral repertoire during acute hypertermia and hypoxia stress suggesting that behavior may be linked to resistances.

In the present study, we seek to understand whether resistance to acute hypertermia and hypoxia could be linked to behavior and discuss the possibility of using some behavior traits as a novel way of phenotyping these resistances. For this purpose, we used the rainbow trout isogenic lines, previously shown to exhibit different levels of resistance to either acute hypertermia or hypoxia (Lagarde et al., 2023). Global warming is expected to increase the frequency and intensity of heatwaves, resulting in more common combined acute hypertermia and hypoxia conditions in fish farms. Such poor thermal and oxygenation conditions induce problems, including growth losses, increased pathogens pressure and mortality. Selective breeding is a promising solution to improve resistance to non-optimal water quality. Indeed, genetic variability to survive in acute hypertermia or hypoxia conditions has been proved in fish. However, the characterization of these traits is not yet detailed enough to include them in a selection program. Here, we investigated the ranking stability of genotypes for acute hypertermia or hypoxia resistances over age and between acute hypertermia and acute hypoxia resistances. To this end, we established rankings of six isogenic lines of rainbow trout (Oncorhynchus mykiss).

Materials and methods
Six heterozygous rainbow trout isogenic lines were produced at the INRAE PEIMA experimental fish farm (doi: 10.15454/1.557239612068406E12, Sizun, France). At 177 days post fecundation (dpf), 6 fish per isogenic line were randomly chosen and subjected to an individual challenge and then gathered in a group challenge under moderate heat stress. In individual challenge, fish were placed in 12-l aquariums backlighted by an infrared device. The aquarium was divided into two zones: on one side, a gated zone covered by an opaque plate (safe zone) and on the other side, an uncovered zone (risk zone). After a 5-min acclimation in the safe zone, the gate was open and behavior recorded over 25 minutes. Immediately after the end of the individual challenge, the six fish were transferred in a 75 x 75 cm tank for group challenge. Temperature was gradually increased, from 12°C to 23°C in two hours and kept at 23°C for 0.5 hour. At the end of the challenge, fish were anesthetized, weighed and euthanized. Both tests were repeated three times for each line. Fish activity was video recorded and later analyzed with EthoVision XT15.0 software. A total of seven traits were measured in individual challenge: the maximum acceleration (ACC_MAX, cm.s⁻²), the distance travelled (DIST_TRAV, cm), the zone-change frequency (FRQ_CHAN, #.min⁻¹), the absolute meander (MEANDER, deg.cm⁻¹), the moving duration (MOV%, % of the time), the risk-zone duration (RISK%, % of the time) and the maximum velocity (VEL_MAX, cm.s⁻¹). In group challenge, 7 traits were measured: ACC_MAX, the average inter-fish distance (DISPERSION, cm), DIST_TRAV, the body contact frequency (FRQ_CONTACT, #.min⁻¹), MEANDER, MOV, and VEL_MAX. A linear mixed model was fitted for each variable, with replica as random effect, time bins and line as fixed effects, body weight as covariate, and the interactions between time bins, line and body weight.

At 182 dpf, isogenic lines were phenotyped for acute hypertermia and hypoxia resistances with a robust experimental design constituted of 150 fish per line and type of stress. The effect of isogenic line on acute hypertermia and hypoxia resistances were analyzed by fitting a linear mixed model with replica as a random effect, line as a fixed effect, body weight as a covariate, and the interaction between line and body weight as explained in Lagarde et al. (2023).

(Continued on next page)
Different individuals were phenotyped for resistance to acute hyperthermia and hypoxia and behavioral traits. Nevertheless, within each isogenic line, fish had the same genotype and could be considered as repetitions of the same genotype. Behavior traits for which least squared means of isogenic lines on behavioral traits were highly correlated with least squared means of isogenic lines on resistance phenotypes were considered as potentially genetically linked with resistance phenotypes and therefore discussed.

Results and discussion
There were significant differences between isogenic lines for most behavior variables. Some behaviors were found to be highly correlated with acute hyperthermia and hypoxia resistances (Figure 1). In general, lines with a higher activity level were found to be more sensitive to acute hyperthermia and more resistant to acute hypoxia than lines with a lower activity level. It suggests that some behavior variables could be used as proxies for acute hyperthermia and hypoxia resistances in fish, leading to more ethical phenotyping methods than classical resistances phenotyping ones.

These results must be confirmed in additional studies as only 6 isogenic lines were used.

E-mail: Franz.Lahnsteiner@baw.at

Introduction

Hematology is a simple but reliable method to determine the influence of thermal stressors on physiology and performance of fish (Fazio 2019). It is also used to evaluate the effects of temperature stress on fish. A recent study on Salvelinus fontinalis and Oncorhynchus mykiss demonstrated that erythrocyte size is affected by elevated temperature (Lahnsteiner 2022). Erythrocyte cell volume, nucleus volume, cell surface, and nucleocytoplasmatic ratio were significantly decreased after 32 days exposure to 20 °C in comparison to 9°C. The mechanism and significance of this adaption process are unclear at present.

Therefore, the present study continues the previous investigations. The study is conducted on the brown trout, Salmo trutta. Involvement of an additional species allows to detect if the above-described changes in erythrocyte morphometry can be generalized within the Salmonidae. Further, the present study focusses on the chronological sequence of changes in erythrocyte morphometry in response to elevated temperature. It is a goal to find potential regulation and compensation mechanisms. Complementary, growth rate and metabolic rate are investigated, too.

Material and Methods

Brown trout (total length 7.9 ± 0.5, body mass 4.9 ± 0.7 g), acclimated to 10 ± 0.2 °C and kept at a natural photoperiod during their whole life span, were used for this study. Experiments were carried out in accordance with Austrian regulations governing animal welfare and protection and with the EU directive 2010/63/EU for animal experiments.

A number of 250 brown trout, respectively, was stocked in 4 stream channels (190 x 25 x 35 cm, length x width x height) under flow through conditions (0.2 l/sec). Two stream channels were maintained at 10 ± 0.2 °C and served as control. The others were gradually tempered to 15 °C during a 7-d period using a geothermal heat pump and kept at 15°C for 28 d.

The percentage of fish tolerating the experimental conditions, the growth rate, and the metabolic rate were determined in 7-day intervals according to previously published methods (Lahnsteiner 2020b). Also, in 7-day intervals 10 fish per stream channel were haphazardly sampled and euthanized with MS222. Blood was collected via the heart ventricle. 10 µl of blood was fixed in 1 ml 0.1 mol l⁻¹ cacodylate buffered 4% glutaraldehyde solution (pH 7.4). A differential blood cell count was made in a light microscope at 1000-fold magnification based on the classification of Fazio (2019). Erythrocyte morphometry was analyzed in twenty erythrocytes per fish as described previously (Lahnsteiner 2020a). Cell dimensions were measured by Image J analysis software and cell volume (µm³), nucleus volume (µm³), cytoplasm volume (µm³), cell surface area (µm²), volume to surface ratio, and nucleocytoplasmatic ratio, were calculated for the single erythrocytes (Lahnsteiner, 2020a). The mean values per individual were used for further statistical analysis. Data are presented as mean ± standard deviation. Data were analyzed by one-way ANOVA with treatment procedure as independent variables.

Results

Survival rate of brown trout was 98 ± 1% at 10°C and 97 ± 2% at 15°C. Growth rate during the course of the experiment was 115 ± 4% at 10°C and 98 ± 5% at 15°C. Erythrocyte volume, nucleus volume, cell surface, surface to volume ratio and metabolic rate revealed specific changes during temperature increase from 10 to 15°C (0 - 7d) and during the exposure period at 15°C (8 - 28 d) (Figure 1). Concentration of erythrocytes, granulocytes, lymphocytes, thrombocytes and aberrant cells did not differ during the course of the experiment.

(Continued on next page)
Discussion

The results demonstrate that metabolic rate and erythrocyte morphometry of *Salmo trutta* change due to a temperature increase from 10 to 15°C. During exposure to 15°C recompensation processes occurred. This is a clear indication that brown trout can adapt to elevated temperature. However, the recompensation was partial as values did not reach the initial ones measured in fish acclimated to 10°C. The reduced erythrocyte size and the increased surface area to volume ratio may improve the oxygen uptake / release capacity of blood which is an advantage due to increased metabolic rate. A reduction of erythrocyte size may also be important in decreasing blood viscosity to optimize blood flow. During the course of the exposure to 15°C erythrocyte size increases again parallelly to the decrease in metabolic rate. This indicates that both processes are coupled with each other.

Introduction
Over the last 40 years, Norway has become a world leader in salmonid production, but despite the economic growth, farmers continue to experience high fish mortalities after post-seawater transfer (1). The transfer success of farmed post-smolt Atlantic salmon to sea is largely dependent on the smolt’s physiological ability to counteract environmental challenges. Early life experiences, in particular, as a result of different rearing conditions, are known to differentially influence physiological responses and plasticity that lasts later in life (2). The transfer success of farmed post-smolt Atlantic salmon (Salmo salar). Over the last decade RAS systems have been adopted as a key technology in the production of juvenile salmonids and it is estimated that RAS fish currently make up the majority of the smolts stocked in Norwegian sea cages. In comparison to the more conventional extensive flow-through (FTS) system, RAS provide a more stable and controlled rearing environment, although it is not fully understood how this affect the physiological plasticity and ability to withstand abrupt and seasonal changes in environmental factors once the fish is transferred to the sea. In this study we compared growth performance, physiological traits, and environmental adaptation in Atlantic salmon (Salmo salar) transferred into sea cages from fresh water intensive RAS (high and constant temperature) to a similar group produced in fresh water under extensive FTS conditions (natural temperate water).

Materials and methods
Circa 300k fish from RAS and FTS systems, respectively, were released in 6 commercial cages (triplicates cages; 25 x 25 m, 40 m depth.) in one of the commercial breeding facilities of Lingalaks AS. Biometry data and biological samples were collected monthly, from before transfer to seawater and until slaughter (12 months later). Water conditions at different depths (temperature, salinity, current, pO2, fluorescence) was collected by SAIV-CTD during the entire seawater production.

Results
There were no significant differences in growth and smolt development between FTS and RAS-produced smolts at the end of the freshwater phase. However, after transfer to SW the RAS fish showed several underlying physiological and molecular differences. Remarkably the final slaughter weight was 3646 ± 8.3 g in RAS compared to 4229 ± 70.5 kg in FTS fish; i.e 600 g less. A distinct lower HSI, and plasma levels of lactate and triglyceride were observed in the RAS smolts, before and after seawater transfer. RAS fish showed also lower NKA activity, and plasma levels of Na+, Ca2+, and P+ compared to FTS fish once transferred in seawater, suggesting hypo-osmoregulatory maladaptation in the first months in seawater. Both FTS and RAS fish showed physiological adjustments during the seawater production which were mainly linked to the seasonal variation in water temperature, but compared to the FTS, RAS growth showed a stronger negative interaction.

Discussion
The physiological difference observed between the RAS and FTS fish once in sea cages was likely linked to pre-history water temperature in freshwater. The two groups were exposed to different environmental conditions in fresh water, likely allowing the FTS fish to develop a more physiologically plastic response to environmental changes than the RAS fish once in seawater.

In conclusion, the current study emphasises the crucial role that pre-history freshwater rearing conditions play in laying the foundation for the fish successful physiological adaptation to seawater, growth performance, and ultimately the success of farming production.

Email: floriana.lai@uib.no

Introduction
During the growth phase in sea cages, Atlantic salmon (Salmo salar) is subjected to diurnal and seasonal changes in environmental conditions. As an ectotherm animal, temperature is one of the most important environmental factors influencing and limiting metabolism, growth, energy allocation, and fish welfare. Temperature, in particular, has a strong influence on feed intake, digestion rate, and efficiency, as well as the required supply of nutrients for the fish to grow. However, little is known about the dynamics of gastro-intestinal tract (GIT) transit and how this relates to the signalling factors involved in digestive process control, and the links to appetite-controlling systems in the brain. Thus, we investigated feed intake and fish growth and assessed involvement of hormones and neuropeptides involved in GIT transit and the control of feed intake in Atlantic salmon reared at 8, 12, and 15°C.

Materials and methods
Post-smolt Atlantic salmon of approximately 200 g were reared to either 8°C (low-temperature), 12°C (control) and 15°C (high-temperature) for two months at the Department of Biological Sciences at the University of Bergen. Fish were fed once a day for 2 h using automatic feeders, and feed intake assessed by collecting and quantifying uneaten feed. At the end of the two months, 10 fish from each temperature group were collected 2 h post-feeding, followed by sampling every 4th hour for 24 h. Biometry data for growth and somatic indexes, plasma, GIT compartmental content, stomach tissue and brain samples were collected.

Figure 1. mRNA expression levels of npy (orexigenic) and pomca (anorexigenic) paralogs in the hypothalamus of Atlantic salmon at different rearing temperatures. Graph points represent mean ± SEM (n = 10/group) of normalized mRNA copy number to the total ng of RNA for target gene, and the geometric mean copy number of actb and rps20.

(Continued on next page)
Results
Temperature had a significant influence on growth rate, feed intake, and appetite-related key neuropeptides in post-smolt Atlantic salmon. The highest temperature groups showed better growth performance, feed intake and gut evacuation. Temperature influenced gene expression of appetite-related genes in the brain (Figure 1), which were found to be higher expressed during the postprandial period in the low temperature group, while the 12°C and 15°C groups had a higher during the pre-prandial period. Plasma levels of ghrelin, on the other hand, was statistically higher at 8°C than at 12°C or 15°C pre-prandial. However, this did not correlate to significant differences in the gene expression of ghrelin nor the enzyme that activates ghrelin (Ghrelin O-acetyltransferase) in the stomach.

Discussion
The different growth regulation and mechanisms underlying feed intake and appetite observed in the three experimental groups highlight the critical role of temperature in establishing the foundation for a physiological adaptation to the environmental condition. Temperature had a significant impact on post-smolt Atlantic salmon growth rate, feed intake, and appetite-related mechanisms. Several differences in the regulation of hormones and neuropeptide appetite key levels between the experimental groups were observed, with a significant difference between the low temperature group at 8°C, and the two groups at 12°C and 15°C.

ANTISHARK MEASURES TO AVOID INTERACTION OF SPINY DOGFISH (*Squalus acanthias*) WITH AQUACULTURE INSTALLATIONS

P. Lal*, M. E. Brynildsrud, A. Oosterkamp, N. Gharbi, S. Bamber

NORCE Norwegian Research Centre, Nygårdsgaten 112, 5008 Bergen, Norway

*Email: plal@norceresearch.no

Introduction
The spiny dogfish is one of the common shark species found in Norwegian coasts and fjords. However, their interaction with aquaculture installation is a financial, welfare and ecological challenge. The fish farmers report that spiny dogfish often bite through the net and get in the fish cages. The holes in the cages cause escapees of farmed fish leading to both financial loses and ecological challenge. The dogfish are usually attracted to dead fish found at the bottom of the cages. But inside the cage, they also eat and harm the live farmed fish causing welfare challenge. To prevent this, farmers continuously remove dead fish and must constantly inspect the cages with the help of divers and underwater cameras for any holes. To date there is no effective method to prevent spiny dogfish incidents in fish farms. Hence, it is crucial to test and develop active and passive methods to prevent spiny dogfish incidents in fish farms.

Materials and Methods
Here, we have tested active measures that acts through sensory system. Spiny dogfish of size 60-85cm were caught and housed in laboratory aquarium (flow through) of size 2m diameter and 85cm water height. It was supplied with sea water at 9 °C; the light intensity was 10 lux at 10cm above the water surface. Experimental tank was equipped with a custom-made low light camera. The ectromagnetic (EM) field change, sound of orca (natural predator) and skin extract from conspecific were used as deterrent stimuli; an extract form mackerel was prepared and used as an attractive stimulus. The animal behavior is recorded before and after application of stimuli and analyzed for change in locomotive behavior.

Results
The spiny dogfish showed change in locomotive behavior (increased/decreased speed) in response to EM, skin extract and food stimuli; however, it showed no change in response to sound of orca. Food stimulus or smell of dead mackerel induced food-seeking behavior- sharks were found probing the odour inlet. Both EM and skin extract induced avoidance response- sharks moved away from the source area.

Discussion
Shark barriers and deterrents have been developed against specific species of sharks; these have been used to keep sharks away from bathing areas, to offer personal protection for swimmers, divers and surfers; some of these have also been tested to keep sharks away from bait and catch in line and net fishing. However, their effectiveness varies depending on the species and geographical area; none of the measures provide a full deterrence. Here, by evaluating the candidate shark-deterrents in a series of laboratory trials, we find that both EM and skin extract could be used as effective shark deterrent. Additional field trials are necessary to evaluate the effectiveness of these methods.

Introduction
Recent studies have shown that early exposure to environmental stimuli (such as hypoxia or temperature) could impact fish physiology, growth, metabolism and nutrition at mid-or long term. There are several possible mechanisms underlying this programming phenomenon, among which epigenetic regulations such as DNA methylation (Best et al. 2018). The objective of this study was to understand by which molecular mechanisms early cold exposure (at eyed-eggs stage) can impact fish physiology later in life (at juvenile stage), by analysing DNA methylation patterns in rainbow trout. This study was based on 2 experimental divergent lines for muscle lipid content (Quillet et al. 2005) that have been shown to utilise differently feed and to possess a well differentiated intermediary and energetic metabolism. Our hypothesis is that they will react differently to the cold exposure during incubation.

Materials and methods
At 17 days post fertilization (dpf), eyed-eggs from two experimental lines selected for high or low muscle lipid content, fat line (FL) and lean line (LL), were either incubated at normal temperature (11°C) or incubated at 3°C for 15 days in 12 tanks (2 lines x 2 incubation temperatures x 3 tanks). Hatching and the rest of the rearing was performed at standard temperature (11°C). Eyed eggs were collected at a similar stage of development (220 degree days; 19 and 31 dpf for the control and cold conditions respectively) and analysis of gene expression was performed by qPCR on 5 eggs per line, per incubation temperature and per tank, for 12 genes: hsp47 (Heat Shock Protein 47), two cirbp (cold-inducible RNA-binding protein), ucp2 (Uncoupling protein 2) and eight dnmt3 (DNA methyltransferase 3). Genome-wide patterns of DNA methylation was assessed by RRBS (Reduced Representation Bisulfite Sequencing) on liver samples of 48 juvenile trout (2 lines x 2 incubation temperatures x 3 tanks x 4 fish per tank) collected at 189 dpf, snap frozen in liquid nitrogen and kept at -80°C until DNA extraction. Liver was chosen as it is the central organ for intermediary metabolism. RRBS libraries were prepared using MspI and size selection of 40-290 bp fragments and then sequenced on an Illumina NovaSeq6000 sequencer to produce 100 bp paired-end reads (Integragen SA, France). Trimmed reads were aligned to the current Arlee rainbow trout reference genome with the bisulfite mapping tool Bismark. Differential methylation analyses were performed using methylKit (qvalue<0.01, minimal methylation differences between temperature groups>20%). Identified DMCs (Differentially Methylated Cytosines) and DMRs (Differentially Methylated Regions) were finally annotated relative to gene features.

Figure 1. Venn diagrams of geneIDs found in DMCs and DMRs in the two experimental lines, FL (fat line) and LL (lean line).

(Continued on next page)
Results
Globally, there were significant but low differences in gene expression for 8 of the 12 targeted genes, with a minor impact of incubation temperature or line at eyed-stage. For the RRBS sequencing data, an average of 47 million paired-end reads were obtained per individual (lowest: 28 million; highest: 74 million). Bisulfite conversion rates were very high (>99.7%). Sequences that aligned to unique positions of the genome represented 50% of all reads on average and were used for subsequent analysis. Numbers of CpGs tested by methylKit (i.e. CpGs with a minimal number of 9 samples in each group satisfying the coverage range of 10-500 reads per CpG) were 1,273,685 for FL line and 1,240,712 for LL line. Differential methylation analyses between control and cold exposure groups revealed 3187 DMCs and 89 DMRs for the FL line; 3442 DMCs and 79 DMRs for the LL line. Annotation of DMCs and DMRs revealed that different genes were involved in the two genetic lines, with a certain degree of overlap (Figure 1).

Discussion
Using two divergent lines for muscle fat content allowed testing the impact of the genetic background on the establishment of DNA methylation patterns in response to early cold exposure. Preliminary results suggest that the two lines responded differently, although some genes with DNA methylation varying according to cold exposure were also found in common. Ongoing interpretation of the biological pathways involved will lead to a finer understanding of underlying mechanisms. This study will contribute to use early programming as a lever to improve long term performances of animals.

Introduction

Fish farm cages are commonly used as case studies for the assessment of the effects of organic enrichment, occasionally inducing hypoxic conditions below the cages as a source of disturbance for benthos. As a consequence, this might alter ecosystem services and biogeochemical processes, as well as the structure of benthic communities and result in loss of diversity (Quero et al., 2020; Keeley et al., 2013). However, as the distance from the fish cages increases, the concentration of organic matter and other pollutants decreases and the benthic communities gradually recover from disturbance, as is evident in the successional model of benthic enrichment responses for macrofaunal communities (Karakassis et al., 1999). The commonly used Before-After Control-Impact (BACI) methodology is a useful approach for evaluating fish farming effects through observational studies. By incorporating both time and control sites in the analysis, it minimizes the effects of unmeasured factors on the observed outcomes of the study (Seger et al., 2021, McDonald et al., 2000). The main objective of this study was to employ the BACI methodology to examine the environmental impacts resulting from the relocation of a fish farm’s cages, which involved dividing and transferring a portion of the cages to a different, nearby, location.

Materials and Methods

A fish farm located in the northern Evoikos Gulf, operating for more than 20 years planned in 2020 to make a major rearrangement of the fish cages. Until summer 2020, the farm had five large clusters of cages located 50m apart from each other resulting in high precipitation of organic matter in a relatively small area. In 2020, two of the clusters were moved to an adjacent area 500m away, therefore creating two “parks” with the same total fish load as the original. Thus, a BACI study was conducted. Specific sampling stations were designated to assess changes in the environmental impacts of fish cages resulting from the reconstruction process. Benthic samples were collected on three sampling occasions: before the transfer in 2020, immediately after the transfer in 2021, and one year after the transfer in 2022. The sampling stations included the old and new cage locations, as well as control stations without any fish cages. Additionally, a sampling station was positioned near the cages that were transferred, but remained unchanged across time. This station was included to assess the impact of the two cage locations being in close proximity prior to the transfer, and to evaluate the subsequent recovery. Sampling at this location can provide an insight into whether the reduced impact due to the transfer of some of the cages affected the environmental conditions for the remaining cages in the vicinity. From these stations, benthic macrofaunal samples were collected by means of a Van Veen grab (0.025m²), sieved through a 0.5mm mesh size sieve and preserved in 4% formalin. Furthermore, three replicates of every sample were collected from each station. Several environmental variables were also measured. These include temperature, depth, Redox potential (Eh), Organic Matter (OM) with the Loss of ignition (LOI) test, granulometry and Chlorophyll-a.

Results

Prior to the 2020 transfer, sediment redox potential values indicated hypoxic conditions at the impacted site, leading to low benthic diversity and poor ecological status. While there was some improvement in environmental conditions after the transfer, the ecological status at the old site remained moderate throughout the second year (2021), and the relocation of cages did not appear to have a significant effect. However, signs of recovery were observed after 2022 in both the old site and the station with unchanged cages, with a gradual reduction in organic matter, improvement in sediment redox potential values, and an increase in ecological status and benthic diversity. In contrast, pre-transfer, the new establishment area showed higher values of diversity and good ecological status, which was similar to the control station, but the new impact site’s environmental conditions deteriorated post-transfer due to increasing impact.

(Continued on next page)
Conclusions

Based on the results of the study, it is concluded that the translocation of fish cages has a significant impact on the environmental conditions and benthic communities of the affected areas. It is evident that the relocation of cages can have both positive and negative effects on the environmental conditions and benthic communities of impacted areas. While dispersion of the cages can improve environmental conditions locally, relocation can also impact a new, undisturbed area. Further analysis is required to fully assess these effects and assess if the movement of cages improved in total the conditions of the fish farm area.

Overall, this study emphasizes the need for regular monitoring and evaluation of fish cage operations and their impact on the environment to ensure sustainable aquaculture practices as even a cages relocation event can significantly alter the biodiversity and environment of an area.

EFFECTS OF FISH ASSEMBLAGE AND PRACTICES IN FRESHWATER FISHPOND POLYCULTURE: A TROPHIC WEB MODELING APPROACH

A. Larivain*1, P. Ralien1, M.S. Corson1, J. Aubin1
1INRAE, Institut Agro, SAS, 35000 Rennes, France.
*angela.larivain@inrae.fr

Introduction
In Europe, freshwater pond aquaculture, which has high potential to meet the growing consumer demand for fish, is facing environmental restrictions, leading to a decrease in the sector’s production. Monoculture and polyculture systems are facing many challenges to become more sustainable, that is, more productive, resilient, robust and mature, as well as providing more support for natural and cultural values, human beings and biodiversity (Dong et al., 2022). Current aquacultural research recommends combining multiple species in polyculture, with one reference model being carp polyculture, first established in China. This type of polyculture originally focused more on the fish than on the other trophic compartments of the ecosystem. The SEPURE project aims at improving understanding of complex trophic interactions in pond ecosystems in order to identify innovative assemblages of fish species that use and recycle nutrients better. In this study, trophic web models were built for several polyculture fishponds with different management practices to develop a method to assess the structure and functioning of aquacultural ecosystems.

Materials and methods
Using data for 10 fish ponds (with fish fed or unfed) studied in different regions of France in 2021 and 2022, a model of the trophic web of each pond ecosystem was built using Ecopath software. Each pond was considered an independent case study. The ponds differed in feeding, fertilization, the amount of bird predation and the number of trophic compartments represented. The fish assemblages varied, including the common carp *Cyprinus carpio* and/or grass carp *Ctenopharyngodon idella*, roach *Rutilus rutilus*, rudd *Scardinius erythrophthalmus*, tench *Tinca tinca*, largemouth bass *Micropterus salmoides*, pikeperch *Sander lucioperca*, northern pike *Esox Lucius* or white sturgeon *Acipenser transmontanus*. The species selected and their ratios differed among ponds. Using Ecopath software, which models the balance of mass circulating among the compartments, each compartment’s contribution to ecosystem productivity was studied. To assess each pond ecosystem, performance indicators such as ecotrophic efficiency (EE), total system throughput (TST), net system production (NSP) (i.e. respiration minus primary production) and system omnivory index (SOI) (i.e. the complexity of feeding interactions between trophic levels) were calculated. Indicators such as Finn’s cycling index (FCI) (i.e. the percentage of TST recycled) and the ratio of primary production to respiration (PP/R) were then used to assess the maturity of the system.

Results
Initial model outputs predicted a variety of dynamics among the ponds. EE remained $\leq 1$ for all trophic compartments of each pond, which is necessary for a model to be considered a satisfactory representation of a trophic web. The EE were high for macro-invertebrates and zooplankton in most ponds, indicating that they were key factors that limited fish growth in the ponds, even when the fish were fed. TST ranged from 513.8-1095.0 g/m²/cycle, indicating that the size and activity of the ponds differed, with the largest values indicating the highest turnover in the systems. SOI ranged from 0.17-0.21, which indicated many, and thus more complex, feeding interactions among the trophic compartments. NSP ranged from 140.5-264.4 g/m²/cycle, with the larger values indicating more immature systems that are still developing. In addition, PP/R ranged from 4.64-9.40, likewise indicating the immature state and small size of the ecosystems, with no clear differences between systems with fed vs. unfed fish. FCI ranged from 4.4-10.2%, which seemed to indicate high stability and resistance to external disturbances.

Discussion and conclusions
This study is a preliminary approach to build accurate reproducible mass-balanced Ecopath models of European freshwater fishpond systems. SOI, NSP and PP/R indicated that the structures of the food webs during the cycle were incomplete, which means that the primary production could not be fully used. The high variability in performance indicators seems to indicate room for improvement in management practices, fish assemblages and their interactions. Nevertheless, the model results provided guidance on better understanding the functioning of each ecosystem and reflecting on how to improve management of the systems. Analysis of the variety of fish assemblages provided new knowledge to help reconsider polyculture characteristics and potentially develop future experimental designs and recommendations for sustainable management of aquaculture.

Introduction

Climate change poses a significant challenge to aquaculture. In recent years, extreme events such as oceanic heatwaves and unpredictable environmental conditions reveal the need to understand the severity of these impacts and develop evidence-driven mitigation strategies to support the sustainable growth of aquaculture. Climate prediction models have offered insights into these consequences, however, many of these models require experimental verification. Despite significant strides made in recent years, there is still a significant knowledge gap on how climate-related stressors affect the health and welfare of farmed fish.

This study focused on the impacts of several climate-related stressors on the nasal mucosa of two relevant farmed fish in Norway, Atlantic cod and Atlantic salmon. The mucosa of the olfactory organ is considered the first of defence, as it constitutes the interface between the internal and external environments. In terrestrial vertebrates, nasal mucosa protects the host from airborne antigens and hazardous chemicals. Similarly, the olfactory organ of fish exhibits a similar defence function as it is directly and constantly exposed to the biological and chemical threats of the aquatic environment. This paper presents a series of studies on salmon and cod that reveals the consequences of climate-related stressors on nasal health.

Materials and Methods

Atlantic salmon trial: Fish were reared at three thermal conditions – Control group was at 12°C, High temperature group was at 17°C and the Heatwave group was reared at 12°C, then gradually increased to 17°C, then progressively lowered again to 12°C. The experiment was carried out over 2 months. There were 2 rounds of heatwave episodes in the trial.

Atlantic cod trials: A) Interaction of elevated temperature and Franciscella noatunensis infection. Fish were reared at two temperatures – either 12°C or 17°C. Thereafter, fish were challenged with the pathogen, and the disease was allowed to develop for 5 weeks. B) Interaction of heatwave and ocean acidification. Fish were reared under 4 experimental conditions – 8°C, heatwave (8°C → 17°C → 8°C), 8°C + acidified environment and heatwave + acidified environment. Responses of the olfactory organ in all trials were studied at molecular and histological levels.

Results and Discussion

Elevated temperature altered the transcriptome of the nasal mucosa of both species. Genes related to immunity, extracellular matrix and stress exhibited striking regulation by heat stress. It appeared that in both species, heatwaves and not prolonged exposure to higher temperatures significantly affected the olfactory organ. For instance, in salmon, heatwave affected the genes involved in pathogen recognition, communication and signalling via chemokines and cytokines, humoral and cellular effectors, and development and differentiation of lymphocytes in the olfactory organ. In addition, the migratory potential of epithelial cells of the olfactory organ and the ability of the organ to respond to oxidative stress diminished following a single round of heat wave.

The transcriptomic changes in the olfactory organ of Atlantic cod can be considered local or remote responses to the systemic F. noatunensis infection. Five weeks after the challenge, the nasal transcriptome of infected fish, both from 12°C and 17°C, was almost similar to the uninfected control. However, comparing both infected groups identified 754 DEGs, many of which were involved in signalling, defence, transmembrane and enzymatic processes.

Increased temperature, heatwave, acidification and their combinations altered some of the structural features of the nasal mucosa. We found that both heatwave and prolonged elevated temperature resulted in mucus cell hyperplasia in the olfactory organ of salmon. Such a phenotypic response was not evident in Atlantic cod. Nonetheless, elevated temperature and infection showed lower mucus cell counts.

(Continued on next page)
This paper will also present evidence of how the nasal microbiota is altered by climate-related stressors. In addition, the changes will be compared with the transcriptomic alterations in the olfactory organ. These analyses are currently ongoing.

**Conclusion**

The results reveal that the olfactory organ of Atlantic salmon and Atlantic cod was sensitive to climate-related stressors. Both species shared a number of common mechanisms in response to these stressors, but some distinctions were also identified. These climate-related stressors affected the immune responses in the olfactory organ, indicating that mucosal barrier functions are likely at risk to future climate scenarios. The results are expected to shed insights into the physiological consequences of climate change in these species, which will be valuable in developing targeted climate mitigation plans that are supported by both predicted and empirical data.

Introduction
Intensive aquaculture and globalization of trade contribute to the emergence and spread of infections in fish farms. In a context of restriction of antibiotics use, probiotics could represent an interesting bioalternative to control infections and improve the zootechnical performances while minimizing the environmental impact. We investigated the probiotic potential of sporulated bacteria extracted from the marine environment on seabass, *Dicentrarchus labrax*, one of the major marine fish species produced in Mediterranean.

Methodology
*Bacillus* strains were screened *in vitro* and fully sequenced to identify their potential probiotic properties and assess their safety. The efficacy of probiotics was evaluated by dietary supplementation of juveniles seabass (average initial weight: 5g) with the candidates of interest for several months at 21°C. During the supplementation, their ability to persist in the intestine, their effects on growth (length and size), immune system (blood formulation, phagocytosis activity) were evaluated. After two to five months of supplementation, some fish were experimentally infected with *Vibrio harveyi*, *Vibrio anguillarum* or nervous necrosis virus (NNV) to evaluate their disease resistance.

Results
Genome analyses confirmed the absence of antibiotic resistance and pathogenicity genes and revealed interesting capacities of production of amino acids, vitamins and digestive enzymes. Strains selected showed antibacterial properties against various genus of pathogenic bacteria isolated from farms, associated with the identification of gene clusters encoding secondary metabolites with potential antimicrobial activities.

The survival of probiotics in the intestinal tract of supplemented fish was confirmed with the detection of concentrations up to 1.10^5 CFU per intestine at different time. Probiotic supplementation increased survival rates after infection with *Vibrio harveyi* and *Vibrio anguillarum*. However, survival rates are not impacted for NNV infection. Furthermore, fish supplemented with probiotics showed significantly higher leukocytes counts, with an increased proportion of phagocyte (expression of immunity genes ongoing).

Conclusion
The *In vitro* and bioinformatics analyses performed confirm the probiotic potential and the safety of the marine strains of *Bacillus* selected. These probiotics have beneficial effects on components of the immune system and improve resistance to bacterial pathogens of juveniles sea bass.
Introduction

The development of Rainbow Trout (RT) aquaculture industry in combination with limited availability and high prices of fishmeal has prompted feed producers to include more plant proteins (PP) in aquaculture feeds. However, PP do not meet the necessary nutritional requirements of animals, in particular due to imbalances in Amino Acid (AA) profiles compared to fishmeal, the historical ingredient. Although representing building blocks of proteins, AA also have many crucial roles as signalling molecules as well as substrates for cellular metabolism. However, the maintenance of cellular AA homeostasis begins with the absorption and transmembrane traffic of AA within cells, ensured by Amino Acid Transporters (AAT). While characterized in mammals, in which regulation of AAT by nutrients, including AA, has been demonstrated, few data exist in fish to date. The aim of this study was to 1) identify for the first time all AAT expressed from RT genome and 2) address their regulations by nutrients, and mainly by AA, to evaluate whether AA imbalance profiles could impact AA homeostasis. To reach these objectives, AAT were first identified in RT genome in silico before assessing their expression in different RT tissues, while the study of their regulations by nutrients was conducted by taking advantage of a cellular model: the RTH-149 cell line. Such approach, already validated for the study of AA metabolism in RT, allowed us to decipher AAT regulations independently of systemic regulations that could occur in vivo. Finally, consequences of nutritional AA-induced AAT dysregulations were investigated through their impacts on intracellular AA contents as well as on the mTOR (mechanistic Target Of Rapamycin) signalling pathway, a major regulator of cell metabolism, also described for being controlled by AA availabilities. Results presented hereafter, not only allowed us to refine AAT classification according to their nutrient-dependent regulations but also highlight several interdependencies regulated by AA availabilities, AAT and signalling pathways and their potential physiological outcomes in fish fed with alternative protein sources.

Materials and Methods

First, potential AATs in the RT genome were identified by in silico analysis and primers were designed for each AAT, before being tested and validated on a pool of RT tissues including brain, gut, stomach, liver, ovary, adipose tissue, kidney, spleen and muscle. In vitro experiments were performed using the RT hepatocyte cell line called RTH-149 (ATCC® CRL-1710, LGC standards, Molsheim, France). Cells were subjected to 13 experimental conditions using Hank’s balanced salt solution (HBSS, #14025-092, Gibco) supplemented in combination or not with total AA, Non-essential AA, Essential AA, Foetal Bovine Serum or using MEM deficient in single AA (c4086, Genaxxon Bioscience: -Arginine, -Lysine, -Methionine, -Leucine) as well as 3 conditions with MEM supplemented with pharmacological activators/inhibitors of key signalling pathways (Halofuginone and Tunicamycine, activators of the Integrated Stress Response pathway, and rapamycin, a mTOR inhibitor). Cells were treated for 24h prior being collected and subjected to the following analyses: RTqPCR analyses of AAT expression, UPLC intracellular AA content analyses and Western Blot analyses of 4EBP1 and S6 phosphorylation, two known targets of mTOR. Data gathered from these 3 sets of analyses were cross-analysed (Pearson correlations, generalised linear models) to define correlations and fitting models that could help to decipher relationship between AA availabilities, AAT dysregulations, AA uptake and mTOR activation.

Results

From the 71 AATs identified in mammals, 212 were found in the RT genome, while at least 116 were expressed in RT tissues. Of the 116 AAT expressed in vivo in RT, 74 are identified in the RTH-149 cell line covering 86% of AAT specifically found to be expressed in the liver. All AAT expressed in RTH-149 were shown to be dysregulated by at least one of the experimental conditions tested, the vast majority of which being under the control, positively or negatively, of AA and/or FBS. Interestingly, our study revealed an antagonistic response between two major classes of AAT: Cationic AAT (CAAT)
being predominantly upregulated by starvation, while Anionic AAT (AAAT) were mainly downregulated, which is mainly explained by AA, and more specifically on essential AA. According to the whole set of dysregulations observed in the 13 conditions tested, a hierarchical clustering of AAT expressed in RTH-149 cells has been generated highlighting the existence of 3 main groups of AAT according to their nutritional regulations. Following the analysis of the outcomes of nutritional-induced AAT dysregulations on intracellular AA contents together with effects on the activation of the mTOR signalling pathway, we potentially identified AAT candidates that appear as the main gatekeepers controlling AA homeostasis, and certainly their cellular functions.

Discussion

For the first time, AATs in RT have been identified in RT genome and characterized for their expression in several RT tissues while in vitro assays performed in RTH-149 cells allowed us to refine the current AAT classification by providing new insights in their regulations by nutrients. These results confirm the key role played by AAT in the maintenance of cellular homeostasis, but more significantly illustrate the butterfly effect that a deficiency in a single AA can have. Indeed, we observed that single AA starvations induce dysregulations of large pools of AAT, which consequently strongly influence the intracellular content of many AA and thus the global cellular AA homeostasis. More widely, this questions the actual outcomes of diets with imbalanced AA profiles, when compared to fishmeal-based diets, on the physiology of farmed trout. If such observations are to be soon confirmed (work in progress), results gathered from this study provide a wide understanding of AAT regulations by nutrients in RT, but it also has the potential to supply a new method to assess, in a unique so far, comprehensive way to study AAT functions and activities in cells, and that, disregarding the species considered. Thus, such method could be useful not only for the fish nutrition field but for any biological study related to AAT and AA cellular functions which are still deeply required but overlooked due to notably to the lack of tools and methods.

corresponding author: g.lereste@halieutica.net

Introduction

Omega-3 (ω-3) are a demonstrated as an essential fatty acid (FA) family for human as their synthesis is either not possible for the a-linolenic acid (ALA, C18:3 w3) precursor or very weak starting from the precursor for the eicosapentaenoic acid (EPA, C20:5 w3) and docosahexaenoic acid (DHA, C22:6 w3) long chain derivatives. They must therefore be supplied by foods. Seafood products are the major source of ω-3 long chain derivatives in human diets and shrimp *L. vannamei* may contribute to this intake. Shrimp flesh fatty acids (SFFA) composition is influenced by feed fatty acids (FFA) composition. Omega-3 sources are rare and expensive, it is therefore essential to optimize their utilisation to produce sustainable and cost-effective feeds.

In this context, the present study aimed to screen the relative part of ALA and EPA among the total SFFA and their kinetics of assimilation regarding two different sources of dietary lipid: linseed oil (LO) and krill oil (KO) respectively. According to IAFFD, a reference database for raw materials composition, LO possesses 53.3%ALA and almost no EPA while KO includes 2.4%ALA and 17.4%EPA.

Materials & Methods

Two batches of experimental feeds were manufactured by coating 3% of the tested oils (LO or KO) on a control feed (37.3% crude protein and 7.8% fat).

135 juveniles of *L. vannamei* (0.1 g) were randomly distributed in 3 tanks (45 individuals/tank) resulting in a total biomass of 4.7±0.1g per tank.

They were acclimatised in the tanks for 7 days with the control feed. A first sampling of 3 individuals per tank was performed at day 0 (9 shrimps). Then, juveniles were fed with the experimental feeds: 1 tank with control+3%KO, one with control+3%LO and one with the control. The juveniles were fed at 5% of their estimated biomass per day. During the next 2 weeks, 4 samplings were made of 5 juveniles per tank for a total of 60 shrimp (20 shrimp per treatment). The SFFA composition was determined by Gas Chromatography with Mass Spectrophotometry (GC-MS) after extraction and saponification of the lipids of the abdomen.

![Fig. 1- %EPA among FA in flesh](image1.png)

![Fig. 2- %ALA among FA in flesh](image2.png)

(Continued on next page)
Results and Discussion

The results showing the % of ALA and EPA as a function of time are presented in Fig.1 and Fig.2, respectively. The SFFA profile matches the FFA profile obtained with GC-MS and the FA oil’s profile described by the IAFFD database. These results suggest that coating is an efficient process to include specific FA in shrimp’s flesh.

Moreover, the relative part of ALA and EPA in shrimp flesh fed with control+3%LO and control+3%KO respectively increase by 1.8 % ALA for the juveniles fed with control+3%LO and by 2.5% EPA for the juveniles fed with control+3%KO between the 2 first samplings (T0 and T+3). This result suggests that the kinetics of assimilation of ω-3 in shrimps flesh is quick.

Further experimentations with shorter sampling intervals are needed to precise these results.

CHARACTERIZATION OF DETECTION AND ATTRACTIVITY BEHAVIOR OF THE PACIFIC WHITE SHRIMP Litopenaeus vannamei

g.lereste@halieutica.net

Introduction

Litopenaeus vannamei is an omnivorous shrimp species with a scavenger tendency. Its clear preference for feed containing high proportion of marine animal products lead to unsustainable feed formulas. Continues and impressive efforts have been made by feed formulators to spare marine proteins with alternative raw materials. One of the actual limits of this process is the poor attractivity and palatability of those ingredients for the shrimp. There is a consequent need to characterize feed ingredients based on their capacity to attract the shrimp toward sustainable pellets. Ethograms such as the one established by Lee and Meyers (1996) could be improved thanks to new observation methods.

The goal of this study was to observe and analyze individual behaviors of shrimp confronted with pellets or dissolved amino acids (AA). This work was divided into two experiments: the first (Exp I) looked at the behavior of shrimp when confronted with feed pellets and the second one (Exp II) looked at their behavior when confronted with free AA dissolved in water.

Material and Methods

Twenty PL20 L. vannamei were bought in a commercial shrimp farm and acclimatized in Halieutica research station (Angers, France).

In Exp I, 14 shrimp were tested individually in a random order. Each animal was successively placed in a close tank filled with artificial marine water (salinity 30ppt, temperature 27°C) and was acclimatized for 5 minutes. At this time, experimental pellets were introduced in the tank. Animal behavior was recorded from above for ten minutes (Fig. 1). Videos were analyzed in order to find characteristic behaviors of detection and attractivity.

![Diagram of devices used for Exp I and Exp II](image)

Fig. 1: diagram of devices used for Exp I and Exp II

![Ethogram of detection and attractivity behavior of L. vannamei shrimp confronted with pellets (Exp I) or MFAA (Exp II)](image)

Fig. 2: Ethogram of detection and attractivity behavior of L. vannamei shrimp confronted with pellets (Exp I) or MFAA (Exp II).

(Continued on next page)
In Exp II 6 individuals were tested individually in a random order. Animals were placed in a small recycling aquaculture system made of two tanks. Animals were kept in a first tank, which was the same tank as in Exp I. The second tank was used as a buffer tank. After 5 minutes of acclimatization, different quantities of a dissolved mix of free amino acids (MFAA, KERASTIM® 50, BCF Life Sciences, France) were placed in the second tank (0 ppm; 30 ppm; 60 ppm and 90 ppm). Water movements between the two tanks were allowed by a peristaltic pump (Fig. 1). Animal behavior was recorded for 5 minutes before the adding of amino acids and 5 minutes after. Video recording and analysis were performed the same way as during Exp I.

For the observed behaviors, statistical analysis have been performed in order to show a potential effect of the concentration of MFAA, and an effect of the adding of pellets. Permutation test and Wilcoxon post hoc were made using RStudio (version 4.2.1).

Results
For both experiments, the main behaviors observed were immobility duration, antennal, antennular and scaphocerites flicking and eye beats.

In Exp. I none of those behaviors were significantly impacted by pellet addition. A tendency was however observed for antennal and antennular flicking, eye beat and immobility duration. In Exp. II, behaviors significantly influenced by the concentration of MFAA dissolved in water were immobility duration and scaphocerites flicking. A tendency was shown on antennal and antennular flicking.

Animal behaviors analysis resulted in a classification of the individuals within three different groups for each stimulus (Fig. 2).

Discussion/Conclusion
Results obtained through this preliminary study did not allow us to create a clear ethogram. There was a strong individual variability in the studied behaviors. It could be the sign that every shrimp behave differently. Thus, it could be interesting to further this study with a higher number of individuals or to test individuals ingroups.

Introduction

Functional health feeds are a pillar of modern aquaculture. Inactivated yeast cell wall (YCW) fractions are widely documented to conditionally confer health and/or performance benefits across a diversity of species. However, only few dose-response studies have been reported and none in marine species limiting the optimal application of this biotechnology. The aim of this study was to document the animal performance and mucosal health response to graded intake of a specific YCW paraprobiotic with the view to inform the strategic use of this ingredient. The specific YCW tested in this study was previously selected based on its specific parietal features and promising functional benefits on the intestinal barrier and immune homeostasis (YCW 2; Rawling et al., In Press).

Materials and Methods

The 9-week trial (Riasearch Lda; Murtosa, Portugal) tested 4 diets in quadruplicate tanks (500 L tanks flow-through indoor, pumped-ashore natural seawater ~22 °C; ~36 ppt) in juvenile European seabass (BWi = 11.3 g; 45 fish/tank) reared under ideal conditions (43 days) then chronically exposed to environmental and handling stress (20 days) (Fig 1). The basal diet was formulated to the species requirements and according to current commercial practices (55% plant meal, 20% fish meal; 15% LAPs; 6% fish oil, 6.5% rapeseed oil; 46.3% crude protein; 16.4% crude lipid; gross energy 21.1 MJ/kg). Test diets were prepared by incorporating graded level of a selected, proprietary YCW ingredient (Lallemand Animal Nutrition, Blagnac, France) “on-top” the basal recipe at 0 (Control), 1.5; 3.0 or 4.5 kg/T feed and manufactured by traditional hot extrusion. Test diets were hand-fed to apparent satiation 4 times daily over the trial’s duration.

Growth and feed performance were assessed over phase I, phase II and the overall trial’s duration based on total tank biomass, individual body-weight (15 fish/tank) and apparent daily feed intake per tank. Tissues were sampled at T1 and T2 as follow: crude skin mucus quantity (4 fish/tank, surgical absorbent sponges), skin mucus, faeces, gill, gut and skin (3 fish/tank). Skin mucus and plasma were assayed for immune biomarkers; faeces for intestinal health markers; mucosae histology focussed on morphometry and goblet cell population and mucosal gene expression was performed using tissue-specific panels of 20 genes (immune, cellular and oxidative stress, epithelium barrier function). Data were analysed by 2-way ANOVA and post hoc analysis with significance accepted at P < 0.05.

Results

Growth performance increased with increasing YCW level (Fig 2a, b). Mean body-weight was significantly higher in YCW 4.5 compared to the Control at the end of Phase I and II, with YCW 1.5 and 3.0 showing intermediary values. Similar trends were evident for SGR although differences were significant over the full trial period only for YCW 3.0 (+4.5%) and YCW 4.5 (+6.8%) compared to the Control.

There was a significant diet effect on FCR which was increasingly improved with increasing YCW intake over the whole trial’s duration (Fig 2c). FCR overall improved by up to 8.3 % in YCW 4.5 compared to Control with, interestingly, an apparent mitigation of its degradation over the period of chronic-stress exposure (Phase II) in this group.

Skin mucus excretion was significantly higher in YCW 4.5 compared to the Control at the end of the trial (Fig 2d) with numerical increases at lower YCW intakes. Similar trends were measured at the end of the Phase I (ideal conditions). Further tissues analysis will be presented.

Conclusion

There was a positive dose relationship between dietary intake of YCW and zootechnical performance as well as skin mucus excretion. In particular, the highest level of YCW tested (4.5 kg/T feed) appeared to mitigate the degradation of the zootechnical performances but also to boost skin mucus excretion during chronic-stress exposure.

Taken together, this YCW paraprobiotic as the potential to support the performance and robustness of European seabass juveniles. The feed supplementation strategy can be tailored to the levels of challenge expected and of benefits targeted.

CAN WE DISCUSS ABOUT CIRCULAR ECONOMY IN THE ANGLING SECTOR? CASE STUDY THROUGH A HUNGARIAN EXAMPLE

Kinga Katalin Lefler1*, Árpád Hegyi1, Krisztián Kocsis1, Béla Urbányi1

1MATE, Institute of Aquaculture and Environmental Safety
Department of Aquaculture

E-mail: lefler.kinga.katalin@uni-mate.hu

Introduction
Over the last decade, the need for a circular economy has emerged and is now pervading the day-to-day functioning of the economy. It is attracting increasing attention, will and action from economic and social actors, not only in the EU but also worldwide.

The definition of a circular economy is relatively simple: it is a system or set of systems that does not generate waste material and whose products today (whether they are consumable or usable immediately or even waste material) are the raw materials of the future. The current complex material and energy flow systems are primarily linear units (production-use-disposal), whereas in the circular economy, materials are recycled in various forms back to the production line. The circular economy, even before the term was coined, was instinctively practised by many families and individuals: composting and using kitchen waste as fertiliser at home, or separate collection of waste, are all part of this system, necessary but not sufficient solutions in themselves. Addressing the problem requires more complex, longer-term strategies and planning by all economic actors to make measurable progress (Henriksson et al., 2021).

In the agricultural sector, circular economy and farming is a priority, and there is already a clear move towards conscious thought and action, with the development and deployment of technologies offering different solutions well underway, but the principle of starting with the basics of production technology is the same in almost all sectors.

The aquaculture-angling aspects of the circular economy have recently begun to be examined at a general (global) level. The problem is still being identified and solutions explored primarily at the theoretical level, but pilot systems are being set up to analyse causes and possible solutions in real time and space (Chary et al., 2021).

At EU level, the aquaculture sector operates in an autonomous system, independent of agriculture, given the particular importance of marine fisheries, in particular those with “industrial characteristics”. However, this approach cannot be applied to domestic, Central and Eastern European, pond-based fish production units and fishing ponds. Pond fish production and pond fishing cannot be separated from agriculture and the natural and built environment. They must be treated as one and only as such a complex entity can the complexity and simplicity of this system be understood (Muscat et al., 2021).

Materials and methods
The research was based on a 31-question questionnaire. This questionnaire aims to explore the popularity of the circulating system of angling ponds and, in addition to popularity, the attitude and openness of pond owners and pond keepers towards this issue. The research covers general knowledge as well as more specialised areas of knowledge and expertise.

The 56 completed questionnaires aim to develop a comprehensive picture of the attitudes of pond owners and managers towards the issue of pond management, which is representative of the current and potential future situation of the sector in the Hungarian angling sector.

Results and conclusion
A high percentage of those working in angling waters do not know what circular economy/farming is (44.7%). The owners of angling ponds are reluctant to open up to circular systems, and in order to change this and to reach more people with this knowledge, it will be necessary to organise and hold awareness-raising lectures on this topic.

From the answers given to the practical questions in the questionnaire, it was found that 23% of pond managers do not carry out any water quality monitoring, which can have a significant impact on the success and sustainability of their business.

(Continued on next page)
Focusing on agro-technical interventions, it was found that 13.6% of respondents do not use any interventions on their water bodies. The majority of respondents are not concerned with the quality and quantity of feeds (baits) applied to the water, despite being mostly aware of their harmful effects.

The last and one of the most important observations in the research is the question of education and training. Only a certain percentage (35.8%) of fishing pond managers have some form of education, a lack of knowledge and skills that may be fundamental to the management of problems and the use of technologies. 77% of the respondents would like to participate in further training on angling issues and are open to the learning process.

Historically and based on tradition, aquaculture, and within it pond fish farming, represents and embodies a significant part of the principles of the circular economy. A significant proportion of the fishing ponds in Hungary fall into this category - pond farming - and the findings on fish farming are therefore also applicable to these ponds in general. In addition, this sector is in an excellent position with regard to the various emission standards (emission limit values). Considering that the EU’s objective of achieving sustainable agriculture will be a mandatory requirement for agriculture, the angling and pond farming sector is at an advantage. This advantage needs to be reviewed and developed in a targeted way, based on basic information, a thorough mapping of the initial situation and a careful definition of development proposals.

The work is supported by the iFishIENCi project (European Union’s Horizon 2020 research and innovation programme under grant agreement No 818036).

PLANT-BASED DIETS SUPPLEMENTED WITH SUSTAINABLE PROTEIN SOURCES FOR ENVIRONMENTALLY FRIENDLY EUROPEAN SEABASS IN ADRIATIC SEA

Introduction

Over the last three decades, aquaculture has become the fastest growing sector of the food industry, providing one-third of the seafood consumed worldwide (FAO 2018). An upward trend in the consumption of farmed European seabass (Dicentrarchus labrax) and gilthead seabream (Sparus aurata) has led to a significant increase in their production worldwide over the past decade, and these species are now among the most important European aquaculture products (WWF, 2021). However, the farming of carnivorous fish species, such as seabass and seabream, depends on large quantities of fish meal and fish oil, as optimal sources of protein and lipids to ensure normal growth, and consequently on small pelagic fish as the basic ingredient of fish meal and fish oil. This ultimately led to additional fishing pressure on already endangered stocks of small pelagic fish and a significant increased the market prices for fish meal and fish oil (Rana et al. 2009). European aquaculture is therefore faced with the challenge of maintaining a balance between the increasing demand for fish production and the need to alleviate pressure on natural fishing grounds. One of the obstacles to the adoption of sustainable aquaculture is the lack of sustainable fish feed ingredients, whose production would be economically and environmentally sustainable while providing optimal nutrients for the farmed fish themselves itself (Aas et al. 2016; Luthada-Raswiswi et al. 2021). Recently finalized Interreg project Enhancing Innovation and Sustainability in Adriatic Aquaculture (AdriAquaNet) project, funded by the INTERREG V-A 2014-2020 Italy-Croatia program was dedicated to enhancing the innovation and sustainability of Adriatic aquaculture, through development of sustainable feed formulations. Within the project, new feeds were designed and tested at a laboratory scale on sub-adult European sea bass.

Material and methods

Two types of fish feed formulations were developed and tested, one based on vegetable protein and one based on animal protein (fish meal and fish oil): a plant protein-based diet (CV), two plant-based diets in which graded amounts of vegetable protein mixtures were replaced with Hermetia illucens meal alone (VH10) or in combination with poultry by-product meal (PBM) (VH10P30), a fishmeal diet (CF) and a fishmeal diet supplemented with H. illucens (FH10). The experiment lasted 147 days, after which the effect of the test feed formulations was evaluated by growth, muscle tissue composition, skin color, gut morphophysiology, digestive enzyme activity, and gut bacterial community composition.

Results and discussion

Fish fed VH10 and VH10P30 showed the highest specific growth rates and lowest feed conversion ratios of all groups tested. Fish fed CV diet exhibited significant degenerative changes in the proximal and distal intestine. However, PBM supplementation significantly improved all gut morphometric parameters in the VH10P30 group. Partial substitution of the vegetable mixture with insect meal alone or PBM also induced most BBM genes and stimulated the activation of BBM enzymes, suggesting a beneficial effect of H. illucens /PBM on intestinal digestive/absorption functions. Fish fed diets containing H. illucens meal also had the highest richness of bacterial communities and increased abundance of beneficial genera such as Lactobacillus and Bacillus. On the other hand, fish fed CV, although having the highest microbial diversity, lost one of the major components of fish intestinal microbiota, phylum Bacteroidetes. Skin pigmentation most similar to that of wild seabass was also observed in the group of fish fed VH10P30. Our results showed that feed formulations based on vegetable ingredients enriched with H. illucens meal, both independently and in combination with a meal derived from poultry by-products, have the potential to be an alternative feed for farmed European seabass, without affecting cellular homeostasis, growth, and overall fitness and even providing some beneficial effects. However, the results of the study also highlighted the importance of animal proteins in the diet of carnivorous species, as the addition of a small amount of insect and poultry meal to plant-based feeds significantly improved all measured parameters compared to the experimental group to which no insect and/or poultry meal was added.

Bacterial and viral infections in fish including koi herpesvirus disease and furunculosis are among serious problems of modern aquaculture. A number of substances with potentially positive effects on the fish health have been tested in order to reduce the use of chemotherapeutic agents. In recent years, attention has been focused on beta-glucans, too. These are polysaccharide derivatives of bacteria, fungi, yeasts, algae and plants that play an important role in immunomodulation, especially in the non-specific immune response. Their effects have been assessed in various fish species.

In our experiments we assessed the effects of beta-glucans in the feed on haematological, biochemical and immunological parameters of rainbow trout (Oncorhynchus mykiss) and common carp (Cyprinus carpio), as well as on the fish ability to resist infection. In common carp, beta-glucan concentration of 0.1 and 0.5 % were tested. After 7 weeks the fish including control group were challenged by Cyprinid herpesvirus 3. In rainbow trout beta-glucan concentration of 0.2; 0.5 and 1 % were tested. After 7 weeks the fish including control group were challenged by Aeromonas salmonicida. The fish were supplemented with beta-glucans for other 5 weeks. Mortality, fish behavior and feed intake were monitored throughout the whole experiment. Blood samples were taken and used for analyses of haematological, biochemical and immunological parameters. The level of lysozyme was determined from skin mucus samples.

If positive effects on fish health are confirmed, the tested food with supplement of beta-glucans could be used for preventive treatment of the fish in intensive aquaculture systems.

This study was funded by the Internal Grant Agency of the University of Veterinary Sciences Brno (project no. 216/2023/FVHE) and by project PROFISH CZ.02.1.01/0.0/0.0/16_019/0000869 (Sustainable production of healthy fish in various aquaculture systems).
MULTIFUNCTIONAL USE OF FISHPONDS: THE HUNGARIAN EXPERIENCE

Ferenc Levai\textsuperscript{1*} and Emese Bekefi\textsuperscript{2}

1. Aranyponty Fishfarm, Hungary  
levai@t-email.hu  
2. Research Center for Fisheries and Aquaculture HAKI AKI MATE, Hungary

Introduction

Pond fish farming is by far the most widespread culture method of raising finfish globally. It is also the dominant type of fish production in Hungary just like in several other Eastern European countries. However, pond fish farming - similarly to other food production sectors - faces new challenges such as need for resilience to climate change, increasingly responsible use of water and land resources, adaptation to unexpected external impacts and changing market conditions. Multifunctional use of fishponds can be a possible response to these challenges as some examples demonstrates. However further efforts are needed to explore the opportunities offered by multifunctional pond fish farming.

Structure and function of the Aranyponty Fishfarm as a pioneer in multifunctional pond fish farming

Aranyponty was one of the first aquaculture companies established after the transition of Hungary in 1989. In 1993, the family-owned business acquired the nearly 1000ha large fishpond system called Rétimajor. Besides the challenge of reconstructing an extremely neglected farming infrastructure, the owners also had to adapt to the fact, that the farm is part of the Duna-Ipoly National Park area as well as other international environmentally protected network. The biodiversity attracted by the large fishponds are unique, with special emphasis on aquatic birds, mammals, and amphibians. However, most of these animals are also competing for resources – dominantly fish – with the farmer. Since these ponds are used for production and not for feeding wildlife, a delicate balance had to be found.

The uniquely attractive landscape with its abundant wildlife created another opportunity, which is eco-tourism. In today’s extremely fast urban lifestyle, Rétimajor provides an opportunity to relax and reconnect with nature. However, most of the visitors are not looking to completely isolate themselves from civilization, therefore certain hospitality facilities were needed, including a restaurant, accommodations, and other services. These developments in turn brought along another demand by the customers, which was safe, healthy, and locally produced food products, including meats, seasonal fruits and vegetables.

Status and perspectives of multifunctional pond fish farming

Based on extensive survey in Hungary and other countries in Central and Eastern Europe and Asia, where pond aquaculture has a great importance in food fish production, it was found, that managers of pond fish farms and competent experts believe that the role of multifunctionality and diversification will increase. The development of multifunctional pond fish farming is basically driven by the stability and economic growth inherent in the diversification of activities, but it is also important to create harmony between farming and the natural environment. Although fish farmers consider the production function to be the most important, nevertheless they are well aware of the importance of ecosystem services and are ready to strengthen this function if they receive measurable financial recognition. Within the fish production function, fish farmers consider the production of healthy and safe fish products to be the most important but are aware of the importance of animal welfare and ethical functions which indicates the need to meet consumer needs at the highest possible level. Analysing the ranking within the environmental functions, it can be seen that the “conservation, maintenance and protection of natural values / resources / ecosystems, biodiversity and valuable natural habitats” was considered by farmers to be by far the most important in the “regulatory” and “landscape preservation” functions. Analysing the significance of social roles, it can be stated that fish farmers consider the dissemination of knowledge about the aquatic environment and fish to be of paramount importance, preceding even the “recreation and tourism” function, recognizing that raising interest in fish also serves their business interests.

Conclusions and recommendations

Multifunctional pond fish farming is a good development opportunity to maintain sustainable production of species low on the value chain and also the ecosystem services provided by fishponds. Operation of multifunctional pond fish farms also contribute to increasing the awareness of the benefits of pond aquaculture including the valuable contribution to the preservation of natural values and to the enrichment of biodiversity. Aranyponty Fishfarm in Hungary is an excellent example of a well-managed multifunctional pond fish farm. The farm in cooperation with research institutions is ready to collaborate with partners from countries where pond fish production dominates to develop management strategies for the better exploration of opportunities offered by the multifunctional use of fishponds.

EUROPEAN-ASIAN BUSINESS COLLABORATION IN POND FISH FARMING

Ferenc Lévai
Aranyponty Zrt.
Hungary
flevai@t-email.hu

Introduction
Freshwater pond fish farming is a dominant type of aquaculture both in Asia and in Eastern Europe. There have been several collaborations between the two regions in freshwater aquaculture development that included expert consultancies, research and development and training. Hungary has also been active in aquaculture development cooperation with Asian countries, especially with Laos and Vietnam mainly through bilateral institutional collaboration and some specific EU projects (e.g. Aqasem; Eurastip). When Hungary became EU member, new opportunities became available to strengthen economic and business collaboration financed by the Hungarian International Development Cooperation fund and also by tied aid loans provided in the frame of OECD rules. An important objective of the tied aid loan projects was to assist the business development of SMEs both in Hungary and in Laos. Thus, the main contractor of the project was the Hungarian Vitafort Agro Asia Company. The results, experiences and personal contacts gained through traditional institutional collaborations provided a good basis for business partnerships. A good example of such business cooperation is the establishment and operation of an aquaculture joint venture company in Laos, the ADC Aquatic Development Company Ltd. An old fish fingerling farm near the capital city of Vientiane in Nam Houm village was upgraded by projects financed by the Hungarian government, however Hungarian and Lao investors established a joint venture company for the long term operation of the farm.

Establishment and operation of a pond fish farm for the production of high-quality fish fingerling
ADC Aquatic Development Co. Ltd. was established in 2015 as a Lao-Hungarian joint venture company. The Hungarian parent company of ADC is Aranyponty Zrt., one of the largest private aquaculture producers in Hungary, with over 30 years of experience in freshwater fish production.

The primary activity is the production of high-quality tilapia fingerlings to supply the local fish farmers. ADC is also involved in several other activities, including the establishment of common carp breeding with Hungarian genetic background, diversification of farmed species with indigenous fish, training and education of local farmers, research and development of aquaculture production technologies.

Contribution to commercialization of aquaculture in Laos
The development of the high-quality fish seed supply has been integrated into the overall development of the fish value chain in Laos that was the objective of the aquaculture component of the Hungarian tied aid loan project between 2019-2023. The development of the fish value chain also included primary activities such as: development of grow out, feed supply, processing and marketing, and secondary activities such as training, demonstration, R&D and innovation. ADC has also been participating in the implementation of both primary and secondary activities contributing to the fulfillment of the project’s goals.

The company has been actively involved with several NGO and donor funded projects in the field of capacity-building in aquaculture. ADC was an important partner of CRS (Catholic Relief Services) and WFP (World Food Programme) in their “school lunch” programs in the Northern and Southern parts of the country, providing advisory and training services. With the support of the Hungarian Tied Aid Loan projects, ADC was assigned to provide training and development services in four provinces in the Northern part of the country, resulting in successful aquaculture businesses.

ADC is also a member of the SUN (Scaling Up Nutrition) Business Network, a UN organization aimed at improving nutrition related issues in less developed countries. In 2021 the company was awarded the “UN Best Small Business, Good Food for All” title, a competition where 50 companies were chosen worldwide to become examples of good food production practices. The same year, ADC signed a working agreement with the National University of Laos and the National Fisheries Development Center to start a public private partnership with the goal of Human Resource development and R&D activities in the field of aquaculture.

(Continued on next page)
**Conclusions and recommendations**

It is always challenging to start a business in a foreign environment, let alone one that is different in basically every aspect, culturally, politically or even climatically, just to mention a few. The most important tasks of starting a foreign aquaculture investment in a less developed country is to take the time to assess the opportunities and the business environment in the country as well as finding trustworthy local partners. We were lucky in both regards, due to the long-standing relationship between Hungary and Laos.

Despite the careful evaluation work that has been done before the investment, difficulties still had to be faced. These included the understanding of the works of local government institutions, the mindset of the local employees and the local farmers.

ADC is planning to expand its activities in the field of fish breeding by developing a country-wide network of partner nursery farms. However, this will require extensive HR development work, to ensure the same product quality throughout the country. The company continues to work in close cooperation with active local NGO’s, including FAO and WFP.
VALIDATION OF A TEMPERATURE-MATURATION MODEL FOR M. gigas IN SWEDISH WATERS: IMPLICATIONS FOR CULTIVATION AND MANAGEMENT

Introduction

The Pacific oyster, Magallana gigas, has been present along the Western Swedish coastline since 2006. However, sea-based cultivation is prohibited to prevent further growth of wild populations. Understanding the reproductive cycle of M. gigas in Sweden is the first step towards changing legislation and building management strategies for cultivated oysters. A model based on cumulative heat exposure (Mann, 1979), predicts the progression of gametogenesis in M. gigas. It postulates that surpassing a threshold temperature (t0) of 10.55˚C will initiate gametogenesis and 592-thermal degree days must be accumulated before spawning can occur. This study aims to validate this model for accurate prediction of maturation and spawning in M. gigas in Sweden.

Materials & Methods

Over 18 months, 15 wild-collected oysters were harvested every 2 weeks from a submerged culture system. Biometric data, histology, and image analysis were conducted on each oyster to classify the reproductive stage and quantify gonadal material for identification of spawning.

Results

Two consecutive reproductive cycles of M. gigas were described for the first time in Swedish waters, with two spawning events occurring in the first cycle. Gametogenesis was initiated before the previous cycle ended and continued throughout the winter. Subsequently, the threshold temperature was adjusted to represent the proliferation period when there was a significant increase in gonad fullness. Evaluation of the temperature maturation model found that using t0=10.55˚C correctly predicted full maturity after 592-degree days in both years.

Conclusion

This study provides fundamental knowledge for developing an M. gigas cultivation industry in Sweden. Predicting oyster spawning will enable strategic management such as pre-spawning removal of cultivated oysters and cultivation in suitable temperature zones. It could also inform timely collection of wild spat for hatcheries. Further in-situ validation studies are needed to refine the threshold temperature in relation to continuous gametogenesis and proliferation.

Introduction
Parasitism is a common occurrence in aquatic ecosystems, where fish often serve as hosts to a variety of parasites. Fish parasites include protozoans, worms, crustaceans, and external parasites like leeches, lice, parasitic fish that influence their hosts through complex and varying mechanisms. These parasites can reside internally or externally, deriving nutrients and protection from their hosts while exerting detrimental effects on host fish, sometimes through reduced growth, impaired reproduction, and altered immune function. Subsequently, fish parasites can have substantial negative implications for fisheries and aquaculture operations.

Understanding the sublethal effects of parasitism on fish performance is crucial. While empirical measurements at the molecular, cellular, or tissue level provide valuable information, they alone are insufficient to grasp the whole impact on individual fish performance. Parasitism is energetically demanding for hosts, and to model the energetic consequences and connect them to individual effects, the dynamic energy budget (DEB) theory is a valuable tool (Kooijman, 2010). To demonstrate the relationship between parasitism and individual processes, we present a case study involving sea lamprey parasitism on lake trout (Salvelinus namaycush), a species of concern in the Laurentian Great Lakes that is cultured for reintroduction and conservation efforts (Firkus et al., 2023).

Material and Methods
To investigate the impact of parasitism on fish growth and reproduction, we first developed a base DEB model (Figure 1) that accounts for energy allocation and dynamics throughout the fish’s life cycle, considering the energetic trade-offs influenced by their life history. This model expands upon the standard DEB model (Kooijman, 2010) and incorporates three feeding life stages (larvae, juvenile and adult), as well as metabolic accelerated development during early stages (Lika et al., 2014, Stavrakidis-Zachou, 2019). Additionally, as we focus on the effects of parasitism, a significant stressor impacting maintenance costs, our model also includes rules that account for energy utilization when available energy in the κ fraction is not sufficient to meet somatic maintenance demands.

After parameterizing the base DEB model with available data (Marques et al., 2018) for the target fish species, the next step is to identify the physiological mode of action (pMoA) and specific DEB parameter(s) through which parasitism affects the fish’s life history (Ashauer and Jager, 2018), based on empirically observed endpoints, such as alterations in length, weight, and ovarian mass. Once the relevant DEB parameter(s) is determined, it is necessary to establish a relationship, referred to as „damage,” between the stressor (parasitism) and the model parameter(s). For the sea lamprey parasitism case study on siscowet lake trout growth and reproduction, we used data from studies on the long-term effects of non-lethal sea lamprey attack. The model was parameterized to capture the observed changes in energy allocation towards growth and reproduction in parasitized lake trout. It incorporated an estradiol module to describe the conversion of reproductive reserves to ovarian mass based on estradiol concentration. In our DEB model, parasitism increased maintenance costs, reduced estradiol levels, and lowered the efficiency of converting reproductive reserves to ovarian mass. Additionally, muscle lipid composition influenced energy mobilization and reproductive efficiency.

Results
The model successfully replicated key life history characteristics specific to the siscowet lake trout ecomorph and produced model estimates that aligned well with data collected from field and laboratory studies. The proposed pMoA accurately captured the observed changes in ovarian mass and growth. The model scenarios demonstrated that parasitism led to reduced ovarian mass across muscle lipid concentrations, consistent with findings from laboratory investigations. Importantly, the model also captured how parasitism leads to skipped spawning in host lake trout.

(Continued on next page)
Conclusions
Parasitism is a complex stressor for host species, affecting multiple physiological processes simultaneously, which complicates the assessment of cumulative impacts on growth and reproduction. The DEB approach presented here offers a means to interrogate these cumulative effects, as well as interactions with other factors such as food consumption and muscle lipid concentrations. By employing this approach, we gain a comprehensive understanding of the overall parasitism-driven changes in growth and reproduction that can be used to better anticipate the effects of parasites on wild fisheries and aquaculture operations.

GENETIC VARIATION IN GROWTH BETWEEN *Seminavis robusta* STRAINS ASSESSED THROUGH CROSSBREEDING

M. Lillehammer1*, F. Pisapia2, J.L.G. Pinchetti2, P Chaerle3, and A.K. Sonesson1

Introduction
Micro algae show a large potential to become a future food and feed ingredient. They can be cultured at large scale and hence be a sustainable option to harvest oil rich wild marine species. with stable access and quality of essential fatty acids, not limited by nature (Ganuza et al., 2008). Currently, culturing microalgae is not economically competitive to other fat and protein sources (Ruiz et al., 2016). Optimization of the culturing protocol is thereby necessary, including strain selection and optimization. For micro algae that do sexual reproduction, like the diatom *Seminavis robusta*, new strains can be generated through crossbreeding of existing strains and strain selection hence be made from a broader selection. If successful, this process can be repeated each generation to form a breeding program. The aim of this study was to document whether genetic variation between existing strains is inherited to the next generation after crossbreeding.

Materials and Methods

Eight strains of *Seminavis robusta* were used, four male and four female strains, coming from three different clades, derived from analysis of the rbcL gene. Each male was crossed with each female, to produce as many novel combinations as possible, but not all crosses were successful, producing 64 cross-bred cultures, from 11 full-sib families. The parental and offspring strains were grown in 2 replicates in a 12 days growth experiment where biomass development was measured through CY5 fluorescence data on day 0, 3, 6, 9 and 12, using Cytation™ 3 plate reader and imager from BioTek. Cell-length on day 0 was measured for 30 random cells from each culture. Based on visual inspection of the parental growth curve (Fig. 1), three growth parameters were selected for analyses: growth from day 0 to day 6 (Gr06), growth from day 0 to day 9 (Gr09) and growth during the 3-day interval where this line had the highest growth (MaxGr). The growth traits were analysed with a general linear model in R, fitting replicate, cell-length (as a proxy for culture age) and whether the crossing was performed within or between clades as fixed effects together with the fixed effects of the two parents.

Results
The effects of parents were significant for all three growth parameters (p<0.01), demonstrating that genetic variation in growth between the strains exists and is passed on to the next generation when crossing the strains. Replicate and whether the cross was an inter-clade crossing was non-significant (p>0.05) for any of the studied traits. Cell length was significant for MaxGr (p<0.05), where cultures with longer cells, i.e. younger cultures, grew significantly better than cultures with shorter cells. By comparing $r^2$ from models with and without parents fitted in the model, the effect of the two parents together could explain 0.25, 0.22 and 0.32 of the total variance in Gr06, Gr09 and MaxGr, respectively, indicating heritability spanning from 0.44 to 0.65.

![Figure 1 – Growth curves for the parental lines](image-url)

(Continued on next page)
Discussion and Conclusion

This study clearly showed a heritable variation in growth between the *S. robusta* strains which was herited from parents to offspring when crossing parents. Hence, selective breeding for growth is expected to be successful. Among the growth traits explored, MaxGr gave the highest heritability, estimated to 0.65. The parental growth curves (Fig. 1) showed that the strains differed in when they reached exponential growth as well as the growth rate in the exponential phase. The fact that MaxGr has a higher heritability than Gr06 and Gr09 indicates that the achieved maximum growth rate is controlled more by genetics and less by other random factors than the time when exponential growth is reached. MaxGr is also the only growth definition significantly affected by average cell-length in the culture. Gr06 and Gr09 seem more affected by other random variables, not controlled in this study, causing larger residual variation. This study is a proof of concept that growth in microalgae may have a significant and considerable genetic component which can be utilized for strain development and optimization. Crossing of existing strains can be used to generate variation to select among when the species of interest do sexual reproduction.

EFFECTS OF POPULATION AND PHOTOPERIOD ON EARLY SPOROPHYTE GROWTH IN SUGAR KELP

M. Lillehammer1*, E. Durland1, X. Wang12, and P. James1

1 Nofima AS, Postboks 210, NO-1431 Ås, Norway
2 Akvaplan-niva, Pirsenteret, Havnegata 9, 7010 Trondheim, Norway
E-mail: marie.lillehammer@nofima.no

Introduction
Sugar Kelp (Saccharina latissima) dominates as a commercially produced seaweed species in Norway, but relatively little is known with regards to how different populations perform in standardized growing conditions. Variation for fundamental traits such as growth are of particular interest to the aquaculture industry as raw material for breeding programs to enhance. In this study, we evaluated the growth performance of young sporophytes from two geographically distant Sugar kelp populations in Bergen and Tromsø.

Materials and Methods
Wild broodstock algae were collected from two areas in Norway; 25 individuals from outside Bergen, located at the west coast, and 25 from outside Tromsø, north in Norway. The sporophytes from Bergen, which under natural conditions would have matured earlier, were collected in November and transferred to flow-through seawater tanks at Havbruksstasjonen in Tromsø for ~2 months to delay sporulation. In late December, wild Tromsø broodstock algae were collected and spores from the two populations were released at the same time, separately, producing offspring populations of the same age. Two months later, ~800 young sporophytes from each population were identified, measured and divided into 10 flow-through seawater tanks with overhead lighting. Two photoperiods were tested: 8 hour light per day and 12 hour light per day. After 7 weeks of growth under this regime, all sporophytes were imaged on a hyperspectral imaging platform from which total area and average spectral absorbance was calculated. Surface area at the end of the experiment was analysed with a linear mixed model in R, fitting population, light-regime, interaction(populationxlight) and length at the start of the growth period as fixed effect and tank as a random effect together with the random residual.

Results
All fixed effects tested in the model were significant (p<0.01). The Bergen population grew significantly better than the Tromsø population, under both light regimes (Figure 1). The effect of light regime was larger for Tromsø than for Bergen. Initial length at start of the experiment also differed between populations. The Tromsø population showed reduced growth also in the very early stage and produced fewer sporophytes than the Bergen population. Spectral analyses reveal that the mean absorbance of sporophytes from each population were significantly different from one another at light wavelengths from ~450-675nm, even after accounting for differences in size (Figure 2).

Discussion and Conclusion
These results demonstrate that sugar kelp from different regions of Norway display different phenotypic traits when grown under the same conditions. This may be a consequence of genetic differences between macroalgae collected from different Norwegian regions, although it could also be a result of poor viability of the Tromsø sporophytes, shown by fewer and smaller offspring produced from the same number of parents. However, significant growth of both populations under both light regimes shows both offspring populations were viable with growth potential, supporting the hypothesis that the differences between the populations are genetic.

The growing season for sugar kelp in Norway is during winter and spring but the bulk of growth takes place during the latter half of this period when day length increases. The high latitudes of Northern Norway experience more variation in day length than coastal environments in the West. Even though we tested early sporophyte growth in this study, the results show that population from the northern region were already at this stage more sensitive to photoperiod, which could be a sign of adaptation to different regions in Norway. The distinct patterns of spectral absorbance of the two populations support this theory: suggesting chemical compositions to be affected from origin even when grown in the same environment.

Introduction
In recirculating aquaculture systems (RAS), off-flavors can accumulate in fish muscle tissue. Dozens of compounds have been identified, including alcohols, aldehydes, and terpenes. They affect the perceived sensory properties in fish and cause earthy, musty or other unwanted flavor to fish flesh. Off-flavors are problematic for consumer acceptance and the reputation of farmed fish products. Accumulated off-flavors are typically removed from the fish flesh by depurating the fish in clean water before sale.

This study aimed to follow the change in sensory quality attributes of rainbow trout during the depuration period and compare the results with the content of off-flavor compounds. We hypothesized that a group of trained sensory panelists could recognize and describe the off-flavors and the change in their intensities during the depuration.

Materials and methods
Rainbow trout (Oncorhynchus mykiss) was reared in a pilot-scale RAS as reported by Pulkkinen et al. (2021). Fish were reared for 3 months in RAS until they were on average 1.89 kg (tank density of 46 kg m\(^{-3}\)). Selected fish were transferred to the depuration (flow-through in clean water, feed withheld) which continued for 16 days.

Samples were taken directly from the rearing tank in RAS (D0) and during depuration after 4 days (D4), 8 days (D8), 12 days (D12), and after 16 days (D16). Additionally, selected fish individuals were depurated for 26 days and used as a reference (REF). These individuals and were considered to represent fully depurated fish without any off-flavors from the RAS.

The fish were humanely euthanized, instantly gutted, fileted, and carefully washed to ensure high quality for sensory evaluation (ISO-8589:1988). The fish were cooked sous vide at 55°C for 25 min prior to the sensory analysis. The sensory properties of the samples were analyzed using a generic descriptive method. A group of panelists was specifically trained in analyzing rainbow trout samples. The panelists evaluated the fish with a sensory profile of 29 sensory attributes (12 odor, 5 taste, and 12 flavor properties).

For chemical analysis, 14 selected off-flavors compounds were analyzed with a validated method based on automated SPME and GC-MS/MS. The off-flavor compounds were quantified using the method reported in Lindholm-Lehto (2022).

Results and discussion
All the detected concentrations decreased during the depuration. For most of the compounds, the concentrations decreased to below the LODs. Before the depuration (D0), the highest concentrations were found for GSM (950 ng kg\(^{-1}\)), MIB (1 600 ng kg\(^{-1}\)), and octanal (600 ng kg\(^{-1}\)), while the concentrations of other off-flavor compounds remained below 250 ng kg\(^{-1}\). D0 differed significantly from the other samples in fish-like, mud-like, and in total intensity of odor and flavor.

During depuration, the concentrations of some of the compounds decreased to below the level of detection (LOD), while the others (acetoin, hexanal, octanal, octanoic acid, phenyl acetaldehyde, and vanillin) remained at a certain low level. Even after 26 days (REF), no further decrease in concentrations was observed.

The intensities of mud-like, earthy, and musty odor and flavor already began to decrease in the early stages of depuration but decreased to low intensities between days 8 and 12 of depuration at the latest (Figure 1). However, the certain flavors seemed to slightly increase between D16 and REF. Many off-flavor compounds are lipophilic and accumulate in the lipid tissue of fish. The lipid content of fish affects the perception of these off-flavor compounds by increasing the sensory threshold values. As the lipid content of fish decreased during the depuration due to withheld feeding, the intensities of the compounds can increase. However, no statistically significant differences were detected.

(Continued on next page)
This study showed the consistency between sensory observations and chemical analyses. Intense earthy, mud-like, and musty odors and flavors were observed. However, not all the odors and flavors induced by the studied compounds were observed by the panelists, possibly due to the masking of other compounds or higher sensory threshold limits than the concentrations in the samples.

This study gives important information about the effect of the depuration period in RAS on the chemical and sensorial quality of rainbow trout. Fish producers could benefit from using chemical and sensory analyses more extensively for the evaluation of off-flavors and sufficient depuration time.

Introduction
The efficient management of feed intake plays a vital role in the successful and sustainable aquaculture production. Feed is the main input and constitutes the primary fraction of production costs, which can exceed 50% of the total production cost (Buentello et al., 1999; Iversen et al., 2020). This fact highlights the importance of developing tools to support the definition of better feeding management practices, aiming to contribute to improved economic performance and precision farming. In particular for species, like meagre, for which not much information on feeding and nutrition is yet available.

Feed intake is a complex behavioral process, regulated at different levels, and affected by both physiological and environmental factors. With the use of feed intake models to support feeding operations at the farm it is possible to optimize feeding strategies and avoid overfeeding or underfeeding. In order to evaluate and quantify the effects of nutritional and environmental factors (such as oxygen levels) on feed intake, it is important to characterize the effect of central factors (such as fish size and water temperature) through the development of feed intake reference models.

In this work, we develop reference feed intake models for meagre to support the characterization of the effects of some key environmental and nutritional factors on feed intake and the development of more advanced models of meagre feed intake.

Material and methods
To develop the reference models, data from commercial feeding tables and growth trials from scientific publications was collected and processed. In total, 54 commercial feeding tables and 55 scientific publications were collected and the information therein extracted (name, recommended feeding rates according to fish body weight, feeding rate or FCR values, and water temperature, feed nutritional composition,) for downstream analysis.

Using the data collected, mathematical models were developed using the general model (equation 1):

\[ F_i(BW, temperature) \approx a \times f(BW) \times g(temperature) \]  

(1)

Assuming that the effect of body weight on the feed intake of fish follows a specific power law, while the effect of temperature follows an exponentiated quadratic relationship, the following specific form is obtained (equation 2):

\[ F_i(BW, temperature) \approx a \times BW^{2/3} \times \exp(b \times temperature + c \times temperature^2) \]

(2)

Taking the logarithm on both sides and applying a mixed-effects modelling function (to account for possible different values of “a” in each data source), the unknown coefficients are estimated to obtain a reference model.

(Continued on next page)
Results

![Predicted vs. Measured FI (log-log scale)](image)

**Figure 1** – Scatter plot showing estimated feed intake (g/fish/day) values as a function of measured feed intake (g/fish/day). Black points represent independent feed intake information from the growth trials reported in the scientific publications collected. Testing of the developed reference models against independent data (see example in Figure 1) suggests a good prediction of measured feed intake data ($R^2 = 0.77$). Preliminary analyses using feed intake data normalized using the reference model illustrated in Figure 1 indicate that the levels of gross energy and fiber in meagre diets have an impact on feed intake.

Discussion and Conclusion

Temperature and body weight play crucial role in determining the feed intake of meagre, since a simple reference model using these factors explains most of observed variance. The validation of the reference model for feed intake represents a significant achievement, since it can be used to support the investigation of different variables that affect the feed intake (e.g., nutritional factors, oxygen levels).

Introduction
In recent times, sustainable farming has evolved with the rise of soilless plant cultivation techniques, particularly aeroponics, where plants grow suspended in the air with nutrient-enriched aerosol sprays, ensuring consistent growth conditions. Notably, aeroponics offers faster growth and superior nutrient uptake than traditional hydroponic systems while minimizing water, fertilizer, and pesticide usage (4). The nutrient composition, mainly ionic forms like NH4+ and NO3-, critically affects plant growth and quality (6-8). Though nutrient deficiencies are known to hinder yield and bioactive compound content, comprehensive research on the effect of deprivation of essential ions in soilless systems is still wanting. While aeroponics often employs hydroponic nutrient solutions, the potential of aquaponic solutions, where fish, bacteria, and plants symbiotically interact, has seen limited exploration. Although balancing aquaponic systems presents challenges, especially with specific mineral deficiencies, they can still match hydroponic system yields, possibly due to beneficial microbial interactions (22). The study delves into comparing aquaponic solutions with hydroponics in aeroponic settings, focusing on growth and nutritional content, aiming to enrich discussions on nutrient management in sustainable soilless farming.

Materials and methods
Lettuce (Lactuca sativa L.) seeds were germinated and transplanted into an aeroponic growing system. Two different nutrient solutions were used: a conventional hydroponic solution (HS) and an aquaponic solution (AS) derived from external fish farming systems. Both systems were maintained under the same controlled conditions (e.g., light period, humidity, and temperature), enabling the comparison of growth parameters, leaf area, antioxidant activity, mineral content, and sensory characteristics of the lettuce.

Results
Lactuca sativa L. grew differently in hydroponic (HS) and aquaponic (AS) systems. HS exhibited significantly higher fresh weight of lettuce heads, fresh weight of roots, and number of leaves compared to AS. However, the AS system outperformed HS regarding the dry matter content of lettuce heads and root-to-shoot ratio. There was a marked increase in leaf area in HS compared to AS, with the difference peaking at later stages of cultivation. Water quality assessment showed elevated NO3- levels in HS, almost 15 times higher than in AS, while AS dominated in Cl and Na concentrations. Elemental analysis showed that HS generally contained higher concentrations of several elements, such as P and K, with a few exceptions, such as Mg, Na, Cl, and S. AS outperformed HS regarding total flavonoids and phenolics and showed significantly higher antioxidant activity with an ORAC value of 2.6 times higher and DPPH radical scavenging activity 2.4 times higher than HS, both in terms of dry weight. While both systems showed comparable vitamin C content, HS showed significantly higher vitamin B2 concentration. Analysis of the mineral content of lettuce leaves revealed significant differences between the systems, with lettuce grown in HS containing significantly more P and K, whereas lettuce grown in AS contained significantly more Na, Mg, and nearly three times the amount of Si. Organic acid and anion evaluations showed a different profile, with AS being higher in tartrate and citrate and elements such as Cl-, SO42-, while HS showed elevated NO3- and PO43- content. Sensory analysis showed that, except overall acceptability, the two systems had no significant differences in flavor characteristics. The majority favored the HS lettuce mainly for its aesthetic appearance and size.

(Continued on next page)
Conclusion

This study underscores the aquaponic system’s potential in sustainable agriculture. While the aquaponic system (AS) demonstrated a lower nutrient composition than the hydroponic system (HS), it exhibited resilience with sustainable yields. Despite its lower nitrogen content, AS effectively produced satisfactory lettuce yields without traditional fertilizers, emphasizing resource efficiency. Notably, lettuce grown in AS showed heightened flavonoids, phenolic compounds, and antioxidant activity, possibly due to increased salinity and nutrient scarcity. Elevated silicon content in AS lettuce indicates a potential role in boosting antioxidant activity, warranting further exploration. Despite yield constraints, AS showcases resource efficiency and potential nutritional enhancements, underscoring the need for continued aquaponic research.

Cardiomyopathy syndrome (CMS) is a severe cardiac disease occurring in the grow-out sea phase of farmed Atlantic salmon with approximately 100 outbreaks annually in Norway. Piscine myocarditis virus (PMCV) is believed to be the causative agent of CMS. There is no vaccine available to control CMS, partially because PMCV withstands propagation in known cell cultures. In the present study, we selected the putative capsid protein of PMCV as the candidate antigen for immunization experiments and produced it in the plant Nicotiana benthamiana by transient expression. The recombinant PMCV antigen formed virus-like particles (VLPs). To evaluate the efficacy of the plant made VLP vaccine, a PMCV infection model was established. In an experimental salmon vaccination trial, the VLP vaccine triggered innate immunity, and indicative but not significant inhibition of viral replication in heart, spleen and kidney tissues was observed. Similarly, a reduction of inflammatory lesions in cardiomyocytes and subendocardial infiltration by mononuclear leukocytes were observed. Therefore, there was no difference in efficacy or immune response observed post the plant made PMCV VLP antigen vaccination. Taken together, this study has demonstrated that plant made VLP antigens should be investigated further as a possible platform for the development of PMCV antigens for a CMS vaccine.
CHARACTERISATION, DEVELOPMENT AND ECONOMIC BENEFIT OF VARICON AQUA’S CELL-HI NUTRIENT PRODUCT LINE

The Cell-Hi All-In-One product range is the only complete, free-flowing, dry and fully soluble algae nutrient blend available on the market. The products incorporate a balance of all essential, macro and micro nutrients coupled with vitamins. Each of the Cell-Hi products is based on industry-standard formulations from literature and culture collections. The product is widely used in academic settings, as well as aquaculture and production facilities worldwide. There are over 24 peer-reviewed academic journal articles in which the Cell-Hi product range is referenced [1].

We estimate between 2-5% [2] of OPEX costs associated with microalgal production at typical hatcheries as being attributable to the costs associated with making media for algae cultivation. To prove the efficacy of the Cell-Hi range, we benchmarked the biological and economic performance of the product line against commercially available alternatives. Experiments were undertaken in a Varicon Aqua (CTC) controlled temperature chamber using 250 ml conical flasks aerated with 1% CO₂, and surface illumination of 150 µmol m² s⁻¹ achieved with red/blue/white (400-760 nm) LEDs. The temperature conditions were fixed at specific temperatures depending on the trial strain 25°C ± 1°C for Nannochloropsis spp. and 20°C ± 1°C for Tetraselmis suecica.

Our results showed that Nannochloropsis spp. grown on Cell-Hi F2P had identical performance to laboratory-made or commercially supplied nutrient (no significant statistical difference, average productivity of 0.15 g L⁻¹ d⁻¹ and final yield of 1.1 g L⁻¹ over a 7-day batch). Similarly, no significant differences were observed in growth rates between T. suecica grown on Cell-Hi-WP and laboratory-made equivalents (average productivity 0.25 g L⁻¹ d⁻¹ and a final yield of 1.7 g L⁻¹ over a 7-day batch).

Furthermore, techno-economic evaluation demonstrated 60% cost savings per kg of nutrient used within a hatchery when substituting conventional media protocols with Cell-Hi products. We have shown that our Cell-Hi range is comparable in biological performance and superior in economic performance to many conventional alternatives (both pre-formulated and formulated from analytical grade chemicals). These findings provide a compelling argument for making the switch to Cell-Hi All-In-One within commercial hatchery operations.

PREDICTABILITY OF LATENCY TIME USING THE IN VITRO OOCYTE MATURATION IN PIKEPERCH (Sander lucioperca)

*aHungarian University of Agriculture and Life Sciences, Institute of Aquaculture and Environmental Safety, Research Centre for Aquaculture and Fisheries, Anna-Liget Str. 35, H-5540 Szarvas, Hungary

E-mail: u.ljubobratovic@gmail.com

Introduction
The main problem of artificial reproduction of pikeperch presents the unpredictability of the latency time (LT) (Żarski, et al., 2019). Therefore, a special final oocyte maturation (FOM) classification was developed in order to tackle this (Żarski et al., 2012). Although useful, this procedure still requires frequent handling especially in cases of out-of-season reproduction when the fish are commonly hormonally stimulated in the first stage of FOM. A recent paper showed high agreements in the post-stimulation maturation dynamics in pikeperch between in vivo and in vitro oocyte maturation (Ljubobratović et al., 2023). Therefore, using the in vitro maturation (IVM) technique, we are aiming at developing a method that predicts the individual latency time and thus minimizing the number of handling procedures that require the biopsy of oocytes.

Materials and methods
In early November 2022, during out-of-season pikeperch reproduction, in total 13 females were hormonally stimulated with salmon gonadoliberin analog using the warming thermal regime (Ljubobratović et al., 2021). At the time of ovulation, a sample of oocytes was taken from each female using a catheter (CH06 infant feeding tube). Immediately upon biopsy, the oocytes of each female were stocked in separate wells of 6-wells cell culture plates. Each well was filled with 90% L15 medium and 5 IU/mL of human chorionic gonadotropin. Wells were further placed onto an orbital shaker and incubated at 13°C for in total 96h. Starting from 48 h post-stimulation, IVM of oocytes were monitored each 4 h, while the same procedure in females was started 120 h post-stimulation and was performed each 24 h. On this way, FOM dynamics and both in vivo and in vitro latency times were assessed and correlated.

Results
All injected females ovulated, while all the IVM oocytes samples reached germinal vesicle breakdown (GVBD). The LT in females ranged from 6 to 9 days, while in vitro oocytes took 56 to 76 h to GVBD. The strongest correlation between the LT and IVM was found in 52 and 56 h post-stimulation, showing higher correlation compared to the in vitro LT.

Discussion
The IVM techniques appear to be a promising tool for estimation of optimal female state for hormonal induction as well as the prediction of the latency time in out-of-season pikeperch reproduction. Rather than using the time until GVBD during the IVM, a given FOM stage at a certain time post-stimulation might be more useful to predict the state of female readiness for ovulation induction as well as the prediction of its LT.

Introduction
The rapid expansion of the aquaculture industry has brought about a heightened focus on the waste produced by high intensity fish farming. In closed-containment, recirculating aquaculture systems (RAS), fish solids are mechanically separated and/or coagulated before being disposed as waste. Subsequent revalorization is typically limited to the direct dispersal of aquaculture solids onto agricultural fields.

Here, we developed a novel, continuous flow, low-cost solids waste treatment system for freshwater and saline RAS. Rotating drum filter backwash was collected as the primary feedstock for anaerobic digestion. A laboratory scale set up was used to monitor the conversion of the solids into a methane-rich (60-80% purity) biogas stream. Iron supplementation (ferric iron at 100 mg/L and 1000 mg/L) improved salt tolerance of the methanogenic community, leading to higher methane yields in a supplemented (FeCl 3 at 1000 mg/L) saline treatment than the saline control. The application of iron additionally improves pH stability and volatile fatty acid utilization. The methane yield ranged from 0.1-0.4 NL CH 4 / g VS across the three freshwater treatments and the iron-supplemented saline treatment, however, it was significantly lower for the saltwater control: ranging between 0.08-0.25 NL CH 4 / g VS. These values correspond to a percentage yield of 57% - 86% of the total biomethane potential.

Overall, implementing anaerobic digestion for RAS waste valorization may generate significant amounts of biomethane to be used in electricity and heating for large-scale aquaculture facilities, while even for smaller facilities it may off-set costs and mitigate environmental impacts of the waste streams.

Introduction
Recently, several products have emerged on the market as new sustainable fish feed ingredients with presumable health promoting effects. One such product is Coryne Pro (Agrifeed), a single cell protein (SCP) of bacterial nature as by-product from fermentation of *Corynebacterium glutamicum* for industrial production of threonine. Coryne Pro has a high protein level (~70%) and is described to constitute a good protein source for growth, as well as having beneficial health effects. While in vivo trials are the best way to evaluate new ingredients, it would be helpful to develop complementary in vitro methods to reduce the number of animals involved according to 3R principles. The H2020-FETOPEN project Fish-AI, aims to develop such a platform but it requires an experimental set-up that facilitates the in vivo vs. in vitro correlation. To this purpose, as part of this project, we tested Coryne Pro at two different inclusion levels in the feed for rainbow trout and compared it to three reference feeds: one presumably healthy fish meal-based feed, one challenging feed with high soybean meal content and one feed with high inclusion of feather meal with presumable low protein digestibility value. Rainbow trout were fed the five different feeds for nine weeks, and growth performance, organ indices, histology, gene expression, blood values as well as digestive enzyme levels were investigated.

Material and methods
Rainbow trout (~160 g) were fed five different diets; fish meal diet (FM), soybean meal diet (SBM), feather meal diet (FTHM) or diets containing single cell protein at 10% and 20% inclusion levels (SCP-10 and SCP-20, respectively) (Table 1). Feeds were produced by extrusion with pellet size 2mm, and yttrium was added to calculate nutrient digestibility. Macro and micronutrient content were adjusted to meet the NRC standards when formulating the feeds and kept constant in protein and lipid level.

The feeding trial was run at Skretting Aquaculture Innovation’s research facility in Mozzecane, Italy. Rainbow trout were randomly distributed in 0.6 m³ tanks, 35 fish per tank and three replicate tanks per diet. The feeding regime was two meals per day with overfeeding. Fish were held at 15°C water temperature and 24-hours light regime. After 9 weeks of feeding, 6 fish per tank were randomly sampled and euthanized with an overdose of MS-222. Weight, length and organ indices were recorded from individual fish. Blood samples were collected in heparinized syringes from the caudal vein and analyzed for plasma indicators of nutrient metabolism. The intestinal tract (posterior to the stomach) was dissected from the same fish, and divided into pyloric intestine, mid intestine and distal intestine. The intestinal sections were opened longitudinally, and intestinal content collected for analyses of bile salt and trypsin activity. Tissue samples were fixed in formalin for histology, RNA later for gene expression and snap frozen in liquid nitrogen for enzyme analyses. Fecal samples were pooled by tank.

Results and discussion
The SCP diets performed equal to the fish meal diet concerning fish growth, feed intake, and feed conversion ratio, indicating that the SCP may partially replace fish meal as a protein source in diets for rainbow trout. Results indicated however some immune stimulation from the SCP diets by slightly higher numbers of mucosal immune cells in the distal intestine and elevated levels of certain immune genes. Increased levels of liver enzymes in the blood from SCP were moreover observed, although large variation within the groups requires further analyses to conclude. As expected, the SBM diet induced intestinal inflammation in the distal portion of the rainbow trout gut evidenced by infiltration of inflammatory cells in the gut mucosa, reduced intestinal fold height, loss of supranuclear vacuoles, as well as reduced expression of functional brush border genes and reduced organ indices. Further, results indicated that the FTHM diet had a lower protein digestibility compared to fish meal, as feed intake and final body weight were significantly higher in this diet group, although there was no difference in feed conversion ratio. Also, increased organ indices of the pyloric intestine was observed in this diet group possibly from lipid accumulation as known from choline deficiency in salmon.

(Continued on next page)
Conclusions
The SCP diets performed equal to the fish meal diet concerning growth and organ indices. Gene expression results indicated however slight immune stimulation from the SCP. Results confirmed intestinal inflammation in the distal intestinal region from the SBM diet and indications of sub-optimal digestibility from the FTHM diet. The experimental set-up used in the current study with three contrasting reference diets with known characteristics, was thus successful for testing of new feed ingredients and will provide a clear reference for testing the predictive ability of the in vitro platform that is under development by the Fish-AI consortium.

raul.lopez@inia.csic.es

Introduction
The most important marine fish species farmed in the Mediterranean are European seabass (Dicentrarchus labrax) and gilthead seabream (Sparus aurata) and for both species, selective breeding programmes have been initiated in recent years. In these programmes, the control of inbreeding is crucial to achieve sustainable production. Monitoring inbreeding is also important when dealing with wild populations.

Recently, a combined ~60K SNP array for both species has been developed (Peñaloza et al. 2021). The use of this tool (the MedFish SNP array) allows to obtain more accurate estimates of inbreeding coefficients than those obtained using pedigree information and also enables the evaluation of inbreeding patterns across the genome. Villanueva et al. (2022) compared inbreeding of wild and farmed populations for both species using the aforementioned array but their analysis was limited to average genome values. This study aims to compare patterns of inbreeding throughout the genome of wild (W) and farmed (F) populations for European seabass and gilthead seabream.

Material and Methods
Samples of both species were the same as those used for the SNP array development and were collected from W and F populations located from East to West Mediterranean. Three Atlantic populations of seabream were also sampled. For seabream, SNP genotypes were available for 462 fish from 14 W and 12 F populations. For seabass, SNP genotypes were available for 516 fish from 9 W and 15 F populations. After quality control, the total number of SNPs was 24,548 and 21,797 for seabream and seabass, respectively.

The proportion of genome-wide homozygosity and the molecular inbreeding coefficient were obtained using the software PLINK (Purcell et al., 2007) and an R script. The measure of molecular inbreeding (F_{mol}) used was that based on deviations from Hardy-Weinberg proportions (Li and Horvitz, 1953). Patterns of genomic homozygosity and inbreeding were calculated using a sliding window approach. For both species, the length of the windows was ~ 1 Mb and they were moved one SNP at a time. For each window, homozygosity and inbreeding were estimated by averaging the values for all SNPs lying in that window. Afterwards, values were averaged across individuals.

Results
For seabream, patterns of observed homozygosity were very similar across the genome in both W and F populations (Fig. 1). Also, differences between W and F populations were negligible. Values for homozygosity ranged from 0.485 to 0.725. In general, seabass populations showed higher variation among them than seabream populations. In fact, some distinct patterns were observed in seabass populations (Fig. 1). For instance, the Moroccan wild population (purple line in Fig. 1C) showed high peaks of inbreeding across the genome while one of the Greek farmed populations, exhibited lower levels of homozygosity (green line in Fig. 1D). Values for homozygosity ranged from 0.415 to 0.880. Values for F_{mol} ranged from -0.386 to 0.193 in seabream and from -0.463 to 0.366 in seabass. Negative values appear because current population frequencies were used when computing F_{mol} and then its values are centered around zero.

Discussion
This study shows that differences between W and F populations in terms of inbreeding are small in both species. Results are in agreement with previous population structure results where W seabream populations showed lower levels of differentiation than W seabass populations and where the Moroccan seabass population presented a higher genetic differentiation when compared to other populations (Villanueva et al. 2022). Here, the measures used to evaluate inbreeding have been the observed homozygosity and F_{mol}. Many other measures have been proposed, but they can lead to inconsistent results in terms of loss or gain of genetic variability (Villanueva et al. 2021). In conclusion, in most cases the selection pressure exerted on farmed populations for a number of generations (7-8 for the older breeding programmes) did not drastically increase homozygosity.

Introduction
Genetic selection has played a crucial role in the success of agriculture and animal husbandry, driving the systematic adaptation of the evolution of domesticated plants and animals to the societal demands. In recent decades, industrialization of the agri-food industry has opened up new possibilities for the creation of completely new products. In this paper, we describe the non-profit organization (cluster) of 35 French breeding companies selecting 31 poultry, aquaculture or insect species and compare it to other models of industrial organization of business groups and companies in which genetic selection has been integrated.

Methods
The data were acquired from SYSAAF’s historical records since 1952, and the model was described owing to collaborative effort with the aquaculture department’s management and surveys conducted with the leaders of the enterprises and departments.

Results
Our results show that the non-profit and collective nature of SYSAAF is adapted to invest in R&D projects in sharing results within or between species and companies. Its interactions with INRAE and Ifremer or ANSES and the French ministry of agriculture is insuring management the national genetic resources and their improvement in stimulating multiple innovative processes and transfer and implementations of results.

One of the main advantages of this style of organization is that it allows small companies to access high-value technologies (as genomic selection or GWAS assisted selection), shared computational capacities and expertise (23 geneticists) while reducing their individual costs Teece, D. J. (2010).

Conclusions
Overall, this paper sheds light on the feasibility to develop collective and shared knowhow in genetic selection, a unique economical Model adapted for the domestication of new species and the support of SME’s. We believe that the SYSAAF organization serves as an excellent example of how a public and collective model can benefit both large and small companies in the industry to ease implementation of innovations.

THE EFFECT OF FEEDING WITH THE COPEPOD *Acartia tonsa* DURING THE FIRST DAYS OF LARVAL REARING ON THE ONTOGENY OF THE INTESTINE AND LIVER IN GREATER AMBERJACK (*Seriola dumerili*) AND GILthead SEA BREAM (*Sparus aurata*)

Introduction
Ontogenesis is a process of growth, differentiation and maturation of cells, tissues, organs, and systems (Chambers and Leggett, 1987), where fish larvae undergo dramatic changes in body shape, swimming ability, metabolism and behavior. Nutrition is one of the most important factors influencing the ontogeny of the organs in the digestive tract (Chambers and Leggett 1987). Copepods have the advantage that the fatty acids docosahexaenoic acid (DHA) and eicosapentaenoic acid (EPA), are found in the phospholipids of cell membranes. Copepods do not need enrichment like rotifers and *Artemia* metanauplii and so their use does not increase the problem with the oily surface of the rearing tanks (Conceição et al. 2010). In addition, copepods are very rich in free amino acids, which stimulate the sense of smell of fish larvae and enhance feeding behavior and food search in the tank (Rønnestad et al. 2013).

Materials & Methods
In a marine hatchery (Galaxidi Marine Farms A/S), four cylindroconical tanks of 2,700 L were stocked with 150,000 greater amberjack larvae (*Seriola dumerili*) in each, which were reared until 45 days post-hatching (dph). The larvae were initially fed from 3-17 dph in two tanks with copepod nauplii and rotifers (*Brachionus* sp.) (Copepods group), while in the other two tanks, the larvae were fed only with rotifers (Control group). All the tanks were fed with rotifers (3-27 dph), Artemia nauplii (12-22 dph), enriched Artemia metanauplii (20-30 dph), and formulated diet (25-45 dph).

A second experiment with gilthead seabream was carried out at the facilities of the Department of Biology at the University of Patras. Six cylindroconical tanks (three tanks – Control and three tanks – Copepods group) were stocked with 10,000 seabream eggs (*Sparus aurata*) in 100 L tanks and these were reared until 25 dph. The feeding protocol was similar to the greater amberjack experiment with the only difference being that the Copepods group fed with *Acartia tonsa* nauplii days 3 to 14 after hatching. In both experiments, samples were taken every three days anaesthetized and transferred to a fixative (4% formaldehyde solution). Fixed samples were rinsed in distilled water, dehydrated in graded ethanol 70, 80 and 100% and then embedded in methacrylate resin (Technovit 7100 Heraeus Kulzer, Germany). Serial sections of 5 mm were obtained with a microtome (Leica SM200R, Germany), stained according to Bennett et al. (1976) and observed through a light microscope. The factors that we choose to study to determine the effect of the copepods in the ontogeny of the intestine and the liver were the length of the villi, the abundance of goblet cells (intestine), and the percentage of area covered with lipid vacuoles - ACLV (liver).

**Fig. 1a**: Intestine of *S. aurata* 25 dph. Black squares indicate the goblet cells. **1b**: Liver of *S. dumerili* 36 dph Black squares indicate the lipid vacuoles (Scale 100 μm).

(Continued on next page)
Results
Villi and goblet cells in the intestine of *Sparus aurata* 25 dph are shown in Figure 1a and in ACLV in the liver of *Seriola dumerili* juveniles 36 dph are shown in Figure 1b.

The use of copepods during the first days of rearing affected positively the intestine and the liver in both the species, *S. dumerili* and *S. aurata*. More specifically, the length of the villi and the abundance of the goblet cells in the intestine were greater in the Copepods group throughout the whole rearing of both species with statistically significant differences in several days after hatching (p<0.05). Moreover, it seems that the percentage of ACLV in the liver was also greater in the Copepods group throughout both experiments, with statistically significant differences during the copepod feeding period (p<0.05).

Conclusions
In conclusion, the use of copepods in the rearing of both species, *Seriola dumerili* and *Sparus aurata* affected positively the ontogeny and development of the intestine (length of the villi and abundance of goblet cells) as well as the lipid accumulation in the liver.

Introduction
The aim of this study was to assess the health status of the farmed fish gilthead (*S. aurata*) and seabass (*D. labrax*) at ANDROMEDA AS facilities in Vóntasa, Greece by histological examination and evaluation of tissues from fish sampled from RAS. In addition, we made surveillance of protozoans encountered in various parts of the rearing system as well as in the intestine of the fish.

Materials and Methods
Five fish for each species (seabream 102 dph and seabass 142 dph) were sampled, anaesthetized, dissected, and pieces of isolated tissues (gills, intestine, liver, and spleen) were transferred to fixative (4% formaldehyde solution). Fixed tissue samples were rinsed in distilled water, dehydrated in graded ethanol 70, 80 and 100% and thereafter embedded in methacrylate resin (Technovit 7100, Heraeus Kulzer, Germany). Serial sections of 5 mm were obtained with a microtome (Leica SM200R, Germany), stained according to Bennett et al. (1976) and observed through a light microscope. To evaluate the pathology of the tissues we applied a scoring system (Multiparametric Semi-quantitative Scoring System – MSSS, scoring range 1-5) for some descriptors (Table 1). The scoring system MSSS was a modification of Pacorig et al. (2022).

For the surveillance of protozoans, eight samples were taken for both species seabream and seabass which consisted of Tank water (TW), Tank biofilm (TB), Biofilter biofilm (BB) and Intestine (GUT) samples. For these samples DNA isolation was done using the ZymoBIOMICS DNA Miniprep Kit, followed by 18S rRNA gene amplicon library preparation and Illumina MiSeq sequencing.

Results
The histological evaluation showed that gilthead seabream was in a better health state compared with seabass indicated by a lower incidence of oedema in the gills (Fig. 1a), a higher abundance of goblet cells in the intestine (Fig. 1b), and a lower incidence of steatosis (Fig. 1c) and necrosis (Fig. 1d) in the liver. On the other hand, melanomacrophage centers, multifocal exudates (Fig. 1e), and necrotic areas (Fig. 1f) in the spleen were more abundant in gilthead seabream.

Five genera of protozoans were identified based on the 18S rRNA amplicon sequences: *Pseudovorticella*, *Zoothamnopsis*, *Zoothamnium*, *Dysteria* and *Acineta*. The highest relative abundance of protozoans was recorded in the tank biofilm dominated by members of the *Zoothamnopsis* in seabream tanks and *Zoothamnium* in seabass tanks (Fig. 2).

Conclusions
1. Based on the histological analysis, seabream showed a better health state compared with seabass.
2. Abundances of protozoa in the rearing systems of the two fish species showed a different pattern.

Introduction
Maternal provisioning and nutritional level can have a significant impact on the reproductive performance and offspring quality of marine invertebrates. In sea urchins, the energy for embryo and larval development up to the onset of feeding is primarily driven by nutrients acquired from the egg (Carboni et al., 2013). The high mortality rates occurring during larval development remain a major bottleneck to the full-cycle production of sea urchin aquaculture. The provision of broodstock feeds with key ingredients could help to improve offspring development. Carotenoids, especially b-carotene, are known to improve gonad growth, fecundity, and larval survival. While lipids and fatty acids, particularly the absolute levels of polyunsaturated fatty acids (LC-PUFAs) such as docosahexaenoic (DHA, C22:6n-3), eicosapentaenoic (EPA, C20:5n-3) and arachidonic (ARA, C20:4n-6) have been proven to be critical factors in regulating the reproductive performance, egg, and larval performance. The present study aimed to evaluate the growth and offspring performance of the sea urchin Paracentrotus lividus (Lamarck, 1816), after conditioning broodstock on different feeding diets.

Materials and Methods
P. lividus broodstock was acclimated and maintained in recirculating aquaculture systems (RAS) and starved for one month before conditioning to the experimental diets. The individuals were conditioned for two months on five different jellified diets consisting of different proportions of carotenoids (High and low content - HC and LC) and lipids (Fish oil – FO, and Colza oil - CO) as the main ingredients, and seaweed-based diet (Saccorhiza polyschides). By the end of the feeding experiment, the maturity level of both males and females was assessed and compared with a wild group. Spawning was chemically induced in both sexes and eggs from each broodstock diet were collected for measurements. The larval rearing experiment was carried out in 600 mL glass flasks (in triplicate) and maintained in a climate chamber. Larvae were stocked at a density of 4 ind.mL⁻¹, kept at a salinity of 35, an average temperature of 18 °C, continuous fluorescent light (12.62 µE.m⁻².s⁻¹), and reared in aerated static seawater. Larvae were fed with a mixed microalgal diet (Chaetoceros calcitrans and Tysochrysis lutea) during their exponential growth phase. Additionally, a group of larvae were left unfed to assess the effects of, exclusively, egg maternal reserves. Larval body length (BL), body width (BW), and stomach length (SL) were measured to characterize the larval growth and morphology. Larval competence was defined as the number of days post-fertilization (DPF) required for at least 75% of the larvae to reach competence for settlement.

Results
After two months of feeding, all individuals fed with seaweed-based and LC diets were at stage II (growing), whereas when fed with HC-FO and HC-CO were equally distributed between stages III (premature), IV (mature), and V (partly spawned). Across females, the broodstock fed with HC-FO (103.84 ± 3.17 µm) and HC-CO (110.30 ± 8.83 µm) produced larger eggs in relation to the other diets. Only the individuals fed with HC-FO, HC-CO, and LC-FO and the individuals from the wild produced viable gametes. The competence for settlement was reached earlier for fed larvae from the wild broodstock at 20 DPF, while larvae from experimental fed treatments attained at 22 DPF. Significant differences in survival rate at competence were found between feeding treatments (Hcₚ = 16.37, df=2, p-value < 0.001), with a higher survival for larvae from HC-FO (38.93 ± 6.21%). At 20 DPF, larvae from the wild broodstock showed a larger BL (529.13 ± 67.35 µm), BW (477.97 ± 57.92 µm), and SL (202.51 ± 27.35 µm) while larvae from the HC-CO diet showed a longer POAL (326.96 ± 54.94 µm) when compared with the other treatments. Across the non-fed larvae, the larvae from broodstock maintained on HC-FO, HC-CO, and from the wild survived for the longest amount of time (13 DPF), when compared with larvae from LC-FO treatment (11 DPF).

(Continued on next page)
Discussion
The broodstock diets tested supported the gonadal development and maturation, except for the seaweed-based diet. Fed larvae from HC-FO broodstock showed the best larval survival and optimal growth throughout larval development. Across the non-fed larvae, the larvae from broodstock maintained with a HC-FO diet survived for the longest amount of time, when compared with a low-carotenoid diet. This indicates that this specific diet is an effective broodstock conditioning feed that can be assimilated for reproductive purposes and likely had a greater extent of maternal provisioning. In contrast, non-fed larvae from wild broodstock had the longest post-oral arms, which indicates that their maternal reserves were depleting, and these were being used to extend their arms to capture food. Future research should focus on the development of formulated feeds to improve reproductive performance, rather than gonad enhancement, to improve sea urchin reproductive success in aquaculture.

Introduction
The success of a commercial aquaculture depends on providing the optimum environment for rapid growth at the minimum cost and resource use. Oxygen is an important and critical parameter, requiring continuous monitoring and is one of the most significant costs at non-cage intensive aquaculture production. Several studies carried out with seabream and seabass, indicate that low levels of oxygen affect feed intake and, consequently, growth performance (Araújo-Luna et al., 2018; Pichavant et al., 2001; Samaras et al., 2023). A concentration of at least 5 mg L\(^{-1}\) is usually considered the minimum required for a normoxia condition and less than 4 mg L\(^{-1}\) is considered hypoxia, and is reported to cause fish stress. The mechanisms involved in hypoxic stress have not yet been fully investigate on meagre rearing, a relevant species for Mediterranean aquaculture. The aim of this study was to investigate two levels of hypoxia in comparison with a normoxia condition on the feed intake, blood parameters and meagre growth performance.

Materials and methods
The study was carried at the Aquaculture Research Station of the Portuguese Institute for Sea and Atmosphere (EPPO/IPMA). A total of 576 meagre (Argyrosomus regius) with an initial weight of 256.0 ± 1.8 g were distributed in 9 fibre-glass tanks (density of 10.9 ± 0.1 kg m\(^{-3}\) per tank). Three different levels of hypoxia were tested: moderate hypoxia (DO-1: 2-3 mg L\(^{-1}\)), mild hypoxia (DO-2: 4-5 mg L\(^{-1}\)) and normoxia (DO-3: 6-7 mg L\(^{-1}\)), in triplicates. The 1.5 m\(^3\) tanks were set up in a flow through system with a water renewal of 60% per hour, salinity kept at 37 ppt and temperature at 20.7 ± 1.0°C. Oxygen and temperature were registered automatically every hour through Synergia® equipment, and when oxygen values dropped, pure oxygen was injected in the water column until oxygen levels were re-established, according to the levels defined for each treatment. The experiment lasted 31 days. Fish were fed with an experimental diet, produced by Sparos, Lda. (Olhão, Portugal), four times a day, until apparent satiety. The uneaten pellets were counted and registered. For the final sampling, all fish were individually weighed and six fish per tank were anesthetized for blood collection. Haematological parameters were analysed: haematocrit (Hct) and haemoglobin (Hgb), glucose (Glu) and potassium (K\(^{+}\)) using an EPOC® card reader.

(Continued on next page)
**Results**
Survival rate was considered 100%, as only 2 fish died during experiment, because they jump out of the tank, a normal behaviour for this species. Meagre from treatment DO-3 had a higher feed intake than DO-2, which also had a higher feed intake than DO-1 (Table 1). Final fish weight on DO-1 treatment was significant (p < 0.05) lower than DO-2 and DO-3 and the same trend was found for Specific Growth Rate (SGR; Table 1). Despite the increase in feed intake and SGR with the increase of oxygen concentration in the water, there were no significant differences in the FCR, although there was a decrease tendency with the increase of oxygen concentration. In all blood parameters analysed, no significant differences were found between treatments (p > 0.05).

**Discussion**
In this experiment, fish survival was not affected by oxygen levels, thus confirming the high tolerance of meagre to low oxygen concentration. The low feed intake and low growth observed in fish reared at low DO conditions can be explained through the restricted metabolic capacity caused by low DO, and the allocation of energy needs to be prioritized for other body functions, resulting in lower energy available for growth (Araújo-Luna et al., 2018). No differences were observed in the blood parameters analysed, as verified for other species (Araújo-Luna et al., 2018; Samaras et al., 2023), indicating that meagre may have adapted to the different rearing conditions (for instance by the increase on the opercular movements and lowering feed intake). Additionally, the duration of the experiment may have not been enough to observe significant differences on those parameters and future experiments should be longer. In conclusion, the concentration of 4-5 mg L⁻¹ of oxygen can be used for meagre aquaculture production, reducing the costs and the need of pure oxygen addition in non-cage farms. Still, the decision should take in consideration the eventual negative impact on growth.

Introduction

The Danube River is the most important refugium for sturgeon populations in the EU inhabited by four species (Huso huso [beluga], Acipenser gueldenstaedtii [Russian sturgeon], Acipenser stellatus [stellate sturgeon], and Acipenser ruthenus [sterlet]). Whereas the first three species are on the brink of extinction, the fourth species (sterlet) shows a declining population trend since decades. In particular, the illegal hunt for caviar is the major risk for populations. Probably, caviar is the most expensive animal products in international trade with prices exceeding 5000 € per kilo of beluga caviar even from aquaculture. Today, sturgeon fishing is no longer permitted in the Lower Danube and the Black Sea. A study was conducted to quantify the amount of illegal sturgeon caviar and meat in trade. Therefore, 149 samples of caviar and meat from the four Lower Danube countries (Serbia, Romania, Bulgaria, and Ukraine) were investigated in a combined genetic-isotope approach.

Materials & methods

For sturgeon meat and caviar, species or hybrid identification is rarely possible by visual inspection alone. Only DNA analysis can determine the species or hybrid in question, while isotope patterns are essential for detecting wild (poached) fish and identifying the geographic origin. Sampling was managed by authorities. Caviar and tissue samples were stored frozen or in ethanol. DNA was extracted using standard procedure. A combined approach using several genetic markers (mitochondrial DNA; Single Nucleotide Polymorphisms; Microsatellites) was used for secure species/hybrid identification. The stable isotope method is the leading standard analytical tool to verify the authenticity of biological materials. The method relies on the principle that stable non-radioactive isotopes occur in nature in different relative proportions, because biological processes (such as the water cycle) influence their abundance variations. Stable isotope patterns deliver various information on the geographical origin and the source (e.g. wild versus farmed). The stable isotopes of the elements carbon, nitrogen and sulphur measured in sturgeon tissue reflect the available feed and therefore indirectly the source of an animal or in that study if it was wild-caught or captive-bred.

Results and discussion

Isotope analysis uncovered that wild sturgeon products were on sale in all four countries. Alarmingly high numbers were observed of wild-caught sturgeon (31 samples/21%); additional 17 samples (11.4%) were in violation with CITES and EU regulations, and 25 cases (17%) were found of consumer deception. Of the 31 samples originating from wild-caught sturgeons, 28 yielded results with confidence intervals ≥95%. Within these samples, DNA analysis identified all Danube sturgeon species in varying proportions, but with the sterlet being the dominating species. In addition, 25 samples were sold as wild products but originated from aquaculture, thus indicating an existing consumer demand for wild sturgeon products, which fuels a niche market of wild products that guarantees greater profit. Three were fake caviar and three samples were from non-sturgeon fishes. Our results indicate the urgency of establishing an effective monitoring and enforcement network against poaching and illegal trade, which must be coordinated between all Lower Danube countries including producers (e.g. aquaculture), transit and consumer countries.
ARTIFICIAL INTELLIGENCE AND HIGH-PERFORMANCE COMPUTING FOR DECISION MAKING IN AQUACULTURE

M. Luna*, M. Ibáñez, J.L. Bosque, R. Beivide, L. Luna and A. Cobo

Department of Business Administration, Universidad de Oviedo, Oviedo, Spain
Email: lunamanuel@uniovi.es

Introduction
Aquaculture has become one of the fastest-growing industries in the world due to the constant increase in demand, limitations in fishery supply, and innovations in the production process. However, decision-making and planning processes remain particularly complex as they are affected by many technical, biological, environmental, and socioeconomic factors. Therefore, the aquaculture industry is still considered a high-risk and complex industry, in which decisions made throughout the production process are not based entirely on planning and control systems.

In this context, industries would benefit from technological innovation in management and decision-making support systems aiming to maximize efficiency and minimize the environmental impact and risks associated with this activity. In this regard, the main objective of this work is the development and evaluation of new optimization methodologies based on the use of Artificial Intelligence techniques and high-performance computing, to support aquaculture producers in decision-making processes. Thus, the capacity and effectiveness of these techniques to optimize the results of marine farms, from both economic and environmental points of view, will be evaluated.

Materials and Methods
This study follows a two-phase process to achieve the aforementioned objective:
- First, a methodology that integrates a multicriteria model and a Particle Swarm Optimization (PSO) technique, proposed by Luna et al. (2020), is applied to find the optimal production strategy in a farm with multiple cages, batches, feeding alternatives, and products. In this case, this method is focused on improving the results of aquaculture companies from a multicriteria point of view (Figure 1), with low computational cost, addressing decisions regarding stocking and harvesting and the synchronous selection of feed and fry for a large number of cages.
- The optimization process described above would entail a very high computing time due to not only the fact that companies tend to have an increasing number of production units (farms) but also because of the large number of decision criteria included. For that reason, parallelization techniques in distributed systems have been used, based on the techniques published by (Ibáñez et al., 2023), to improve the model computational cost, in terms of performance and energy consumption. The integration of these techniques is especially important since one of the keys to these methods, and what would allow them to be scaled to different production systems, is their ability to find good solutions in a reduced time, even under complex conditions (Blum and Roli, 2003). To this end, the efficiency of the previous design will be compared to new parallel developments executed with 60 and 80 cores, respectively.

Results
That methodology has been tested for different scenarios of sea bream marine farming with respect to location, sea temperature, and scheduling dates. The information used has been collected from primary sources, such as oceanographic buoys or Spanish market prices, and secondary sources of information, as described by Luna et al. (2020).

On the one hand, the optimization phase has proven to be useful for aquaculture farms as it could achieve an improvement in the aggregated results for the criteria of Figure 1 between 20% and 50%. On the other hand, it proves the importance of high-performance computing in these scenarios as they face exponential growth in the computational cost with increasing complexity, either due to the increase in the number of production units or the inclusion of constraints in the process.

As can be seen in Figure 2, parallelization techniques in distributed memory systems (with 60 and 80 cores) have shown great ability to significantly reduce execution time. The use of these techniques has allowed the optimization of 80 cages in a time of 12 minutes or even 200 in just over 20 minutes. Additionally, the problem of searching for feasible solutions has also been solved due to the possibility of improving optimization parameters without experiencing a significant impact on computing time.

(Continued on next page)
Conclusions

Decision-making processes are particularly complex in the aquaculture industry. But, as the results of the present study show, decision-support techniques and systems could be the perfect solution to optimize the results of aquaculture companies, from both economic and environmental side.

This is in line with previously published studies regarding the application in the aquaculture industry of decision support systems (Cobo et al., 2019) or multicriteria decision-making techniques (Vergara-Solana et al., 2019). However, this study shows that parallelization techniques in distributed memory systems allow decision-makers to achieve that in sufficiently low computing times, enabling its application to large companies or conglomerates of companies. Furthermore, these results open the door to the application of these techniques in aquaculture companies with different production processes, some with hundreds of production units, and to decisions and scenarios of greater technical complexity.

Introduction
Aquaculture is the fastest growing food producing industry in the world. It has been subjected to an intensification by an increasing proportion of global farmers (Lulijwa et al., 2020). Especially fed aquaculture has seen a rapid increase and is only expected to grow further (FAO, 2020, IFFO, 2021). This intensification has led to a higher exposure for the animals to disease outbreaks and subsequently to antibiotic treatments (Schar et al., 2020). In turn, this has led to an increasing problem with antimicrobial resistant bacteria (AMR), which quickly has become one of the most pressing public health issues of our time (Léger et al., 2021, Choi et al., 2020). The amount of antibiotics used for aquaculture is expected to increase with 33 percent by 2030 (Schar et al., 2020). With the open nature of most aquaculture production, residues of antibiotic treatments spread into the surrounding waterbody and are very difficult to control (Choi et al., 2020, Bondad-Reantaso et al., 2023). As a result, it affects wildlife, plants, drinking water and subsequently people, making AMR in aquaculture a truly multi-faceted issue. The interconnectedness between public health and animal welfare is at the core of the One Health Approach which aims to design programs, policies, research and legislations to achieve better public health outcomes (WHO, 2017). In this paper we look at the role aquaculture has had in AMR strategies on an international scale up until this point. Furthermore, we analyze whether regulations for antibiotic use in 17 of the largest aquaculture-producing countries match the recommendations set up by the One Health approach by the World Health Organization (WHO) and the Food and Agriculture Organization of the United Nations (FAO). Finally, we compare how two leading aquaculture certification schemes, namely Aquaculture Stewardship Council (ASC) & Best Aquaculture Practice (BAP) work towards limiting the use of antibiotics in aquaculture operations. To retrieve this information, this paper answered the following research questions:

1. How has the presence of AMR been translated into international steering documents and how does it relate to aquaculture?
2. How do the antibiotic regulations in 17 of the largest aquaculture-producing countries/regions compare to these recommendations as defined by the WHO and two leading aquaculture certification programs?

Materials and Method
The findings of the study are based on national regulations, gray literature and international standards and recommendations as well as the standards for best practice set up by the certification schemes. We limited the amount of countries studied to 17 due to document availability as well as production volumes in the observed countries.

For the first research question, we used policy mapping, which is a type of content analysis that is used to make objective and replicable inferences from texts or other forms of communications in this particular context (Krippendorff, 2013, Bengtsson, 2016). More precisely, looking at how the presence of AMR has developed in international commitments over time and how aquaculture has been included. For the second research question we used elements of a comparative case study, where we analyzed and synthesized similarities and differences across multiple cases (Goodrick, 2014).

Results & Discussion
Our results indicate that aquaculture was not included in international steering documents to combat the spreading of AMR until the One Health approach was adopted in 2015 and even now it is not explicitly mentioned but is incorporated in a general animal husbandry consideration. Furthermore, we found that all but three countries allow antibiotics listed as “highest priority” by the WHO in their aquaculture operations. The certification programs have even more stringent standards for the use of antibiotics, banning all antibiotics listed as critical for human health and limiting the number of treatments to maximum three (depending on the species). Other important findings were that nine out of the 17 countries allowed prophylactic use of antibiotics in aquaculture practices and that neither state had a limit to the number of treatments per production cycle. As a result, states still have a long way to go in order to perform according to international recommendations and should start to prioritize this issue in their policies, regulations and strategies for aquaculture production. We argue that a higher emphasis should be put on animal welfare as a means to limiting the use of antibiotics.

URCHIN-ULVA IMTA IN SOUTH AFRICA: FROM RESEARCH TO PILOT COMMERCIAL SCALE

Introduction
Sea urchin gonad (uni) is regarded as a premium seafood product. High international demand for these products has, however, led to extensive exploitation and overfishing, and the consequent decline of natural stocks has stimulated research and commercial interest in echinoculture. *Tripneustes gratilla* is a tropical fast-growing shallow water echinoid that occurs along the east coast of South Africa and is one of the most commercially important sea urchin species in Asia, especially Japan. Our group has been investigating *Tripneustes* echinoculture since 2008 and we have successfully addressed all key areas of the life cycle to facilitate commercial-scale production. However, technology for upscaling from the research phase to commercial-scale production needs to be developed further. As part of the EU funded ASTRAL project, we are taking echinoculture from the research phase to the commercial phase and aim to develop the first commercial echinoculture system, integrated with seaweed, in Southern Africa. This contribution will discuss research that is underway to enable commercial scale cultivation of *Tripneustes* under local conditions.

Materials and Methods
Effect of basket depth and feed type on spine loss and consumption was investigated using a 2×3 factorial experimental design with two-treatment levels, basket depth and food type. Three feed types tested (in triplicate) included: formulated feed (pellets) containing 20% dried *Ulva lacinulata* (Cyrus et al., 2015); fresh *U. lacinulata*; and fresh kelp (*Ecklonia maxima*). Both deep (40×15×35cm, L×W×D) and shallow (40×40×10cm, L×W×D) baskets had an internal surface area of 0.32m² and stocking density in both treatments was ~6kg.m². Trials were conducted over 3 days, with baskets cleaned and animals fed ad libitum daily. The effect of basket removal on spine loss was also conducted. Effects of stocking density on growth and gonad development of *Tripneustes* fed fresh *Ulva* ad libitum were assessed over 3 months. A separate gonad enhancement trial was conducted for 2 months, where animals were fed formulated feed containing 20% dried *Ulva* (1.5% BW.day⁻¹). Initial stocking density of baskets (40×40×15cm, L×W×D) for both trials was 4, 6, and 8 kg.m². Urchin growth, gonad development and gonad quality were assessed before and after treatment. Effects of varying stocking densities on urchin parameters (consumption, faecal production, and spine) were also assessed. The first pilot commercial scale urchin-*Ulva* production and hatchery systems were designed and constructed at Buffeljags Abalone farm in South Africa. Several important functionality aspects were tested in the IMTA, including cycling of nutrients (N, P, NH₃), nutritional content and growth of *Ulva* and optimal harvesting rates of *Ulva*. Data from these studies was used to develop a farm-scale model to inform biotechnical feasibility of *T. gratilla-Ulva* IMTA systems and assist prospective farmers.

Results & Discussion
Literature suggests production of various urchin species is reduced when cultivated in deeper baskets. The present study confirmed these findings, with deeper baskets resulting in significantly lower consumption of various feed types (p<0.026). This is likely the consequence of lower feed accessibility, which in turn causes the observed reduced yield. Baskets of ~10cm depth are therefore recommended to enhance production of *Tripneustes*. Trials provided important management recommendations (e.g., removal of urchins from baskets for extended periods (>5s) or feeding rigid feeds (*E. maxima*) increases spine loss (p=0.0001)). While higher stocking densities did significantly reduce mass SGR (p<0.044), mortality, cannibalism and gonad size/quality were not influenced by stocking density. Difference in SGR are attributed to spine loss from negative behavioural interactions. From our data, the optimal stocking density for both grow-out and gonad enhancement of *Tripneustes* is ~20% coverage (surface area of urchins’ tests by surface area of basket). The farm-scale model suggests *Ulva* can remove 100% Total Ammonia Nitrogen (TAN) from urchin effluent in the IMTA, but TAN emissions from urchins is insufficient to sustain *Ulva* production. The implications of this study for *Tripneustes* echinoculture development will be discussed, and additional key findings from on-going commercial-scale hatchery and grow-out trials at Buffeljags Abalone will be shared.

Introduction
The culture of macroalgae can constitute an important and sustainable source of food and feed, which is why its promotion is an important part of the new agricultural and food policy of the European Commission, formulated in the communication to Parliament “Towards a Strong and Sustainable EU Algae Sector” (COM (2022) 592). These crops usually require significant initial labor, which has an impact on their production profitability. In order to provide a solution to this problem, this experiment has been carried out for developing a more profitable cultivation techniques. The objective of the same has been to evaluate the effect of two environmental variables (temperature and irradiance) and the substrate for the fixation capacity of utricles and filaments of the green algae species Codium taylorii. The species of the genus Codium are expected to have great potential in application both in food for humans and animals (Figueroa et al., 2022).

Material and methods
Specimens of Codium taylorii were collected in the inner bay of Cadiz (approx. 36° 28’ 17” N, 6° 14’ 39” W) in southern Spain and kept in culture for two weeks before the start of the trial in February 2023. Parts of the algae thallus were crushed with a blender in order to obtain the isolated utricles and medullary filaments, following the protocol of Hwang et al. (2005). To determine the optimal conditions for the fixation of utricles and filaments, a factorial experiment was carried out considering two light intensities (60 and 100 μmol of photons m-2 s-1) and two temperatures (15 and 20 °C). For each condition, fixation on three types of substrate was studied: cotton, hemp and polypropylene ropes.

Results and discussion
A significant effect was observed for the temperature factor and for the substrate on the appearance of CFUs. In addition, the ANOVA indicated the existence of three second-order significant interactions: between temperature and substrate, between substrate and light, and between light and temperature. The highest number of CFUs (11 units/cm) occurred in the high-temperature, low-irradiance treatment for hemp yarn (Graph 1).

In accordance with the results, previous studies agree that the greatest growth occurs at high temperatures, while for irradiance the results vary widely between different authors for species of the genus Codium (Park & Sohn, 1992; Yang et al. 1997; Hwang et al. 2005).

Graph 1. Codium forming units per centimeter of seeding yarn (CFU cm⁻¹) for each of the four treatments and for each type of substrate. Error bars represent the standard deviation. The letters above the bars show the significant differences for P<0.05, according to Tukey’s test.

1The Scottish Association for Marine Science, Oban, Argyll, Scotland
Adrian.Macleod@sams.ac.uk

In order for seaweed aquaculture to be economically sustainable, the operational costs must be balanced by the production generated in each cycle. The depth at which seaweed is cultivated plays a crucial role in determining the amount of light energy that the cultivated biomass receives, which is essential for achieving optimal growth. If the cultivated biomass receives Photosynthetically Active Radiation (PAR) that exceeds the capacity of photosynthetic tissues, a phenomenon known as photoinhibition can occur, resulting in reduced growth rates. Optimizing PAR throughout the cultivation cycle is unlikely to be achieved by selecting a single cultivation depth, due to the seasonal variations in PAR with depth. Therefore, a careful evaluation of the appropriate cultivation depth for each stage of the cycle is necessary to optimise PAR exposure and achieve optimal growth of the cultivated biomass.

This study investigates the affect of cultivation depth adjustments for twine seeded Saccharina latissima and Alaria esculenta as a strategy to optimise growth performance and farm efficiency. For each species, two replicate 50m double-catenary lines were connected together using 9 x 4m seeded lines maintaining growing lines under equal tension at 9 depth intervals (0.1m, 0.5m – 4m in 0.5m intervals). In January 2022, lines seeded in October 2021 were removed and yield and morphology established. These growing lines were replaced with growing lines seeded at the same time but maintained on 50m long lines at a depth of 1.5m. This process was repeated in April and the trial concluded in June. Based on the results from this trial only one depth adjustment (spring equinox -21/03/23) was chosen for the following cultivation cycle (October 2022- May 2023). In addition to the double-catenary lines, the affect of depth adjustments was measured across replicate (n=2) 50m longlines maintained at depths of 0.5m (shallow), 1.5m (deep) and 0.5m then 1.5m (shallow-deep) throughout the cultivation cycle. PAR and temperature were recorded at 15 minute intervals at each depth interval using a newly developed sensor chain. Salinity and nutrients were recorded at monthly intervals throughout the trials.

Results show that cultivation depth had a profound impact on growth (yield), morphology and development and this could be correlated with average PAR at each depth selected. Saccharina latissima and A. esculenta lines maintained at 0.5m depth achieved almost twice the yield by January (2020 and March (2023) when compared to lines maintained a 1.5m optimum previously measured at this site across the entire season. Adjusting cultivation depth from shallow (0.5m) to deep (1.5m) improved yield and overall biomass quality at the point of harvest compared to lines maintained shallow (0.5m) and deep (1.5). Whilst cultivation depth choice is likely to be site specific these results validate the utility of making at least one depth adjustment to the supporting buoys of growing systems or across the entire farming infrastructure to improve productivity and biomass quality.

Introduction

High-quality genome functional annotation crucially underpins fundamental and applied genomics studies in all species. The genome sequence of aquatic species, however, typically have limited functional annotation datasets publicly available. Several projects within the international ‘Functional Annotation of Animals Genomes’ (FAANG) initiative (Giuffra et al. 2019) seek to enhance the quality of functional annotations in diverse farmed animal taxa. AQUA-FAANG (https://www.aqua-faang.eu/) has generated extensive functional annotation data for six commercially important finfish species, including Atlantic salmon (Salmo salar) and rainbow trout (Oncorhynchus mykiss). The comparative nature of AQUA-FAANG datasets provides scope to explore the evolutionary conservation of fish-specific genomic features controlling gene expression phenotypes. The aim of this study was to comprehensively map expressed genes and regulatory elements across the genomes of both salmonid species, including their evolutionary conservation following the salmonid-specific whole genome duplication (ssWGD) event, which occurred 100 MYA (Lien et al. 2016; Gundappa et al. 2022).

Methods

For Atlantic salmon and rainbow trout, we generated matched functional genomics data for samples spanning ontogeny, including 14 stages of embryogenesis and a common panel of tissues (liver, brain, gill, intestine, muscle, head kidney, ovary and testis) from males and females at sexually immature and mature stages. The data was generated using standardized methods, and represents approximately 1,000 sequencing libraries, including 130 mRNA-Seq, 70 small RNA-Seq, 80 ATAC-Seq and 270 ChIP-Seq (H3K27ac, H3K4me1, H3K4me3, H3K27me3 histone marks) datasets. Primary analysis for mRNA-Seq, ATAC-Seq and ChIP-Seq was done using nf-core pipelines (Ewels et al 2020). Small RNA data was annotated by the fish microRNA database (Desvignes et al. 2022). All data was submitted to the FAANG data portal (Harrison et al. 2021), and is being used to up-date gene annotations and produce the first regulatory annotations for any teleost species in the Ensembl Genome Browser (ATAC-Seq data for both species publically available as of release 109). We generated novel comparative tools to navigate this new dataset, including a homology prediction integrating phylogenetic and synteny criteria to capture >10,000 high-confidence duplicate gene pairs per species, in addition to a multispecies genome alignment including duplicated regions from ssWGD. ChromHMM (Ernst and Kellis, 2012) was used to model chromatin states in embryonic stages and adult tissues combining ATAC-Seq and ChIP-Seq datasets, separately for each species. We clustered and visualized gene expression and open chromatin regions across samples using self-organizing maps (SOM) and Uniform Manifold Approximation and Projection (UMAP) dimensionality reduction. Enrichment in transcription factor (TF) binding within regulatory elements was done using GimmeMotifs (van Heeringen & Veenstra, 2011).

(Continued on next page)
Results & Discussion

SOM clustering and UMAP identified modules of genes showing specific expression at different stages of embryogenesis in both species, for example genes upregulated during the maternal-to-zygotic transition. In adult tissues, we identified tissue-specific, stage-specific and sex-specific clusters of gene expression. ChromHMM identified several distinct chromatin states, including active and bivalent promoters, active, primed and poised enhancers, polycomb repressed regions, and unmarked open chromatin. We observed the expected enrichment of predicted TF binding in promoter and enhancer elements according to sample types, e.g. Sox2/Oct in early embryo stages, Hox in mid-embryogenesis, DMRT3 in testis, HNF in liver, NeuroD in brain, among many others.

In Atlantic salmon, we identified 313,000 high-confidence open chromatin regions across sample types. SOM clustering and UMAP captured the dynamics of regulatory element activity across ontogeny, and revealed regulatory elements specific to tissues, stages and sexes. In embryos, most stage-specific open chromatin regions were present at the end of segmentation, a stage where conserved non-coding elements were strongly overrepresented. We quantified the average divergence in expression of duplicated genes retained from ssWGD across sample types. We also quantified the conservation of chromatin accessibility and regulatory elements in duplicated and singleton (i.e. where one duplicated copy was lost) regions within the Atlantic salmon genome. These analyses revealed extensive variation in evolutionary constraint acting on duplicated gene expression and regulation across ontogeny, broadly matching with expectations of the hourglass model of development (Uesaka et al. 2022).

As a next step, we will overlay our comprehensive annotations of regulatory elements with genetic variation, including single nucleotide polymorphisms and structural variations defined in the Atlantic salmon genome. This will enable the prioritization of candidate causal genetic variants responsible for gene expression phenotypes, with diverse future applications in support of sustainable and profitable aquaculture.

Introduction

One of the main concerns for the environment due to salmon commercial aquaculture are salmon escapees (Keyser et al., 2018; Besnier et al., 2022). Escapees, breeding with wild conspecifics (Diserud et al., 2022), have the potential to endanger local wild populations by introducing genetic changes that may be maladaptive in nature (Besnier et al., 2022). Induced triploidization has been adopted as a strategy to provoke sterility in commercially farmed Atlantic salmon. However, triploid salmon have shown reduced performance and welfare in commercial settings (Madaro et al., 2021, Stien et al., 2023). This has been suggested to be due to farming suboptimal conditions and impaired stress coping capacity. The aim of this study was to compare physiological responses of diploid and triploid salmon siblings subjected to unpredictable chronic stress.

Materials and methods

Atlantic salmon were reared at the Institute of Marine Research (IMR, Matre, Norway). Diploid and triploid Atlantic salmon were subjected to a 21- days unpredictable chronic stress (UCS) regime and compared with fish that were not stressed. The UCS regime involved exposure of fish to seven unpredictable stressors two times a day. At the end of this period all groups were tested with an acute stressor (netting and transfer in a new tank). Blood chemistry and selected pituitary genes expression were used to assess the stress response. Plasma parameters were sampled before (0) and 15, 30, 45, 60, 90, 120, 240, 300 min post-stress and included measurements of plasma ACTH, cortisol, ions, and metabolites. Gene expression analyses were performed at 0, 30, 60, 120, 240 min post-stress.

Figure 1 Plasma ACTH (a) and cortisol (b) levels of diploid (2N) and triploid (3N) salmon parr exposed to unpredictable chronic stress (UCS) or naive fish (Acute Stress) following a stress test.

(Continued on next page)
Results
Circulating level of ACTH (Fig 1a) and cortisol (Figure 1b) were significantly affected by fish ploidy (diploid vs triploid), type of treatment and time. After the stress test, plasma ACTH levels were mostly higher for triploid than for diploid in both UCS and naïve fish. While pre-stress levels of cortisol were similar between ploidy in both treatments, plasma cortisol levels increased predominantly in both UCS and control triploid groups. More results will be presented at the EAS conference in Vienna (Austria, 2023).

Discussion
The two salmon ploidy groups showed noteworthy differences in the stress response. Post-stress ACTH and cortisol release in plasma were generally higher in both triploid groups. Also, triploid fish showed wider post-stress fluctuations in most of the other plasma parameters. In addition, there were noteworthy ploidy differences in the expression of genes regulating the stress response at the pituitary levels. The study will be discussed in more detail at the EAS conference of Vienna (Austria, 2023).

Funding
This study was part of the NRS TripWell-projected funded by Norway Royal Salmon.

Introduction
Aquaculture has an indubitable contribution to global food production, reducing the gap between supply and demand for aquatic food. The Food and Agriculture Organization of the United Nations estimates that total aquatic food production will increase by 15 percent by 2030, and this growth is mainly attributed to aquaculture.

Intensification of aquaculture rearing conditions contributes to increased stress and susceptibility to disease of farmed fish. Antibiotics use in aquaculture has a positive effect on controlling fish diseases but negatively affects the environment and consumers’ opinions about aquaculture fish. Furthermore, the indiscriminate use of antibiotics increases the potential for antimicrobial resistance (AMR) development among pathogens, leading to strong regulations and a drastic reduction of their use in many countries. Moreover, antibiotics are not allowed as prophylactic agents in many countries, namely in Europe. Consequently, the development of efficient and sustainable alternatives to antibiotics is an urgent need to reduce losses due to disease and ensure the economic viability of the aquaculture sector. White grape marc extracts are rich in polyphenols, with antimicrobial and antioxidant capacity, and are an interesting alternative to replace conventional antibiotics and reduce AMR.

In this work, we assessed the potential of three white grape marc extracts to inhibit important bacterial fish pathogens and evaluated their in vitro potential against several bacteria pathogens, and the effect of their dietary inclusion at three concentrations on European seabass growth, feed utilization, and immune status.

Material and methods
The in vitro antimicrobial activity of three extracts: grape marc extract obtained with ethanol/water 50/50 (ET), with propylene glycol/water 50/50 (PG), and with 100% volatilized acetone (AC) was assessed against fish bacterial pathogens by the well-diffusion assay method and each solvent was used as a negative control. The growth trial was performed with groups of 15 European seabass (Dicentrarchus labrax) fingerlings (initial body weight = 23.3 g) distributed in 30 tanks and receiving ten isoproteic (45%) and isolipidic (18%) diets: a control diet similar to a commercial aquafeed and nine diets with the different extracts included at three polyphenols concentrations: 45, 200 and 450 ppm. The growth trial lasted for 42 days and then the plasma of 9 fish per diet was sampled for evaluation of lysozyme and peroxidase activities. Statistical analysis of data was done by two-way analysis of variance (ANOVA) with the extract and concentration as fixed factors and non-orthogonal contrasts between the control and each test diet.

Results
The grape marc extracts obtained from ET and PG produced clear inhibitory halos against Vibrio vulnificus, Tenacibaculum maritimum, and Photobacterium damselae subsp. piscicida. Additionally, the same extracts interfered with the bacterial growth of Aeromonas bivalvium, V. harveyi, V. parahaemolyticus, Pseudomonas aeruginosa, P. damselae subsp. damselae and the gram-positive Streptococcus agalactiae. Grape marc extract AC produced clear inhibitory halos against the growth of P. damselae subsp. piscicida, V. harveyi, T. maritimum, S. agalactiae, and small inhibitory halos (< 2 mm) against P. damselae subsp. damselae and V. vulnificus. Regarding the growth trial, fish accepted well the experimental diets and no mortality was registered (Table 1). No differences were found between groups in the final body weight, weight gain, daily growth index, feed intake, feed efficiency, and protein efficiency ratio. Also, no significative differences were found in the plasmatic lysozyme and peroxidase activities of European seabass fed with the experimental diets, but in absolute values, lysozyme activity was higher in fish fed with all the extracts than in the control group, and peroxidase activity was also higher in fish fed with the PG450 diet than the control (Table 1).

(Continued on next page)
Conclusions

All grape marc extracts showed antimicrobial activity against *V. harveyi*, *V. vulnificus*, *P. damselae* subps. *piscicida*, *T. maritimum*, and *S. agalactiae*.

Although no statistically significant differences were observed in the growth, feed utilization, and plasma immunity parameters evaluated, there was a trend for a positive effect of the extracts on the immunological response in European sea bass fingerlings fed the extracts-supplemented diets. Once demonstrated the safety of the administration of these products on diet, further studies are required to confirm the potential of the grape extracts as modulators of the immune response and resistance against pathogens in European sea bass.

Introduction

The human population will surpass 10 billion and aquaculture presents itself as a solution to cope with the food demand issue, being a fast-growing food sector. Fish meal (FM) is still an important ingredient as a protein source for aquafeeds, especially for carnivore diets, as it has no anti-nutritional factors, high protein content and balanced amino acid profile, and high palatability and digestibility. Although, its often massive utilization leads to the overexploitation of wild fish stocks and its price is continuously increasing. It’s also important to substitute traditional aquafeed ingredients that are used as human food such as soybean (SBM) wheat meal (WM) and gluten (WG). Thus, this study intends to use low FM diets and look for more eco-friendly and less expensive alternatives with a reasonable protein content such as macroalgae by-products to substitute the traditional plant ingredients for aquafeeds. Therefore, it aims to use Gelidium industrial residues from agar extraction, promoting environmental sustainability by reusing nutrients that would be neglectfully discarded. However, the biggest challenge is to satisfy marine carnivore fish nutritional requirements, as macroalgae ingredients have lower protein and amino acid contents, along with anti-nutritional factors. Thus, this study aims to evaluate how different inclusion levels of Gelidium by-products (up to 15%) in diets for European seabass juveniles will influence fish growth, feed utilization, and whole-body composition.

Material and methods

Five diets were formulated with low FM content (15%) and to be isoproteic (44% crude protein) and isolipidic (16% crude lipid) including graded levels (0, 5, 10, and 15%) of Gelidium residue after the agar extraction in substitution of SBM, WM and WG. The fifth diet contained 15% of treated Gelidium with 1N NaOH (solid: liquid ratio of 4:3) and autoclaved for 30 min at 120°C. The growth trial was performed at CIIMAR, Matosinhos, Portugal in a recirculating water system (RAS) at 24 °C. A total of 300 European seabass (Dicentrarchus labrax) were evenly distributed in the system in triplicate groups of 20, with an initial body weight of 38g. At the beginning of the trial, 10 fish from the initial stock were randomly collected and stored at −20 °C until whole-body composition. Fish were fed 2 times a day, 6 times a week, for 49 days. After that period, fish from each tank were lightly anesthetized with 0.3 mL L⁻¹ of 2-phenoxyethanol, and 3 of them were euthanized by decapitation and collected for whole-body composition. Statistical evaluation of the data was done by one-way ANOVA. When p-values were significant (p < 0.05), means were compared with Tukey’s multiple range test. All statistical analyses were performed using SPSS 27.0 software package for Windows (IBM® SPSS® Statistics, New York, USA).

Results

Results showed no differences in final body weight, weight gain, daily growth index, feed efficiency, and protein efficiency ratio between the diets, with similar results (Table 1). Nevertheless, a slight increase in feed intake was found in fish fed diets with 5 % untreated and 15% treated Gelidium by-products compared to fish fed a diet with 15 % untreated Gelidium by-products (Table 1). Whole-body composition, nitrogen, and energy retention (% intake) were not affected by diet composition (Table 2).

Conclusion

In conclusion, European seabass juveniles accepted very well the experimental diets, with no negative effects on growth performance and feed utilization with inclusion levels of Gelidium by-products up to 15 %. Therefore, this study showed that diets with low FM (15%) and 15 % of SBM+WM+WG substitution by Gelidium by-products can be utilized without negative effects on fish growth, feed efficiency, whole body composition, and nitrogen and energy retention.

A NOVEL APPROACH FOR RECIRCULATING AQUACULTURE SYSTEM (RAS) BASED ON PHYSICOCHEMICAL WATER TREATMENT PROCESS

M. Igal*

BioFishency Ltd, Melach Haaretz 1, Atlit (Israel)
igal@biofishency.com

Aquaculture is the fastest-growing sector in animal protein production projected at 100 million tons by 2030. But with the limited availability of land and water, the only viable solution is intensification – to produce more fish per unit of area and water. This shifted the focus towards longevity and sustainability of aquaculture, now driven by innovative, highly sustainable and cost-effective solutions. One such solution, Recirculating Aquaculture Systems (RAS), are based on the treatment and reuse of water via the application of mechanical filtration, followed by biofiltration, disinfection, and oxygenation. Available RAS technologies suffer from several limiting factors restricting their wide application: (1) Difficulty in meeting desired environmental standards, namely related to inefficient removal of nitrogen and phosphorus compounds; (2) bio-filter limitations, such as long start-up time, temperature dependency, possible amplification of pathogens within the biofilter (3) generation of fish off flavor agents such as MIB & Geosmin generating a muddy taste of the fish causing tremendous lost for the farmer. These factors result in increased production costs due to environmental-related expenses, fish health issues affecting both growth performance and survival rates, and high capital costs particularly apparent in RAS focusing on cold-water fish, which require large bio-filter surface areas.

A new operational approach for RAS, is based on physicochemical water treatment techniques. Within this concept the fish are grown at high TAN concentration and around neutral pH that is calculated to maintain the toxic NH$_3$ concentration lower than a predetermined threshold. The inherently high Cl$^-$ concentration in seawater enables efficient electro-generation of Cl$_2(aq)$ which consequently oxidizes ammonia directly into innocuous N$_2(g)$. The system’s water passes in a semi-batch mode through the water treatment unit and then returns to the fish tanks, supplying disinfected water with zero TAN and off-flavor agents, and most of the acidity required for maintaining the alkalinity mass balance in the RAS. A powered controller with a highly-intuitive graphic UI monitors and controls the water’s pH, temperature, O$_2$, ORP, Cl$^-$ and NH$_4^+$ levels for maintaining optimal water quality for the fish. The BioFishency ELX enables real-time data collection and management via an intuitive dashboard through a cloud-based solution. Remote monitoring and operation are facilitated by an easy-to-use mobile app, accessible from any location, at any time, via any mobile device or tablet. Intelligent process adaptation using Machine Learning technologies, are planned for future versions.

The presentation will include a technical description of the BioFishency ELX technology and describe it value proposition to both investors and fish farmers in three major market segments: Off-flavor purging under regular feeding regime, Full grow-out period in RAS, and Zero discharge transportations of live fish in welboats.
Tetradesmus obliquus AND Raphidonema monicae BIOMASS PRODUCED THROUGH A CIRCULAR ECONOMY APPROACH FOR ATLANTIC SALMON (Salmo salar) FEEDS

Introduction
Biomass from microalgae has the potential to replace fish- and soybean-based ingredients in aquafeeds, improving the sustainability of the aquaculture sector. Nevertheless, the incorporation of microalgae can have an impact on the end cost of feeds. Furthermore, the rigid cell wall of microalgae can lower the nutrient bioavailability and digestibility of farmed fish. Through the present work, we show that by adopting a circular economy approach that relies on re-using nutrients and water from hydroponic drain water for microalgae growth, we can upgrade the produced biomass using a biorefinery process, thus developing innovative bioproducts for agriculture and aquaculture markets.

Material and methods
Tetradesmus obliquus and Raphidonema monicae were produced in an industrial 19-m³ tubular photobioreactor at Necton S.A. facilities, using hydroponic drain water as culture medium, reaching a dry weight of 1.8 and 1.6 g.L⁻¹, respectively. After harvesting the biomass, a simple biorefinery approach (high-pressure homogenization and centrifugation) was applied to generate two bioproducts: aqueous extracts for the agriculture sector and residual biomass for the aquaculture sector. The present study focused on the residual biomass of T. obliquus and R. monicae that was incorporated at 10% into experimental aquafeeds as a substitute for fishmeal. Two experimental diets containing the respective microalgal biomass and a commercial-like diet (control diet with fishmeal) were offered to Atlantic salmon (Salmo salar) post-smolts with an average start weight of 150.70±0.06 g. The experimental fish were reared in flow-through tanks in an indoor seawater research facility, and fed to satiation, twice a day, for 9 weeks. The feeding trial aimed to examine fish growth, feed performance, fillet quality as well as the intestinal health of the fish.

Results
At the end of the experiment, the final average weight of the fish was 368.70±1.20 g. We did not detect significant differences in specific growth rate (average 1.38±0.02 %day⁻¹) and feed conversion ratio (average 0.75±0.02) among the dietary treatments. The proximate composition of the whole body did not reveal treatment-linked differences: protein, fat, and ash content ranged between 52.69-54.55% dry matter (DM), 13.83-14.22% DM, and 1.28-1.45% DM, respectively. The fatty acid profile of the salmon fillet was determined as well, and the total polyunsaturated fatty acid content was in the range of 30.42-30.56%, with the sum of eicosapentaenoic and docosahexaenoic acids ranging between 10.74-11.09% of total fatty acids. With regards to digestibility, the diet containing R. monicae demonstrated a significantly higher protein digestibility when compared with that of T. obliquus and the control diet, while displaying a significantly higher lipid digestibility compared to that of T. obliquus. Histological analysis revealed that the fish fed T. obliquus had shorter villi and the fish fed R. monicae had significantly higher number of goblet cells per villi and significantly higher number of neutrophils. Nevertheless, analysis of the expression of genes connected to inflammation and tight junction proteins did not point to the adverse effects of the microalgal biomass.

Conclusion
The processed microalgal biomass of Tetradesmus obliquus and Raphidonema monicae can be effective substitutes of fish meal in diets for Atlantic salmon smolts. This study points to the potential value of the tested circular approach in developing new ingredients for aquafeeds.

EVALUATION OF SAFETY AFTER INTRAPERITONEAL VACCINATION OF SEA BREAM 
(*Sparus aurata*) WITH THE EMULSION VACCINE AGAINST PASTEURELLOSIS AND 
VIBRIOSIS, ALPHA JECT MICRO 2000

Claudia Maira* and Roberto Guijaro

PHARMAQ part of Zoetis, Harbitzallén 2A, 0275 Oslo, Norway
E-mail: Claudia.maira@zoetis.com

Photobacteriosis (*Photobacterium damselae* subsp. *Piscicida*) and classical vibriosis (*Vibrio anguillarum* O1) are two bacterial diseases that have the potential to cause problems for farming of sea bream. Safe and efficacious vaccines, including Alpha Ject micro 2000, for prevention of photobacteriosis and vibriosis in sea bass (*Dicentrarchus labrax*) have been commercially available many years but no vaccine for sea bream (*Sparus aurata*) has been licensed. The aim of this study was to investigate under controlled laboratory conditions, the safety of Alpha Ject micro 2000 after intraperitoneal (IP) administration to sea bream of the minimum recommended weight at vaccination. Fish groups of 10 - 12 g and >12 - 15 g were IP vaccinated with the recommended dose of the vaccine. The study groups were observed daily for abnormal behaviour and mortality throughout the study period of 12 weeks post vaccination (wpv). Local reactions (adhesions and melanisation) and amount of vaccine residues were evaluated according to Pharmaq scale for local reactions in sea bass and sea bream after IP vaccination, 3 -6- and 12-weeks post vaccination. Individual weights in the study groups were measured at vaccination and at 3, 6 and 12 wpv for assessment of growth.

No mortality post vaccination was observed in any vaccinated group. The severity of adhesions was quite similar between vaccine groups at the different evaluation time points, with 1.4 mean adhesions score for both groups at 12 wpv. The observed severity of adhesions was mild. No melanin was observed on the abdominal organs or the abdominal wall for any group at termination. Moderate amounts of vaccine residues were detected at termination (score of 1-2).

The growth of both vaccinated groups was considered normal and as expected under laboratories conditions, showing that vaccination with oil-adjuvanted vaccines containing inactivated antigens of *P. damselae* and *V. anguillarum* O1 did not result in any growth reduction in sea bream in the 12 weeks observation period of this study.

Safety was satisfactorily demonstrated until 12 wpv for the two investigated fish sizes of sea bream IP vaccinated with Alpha Ject micro 2000.
EFFECTS OF FREEZE-DRIED Rhodotorula mucilaginosa IN FISH FEED OF Sparus aurata ON THE FISH GUT MICROBIOME

Introduction

As the aquaculture sector continues to grow at a rapid pace, there is a need to discover effective feed supplements that enhance the growth and welfare of fish bred in intensive environments. The capacity of yeasts to transform low-value materials into valuable resources has garnered interest as a promising novel ingredient in aquaculture. Among these resources, polysaccharides (e.g. b-glucans, mannans) and pigments (carotenoids) are important ingredients and have attracted significant research efforts. Studies have shown that the dietary inclusion of yeasts could reduce the adverse effects of soybean meal inclusion in Atlantic salmon (Agboola et al., 2021). Dietary hydrolyzed Rhodotorula mucilaginosa has improved the growth performance and antioxidant capacity of Nile Tilapia (Oreochromis niloticus) (Chen 2019). In the current study, the yeast R. mucilaginosa was used as a fish feed additive to investigate its effects on juvenile seabream Sparus aurata individuals’ microbiome.

Materials and methods

Rhodotorula mucilaginosa strain ACA-DC 5340 were grown on Potato Dextrose Agar petri-dishes and freeze-dried into a dry powder. Four experimental isolipidic, isoenergetic and isoproteic diets containing lyophilized yeast at at 0%, 1%, 2%, and 3% inclusion levels, were formulated by the Aquaculture Laboratory of the University of Thessaly. One hundred twenty (120) fish were acclimatized to laboratory conditions. The experiment consisted of four experimental groups (control, R1, R2, and R3), and each group encompassed three replicate tanks. Fish were hand-fed twice daily at a rate of 1.2% BW. At the end of the experiment, three (3) fish from each tank (36 fish in total) were sacrificed and the distal intestine was dissected and stored at -20°C until downstream applications. Bacterial DNA was extracted with DNA Nucleospin Tissue (Macherey – Nagel, Duren, Germany) according to manufacturer instructions. V3-V4 variable region of 16S rRNA was amplified with 341F/785R primers. The corresponding libraries were normalized, pooled, and sequenced (paired-end, 2×250, v2 chemistry) using Illumina MiSeq (Microbiome Core Facility, Technical University of Munich). Normalization of OTU tables and downstream analysis was carried out with Rhea 1.1.6 software.

Results

The results showed that a total of 1.1 million high-quality reads for the 36 samples accounted for 572 operational taxonomic units (OTUs). Corresponding OTUs were mainly classified into five (5) groups with Firmicutes being the most abundant followed by Bacteroidota, Proteobacteria, Actinobacteriota, and Verrucomicrobiota. Microbial richness, was not drastically affected in the fish provided with dried yeast. The alpha-diversity, the Shannon and Simpson indices as well as the effective diversity and effective richness were increased, but not at a statistically significant level, while the composition of their microbial communities was significantly differentiated. Significant differences among treatments were observed in the genera of Acinetobacter, Cellulosilyticum, Clostridium, Corynebacterium, Cutibacterium, Enhydrobacter, Lawsonella, Micrococcus, Paracoccus, Phascolarctobacterium και Staphylococcus. Nine (9) OTUs exhibited significant differences between control and Rhodotorula mucilaginosa enriched treatments.

(Continued on next page)
Discussion

The results of the study demonstrated the existence of two groups of dominant phylotypes for both control and treatment groups. One of the groups tended to significantly differentiate in terms of bacterial strains. The dominance of the phylum Firmicutes in the intestinal microbiota of Sparus aurata is in accordance with previous studies. Firmicutes, Proteobacteria and Actinobacteria are considered as important for nutrition, the immune system, and metabolic homeostasis (Panteli et al., 2021, Moroni et al., 2021). Furthermore, Clostridia reduction is in line with a previous study in gilthead seabream in which diets containing garlic, carvacrol, or thymol essential oils provided effective antibacterial characteristics against fish pathogens, enhancing immune responses (Firmino et al., 2021). Beneficial bacteria in the gut of fish modulate fish innate immune system, compete for nutrients and antagonize other bacteria for adhesion sites. Concluding, R. mucilaginosa addition in seabream diets did not reduce microbial biodiversity and richness; any significant species differentiation seems that positively affect the intestinal microbiome.

**Introduction**

The utilization of yeasts and their derivatives as additives in aquaculture fish feeds, can be an efficient way to promote fish health and robustness (Machuca et al., 2022). Yeast compounds may promote intestinal health and positively modulate the morphology of the intestinal mucosa (Warwas et al., 2023). Dietary supplementation of hydrolyzed *Rhodotorula mucilaginosa* at an inclusion level of 1% has been demonstrated to regulate nutrient composition, immune response and antioxidant capacity of juvenile Nile tilapia (*Oreochromis niloticus*) (Chen et al., 2019). The present study focuses on the effects of *R. mucilaginosa* enriched diets on the intestinal gene expression of gilthead seabream *Sparus aurata*.

**Materials and Methods**

Four experimental isolipidic, isoenergetic and isoproteic diets containing lyophilized *Rhodotorula mucilaginosa* strain ACA-DC 5340 obtained by ACA-DC collection of Agricultural University of Athens, were formulated by the Aquaculture Laboratory of the University of Thessaly. One hundred twenty (120) *Sparus aurata* juveniles were acclimatized to laboratory conditions, and were randomly distributed into 12 tanks (174L). The experiment consisted of four experimental groups (control: 0%, R1: 1%, R2: 2% and R3: 3%) and each treatment included three replicates. Fish were hand-fed twice daily at a rate of 1.2% BW. At the end of the experiment, the hindgut of four (4) fish from each treatment (16 fish in total) was dissected and stored at -20°C. Total RNA was extracted from intestine tissue and samples were sequenced in an Illumina Novaseq platform (Novogene, United Kingdom). After sequencing (PE150, 6Gbp per sample), raw reads were mapped to *S. aurata* reference genome (fSpaAur1.1, GCA_900880675.1) using Hisat2. Raw reads were counted with htseq-count and differential gene expression was assessed using the DESeq2 library in R environment.

**Results**

Significant differences in gene expression were observed among treatments with 293 upregulated and 374 downregulated genes for R1 treatment, 474 upregulated and 419 downregulated genes for R2 treatment and 280 upregulated and 265 downregulated genes for R3 treatment. The three treatments exhibited 177 upregulated and 208 downregulated common genes, while the R1 and R2 treatments had the larger number of common differentially expressed genes. Hierarchical clustering of differentially expressed genes revealed two groups and principal component analysis (PCA) verified the existence of two clusters with 64% of total variance, while different R samples were not clustered per treatment. Gene Ontology (GO) analysis revealed that the major groups of upregulated genes are involved in lipid biosynthetic process (Biological Process), integral components of the membrane (Cellular Component) and iron ion binding (Molecular Function). On the other hand, no significant ontologies were identified for downregulated genes in all experimental treatments.

**Discussion**

Intestinal epithelium is of paramount importance for nutrient absorption (e.g., ions, peptides and lipids) and gastrointestinal status may change due to nutritional synthesis. Gene ontology analysis demonstrated an overrepresentation of genes with biological functions that are involved in the lipid biosynthetic process. For example, fish fed *Rhodotorula* enhanced diets exhibited increased expression of lipid biosynthetic genes (e.g. desaturases, monoxygenases) and solute carrier 13 (slc13) a major carrier of citrate which is important for the regulation of lipid biosynthesis (Akhtar et al., 2023). The R2 group exhibited the highest number of counts in the aforementioned category. These results are in accordance with previous findings where dietary MOS affected the lipid metabolism of European seabass (*Dicentrarchus labrax*) (Torrecillas et al., 2015). Furthermore, iron ion binding genes (e.g. cytochromes P450, monoxygenases) were upregulated in all three experimental treatments. Iron ion binding genes were downregulated in *Salmo salar* fed with soy-derived substances, while simultaneously upregulated inflammation-associated genes (Kiron et al., 2020). These suggest that the supplementation of diets with *R. mucilaginosa* may positively affect lipid metabolism and iron binding in intestinal epithelium.

THE EFFECT OF LIVE PREY FEEDING ON THE HEALTH STATUS OF RAS-CULTURED PIKEPERCH (Sander lucioperca) JUVENILES AS STOCKING MATERIAL FOR THE OPEN WATERS

Malinovsky Oleksandr | Kučera Václav | Pěnka Tomáš | Policar Tomáš

Email: omalinovskyi@frov.jcu.cz

Introduction
Pikeperch (Sander lucioperca) is a top predator of European aquatic ecosystems. It is used as a complimentary fish species in polyculture stocks for bio-melioration (Adámek and Opacak 2005). Recirculating aquaculture systems (RAS), have emerged as vital for rearing pikeperch, with efficiency making it reliable source of the fish aimed for extensive aquaculture and restocking (Policar et al. 2019). The intensive culture in RAS, however, can be compromise the physiological balance and health status of reared fish (Ottinger, Clauss, and Kuenzer 2016).

Live prey feeding is a common practice in aquaculture to provide fish with a diverse and natural diet, promoting their overall well-being and physiological condition (Wang et al. 2009). A commercial dry feed (DD). However, the specific implications of live prey feeding on the health of pikeperch juveniles in RAS systems have not been extensively studied.

By examining the effects of live prey feeding on the health parameters of pikeperch, this study aimed to provide valuable insights into the potential consequences of different feeding practices on the health and welfare of RAS-cultured pikeperch juveniles. Ultimately, it supports the successful acclimatization and survival of pikeperch juveniles in open waters, contributing to the effectiveness of replenishment and conservation of wild populations.

Material and methods
Juvenile pikeperch of RAS origin were produced at the Faculty of Fisheries and Protection of Waters, University of South Bohemia (FFWP, USB). The production method involved a combination of pond culture during early ontogeny (4-50 days post-hatching; DPH) and culture in RAS (50-150 DPH) to facilitate weaning onto dry pelleted feed and subsequent ongrowing. At the time of the experiment, the RAS-cultured fish had a body weight (BW) of approximately 30.7 ± 2.64 g and a total length (TL) of 164 ± 7.86 mm. The experiment was conducted in a recirculating aquaculture system (RAS) equipped with an oxygen reactor, mechanical and biological filters. To evaluate the effect of live prey feeding after eight week feeding experiment with two groups: 1st negative group – fed with artificial pellets and 2nd positive group fed ad libitum with prey fish (Pseudorasbora parva). In total, 30 pikeperch juveniles were dissected at different stages of the experiment for the determination of growth rate, somatic indices, blood haematology, and biochemistry parameters. Ten fish were be sampled at the stocking time to assess the initial health status and the same number of fish at the end of the experiment from both positive and negative control groups.

Results and discussion
Pikeperch juveniles fed with pellets had comparable final body weight and SGR with the fish fed on live prey (Table 1). This indicates that the pellet feed provided similar growth results to the live prey. Similarly, the total length of fish fed with live prey was significantly higher compared to fish fed with pellets. This suggests that the fish fed on live prey experienced greater overall growth and development. Hepatic somatic indices and visceral fat indices were significantly lower in fish fed with live prey. This implies that the fish fed on live prey had lower liver and visceral fat content, indicating a potential difference in metabolism between the two feeding groups.

Analysis of biochemical indices showed significant differences between experimental groups (Table 1). Values of TP were significantly lower in juveniles fed on live prey. This suggests that the fish fed on live prey had lower levels of TP, indicating a potential difference in dietary protein intake and utilization between the feeding groups. Values of GLU were the lowest in the fish fed with pellet feed. This indicates a potential difference in carbohydrate metabolism and the baseline level of the stress between the two feeding groups. Fat metabolism was significantly influenced by live prey feeding. The fish fed on live prey had altered lipid metabolism, as evidenced by the differences in CHOL, ALB, and AST levels. The values of NH3 in the blood plasma of fish fed on live prey was the lowest, indicating a potential difference in protein metabolism and waste excretion between the two feeding groups.

(Continued on next page)
In summary, the study findings indicate that feeding pikeperch juveniles with live prey resulted in improved growth (BW, TL, SGR), lower HSI and VSI, and potential differences in protein, glucose, and lipid metabolism compared to fish fed on pellet feed. Overall, the findings of this study suggest that transitioning pikeperch from pellet feed to live prey before their release into open waters can potentially lead to enhanced growth, and metabolism. These considerations are important for successful restocking programs and the overall sustainability of pikeperch populations into open waters.

Introduction

Nitrification in biofilters of recirculating aquaculture systems (RAS) is an essential process in water treatment. In this process, ammonia produced by aquatic organisms, which is toxic to animals in higher concentrations, is oxidized to the less harmful nitrate. This process is catalyzed mainly by two groups of bacteria, firstly ammonia oxidizing bacteria (AOB) and secondly nitrite oxidizing bacteria (NOB). A stable and active nitrifying bacterial community is important for maintaining a good water quality and thus animal health and welfare. However, nitrification in RAS can be affected by several factors, especially fluctuating operating parameters. These include, for example, temperature, pH, oxygen content, or C/N ratio. Another potential influencing factor on the nitrifying bacterial community in RAS is cortisol. This hormone is released by fish in response to stress and can have negative effects on fish welfare at higher concentrations. Previous studies have shown that certain groups of bacteria can also be negatively affected by cortisol. Other factors can also positively affect fish welfare, such as microalgae as an important food source for fish, because some microalgae species contain valuable nutrients. However, knowledge about the influence of cortisol and microalgae on nitrifying bacteria is limited.

In this study, the influence of cortisol on the turnover rates and composition of the nitrifying community as well as a possible reduction of the stress response by microalgae as a dietary supplement was investigated.

Fig. 1: Box plot of turnover rates of ammonia oxidizing bacteria (a) and nitrite oxidizing bacteria (b) after 0, 14 and 27 days with different treatments in RAS biofilters. NC: negative control (conventional feed); CO: cortisol containing diet; CA: cortisol and microalgae containing diets. *: p-value < 0.05; **: p-value < 0.01.

(Continued on next page)
Results
Mean values of nitrifying turnover rates showed a significant decrease in AOB and NOB activities in the biofilters after feeding fish (*Salmo salar*) with cortisol-containing feed for four weeks relative to the control group (conventional feed). In addition, an even more significant decrease in AOB activities was observed when fish were fed a combination of cortisol- and microalgae-containing diets, whereas NOB activities showed no significant decrease in the combined diet compared to the control group. However, it should be noted that the biological and technical replicates differ significantly in some cases (Fig. 1). For a final assessment of the data, further investigations in this regard would be advisable.

Based on 16S rRNA amplicon sequencing, Bacteriodota, Pseudomonadota and Planctomycetota were identified as the most abundant phyla in all biofilters studied. Dependent on time and treatment, the relative abundance varied between 42% - 49% for Bacteriodota, 18% - 29% for Pseudomonadota, and 7% - 11% for Planctomycetota. *Nitrosomonas* and *Nitrospira* were the dominant nitrifying genera. The total percentage of nitrifiers varied between 3.3% (cortisol and microalgae containing diets) and 4.6% (conventional diet).
SIDESTREAM: SECONDARY BIO-PRODUCTION OF LOW TROPHIC ORGANISMS UTILIZING SIDE STREAMS FROM THE BLUE AND GREEN SECTORS TO PRODUCE NOVEL FEED INGREDIENTS FOR EUROPEAN AQUACULTURE

The goal of the BlueBio co-funded SIDESTREAM project was to evaluate new ways of recycling aquaculture and agriculture wastes to save resources and create value.

Aquaculture and agriculture produce vast amounts of wastes. The SIDESTREAM project regards these wastes as ‘side streams’ and considers them a resource. We investigated to which degree marine organisms such as polychaete worms and gammarid shrimps, and also bacteria can be utilised to recapture nutrients, energy and biochemicals from side streams. Furthermore, we evaluated the suitability of the biomass as a fish and shrimp feed ingredient. Finally, we evaluated the sustainability and economic feasibility of these activities.

All side streams used as feed input for the projects model species were utilized as feeds, in some cases (e.g., liquid phase biogas side streams for bacteria) pre-treatments were necessary. Rearing protocols for the marine polychaete Hediste diversicolor, the gammarid shrimp Gammarus locusta, and the genetically modified Corynebacterium glutamicum have been established. These protocols have been developed to optimize biomass production, resource utilization and production of high nutritional value fatty acids (gammarids and polychaetes), and astaxanthin (C. glutamicum).

During the project we learned how to treat these biomasses to process and stabilize valuable compounds. Further, polychaete, gammarid and bacterial meals were formulated into fish and shrimp feed and tested for their suitability as replacement of either fish meal or fish oil, or as attractants.

Juvenile sea bass (Dicentrarchus labrax) thrived on diets replacing 10%, 20%, or 40% of the fish meal with polychaete meals. None of the fish fed polychaete meals differed in growth, feed conversion, or protein digestion efficiency from those fed commercial sea bass diets.

Juvenile rainbow trout fed diets containing astaxanthin produced within the project showed less appetite for the diets compared to trout fed diets containing commercially available astaxanthin sources, which was also reflected in reduced growth rates. However, it shall be noted that the astaxanthin produced in the project was used as autoclaved bacterial biomass, not as extracted pigments, which clearly differs from using synthetically produced astaxanthin, and the result is hence to be treated with caution.

LCA analysis revealed that electricity and water usage is a main driver of costs and decreased sustainability when biogas digestate shall be used as feed input. The reason for this is the high ammonia content which needs to be removed from the

(Continued on next page)
solid phase. LCC comparing a high-tech and a low-tech scenario revealed that scaling effects in the low-tech scenario by far exceed those in high-tech scenarios. LCA on polychaete meals as a fish meal replacer revealed that suggests that the circular approach of rearing polychaete on aquaculture wastes activities may reduce the environmental impact by 23% as opposed to a linear approach.

SIDESTREAM covered several steps along the value chain – from biomass production to the provision of products through conversion and processing. SIDESTREAM enhanced our knowledge on the ability of invertebrates to produce high value compounds. The project lead to novel and refined production techniques and protocols leading to increased production of these compounds under highly controlled conditions.
BIVALVE GROWTH IN MULTITROPHIC AQUACULTURE AREAS OF GREECE

Introduction

Aquaculture has a long history, but it is only in the late 20th and early 21st centuries that it has reached the point of providing 50% of the world’s fisheries resources (FAO, 2018). As human population increases and aquaculture needs to be more and more effective, there is an on growing interest in Integrated Multi-Trophic Aquaculture (IMTA) which is considered a means for increasing aquaculture sustainability. IMTA is defined as the cultivation of two or more aquatic species from different trophic levels in the same area, imitating the energy flow of natural ecosystems (Chopin et al., 2004). The aim of the present study was to investigate the potential to cultivate bivalve species (Mytilus galloprovincialis, Pinctada imbricata radiata and Pinna nobilis) using IMTA methodology in existing fish farms of Greece and in the Allocated Zones for Aquaculture (AZAs) both existing and under development.

Material and Methods

The present study is based on bibliographic data, satellite data, as well as on data collected in the context of the “PINNA SOS” and IDMA projects. Fish farming sites and AZAs were recorded on a GIS map based on the study of Papageorgiou et al., (2021) and satellite data of chlorophyll-α (Chl-α), sea surface temperature (SST) and salinity (SAL) data from COPERNICUS were downloaded for the same sites. For those environmental variables, the ecological niche of each species was determined using data from the scientific literature and in situ data collected in the context of the above-mentioned research projects. Finding the appropriate value range of the studied variables (Chl-α, SST, SAL and juvenile presence), under which the conditions are more suitable for the growth of M. galloprovincialis, P. radiata and P. nobilis, a bibliographic review was performed focusing on their growth potential for each one of these variables. Therefore, this study identified a range of values where growth is maximized (optimal conditions) and two sets of values where the organism survives with little growth above and below the optimal conditions (experimental study). In the remaining values there is no potential for growth or reproduction. The juvenile presence records were based on spatial distribution data of P. radiata (Katsanevakis et al., 2008) and on existing mussel-farms from which juveniles (M. galloprovincialis and P. nobilis) are released in adjacent sites. Distribution data of natural populations were also used as a potential source of juveniles. Based on the values of each variable, a score was given (0 = unsuitable, 1=medium suitability, 2=high suitability) to determine whether each region was suitable for the growth of each species. The individual scores were then summed to determine the final score in terms of the probability of successful development of multi-trophic aquaculture in the existing units. Technically the minimum score equals 0 and the maximum score equals 10 points. The equation applied was:

SST + SAL + 2x (Chl-α) + 2 x (Juvenile Presence)

Due to the fact that chl-a and juvenile presence are significant parameters for the bivalve growth, they were multiplied by a factor of 2.

Results

From the above results, probability maps of the three studied species were produced, within the AZAs of Greece on an annual time scale. In the case of P. radiata and M. galloprovincialis, the derived maps reflect the current situation in Greek waters, as in situ observations (IDMA project) in most of the studied areas verify the presence probability of the species assessed. P. radiata, as it seems, has no specific ecological requirements conflicting with the existing habitat characteristics and as a result it spreads easily along the entire coastline of Greece. On the other hand, M. galloprovincialis is more sensitive to several environmental changes and thus, as the results of the survey indicated, the probability of its presence is increased in the northern, central and western part of Greece, while in the southeastern part the probability of its presence

(Continued on next page)
is almost absent, in other words, in oligotrophic waters. Although the environmental requirements of *P. nobilis* are not yet clear, it is considered that since it is an endemic fan mussel (i.e., a relative of the mediterranean mussel) (Zotou et al., 2020), it is also sensitive to environmental variables, as is the case with *M. galloprovincialis*. Thus, the extracted maps were expected to be similar for these two species.

**Conclusions**

*P. radiata* is one of a few invasive species that has a high commercial potential in the Mediterranean Sea. Due to its low feeding and ecological requirements, according to the produced maps it can be cultured in oligotrophic fish farms. The main inhibitor seems to be the distribution of natural population as no juveniles are commercially available. On the contrary, juveniles of *M. galloprovincialis* can easily be bought, however suitable IMTA locations require eutrophic waters, more commonly found in northern Greece. *P. nobilis* is a more complicated case since in the recent years, due to a mass mortality of the species, no natural population is available, as an infection by *Mycobacterium* and *Haplosporidium pinnae* has occurred causing the extinction of the species in a huge proportion throughout the Mediterranean region (PINNA SOS Project). The results obtained represent a theoretical scenario for the potential of growth, in order to find the most suitable IMTA locations, which *P. nobilis* could use as nursing ground for raising its juveniles. Although *P. nobilis* prefers *Posidonia oceanica* meadows for settlement, the environmental condition of an IMTA can cover their needs.

**Acknowledgements**

This is a part of the project “Innovative Actions for The Monitoring-Recovering –Enhancement of The Natural Recruitment of The Endangered Species (Fan mussel) *Pinna nobilis*. (MIS 5052394) Funded by the Operational Program for Fisheries & Maritime 2014–2020.

**Bibliography**

Introduction
The gilthead seabream is a widely consumed species in the Mediterranean and due to its extensive aquaculture, the pressure on the improvement of production has increased. One fundamental limiting factor of aquaculture production is the incidence of bacterial and viral infections. Deeper understanding of the underlying mechanisms of the immune response will help to prevent and treat these health problems. To this point, there have not been many studies on genome-wide profiling of the gene expression changes in response to specific pathogens on fish. As part of the AquaFAANG project (www.aqua-faang.eu), this work focuses on the development of genome-wide functional annotation maps (‘ImmunoMaps’) that represent host defense responses of the immune system in the presence of two distinct classes of disease agents, viruses and bacteria, in gilthead seabream (Sparus aurata) by using ATAC and RNA sequencing.

Materials and Methods
The experimental work involved first the standardization of experimental protocols for host immunity activation in the head kidney, the major lymphoid organ that plays a critical role in the generation of pro-inflammatory and anti-microbial responses. Two different pathogen associated molecular patterns (PAMP) were applied in order to study species robust innate responses, in vivo by injecting fish and in vitro in primary head kidney leukocyte cultures. A total of 12 gilthead seabream individuals were stimulated in vivo and 6 individuals in vitro with mimics of bacterial (neutralized Vibrio) and polyinosinic-polycytidylic acid (poly I:C) viral infections versus 12 control individuals. Sequencing was performed using Illumina technologies and library preparations were performed for transposase-accessible chromatin (ATAC-seq) and transcriptome (RNA-seq).

For both ATAC- and RNA-sequencing data, the bioinformatic analyses were performed using pipelines from the nf-core initiative (Ewels et al., 2020). The output of the nf-core pipelines was used to perform differential accessibility analysis as well as differential expression analysis with the use of DESeq2 (Love et al., 2014) in R. Then, the statistically significant elements (adjusted p-value < 0.1) were isolated and the differentially accessible peaks were separated into over-accessible peaks (Log2FoldChange>2) and under-accessible peaks (Log2FoldChange<2); similarly, the differentially expressed genes were separated accordingly into up-regulated (Log2FoldChange>2) and down-regulated (Log2FoldChange<2) genes. Differential accessibility and Differential expression profiles were created in the form of volcano plots and for the RNA-seq data analysis, gene set enrichment analysis was performed with the use of g:Profiler (Reimand et al., 2007) and a circus plot (Krzywinski et al., 2009) was created to represent the genomic distribution of differentially expressed genes (Figure 1). To provide additional insight on the way chromatin accessibility interacts with gene expression, both ATAC-seq and RNA-seq data were integrated: the differentially accessible peaks as well as the differentially expressed genes were mapped onto the genome and the 10 closest genes within 1 Mb from the peaks were selected and Log2FoldChange information was added to explore regulatory links between over- or under-accessible peaks with up- or down-regulated genes.

Results
These analyses revealed more generic immune-related and pathogen-specific responses. Firstly, RNA-sequencing showed 1,205 up-regulated genes for all Vibrio treatments (in vitro and in vivo together) and 1,235 up-regulated genes for all PIC treatments. Similarly, 2,427 genes were down-regulated in all Vibrio treatments and 720 genes for PIC treatments. The bioinformatic data analysis also revealed virus-specific (nkbiaa, nod2, atf3, sting1, traf3, rsad2, tlr7, tnfrsf1a, irf7, traf6, tlr3) and bacteria-specific (pglyrp5, pglyrp6) up-regulated genes in vitro and in vivo. On top of the expression profiles, the association of differentially accessible peaks with differentially expressed genes allowed the assembly of a core immune related gene network, also unveiling a potential regulatory link between the up-regulated genes next to under-accessible peaks in vivo for all treatments (Vibrio-PIC, merged together) where an over-representation for interferon-gamma response terms was present.

(Continued on next page)
Discussion
We present an overall image of the immune response map of gilthead seabream on bacterial and viral stimuli on epigenetic and gene levels. Our study revealed candidate genes for the study of immune response and specifically, an over-expression of virus-related genes (nfbiaa, nod2, atf3, Sting1, traf3, rsad2, tlr7, tnfrsf1a, irf7, traf6, tlr3) and bacteria-related (pglyrp5, pglyrp6) immune response genes that lays the background for further analysis. Furthermore, integration of ATAC-seq and RNA-seq data showed silencer activity on IFN response.

Introduction
The goal of sustainable aquaculture is to provide a continued supply of farmed aquatic food for human and animal consumption without compromising ecosystems. In the last twenty years soy was a valid alternative protein source with positive results on growth and health of several aquatic species, including European sea bass. Despite that, plant ingredients may pose contrasts in sustainability and for this reason, in last years, was necessary to find other ingredients more sustainable, well represented by fishery and aquaculture by-product and microalgae as alternative protein sources. Microalgae are widely used in fish nutrition, especially for the high quantities EPA and DHA but are also extremely rich in protein content. Moreover, they can grow on different substrates, such as wastewater, making them the valid sustainable candidates as soy replacement. This study highlighted the possibility to total replace wild FM and FO and soy using by-product from fisheries and aquaculture and with microalgae as alternative protein source without affecting growth, digestibility, enzymatic activities and nutritional performance.

Materials and Method
Five experimental diets (C, 50FMFO, 50FMFO-50MIC, 0FMFO-50MIC, 0FMFO-100MIC) were formulated to totally replace wild fishmeal (FM), wild fish oil (FO) and soy protein using fisheries and aquaculture by-product and microalgae. Fifty fish per tank (initial body weight 46.66 ± 0.04 g), were reared in recirculated aquaculture system for 88 days. At the end of the trial, growth, feed intake (FI), proximate composition, nutritional index, apparent digestibility, somatometric indexes, blood plasma biochemistry were detected. The activity of major digestive enzymes as total alkaline protease (TAP), trypsin, chymotrypsin (CT), alkaline phosphatase (AP) and leucine aminopeptidase (LAP), was detected spectrophotometrically. The assessment of gut microbiota (GM) was made by Next-generation sequencing.

![Graph](image)

**Figure 1.** AP and CT activities in proximal and distal region of sea bass juvenile intestine

(Continued on next page)
Results
No statistical differences were evaluated for FI and growth parameters. TAP, trypsin and LAP activity did not show any statistical difference among treatments. Results of AP and CT are shown in Figure 1. The activity of AP in proximal intestine increased, reaching highest value in animals fed with 0FMFO-50MIC, then decreased in 0FMFO-100MIC diet. Even in distal segment, the activity of AP presented the highest value in diet with partial replacement of microalgae, 0FMFO-50MIC. The activity of Chymotrypsin was similar in proximal and distal part of juvenile’s intestine. The values increased up to the highest value in 50FMFO-50MIC diet, then gradually decreased. Proteins body content presented lower value in diet 50FMFO-50MIC than in diet 50FMFO and 0FMFO-100MIC. Lipids body content were significantly higher in diet 50FMFO, 50FMFO-50MIC and 0FMFO-50MIC compared to control diet. No statistical differences were detected for apparent digestibility and all nutritional indexes considered. Considering plasma parameters, Creatinine, CHOL, HDL, TP and Fe values were statistically higher in diet C than in other treatments, while lower values were presented in diet with the higher percentage of replacement, 0FMFO-100MIC. On the other side ALP, Na and Cl values were lower in C diets and higher in 0FMFO-100MIC diet.

Discussion
This study highlighted the possibility to total replace wild FM and FO using by-product from fisheries and aquaculture without affecting growth, digestibility and nutritional performance of European sea bass juveniles. The enzymatic activities show the possibility to replace 100% of wild-caught FM and FO with fishery and aquaculture by-product and replace 50% of soy protein with microalgae, with positive effect on intestinal activity. These results make it possible to use by-products and microalgae as an alternative protein source, avoiding the use of soy and making aquaculture more sustainable.

Introduction

Participating in the innate immune response host defence peptides, commonly known as antimicrobial peptides (AMPs), exhibit antimicrobial activity against a range of pathogens including Gram-negative and Gram-positive bacteria, viruses, and fungi. Beyond their direct antimicrobial effects, AMPs possess the capacity to enhance immunity and bridge the gap between adaptive and innate responses by serving as immunomodulators that act on host cells (Erdem Büyükkiraz et al., 2022). The majority of in vitro studies on AMPs have focused on investigating their direct effects on pathogenic bacteria. However, in this study, we aimed to examine the direct impact of AMPs on the viability of leukocytes and their ability to modulate the key immune activities performed by these cells. To do this gilthead seabream leukocytes were incubated with different AMPs (piscidin 1, piscidin 2, hepcidin H1, hepcidin H2C, hepcidin H2E, hepcidin H2H and hepcidin H2I) previously identified and characterized by our research group (Serna-Duque et al., 2022a, b).

Methodology

To assess viability and immune parameters, leukocytes were isolated from the cephalic kidney of seabream, adjusted to 10⁷ cells/mL and incubated for 0 and 2 h at 25°C in Leibovitz L-15 culture medium containing one of the synthetic AMPs mentioned above, at a final concentration of 0 µM (control), 12.5 µM or 25 µM. Leukocyte viability was assessed using propidium iodide and flow cytometry (Cuesta et al., 1999) with flow cytometry (FACScan). Respiratory burst was studied using a chemiluminescence method (Bayne & Levy, 1991) and phagocytic activity was assessed using labelled bacteria as a phagocytic particle and flow cytometry (Rodriguez et al., 2003).

Results

The results indicated that the viability of most cells was not significantly affected by incubation with AMPs. However, the viability of cells incubated with piscidin 1 decreased when incubated with the highest concentration of piscidin 1. The respiratory burst of leukocytes was also significantly decreased when cells were incubated with hepcidin H1 and H2H for 2 h, compared to control cells. The phagocytic ability (percentage of cells with phagocytic activity) increased in leukocytes after incubation for 2 h with hepcidin H2H, compared to the values obtained in control cells.

Conclusion

The results suggest that AMPs generally have on the selected activities a minimal effect on gilthead seabream leukocytes. The immunomodulatory effect of seabream AMPs does not appear to be direct on leukocytes, immune effector cells, obtained from the same fish species, but rather appears to have an indirect effect on them as evidenced by in vivo assays.

Bibliography

Spermatogonial stem cells (SSCs) are the baseline cells of spermatogenesis. They have gained a lot of attention during the last few decades due to their great potential in biotechnology. Namely, as stem cells, SSCs can either self-renew or commit to differentiation through which they produce male gametes – spermatozoa. Okutsu et al. (2007) were the first to observe that when transplanted into recipients of a closely-related species, these cells incorporate into recipient’s genital ridge, proliferate, and differentiate into donor-derived gametes ultimately giving donor-derived progeny. This commenced the research on a novel reproductive biotechnology known as the surrogate production technology.

The surrogate production technology entails the following steps: isolation of SSCs from the donor individuals, sterilization of recipient larvae, transplantation of SSCs into recipient larvae and rearing of recipients. The success of the method depends on the availability of donors and recipients of the appropriate life stage and the availability of good quality germ cells from the donor. To help synchronize the procedure, short- or long-term storage are necessary. The most used methodology for SSC storage is cryopreservation which enables their storage for theoretically indefinite time. SSC cryopreservation protocols have been developed for many fish species, and the aim of this study is to summarize the main conclusions of these studies.

SSCs can be frozen either within the whole testicular tissue, or as isolated cells within the cell suspension. Usually, they are cryopreserved within the testicular tissue, and Pšenička et al. (2016) and Marinović et al. (2017) displayed that freezing within tissues yielded higher viability. The tissue can then be either frozen through slow-rate freezing or vitrified. The choice of the approach should mostly depend on the tissue structure, i.e., whether the testis is mature and contains a lot of spermatozoa, or if it is immature and contains only early-stage germ cells. Most commonly, when the tissue is mature and contains a lot of spermatozoa, freezing is a much better option as vitrification gives very poor results. This is consistent with the poor performance of vitrification for cryopreserving spermatozoa in fish. Next, the cryomedium should be optimized. Both freezing and vitrification outcomes mostly depend on the type and concentration of the permeable cryoprotectant, while non-permeable cryoprotectants (sugars, BSA, FBS) affect the outcome to a much lesser extent. In most of the studies, dimethyl sulfoxide and ethylene glycol yield the most favorable SSC viability after freezing. During vitrification, much higher cryoprotectant concentrations are needed, therefore using equal amounts of two different cryoprotectants yields better result than a very high concentration of a single cryoprotectant. The cooling rate during freezing is mostly kept around -1 °C/min, and several studies that have tested various rates have confirmed the superior performance of this rate.

Cryopreservation of SSCs is a very valuable method, however, without further application, the benefit of cryopreservation is only limited to creating gene banks and frozen zoos. Therefore, development of the surrogate production technology of cell culture technology is essential for the utilization of the cryopreserved SSCs.

Introduction

Aquaculture plays a key role in human nutrition and socio-economic development of many countries and its contribution is expected to increase in the future to fight hunger and undernourishment of a growing world population1. However, its sustainability and productivity can be compromised by climate change effects and occurrence of extreme weather events (e.g., marine heatwaves, MHW), that will be more frequent, intense, and long lasting2,3. Such changes will have implications for farmed fish, negatively affecting their physiology, namely, the immune responses and antioxidant mechanisms which, in turn, may compromise species survival and/or ability to cope with the presence of concomitant stressors, e.g. disease outbreaks4.

Developing non-chemically based climate change adaptation strategies has recently become an urgent matter, as taking such actions will enable the aquaculture sector to overcome the challenges posed by climate change. The use of functional feeds enriched with natural immunostimulating ingredients (e.g., plants/seaweeds) has recently deserved some attention in the animal production sector, as it constitutes an eco-friendly alternative with lower costs and a wider range of efficacy than vaccines and antibiotics5,6.

In this sense, the present study aimed to explore the use of an invasive warm-water macroalgae species in the Mediterranean region, Asparagopsis taxiformis, as an eco-innovative adaptation strategy to improve the immune and antioxidant responses of farmed Diplodus sargus juveniles.

The outputs of this study will enable stakeholders to become aware of the potential impacts of climate change and to successfully apply adaptation/mitigation measures in the aquaculture sector.

Material and methods

Experimental diets: A practical, high-quality diet was used as the control (CTR), and three experimental diets based on the CTR diet were supplemented with Asparagopsis taxiformis (whole, dried, and powdered) at different percentages of inclusion: 1.5%, 3%, and 6%.

Fish Rearing Conditions and Feeding Trial: Diplodus sargus (n=165) were kept in seawater recirculation systems under optimal growth conditions (24°C, > 7 mg/L O2), for 30 days (T30), feeding on different experimental diets (CTR, AT-1.5%, AT-3% or AT-6%). After this period, a heatwave of category II in the Mediterranean area was simulated.

The temperature was slowly increased over 7 days (0.5°C/day) until it reached 28°C (i.e., ΔT = +4°C) and remained at that level for 15 days (T52; Figure 1).

(Continued on next page)
Analytical approach: Blood and plasma from 9 fish/treatment was sampled at T30 and T52 (i.e., 3 fish collected from each of the 3 replicate tanks composed one treatment). A multi-biomarker approach combining haematological (blood cell counts, viability and haematocrit) and innate humoral parameters (IgM, antiprotease and peroxidase activity) was carried out to determine the immunostimulating potential of the different functional diets.

Results
Exposure to the MHW led to a decrease in the viability of erythrocytes and increase in cellular nuclear abnormalities in all treatments, though such effects were less pronounced in fish fed with supplemented aquafeeds, pointing out to a potentially positive effect due to the inclusion of *A. taxiformis*. No significant changes were observed in the peripheral leukocyte population in blood smears.

Fish humoral immune parameters were affected by both macroalgae supplementation and exposure to the MHW, alone or in interactive ways, depending on the analysed biomarker. Plasma antiprotease activity had no significant differences between treatments, whereas peroxidase activity increased in CTR, AT-1.5% and AT-3% treatments following exposure to the heatwave, indicating an enhanced immune response. Additionally, immunoglobulin M (IgM) levels also increased in CTR, AT-1.5% and AT-6% treatments, thereby contributing to the prevention of autoimmune diseases, with the 1.5% supplemented diet exhibiting the most favourable outcome.

Conclusions
The inclusion of macroalgae *Asparagopsis taxiformis* in diets demonstrated a potential for enhancing the immune response of *Diplodus sargus* species when exposed to a MHW, with the 1.5% supplemented diet exhibiting the most cost-effective formulation.

These findings show that red macroalgae may be regarded as promising functional ingredients to be used in aquafeeds for carnivorous marine fish, contributing to a better welfare and resilience to environmental stressors, including those related with climate change.

A comprehensive characterization of regulatory elements of the genome across tissues and developmental stages represents an essential resource to understand the genetic basis of productive traits and to identify genetic variants potentially associated with valuable phenotypes to improve genomic predictions in breeding programs. Here, we identified and characterized regulatory elements in the turbot genome by integrating genome-wide ATAC-seq (open chromatin regions), ChIP-seq (H3K4me3-active promoter regions, H3K27ac-enhancer and promoter regions, H3K27me3-Polycomb repression, H3K4me1-enhancer and promoter regions) and RNA seq datasets from 54 pools of 6 embryonic stages (blastula, gastrula, early-segmentation, mid-segmentation, late-segmentation and prehatching) and 6 immature and 6 mature tissues (gonad, brain, liver, head kidney, gill and muscle) tissues. In total, we identified 10 distinct chromatin states among embryonic stages and tissues and annotated > 200,000 highly reproducible regions, including promoter, intergenic and intronic regions. Furthermore, 15x whole genome resequencing of 44 turbot adults from an experimental farm enabled to detect thousands of SNPs and structural variants on regulatory elements that are being checked for their impact on gene expression of the regulated genes.
UNDER THE ASTRAL EU PROJECT: MICROBIOME STUDY OF DIFFERENT FERTILIZATION TREATMENTS IN THE INTEGRATED PRODUCTION OF SHRIMP IN BIOFLOC SYSTEMS

Introduction
Brazilian inshore Integrated Multi Trophic Aquaculture (IMTA) system functions in a closed system, relying on biofloc, processing waste and stabilizing water quality. Biofloc particles are composed of bacteria, flagellates, ciliates, and other organisms that use uneaten feed and faeces secretions to grow. Moreover, particles can be consumed directly by culture species such as shrimp, oysters, and tilapia, thereby making more efficient use of the nutrients contained within the feed and subsequently lowering total costs. The resulting, integrated, multi-trophic system is potentially more biologically efficient, more environmentally sustainable, and more economically competitive. However, research needs to be developed to optimise these systems and understand their microbiome role and dynamics of potential pathogenic bacteria. We aim to study the IMTA system in Brazil, by analysing two different fertilization methods - organic and inorganic -, as well as its microbiota impact on biofloc and shrimp gut (Litopenaeus vannamei) through different timepoints.

Material and methods
This trial was carried out in 6 independently IMTA systems located at the Marine Aquaculture Centre of Federal University of Rio Grande – FURG. Each production system consisted of three compartments/tanks where the water is continuously re-circulating and different organisms are cultivated (Compartment 1: shrimp; Compartment 2: Oyster and tilapia; Compartment 3: seaweed). Thus, two fertilizations treatments were implemented in triplicates: Chemoautotrophic - with inorganic fertilization - and heterotrophic- with organic fertilization. Continuous recirculation of water between tanks occurred, with daily monitoring of environmental parameters. For this study, we mainly focused on the Compartment 1, where an amount of 400 shrimps were cultivated in tanks of 16m3 and the biofloc is generated. Three timepoints were deployed – T0 (initial), T1 (45 days) and T2 (86 days). Triplicates of shrimp gut and biofloc were collected per system, at the different timepoints and characterised for microbial populations. Bacterial diversity was assessed through 16S rRNA sequencing. Raw data was processed with QIIME2, and taxonomical analyses were performed with R software.

Results
Fertilization type significantly influenced the biofloc bacterial communities. A significant differentiation can also be seen in the microbiome systems at the different timepoints when comparing biofloc and shrimps’ gut, which highly differentiate from T0 to T2 after both organic and inorganic fertilizations. Results showed that biofloc is influencing the shrimp gut microbiota, under both organic and inorganic fertilization. Comparison between biofloc and shrimp showed over 60% of shared ASVs. At genus level, in the inorganic fertilization, biofloc showed to be dominated by Mycobacterium, while in the organic fertilization, shrimp gut had the most abundant differential genus dominated by Woesia. Regarding pathogens, abundance of Vibrio and Coxiella, widespread disease-causing agents in aquaculture, decreased after biofloc implementation under both fertilizations.

Conclusions
Bacterial diversity results in biofloc IMTA systems showed a significant evolution during the aquaculture production. Presence of potential pathogens abundance decreased with time and better results were seen with organic fertilization. Furthermore, potential use of microbiota analyses could be used for pathogen detection and treatment.
EVALUATION OF WINE BY-PRODUCTS AS A POTENTIAL FUNCTIONAL INGREDIENT IN FEEDS FOR JUVENILE Liza aurata

Introduction

Nowadays, a large part of aquaculture is based on the use of intensive systems characterized by increasing environmental stressors, reducing water quality and promoting the appearance of pathologies (Segner et al., 2012; Sneddon et al., 2016). Taking this into account, more attention is paid to the search for biologically active ingredients that can benefit the health and resistance of fish against the aforementioned adverse effects. In this context, it is worth noting the potential interest of looking for natural sources of polyphenols. These are abundant in wine by-products such as grape pomace, which has traditionally been used to feed terrestrial animals, but whose possible application in aquaculture is yet to be developed (Peña et al., 2020; Pulgar et al. 2021). Moreover, in the current situation it is unquestionable to consider the principles of the circular economy in any productive process related to agri-food, and therefore the integration of by-products or co-products generated by the industry in some phase/s of the production of the same or other foods. Considering all the above, the present study was oriented to evaluate the potential benefits of including grape pomace or red wine lees as functional ingredients in aquafeeds for juvenile golden grey mullet (Liza aurata) during a short-term feeding trial and a further hypoxic challenge.

Materials and methods

The wine by-products used in the experiment (red grape pomace and lees) were obtained from two artisanal wineries located in Almería and Cádiz (Spain), respectively. The experiment was carried out at the ‘Servicios Centrales de Investigación en Cultivos Marinos’ (SCI-CM) of the University of Cádiz. For the study, three experimental diets for golden grey mullet (Liza aurata) were formulated: i) control diet (C); ii) diet including 10% of grape pomace (GP); and iii) diet including 10% of lees from red wine (WL). Juveniles of Liza aurata of approximately 54 g were used in experimental triplicates (9 tanks in total), subjected to a feeding period of 47 days, with an average daily intake of 2% body weight. The study was carried out in two different experiments; the first one was focused on testing the general effects derived from the intake of bioactive compounds present in wine by-products on basal metabolism, immune status and intestinal microbiota. The second evaluated the potential protective effect against induced stress (medium hypoxia maintained for 3.5 h) evaluated by variations in the oxidative status. At the end of each sub-experiment, fish were anesthetized with a lethal dose of 2-phenoxyethanol prior to obtain the required samples of mucus, plasma, intestinal microbiota and liver. Samples were used to measure different metabolic parameters (glucose, lactate, triacylglyceride, cholesterol, glycogen and protein levels), welfare (cortisol), oxidative status (quantification of antioxidant enzymes such as catalase, superoxide dismutase and glutathione peroxidase) and functionality of the intestinal microbiota.

Results and discussion

The results showed a positive effect of the inclusion of grape pomace in the feed for golden grey mullet on feed efficiency, as well as on different indicators of the metabolic and immunological status of the fish. In contrast, a negative effect of the inclusion of red wine lees in feed on the abundance and functional diversity of the intestinal microbiota of individuals was evidenced (Figure 1). In addition, after inducing stress by a short-term hypoxia, fish fed on feeds containing any of the two wine by-products presented significantly lower levels of cortisol (Figure 2), this pointing out a protective effect mediated by their content in phenolic compounds. Therefore, it seems clear that wine by-products, especially grape pomace, have great potential as functional additives and that future research should assess how to promote their practical application in aquafeeds.

GROWTH PERFORMANCE AND EFFECT OF FISH MEAL SUBSTITUTION IN *Mugil cephalus* UNDER RECIRCULATION AQUACULTURE SYSTEM

Introduction
The increase in fish consumption nowadays has led to a growing need to explore new species for aquaculture that are more environmentally and economically sustainable. This has encouraged the search for low trophic level species with less dependence on fishmeal and fish oil for their diets, being *Mugil cephalus* one promising candidate.

Nevertheless, even with low trophic species, it is necessary a higher fishmeal substitution, but high substitution by alternative protein sources may have an impact in the intestinal status of rearing animals. Gut microbiota is fundamental in the regulation of digestion, immune response and resistance to disease or pathogen colonies in a fish, then alterations in its functionality can affect the fish health status (Estruch et al., 2015).

Thus, in this study the growth and gut microbiota of *Mugil cephalus* fed with two experimental diets containing 15% and 0% of fishmeal was to evaluate aiming to investigate the impact of different diets compositions on the fish performance and gut microbiota.

Material and Methods
The experiment was carried out from September to December 2022 at wet laboratory of Universitat Politécnica de Valencia. Sixty fishes (9.14 ± 1.52 g; initial weight) were randomly distributed in 6 tanks of 600 L (0.9Kg/m³) under recirculation system. Two different diets, with 15% (HP15) and 0% (HP0) fishmeal inclusion, were tested in triplicate. The feeds were manufactured by extrusion cooking at the UPV feed factory. The fish were fed to satiety, three times a day. Monthly sampling was carried out to analyse fish growth and survival and instantaneous growth rate (SGR), daily feeding rate (FIR) and feed conversion ratio (FCR) were calculated.

Once was finished the trial, 5 fish from each treatment were slaughtered, beyond 5 initial fish, in order to assess the microbiome intestinal content by 16S ribosomal RNA analysis.

Results and discussion
Attending to growth performance, higher SGR and FCR were reported in HP15 diets (Table 1). Despite the omnivorous behaviour of this species, the results have showed that higher fishmeal inclusion provided better growth, then it seems that this species in juvenile state had less omnivorous behaviour.

A global view of *Mugil cephalus* intestinal microbiota shows 25 different phylos where it predominates of Proteobacteria (50.1% ± 9.93) and Firmicutes (34.17% ± 8.26) phylum, without any of two phylum predominant respect the diet or initial status (Figure 1).

In relation to the genus, 316 genus were identified where *Pseudomonas* (47.98% ± 10.33) was the most represented bacteria followed by bacteria of genus *Brevinema* (11.53% ± 4.73). Any significant differences respect the diet or initial status. A predominance of proteobacteria populations have been reported in fish fed with marine protein sources, meanwhile, firmicutes are typical from fish fed with plant protein sources. Therefore, the predominance of both phylum is according to its omnivorous behaviour. With regard to *Pseudomonas*, normally these bacteria can be found in omnivores fish, and they are associated with aid digestion (Egerton et al., 2018). In terms of species diversity between experimental groups, neither were found differences based on alpha Shannon index. A recent study performed by Bertini et al. (2023) in mugil, substituted the fishmeal content up to 10% and 20% by *Corynebacterium glutamicum* single cell protein, obtaining also as most abundant phylum Proteobacteria, but the predominant genus was *Streptococcus spp*. As in the current study, alpha Shannon index did not show differences. Thus, it seems that the fishmeal substitution does not affect importantly the intestine microbiote in *Mugil spp*.

(Continued on next page)
In conclusion, relative high fishmeal requirements seem to be necessary in *M. cephalus* at juvenile state, but no relevant alterations of intestinal microbiota were observed due to the total substitution of fishmeal.

Introductions
There are several etiological agents of acute, chronic, granulomatous, systemic or focal diseases in animals worldwide. In aquaculture, in fish, reptiles, amphibians and crustaceans, these microorganisms have caused large losses in production due to the death of infected animals or the bad appearance of sick animals, which makes commercialization unfeasible. Furthermore, some of these aquatic animal pathogens are zoonotic, with an impact on public health. Thus, from 2009 onwards, the standardization of diagnostic techniques began at the Interinstitutional Aquaculture Health Laboratory (Instituto Biológico/ São Paulo/Brazil), for the detection of pathogens of aquatic organisms as an additional diagnostic tool: in situ hybridization (HI) in optical or photonic microscopy and immunoelectron microscopy (IEM) and immunocytochemistry as immunostaining with colloidal gold particles (IMCG) in transmission electron microscopy. Adaptations to the protocols initially developed for mammals were carried out, such as the removal of melanin from melanomacrophages. As there is a large amount of melanomacrophages (in the organs of ectodermal animals (frogs and fish), with brownish melanin granules, it was necessary to remove this melanin in order to facilitate the visualization of the DAB chromogen (diaminobenzidine) without interfering with the in situ hybridization technique in which specific nucleotide sequences were identified in the histological sections. This modification avoided false positive results. These techniques, after standardization, helped in the correct and efficient diagnosis of pathogens such as: white spot disease in shrimp, occurrence of

Material and methods
Material: organ fragments of in fish, reptiles, amphibians, and crustaceans

Methods: Electronic microscope
Negative Contrast Technique: The negative staining technique consists of a quick and easy preparation, presenting a result in a few minutes, being, therefore, the most productive approach in electron microscopy in terms of sample numbers. Particles from a suspension are adsorbed onto the surface of a specimen support, stabilized and counterstained usually by heavy metal droplets. By this approach, particles can be visualized down to subnanometer size and categorized based on their morphology. (Brenner, & Horne,1959; Curry et all, 2006)

Immunoelectron microscopy (IEM) is used when the number of viral particles in a sample is very low, when the virions are pleomorphic and difficult to identify due to the absence of typical viral morphology, such as a defined symmetry, presence of shape or spikes, particle size or number and arrangement of capsomeres, or when the samples are very electrondense and the aggregated complexes generated by the technique can facilitate identification [Lavazza et all. 2010]. It also allows the identification of the virus by the specific antigen-antibody reaction and such identification takes place through its morphology. It is also used to serotype morphologically similar (but antigenically distinct) particles.

Immunostaining with colloidal gold particles in the negative staining technique: In this technique, the antigen-antibody reaction is enhanced by labeling the antigen with protein A-associated colloidal gold particles using type- and genus-specific antibodies. The method also allows the detection and identification of virus-induced antigen structures and their localization in infected cells, serotyping viral strains [Kjeldsberg, 1986] and determining antigenic variants in isolated strains. (Fig1B).

Technique of inclusion of fragments in resin: The technique of embedding in resin, followed by ultrathin sections is especially important to reveal fine details of the ultrastructure of all types of cells and tissues [Martins et all., 2013] and, in an infectious process, allows observing the pathogenesis of the infection and the agent identification [Fields,1996]. The ultrathin sections have the advantage of allowing the observation of the virus-cell interaction, revealing the site of viral replication and maturation in the host cells, pertinent information in the identification of unknown viruses [Fong ,19899]. The ultrastructural set of details not only determines the infection, but also the disease course in the herds [Catroxo & Martins, 2015].

(Continued on next page)
Optical microscope: **In situ hybridization**, probes are used to locate specific nucleic acid sequences at the subcellular level. Biotin is commonly used in probes for non-radioactive detection. Biotin can be visualized by numerous procedures, whether using avidin or streptavidin and both have high affinity for this amino acid. (FIG 1A)

**Bleaching of Melanomacrophages** from Tissues of Ectothermic Vertebrates for Later Use of Immunohistochemical and in Situ Hybridization Technique Due to the large amount of melanomacrophages in the organs of ectodermal animals, such as frogs and fish, with brownish melanin granules, it was decided to remove melanin in order to facilitate the observation of organ fragments under a direct light microscope when using biotinylated probes. These slides that we used for bleaching were immersed in 10% hydrogen peroxide (H2O2) in 0.2mol/L of Tris-HCl buffer pH 7.4 for 24 hours at room temperature. During this process the material was kept in the dark. (Fig 1C).

**Results**

![Fig. 1. (A) Dark brown positive result blue areas negative result (IHS) Heart and hemocytes x 630. (B) A strong antigen-antibody interaction was evidenced by the gold particles on the virion WSSV (arrows). (C) Granuloma with several melanomacrophages.](image)

**Conclusion**

These techniques, after standardization, helped in the correct and efficient diagnosis of pathogens such as: white spot disease in shrimp, occurrence of *Mycobacterium* spp. and *Francisella* spp. in fish, and chytridiomyosis in frogs.

Introduction

Nowadays there is a growing demand for new sustainable ingredients adhering to circular economy principles and improving animal performance and health. Within these, research has focused on exploring functional ingredients (FI) that act preventively against potential diseases or dysfunctions, thus fostering fish health status (Ruiz-Cano et al., 2022). Insects, such as honeybees (Apis mellifera), are gaining popularity as a possible FI. The queen bee larvae (QBL) are usually discarded during royal jelly production and are typically considered waste. However, recent studies have shown that QBLs are rich in protein, fatty acids, and essential amino acids, enhancing their nutritional value for use in food and feed (Addeo et al., 2021; Zhao et al., 2022). For evaluating new ingredients, animal nutrition research mainly relies on conventional in vivo feeding trials, which are time-consuming, expensive, and ethically challenging. The ethical concerns surrounding animal experimentation have prompted the adoption of the 3Rs principle to minimize the use of animals and reduce their suffering (Mukherjee et al., 2022). The ex vivo model is ethically advantageous as a first approach to evaluating novel ingredients, as it uses tissue slices obtained from an organism and thus substantially reduces the number of animals used in experimentation. The slices (explants) are kept under optimal conditions, mimicking the natural environment, maintaining intercellular connections and interactions, and ensuring that physiological processes more closely represent the in vivo situation (Wang et al., 2015). The purpose of this study was to apply an ex vivo approach to evaluate the viability and inflammatory response of anterior intestine explants of European sea bass juveniles after 4 hours of incubation with QBL immersed in royal jelly (raw ingredient, RAW), its extract (RAWex), and freeze-dried product (FD) and its extract (FDex) and after a lipopolysaccharide (LPS) challenge.

Materials & Methods

QBL extracts were prepared from the raw ingredient and freeze-dried using a sequential extraction with methanol (50/50) and acetone (70/30) solutions. Six European sea bass (Dicentrarchus labrax) juveniles with 106.4±15.7 g were euthanized with excess anesthesia (2-phenoxyethanol); thereafter, the anterior intestine was sampled and slices of 5 mm diameter were cut using a biopsy scalpel. Three slices were placed in each well of 24 well plates and incubated with 1 mL of pre-treatment medium (Penstrep 500 U, 5.5 mM glucose, 2 mM glutamine, and 10% FBS) for 1 hour. Then, the pre-treatment medium was removed, and 1 mL of treatment medium containing Penstrep 100 U, 5.5 mM glucose, 2 mM glutamine, and 10% FBS and, respectively, 0 (Control), 1, 2, 4, 8, and 10% of the RAW, RAWex, FD, and FDex were added to each well and incubated at 22 °C, 100 rpm, for 4 hours. Each treatment was tested in triplicate. At the end of the incubation time, one slice per well was collected and used for a viability test and another slice was stored in Trizol at -80 °C until gene expression analysis. The remaining slice was challenged with 10 or 100 ng of LPS for 4 hours and then stored at -80 °C until gene expression analysis. The slices’ viability was assessed based on cellular metabolic activity using MTT (3-[4,5dimethylthiazol-2-yl]-2,5-diphenyltetrazolium bromide). The expression of proinflammatory genes, namely tumor necrosis factor α (TNF-α), cyclooxygenase 2 (COX2), and interleukin β (ILβ), was evaluated to assess the immune response.

(Continued on next page)
Results

After 4-hour incubation, the viability of the anterior intestine explants was not affected by the ingredients, independently of the type and concentration tested. However, compared to the Control, the inclusion of FD at 10% led to an increase in TNFα expression. After the challenge with 10 or 100 ng of LPS, no differences in the expression of immune genes tested were observed. Nevertheless, when exposed to a 10 LPS challenge, there was an augmentation in ILβ expression within 4% FD as opposed to the unchallenged 4% FD. Similarly, the application of 100 ng LPS led to a rise in ILβ expression within 10% FDEx compared to the unchallenged 10% FDEx.

Conclusions

This preliminary study aimed to assess the potential of the ex vivo approach as a preliminary screening of FIs for use in aquafeeds, using QBL as a potential functional ingredient. According to the present results, tissue viability was not affected by QBL, either as raw or as an extract, independently of the concentration tested. The explants responded to the treatments by increasing the pro-inflammatory cytokinin TNFα expression but only in the FD treatment, whilst differences were observed in 4% FD and 10% FDEx for the ILβ expression after the two LPS-challenging intensities. Overall, results suggest that QBL does not seem to enhance the immune response of European sea bass, but further studies are required to confirm these results and the potential of ex vivo assays as pre-screening tests of the tissue immune responses.

Background
Common carp is the main carp species farmed globally with its annual production exceeding 4 million MT (FAO 2022). Protein is qualitatively the most expensive component in the feed and a more precise understanding of amino acid (AA) requirements will help formulating a cost-effective diet using alternative ingredients. Traditionally, dose-response study has been used to determine AA requirements, but this is quite time consuming and expensive. Recently, the factorial modelling approach was used to determine AA requirements in salmonids (Hua and Bureau 2019) - but for this approach, data on AA maintenance requirements and utilization efficiency are the prerequisites. Ration level technique has been proven to be useful in estimating maintenance requirement and utilization efficiency of AAs in fish (e.g., Helland et al. 2010; He et al. 2013). The objective of this study was to estimate maintenance requirement and utilization efficiency of AAs, specifically of methionine (Met) and Cysteine (Cys) in common carp, using ration level technique.

Materials and Methods
The trial was conducted in grow-out stage common carp with an initial body weight of 147.6 g at the Marine Aquaculture Centre of the Singapore Food Agency. A practical diet was formulated to meet the known nutritional requirements of common carp based on available data. The diet contained, on a dry matter basis, 31.5% crude protein, 18 MJ/kg gross energy, 1.90% Lys, 0.80% Met and 1.22% Met+Cys. The diets were fed to fish at 4 ration levels of 100%, 75%, 50% and 25% apparent satiation. A fifth dietary treatment was a non-protein diet fed to fish at 100% apparent satiation. The non-protein diets were formulated with protein-free ingredients but contained similar levels of energy, vitamins and minerals. The fish were hand-fed to two meals per day for 42 days. Quadruplicate groups of fish were randomly allocated to each of the experimental treatments. Water temperature was maintained at 24.9°C. A simple linear regression model was fit between the AA gain versus intake and the requirement for maintenance was estimated as the amount of digestible AA to maintain zero AA gain, i.e. the intercept on the x axis of the linear regression and the marginal utilization efficiency of the AA above maintenance was estimated as the slope of the regression.

(Continued on next page)
Results
The increasing ration levels showed linear increase on growth rates of fish, with fish fed to apparent satiation showing the highest body weight gain, specific growth rate (SGR) and thermal growth coefficient (TGC) (Table 1). There were no significant differences in feed efficiency among the treatments of 50%, 75% and 100% ration levels. Protein free diet produced no differences in weight gain, SGR and TGC in comparison to the 25% ration level. For digestible protein retention efficiency, only protein free diet was significantly lower than other treatments. No significant differences in digestible Met retention efficiency were observed in all treatments. Maintenance requirement was estimated to be 9.20 mg/kgBW^{0.8}/d for Met and 16.1 mg/kgBW^{0.8}/d for Met+Cys with the marginal utilization efficiency being 50.5% and 45.7%, respectively for Met and Met+Cys. Data were further analyzed to determine maintenance requirements and utilization efficiency of other essential AAs. Data produced in this study can be used to derive AA requirements of common carp and formulate more precise diets for their different life stages.

Introduction

Fish feed are produced primarily with plant ingredients with minimal amount of fish meal possible. While this helps reduce feed cost, it is equally important not to compromise on the nutritional quality of feed and thus, the fish performance. For example, animal ingredients contain certain amount of creatine or its precursor, whilst the plant based ingredients contain no creatine. Creatine and its phosphorylated form phosphocreatine (PCr) play a vital role in the cellular energy metabolism of animals. The adenosine triphosphate (ATP)–creatine phosphate system transfers a high-energy phosphate from PCr to adenosine diphosphate (ADP) to regenerate ATP. Creatine is synthesized in body by its precursor guanidinoacetic acid (GAA) which is more stable under feed production process than the creatine itself. There are studies showing the positive benefits of dietary GAA supplementation in fish including tilapia (e.g., Aziza et al. 2020; Mabrouk et al. 2020) and carp (Yang et al. 2021). Borchel et al. (2014) showed the importance of creatine on the energy metabolism of rainbow trout. The objective of this study was to investigate the effects of increasing levels of GAA supplementation on the performance of juvenile rainbow trout.

Materials and Methods

Experimental basal diet (D1) was formulated with low levels of fish meal (5%) but still meeting the known recommended nutrient levels for rainbow trout. Diets 2-7 were supplemented with increasing levels of GAA at 0.04% increment levels (0.04-0.24%) whilst the Diet 8 was supplemented with the GAA source at 0.30%. All the 8 diets were allotted randomly to the 32 experimental tanks, containing 30 fish (~9 g, mean initial body weight) per tank and giving 4 replicate tanks per diet. Fish were fed 4 times a day over a 98-day study period, which included 90 feeding days and 8 no-feed days (fish were not fed during the weighing days).

![Graph](image)

Fig 1. Effects of guanidinoacetic acid (GAA, %) supplementation on the body weight (mean ± SE) of rainbow trout at the end of 98 days of study period.

(Continued on next page)
Results
At the end of the study (day 98) mean body weight had increased to 143-158 g among the dietary groups and differed significantly (p < 0.05, ANOVA). Diets supplemented with 0.04 and 0.08 % GAA showed a significantly higher body weight gain compared with the basal group (p < 0.05, ANOVA). In terms of growth, fish fed diets supplemented 0.04-0.12% GAA showed significantly better thermal growth coefficient whilst only the 0.08% GAA supplemented diet produced significantly better specific growth rate compared with the basal. Feed conversion rate of fish fed different treatment diets ranged from 0.97 to 1.00 and showed no difference. On the initial and final day, no differences were detected on the whole-body proximate nutrient composition of rainbow trout, however, fish group fed with 0.08% and 0.12% GAA supplemented diet showed marginal increase in the body protein gain compared with the control group (0.05 < p < 0.10%, ANOVA). Overall, our study results clearly indicate that supplementing low-fish meal rainbow trout feed at 0.08 % GAA significantly improves the fish growth performance.

VALIDATING BIOLOGICAL EFFICACY OF METHIONINE SOURCES IN NILE TILAPIA

Karthik Masagounder* and Jorge Dias

1Evonik Operations GmbH, Hanau-Wolfgang, Germany
2SPAROS Lda., 8700-221 Olhão, Portugal

*Email: karthik.masagounder@evonik.com

Introduction
Soybean meal-based diets in fish are limited in methionine (Met) and need its supplementation in order to meet requirements of fish for optimal growth performance. DL-methionine (DL-Met) and methionine hydroxy analogue, DL-MHA (DL-2-hydroxy-4-methylthiobutyrate free acid, DL-HMTBa and its calcium salt, MHA-Ca) are the commonly available supplemental Met sources in animal feeds. In Nile tilapia, Teodosio et al. (2022), using labelled sources of DL-Met and MHA-Ca, demonstrated the better utilization of DL-Met versus MHA-Ca for body protein synthesis. While there debate exists in the literature, based on the published data, NRC (2011) concluded that it is reasonable to assume that the biological efficacy (BE) of MHA in fish is 75-80% that of DL-Met on an equimolar basis. This is equivalent to 63-67% for MHA-Ca on a weight basis considering its 84% product purity. This means 1 unit of MHA-Ca and 0.65 unit DL-Met elicit equal performance in fish. With this background, this study was undertaken to validate the 65% average bioefficacy of MHA-Ca versus DL-Met based on the growth performance and antioxidant status of Nile tilapia.

Materials and Methods
The trial was conducted at the experimental facilities of the University of Trás-os-Montes e Alto Douro (UTAD, Vila Real, Portugal) under the full responsibility of SPAROS. The trial comprised 7 dietary treatments (D1-D7) and all diets were based on a single basal formulation (NC) containing 0.47% Met and 1.00 % Met+Cys. The remaining 6 diets were supplemented with three Met sources (DL-Met, MHA-Ca and PROXYMet containing 65% DL-Met and 35% limestone). D2 and D3 with DL-Met at 0.1 and 0.2%; D4 and D5 with MHA-Ca at 0.154 and 0.308%; and D6 and D7 with PROXYMet at 0.15 and 0.31%. Diets were isonitrogenous (crude protein: 37.5 ± 0.5 %DM) and isoenergetic (gross energy: 19.2 ± 0.1 MJ/kg DM). Diets were fed three times daily over 92 days, to quadruplicate groups of Nile tilapia (50 fish per tank) with a mean initial body weight of 22.5 g (1.2 g, SD). The average water temperature during the trial was 26.5 ± 0.4°C and water dissolved oxygen levels were kept above 6.4 mg/L. Ten whole-fish from the initial stock (start of the trial) and a pool of 9 whole-fish from each replicate tank at the end of the trial were sampled and used for whole body composition analysis. Liver of 3 additional fish per replicate tank were sampled, and used for assessing antioxidant status criteria.

(Continued on next page)
Results
Fish fed the Met supplemented diets (2 to 7) showed a significantly higher body weight, specific growth rate (SGR) and protein efficiency ratio (PER) and a significantly lower FCR than those fed D1, without Met supplementation (Table 1). Diets supplemented with Met sources DL-Met and PROXYMet led to a significantly higher final body weight, SGR, PER and a significantly lower FCR than those supplemented with MHA-Ca (Table 1). Met dose had also a significant effect on performance criteria, with higher FBW and SGR being found in fish fed diets with the highest supplementation dose. Dietary Met dose or supplementation had no significant effect on the whole-body composition of fish. Fish fed diets supplemented with Met sources DL-Met and PROXYMet showed also a significantly higher whole-body protein, fat and energy retention than those fed diets supplemented with MHA-Ca. Increase in Met supplementation doses led to a significant increase of the hepatic levels of the reduced glutathione form (GSH). Overall, all Met supplemental sources and doses generated significant gains on the performance criteria of Nile tilapia. However, these gains were significantly higher with DL-Met and PROXYMet products than with the MHA-Ca product, suggesting bioefficacy of MHA-Ca is even lower than 65% in Nile tilapia on a weight basis. As in our study, lower BE of MHA-Ca (43-52% on weight basis) versus DL-Met was also reported recently in common carp (Zhou et al. 2021). Results of this study need to be considered in formulating tilapia feeds for optimal production and economic performance.

Introduction

In the pursuit of more sustainable fish feed ingredients, polychaete worms are emerging as a popular alternative to replace fish meal and fish oil (Pombo et al., 2020). The Nereis genus, specifically N. virens and N. diversicolor, is being investigated for its potential as a source of high-quality protein, fat, and essential fatty acids like EPA and DHA, which are beneficial for the growth and well-being of aquaculture species (Wibowo et al., 2020; Pajand et al., 2017; Bischoff et al., 2009). The objective of this study was to assess the digestibility of diets containing polychaete meal (Nereis virens, Sars 1835) as an alternative ingredient to replace traditional protein sources, such as fish meal and plant meals, in meagre.

Materials and methods

For the digestibility trial, nine groups of 15 fish (76.3±15.6g) were placed in 250L cylindroconical tanks equipped with a settling column. The fish were fed with a control diet and two experimental diets, which included 10% or 20% Nereis virens meal (ProChaete Innovations LTD, UK). The polychaete meal served as a replacement for up to 9g/kg of plant ingredients and up to 120g/kg of fish meal (Table I). An inert marker, celite®, was added at a level of 10g/kg. The proximate compositions of the feed and feces, as well as the apparent digestibility coefficients, were determined following the methods described in Gasco et al. (2016). The carbohydrate and energy content of the feed and feces were calculated based on the approach by Kounna et al. (2021)

(Continued on next page)
Results and Discussion

Meagre demonstrates good tolerance for diets incorporating alternative ingredients like insects and algae, particularly when the replacement level of fish meal is low (Estévez et al., 2022). However, its ability to effectively utilize invertebrate meals, such as insect meals, is limited, and digestibility decreases when the inclusion exceeds 10% (Coutinho et al., 2021; Guerreiro et al., 2020). Similarly, in this experiment, the inclusion of polychaete meal resulted in a significant decrease in dry matter digestibility (p<0.05). However, protein digestibility remained similar across the experimental diets, ranging from 83.0% to 84.4%. Fat and energy digestibilities exhibited a tendency to decline with increasing levels of polychaete meal inclusion, although the decrease was only statistically significant in the apparent digestibility of energy (p<0.05).

In conclusion, meagre exhibits efficient utilization of polychaete protein up to a 10% inclusion level. However, beyond this threshold, there is a negative impact on the digestibility of dry matter and energy.

Introduction
Global aquaculture grew at a faster rate than other food crops, with an average annual growth rate of 4.6% from 2007 to 2018. (FAO, 2020). The main challenge in growing aquaculture sector is to provide a constant supply of economical and eco-friendly feed in sufficient quantity. Traditionally fish meal is used as protein source in feed of various aquaculture practices. Due to its ever increasing demand, the supply of fish meal is not remained smooth beyond having high price and environmental concerns. In aquaculture, functional feed formulation is an optimal solution of reducing high feed cost in an environmental friendly way; by replacing animal origin ingredients with plant based sources and functional additives.

Material and Methods
An experiment was carried out to examine the effect of 75% replacement of fishmeal as protein source in diet with soybean meal (fermented/ non fermented; 2% probiotic/ 4% probiotic) on growth, immunity, proximate body composition and digestive enzyme status of Oreochromis niloticus. Five treatments of feeding were designated as (T0) containing 100% fishmeal, (T1) 75% fishmeal replacement with fermented soybean meal and 2% probiotics, (T2) 75% fishmeal replacement with non-fermented soybean meal and 2% probiotics, (T3) 75% fishmeal replacement with fermented soybean meal and 4 % probiotics, (T4) 75% fishmeal replacement with non-fermented soybean meal and 4 % probiotics. The comparative effect of these functional feed treatments were investigated with reference to growth response, innate immunity, digestive enzyme activity and body composition of Nile tilapia for 16 weeks in laboratory conditions.

Results
The observed weight gain was 14.1 g in T0, 8.7g in T1, 8.4 g in T2, 10.38 g in T3 and 9.96 g in T4. The better value of FCR (1.88) was observed in T0 group and the maximum value of SGR (1.9) was also observed in T0. The WBCs count and IgM were highly reduced in non-fermented soybean groups. However, FSBM showed significant increase in WBCs count and IgM. Highest level of WBCs counts and IgM was observed in FSBM with 4% probiotics. IgM level of O. niloticus was 10.13 mg/ml in T0, 9.76 mg/ml in T1, 9.30 mg/ml in T2, 11.36 mg/ml in T3 and 10.43 mg/ml in T4. The results of the digestive enzyme activity with non-fermented SBM had negative effect on digestive enzyme activity. Fermented soybean groups showed an improvement in digestive enzyme activity in comparison to non-fermented groups but not comparable to control group. Lipase activity of O. niloticus was 196.6 U/mg for T0, 190.30 U/mg for T1, 186.30 U/mg for T2, 190.21 U/mg for T3 and 186.2 U/mg for T4. Amylase activity was 4.46 U/mg for T0, 4.40 U/mg for T1, 4.56 U/mg for T2, 4.26 U/mg for T3 and 4.50 U/mg for T4. Protease activity was 71.04 U/mg for T0, 68.51 U/mg for T1, 64.42 U/mg for T2, 68.54 U/mg for T3 and 64.54 U/mg for T4. The results of present study indicated that FSBM had no significant effect on the proximate body composition with respect to moisture content, protein, fat and ash content, however crude protein and fat level were significantly decreased in non-fermented SBM groups. The levels of crude protein of O. niloticus were 16.05% for T0, 16.05% for T1, 13.54% for T2, 16.02% for T3 and 13.616% for T4. Total fats were 3.66% for T0, 3.64% for T1, 2.24% for T2, 3.64% for T3 and 2.55% for T4. The moisture contents were 78.26% for T0, 78.16%, for T1, 80.20% for T2, 78.16% for T3 and 80.55% for T4 and total ash contents were 3.19% for T0, 3.21%, for T1, 4.57% for T2, 3.21% for T3 and 4.48% for T4.

Discussion
Use of non-conventional (plant based) ingredients in fish feed due to presence of anti-nutritional factors and poor digestibility affects the fish performance adversely there by reducing overall production (Abowei and Ekubo, 2011). During the current experiment in comparison to the other groups, the growth in control group was higher, but there were slight differences in weight gain and length gain of Tilapia. Although fermented soybean meal was used with the addition of 2% and 4% probiotics through which anti-nutritional factors were removed which halted growth, but poor growth was observed in treatments. Study by Dan et al. (2017) showed similarity with these results as they found that fish growth was maximum in control group then followed by fermented soybean meal.

(Continued on next page)
The digestive enzymes play role in digestion and assimilation of feed by digesting and absorbing the nutrients properly (Deng et al. 2015). In the present study the digestive enzyme activity was significantly varied/reduced in both fermented and non-fermented groups. The soybean meal contains the anti-nutritional factors which negatively affect the digestive enzyme activity. The protease activity was significantly reduced in non-fermented group due to the presence of protease inhibitor in SBM. Liu et al. (2020) reported that as the level of substitution of fishmeal with SBM increased there was significant reduction in digestive enzyme activity.

From the results of present study it is evident that high level fish meal replacement with soybean meal did not provide better growth, innate immunity, digestive enzyme activity or proximate body composition in Nile tilapia, however if we pretreat the soybean meal through fermentation along with probiotic inclusion then a comparable performance may be achieved.

Introduction

Understanding the impact of microplastics (MPs, plastic particles < 5 mm) on aquaculture species has become a growing concern in food safety worldwide [1]. Indeed, MP occurrence has been reported not only in many wild-caught fish species but also in their farmed counterparts [2]. The interdependence between aquaculture production systems and reservoir environments, and their specificities related to plastic gear usage are likely to affect MP availability for uptake by fish [3]. Under the ‘One Health’ perspective, this work aimed to evaluate the MP occurrence in European seabass (Dicentrarchus labrax) produced in three different aquaculture systems by analysing water, fish feed and seabass tissue samples. Trace and non-essential metals in seabass muscle were also determined. Human dietary exposure and toxicological risk from consuming farmed seabass muscle were estimated using European Food and Safety Authority (EFSA) recommendations.

Materials and methods

Approximately 50 specimens were collected from each of the three selected aquaculture systems: a cage farm located in Turkey, and a pond farm and a recirculating aquaculture system (RAS) both located in Portugal. Particles suspected of being made of plastic were quantified in the gastrointestinal tract (GIT) and muscle and visually characterized according to their shape, colour, and size. The chemical identification was performed through Fourier Transform Infrared Spectroscopy (FTIR).

The concentration of trace (Cr, Ni, Cu, Zn) and non-essential (Cd, Hg, Pb) metals in the seabass muscle were determined through Atomic Absorption Spectrophotometry (AAS).

Human exposure to contaminants through seabass consumption was estimated based on European Market Observatory for Fisheries and Aquaculture Products (EUMOFA) data.

Fig. 1. MP occurrence per litre of water (A), and per gram of feed (B) and fish tissue, gastrointestinal tract (GIT) and muscle of European seabass (C) from three aquaculture systems. Different letters indicate significant differences among samples (p < 0.05)

(Continued on next page)
Results

Comparatively higher MP levels were detected in RAS water and feed than in the other systems (Fig. 1A and 1B). MPs with blue and black colour, fibre-shaped, and made out of cellulose/rayon and polyester, were the most common in all systems. MP characteristics were generally similar among fish tissues. Cage-farmed seabass had the lowest MP occurrence, with 89% of the fish having at least one MP recovered from a certain tissue. At the tissue level, RAS-farmed fish had the highest MP levels in muscle, while in GIT, the values were also higher in these fish but comparable to those observed in pond-farmed seabass (Fig. 1C).

Cr, Ni, Zn, Cd, and Hg concentrations detected in muscle were all below the maximum permissible concentrations established for this species. Cu and Pb were below detection limits. No significant differences were observed among systems, except for Zn with pond-farmed seabass displaying the highest value (5.5 ± 0.7 vs. 3.6-4.6 µg/g wet weight).

Based on the available health-based guidance values (HBGVs) provided by EFSA for metals and considering a 150 g meal of seabass fillet, no toxicological risk associated with farmed seabass fillet consumption was observed. A monthly human exposure to MPs ranging from 1.8-9.3 per kg of consumer’s body weight was estimated, depending on seabass consumption habits in each country.

Discussion

Our findings indicate that water and feed are the primary pathways of MP exposure for farmed European seabass, which may potentially result in their retention in fish tissues. The presence of MP in muscle tissue indicates their potential availability to human consumers along with other environmental contaminants. However, the calculated human dietary exposure scenarios revealed low toxicological risks associated with consuming seabass produced from the three analysed production systems. Despite the findings, the controlled conditions in artificial systems such as RAS are more likely to provide better opportunities for minimizing MP contamination through the implementation of mitigation strategies (e.g., development of natural system components) in the systems. This work is in line with the One Health concept, which acknowledges the interdependence of human, animal, and environmental health.

Introduction
The pullet carpet shell *Venerupis corrugata* is commercially exploited in southern Europe (Joaquim et al., 2010). The market demand and commercial value of this species are high. However, populations declined during the last decades due to overfishing and recruitment failure. Thus, it appeared crucial that an active intervention may be necessary to restore stocks aiming to attain reproductive viability. To reverse this declining situation, the hatchery production of larvae should be implemented. This study has the main objective to evaluate the evolution of the maturation state of *V. corrugata*, from different origins, in conditioning, contributing to the development and validation of a new protocol for obtaining larvae and maximizing hatchery production.

Materials and methods
*Venerupis corrugata* from three origins, Lagos coast (VCOF), Óbidos Lagoon (VCOB), located in Portugal and Ria de Arousa (VCRI), Spain, were induced to spawn at Oceano Fresco Biomarine Center in November 2021, and after, placed for conditioning to enhance the gonad development. Twenty individuals from each origin were sampled to evaluate the biochemical composition, gonadal stage and condition index. Sampling, spawning induction, and conditioning were repeated twice on 5 January and 9 February 2022. Larvae from each spawn and each origin were incubated. 50 larvae were periodically sampled to estimate the survival rate and growth.

Results and conclusions
Sexual maturation
In general, clams presented sexual synchronism in all populations except in Óbidos, where a slight advance in females’ gonadal development was observed (Figure 1). In November, most individuals presented the gonad completely mature or in spawning and post-spawning phases. Only in Óbidos were found the early gametogenesis stage. The VCOF population had a higher gonadal index (4,5) when arriving from the natural environment. After a month and a half of conditioning, most individuals from all origins recovered their pre-spawning condition, reaching gonadal index values between 4.7 and 4.9. The first conditioning was more efficient for the VCOB population. The second conditioning was less effective than the first one once most individuals remained in post-spawning (stage 5), and the gonad recovery was not so effective.

Biochemical composition
Proteins were clams’ predominant dry tissue constituent (Figure 1). The glycogen content was the biochemical compound that revealed higher variations along conditioning periods. Clams from VCOF presented the highest value of this compound in November, suffering a pronounced decrease in January. In VCOB, glycogen decreased in the first conditioning and slightly increased in the second. In the VCRI population, contrary to the others, glycogen content increased in the first conditioning, followed by a decrease in the final of the second conditioning in February. Total lipids content decreased in the second conditioning for the VCOF population. In VCOB, this compound increased in the first conditioning. In clams from VCRI, total lipids don’t suffer significant alterations.

Condition Index
In general, the condition index of all tested origins decreased along conditionings, compared to its initial condition. This decrease was more pronounced in the second conditioning for VCOF clams, and in the first one, for VCOB and VCRI clams.

(Continued on next page)
Larval viability
The highest average growth was recorded in VCOF larvae in February on the 12th day of culture (Figure 2). In November, no significant differences were found between the origins at the end of the larval culture. However, differences were visible in January, being the VCOF larvae having the highest average length. The broodstock origin did not have a significant influence on larval growth.

Aquavoltaics in Light of Fish Dependence on Light

dmatulic@agr.hr

Fish, light and aquavoltaics
Global environmental concerns and increasing energy demand, combined with steady progress in renewable energy technologies, are opening up new opportunities for the use of renewable energy sources. Solar energy is the most abundant, inexhaustible, and cleanest of all renewable energy sources (Parida et al., 2011). Photovoltaic conversion is the direct conversion of sunlight into electricity without the interposition of a heat engine. All solar cells require a light-absorbing material present in the cell structure to absorb photons and produce free electrons through the photovoltaic effect.

‘Floatovoltaic’ represent an emerging power-generation technology utilizing idle water and solar energy systems—comprising floating photovoltaic (FPV) panels over water. They are an attractive source of low-carbon energy because they free up land for other uses and produce greater electricity yields compared to land-based systems. FPV designs for freshwater are evolving as the technology matures and primarily include PV panels mounted on individual floats, on racks attached to floating pontoons, or on poles fixed to the water’s bottom (Fig. 1) (Liu et al 2018).

However, to date little is understood of the impacts of FPV on the hosting water body. Anticipating changes to water body processes, properties and services owing to FPV deployment represents a critical knowledge gap that may result in poor societal choices and water body governance (Armstrong et al., 2020). As the world’s population increases and competition for land rises, dual-use approaches are becoming essential solutions in the agriculture and aquaculture sectors. With the constantly growing aquaculture industry and the increasing demand for eco-friendly production processes, the necessity for employing optimized aquaculture systems, supplied by renewable energies, gaining progressively attention in the global food production sector. Teaming up photovoltaics with agriculture or aquaculture, namely, the agrivoltaics and aquavoltaics (AquaPV), create novel energy-food (land or water) nexus offering mutual benefits potentially (Jing et al., 2022). AquaPV is a concept emerged with combining electricity production and aquaculture. The goal of AquaPV is the efficient use of water with the dual use for both food and energy generation. The AquaPV approach aims to maintain parameters such as water and air temperature, light availability, water pH, dissolved oxygen, feeding system, and predator pressure, and improve the system by exploiting synergies between aquaculture and FPV systems. While solar panels above the water or on its surface provide the electrical energy, the aquatic organisms living within the water below provide a sustainable food source.

Light characteristics are very specific in an aquatic environment and light is extremely variable in nature. ‘Receptivity’ of fish to light profoundly changes according to the species and the developmental status (Beouf and La Bail, 1999).

Fish move within their environment and often their environment moves around them, affecting the light that the fish receives (Sumpter, 1992). Moreover, light shows interesting characteristics in the aquatic environment. In fact, ‘quality’ (the different wavelengths which are absorbed by water to various extents), ‘quantity’ (different intensities) and ‘periodicity’ (daily cycles, which vary seasonally according to latitude) should also be considered. Fish behaviour can be affected even by artificial light stimuli. A common reaction of fish groups to the presence of artificial light is to school and move towards the light source (Ben-Yami, 1976). Functional explanations for such a reaction include predator avoidance and enhancement of feeding efficiency (Pitcher and Parrish, 1993). In terms of aquavoltaics, light emitting diodes (LEDs) can be installed on the bottom of the pontoon structures in the aquavoltaic system, powered by the PV portion of the system to affect the photoperiod of aquatic life. This design provides a powerful tool for the aquaculturist to increase and further optimize production for specific aquatic species but needs to be tested further, while the effects of energy conversion need to be considered, also. (Pringle et al., 2017). Normally, fish are either more active in light and less active in darkness or vice versa, and this can be altered by daily changes in factors such as temperature or oxygen. Growth of aquatic organisms is linked to light, but it is not unique because species vary in their growth conditions. Fish and larvae, for example, must be reared in specific light ranges depending on the species and stage of development (Beouf and Le Bail, 1998). Aquavoltaics provide shade on the fish pond water surface, and the blocked light is absorbed by solar panels and converted into usable energy. If uncontrolled, an increase in shading decreases algal growth, general plant life, and microbial density are reduced, affecting the entire food chain down to the fish intended for breeding. With a suitable system approach, aquavoltaics can contribute to sustainable water use and fulfil the concept of the food-water-energy nexus. More research is needed to understand the effects of direct contact with pontoon structures and solar arrays on aquatic life.

Introduction

The jump-like processes of sturgeon fish development in early ontogeny create conditions for the use of immunostimulants in order to effectively overcome the stress caused by their cultivation in recirculating aquaculture systems (RAS). The synthetic substance levamisole is used in aquaculture. It has been reported that the use of this substance in the diet of juvenile pacu during stress altered circulating cortisol levels and also improved the innate immune response to infection with Aeromonas hidrophila (Pahor-Filho E., 2017).

The immune-stimulating properties of this substance added to carp and sea bass food have also been described (Guesta et al., 2004, Rymuszka et al., 2005). However, most data on the effects of levamisole relate to mature fish, and information about its effect on juveniles, especially sturgeons, is insufficient. Therefore, the purpose of this study is to evaluate the effects of the levamisole on the growth, development, and viability of juvenile sturgeon fish.

Material and methods

Larvae and juveniles of the hybrid bester (♀ Huso huso X ♂ Acipenser ruthenus) and freshwater sterlet (Acipenser ruthenus) (BSS) were used in the study. Experiments were performed at RAS on larvae of Bester sturgeon, immediately after their transition to exogenous nutrition and lasted 28 days at temperature 18°C (n=1000). In the first month of rearing, live food, Artemia nauplii (Artemia salina), was used. Live Artemia nauplii were enriched with levamisole according to the method used to create a concentrate for the enrichment of rotifers and nauplii (Watanabe, 1983). In the experiment, a levamisole concentration of 14.6 mg per 1 g of live nauplii was used in 100 g of enrichment substrate for 8 hours. The main indices of fish were studied: weight, body length, growth rate, mortality.

Results and discussion

The addition of levamisole to the diet during the first week of exogenous feeding had a positive effect on the growth of young sturgeon. The average weight of fish in the experimental group increased by 3.96 times for a week, which is 9% higher than the control values. Average daily weight gain in the experimental group was 24.9%, in the control group - 22% per day. During levamisole application during the first and second day the growth rate of fish was 19 and 20%, after that it increased to 27.3% and by the end of the seventh day it remained at 27%. In the control group, the growth rate was 17 and 18% per day during the first two days, after which it also reached the level of 27%.

After 21 days of the experiment, it is noticeable that the average body weight of young sturgeons in the group consuming levamisole increased to 0.794 g statistically reliably (p < 0.05), which exceeds the control values by 50.5%. The average growth rate was 9.3% and 11.3% in the experimental and control groups, respectively. Thus, the positive difference in the average weight of the experimental fish is a consequence of the prolonged action after levamisole application during the first week of the experiment. However, analyzing the daily growth rates, the negative effect of repeated application of Levamisole is observed, which leads to a decrease in the growth rate relative to the control group.

Conclusions

Thus, levamisole in an amount of 14.6 mg/g of Artemia nauplii is reasonable to use during the first week when larvae switch from mixed to exogenous nutrition. Its repeated use after three weeks is inexpedient because of the lack of positive indicators in fish. Finding and developing safe and effective ways to apply new substances that positively affect the survival of juvenile sturgeon is a promising area of research. Our work will continue, and in the future we plan to extend the results obtained to other sturgeon species.

Introduction

The jump-like processes of sturgeon fish development in early ontogeny create conditions for the use of immunostimulants in order to effectively overcome the stress caused by their cultivation in recirculating aquaculture systems (RAS). The synthetic substance Levamisole is used in aquaculture. Thanks to its use in the diet of the juvenile paku during stressful situations, the circulating cortisol level was modulated, and the innate immune response to Aeromonas hidrophila infection was also improved (Pahor-Filho E., 2017). Also, the immunostimulating properties of this substance in the process of feeding it to carp and seabream have been described (Guesta et al., 2004, Rymuszka et al., 2005). Most of the information on the action of Levomizole concerns mature stages of fish, but there is insufficient information on its effect on juveniles, in particular sturgeon. This abstract presents the effect of the Levamisole on the growth, development, and viability of juvenile sturgeon fish.

Material and methods

The object of the study were larves and juveniles of the bester hybrid (♀ Huso huso X ♂ Acipenser ruthenus) and freshwater sterlets (Acipenser ruthenus) (BSS). The experiments were carried out in RAS on small bester sturgeon larvae, immediately after their transition to exogenous nutrition and lasted for 28 days at a temperature of 18°C (n=1000). In the first month of cultivation live feed was used - artemia nauplii (Artemia salina). Live artemia nauplii were enriched with Levamisole according to using the method used to create a concentrate for enrichment of rotifers and nauplii (Watanabe T., 1983) In the experiment, a concentration of Levamisole was used in the amount of 14.6 mg per 1 g of live nauplii, in 100 g of enrichment substrate for 8 hours. The main fish indicators were studied: mass, body length, growth rates, mortality.

Results

The addition of Levamisole to the diet during the first week of exogenous feeding has a positive effect on the growth of juvenile sturgeons. The average weight of experimental fish in the experimental group increased during the week by 3,96 times, which is 9% higher than the control values. The average daily weight gain in the experimental group was 24,9%, in the control group - 22% per day. In the process of using Levamisole during the first and second days, the growth rate of fish was 19 and 20%, after which it increased to 27,3% and by the end of the seventh day it was still at the level of 27%. In the control group, the growth rate was 17 and 18% per day for the first two days, after which it also reached the level of 27%.

After 21 days of the experiment, it is noticeable that the average body weight of young sturgeons in the group that consumed Levamisole increased to 0,794 g was statistically significant (p < 0.05), which exceeds the control values by 50,5%. Average growth rates were: in the experimental group – 9,3%, in the control group – 11,3%. Thus, the positive difference in the average weight of the experimental fish is a consequence of the prolonged action after the use of Levamisole during the first week of the experiment. However, analyzing daily growth rates, a negative effect of repeated use of Levamisole is observed, which leads to a decrease in growth rates relative to the control group.

Conclusions

Thus, it is advisable to use Levamisole in the amount of 14,6 mg/g of artemia nauplii during the first week during the transition of larvae from mixed to exogenous nutrition. Its repeated application after three weeks is impractical due to the lack of positive fishery indicators. The search for and development of safe and effective ways to use new drugs that positively impact the survival of juvenile sturgeon is a promising area of research. Our work will continue and we plan to extend our results to other sturgeon species in the future.

E-mail: alkistibatzina@gmail.com

Introduction
The SaltBox project aims at designing and manufacturing a fish size/biomass estimator by using Coded Structured Light and adapted to the two major Mediterranean aquaculture species, gilthead seabream and European seabass. For the image captured by the estimator to be “translated” to actual body weight it is necessary to establish accurate weight-morphometrics relationships from traits that the estimator can accurately “see”. The aim of the present study is to report these relationships for European seabass.

Materials and Methods
A total of 2933 specimens were individually weighted and photographed with embedded ruler. Targeted body weight ranged from 50 to 1000 g and special attention was paid to obtain at least 75-100 observations in a range of 25 g weight classes. Photographs were analyzed by digital image analyses and several morphometric traits were obtained. Spearman rank correlations were calculated, regression analysis was performed, and several models were applied to identify the most accurate one predicting weight from one or more of the morphometrics traits.

Results
The strongest correlation was obtained between weight and body monolateral area, followed by body lengths (i.e. total, fork, standards length, body height). The best model to describe weight (W)-morphometric traits (MT) relationships was of the type: \( W = aM^b \), with the exception of W-eye diameter and W-eye area relationships, which were neither strong nor well fitted. Multiple or polynomial regression also produced inferior estimations and the same result was obtained when the ratios of several combinations between traits examined were used. Also, when data were analyzed separately for body weight ranges of productive interest (i.e. 50-100 g, 100-500 g and 500-1000 g), relationships obtained were weaker and did not offer any advantage over those of the full body weight range examined.

Conclusion
Results obtained indicate that body monolateral area can be best used to accurately estimate actual body weight. The size/biomass estimator resulting from the SaltBox project can be tuned towards the precise estimation of this morphometric trait.

Introduction
The Atlantic sturgeon is one of the largest and most endangered fish in Europe. The last records of the natural population are dated to the 1970s and currently, the species is recognized as extinct in the wild in Poland, while the last specimen in the Baltic Sea was recorded in 1996. Its reintroduction projects are based on hatchery material and fish raised in captivity. Thus maintenance, as well as nutrition guides, must be developed for successful species propagation and restocking.

Materials and methods
1800 juvenile Atlantic sturgeons (10.3 g each) were used in the 50-day-long feeding trial. They were divided into 3 treatments using 6 tanks per group and 100 fish per tank. The control diet (CON) contained 300 g/kg of fish meal. In 2 experimental treatments 150 and 300 g/kg of *Hermetia illucens* partially defatted meal (BSFM) was introduced. After 50 days of feeding growth performance and somatic indices were measured, and all the data were analysed using analysis of variance and post hoc Duncan’s test.

Results
There was no fish mortality recorded. Among all treatments, there were no significant differences in final body weight, body weight gain, specific growth rate as well as feed conversion ratio. Condition factor and viscerosomatic index were not differentiated between insect meal inclusion levels. However, in treatment with 300 g/kg of *Hermetia illucens* meal the lowest hepatosomatic index was observed. There were no differences in fin length indices.

Conclusions
*Hermetia illucens* meal may be used in Atlantic sturgeon nutrition even with high inclusions of up to 300 g/kg of feed with no negative effects on growth performance, somatic indices or animal welfare. It may be concluded that insect meals are suitable feed materials for wild fish rearing for restocking purposes.

This study was carried out as part of the project entitled: “Innovative technology of highly adaptative juvenile sturgeon fish rearing for the natural and seminatural environment”, no. 00001-6521.1-OR1500001/20, Task 2.1 “Innovations” according to EU Regulation No. 508/2014, Priority 2 – “Supporting environmentally sustainable, resource-efficient, innovative, competitive and knowledge-based aquaculture” realized in the Operational Program “Fisheries and Sea”.

Introduction
Rheophilic cyprinids populations decrease in European rivers during the last 50 years due to human activity and its effect on the environment. As an important element of trophic systems, they may be considered an „umbrella species” for the entire ecosystems of lowland rivers. Thus methods of their reproduction and rearing of juvenile stages must be developed and improved for the effective production of restocking material.

Materials and methods
Adult females of common barbel (Barbus barbus), vimba bream (Vimba vimba), ide (Leuciscus idus) and European chub (Squalius cephalus) were obtained from a long-term captive population maintained in the Experimental Station of Feed Production Technology and Aquaculture in Muchocin. In the experiments, the possibility of stimulation for egg production was assessed. 80 fish per species were divided into four treatments (20 females each) CON – control with no stimulation, E – with environmental stimulation by prolonged photoperiod and increased water temperature, H - with hormonal stimulation (ovopel) and EH - with both environmental and hormonal stimulation.

Results
In CON treatment ova were obtained from 20% of common barbel only, while environmental induction did not increase the number of females producing eggs. In the case of vimba bream, ide and European chub environmental stimulation did not induce ovulation. When hormonal stimulation was applied 40% of ide, 60% of common barbel and European chub and 100% of vimba bream produced eggs. EH treatment increased ovulation success up to 80% in common barbel and European chub as well as 100% in vimba bream and ide.

Conclusions
Despite the highest increase in ovulation due to hormonal stimulation use the application of environmental stimulation of females in rheophilic cyprinids seems to be an important element of effective and sustainable breeding in this group.

This study was carried out as part of the project entitled: “Innovative system of rheophilic cyprinid fishes reproduction and rearing in biologically effective and low emission conservative aquaculture”, no. 00001-6521.1-OR1500001/22, Task 2.1 “Innovations” according to EU Regulation No. 508/2014, Priority 2 – “Supporting environmentally sustainable, resource-efficient, innovative, competitive and knowledge-based aquaculture” realized in the Operational Program “Fisheries and Sea”.
INSIGHTS INTO INTEGRATED MULTI-TROPHIC AQUACULTURE IN A CLOSED RECIRCULATING SYSTEM FOR PRODUCTION OF NORTH SEA MACROALGAE, BIVALVES, AND SHRIMP

Introduction
Infectious diseases are a common and on-going problem for reared aquatic species. Microbial management tools allow for increased control in aquaculture production systems, reducing the spread of pathogenic microbes while improving the health of cultured organisms. Recirculating aquaculture systems (RAS) are one such tool that is used to select for neutral and beneficial microbes that competitively exclude specific and opportunistic pathogens. However, the high investment costs and complexity of RAS inhibits its widespread implementation. Integrated multi-trophic aquaculture (IMTA) holds the potential to reduce or replace some of the expensive and sophisticated units that comprise RAS, making this technology more widely available while contributing value-added product, a proposition that may contribute to global food sovereignty. This project focuses on the co-culture of three species from different trophic levels in a closed cold-water multi-trophic marine RAS: nori (Porphyra umbilicalis), Pacific oyster (Crassostrea gigas), and North Sea prawns (Palaemon sp.). The effect of different types of nutrient bioremediation (traditional bacterial biofiltration versus macroalgae) on nutrient uptake efficiency, the microbiome, and the growth and survival of all trophic levels is evaluated.

Materials and Methods

P. umbilicalis was obtained from the Ghent University Phycology Research Group, C. gigas was obtained as T6 spat from Aquacultuur Oostende bvba (Ostend, Belgium), and Palaemon post-larvae and adults were wild-caught via dip nets from rocky tidal pools in coastal Belgium and Northern France. Three closed RAS comprised the experimental set-up and were operated at the Laboratory of Aquaculture and Artemia Reference Centre (ARC), Ghent University. Each up-flow RAS had a total fill volume of 500L, composed of three cylindroconical poly-ethylene culture tanks (100L; 90L fill volume) arranged in parallel with outflow to a drum filter (40 µm-mesh size) and protein skimmer before reaching the nutrient bioremediation tank (Figure 1). All systems were filled with filtered natural seawater, operated at a flow rate of 70L/h, a 12:12 L:D light regime, and with an ambient room temperature of 18°C. Three approaches to nutrient bioremediation were compared: a traditional biofilter (system 1), a traditional biofilter in combination with P. umbilicalis (system 2) and P. umbilicalis alone (system 3). The biofilter volume was dimensioned to treat the expected nutrient release from the C. gigas and Palaemon sp. as well as the residual nutrients in the microalgae supernatant fed to the C. gigas. P. umbilicalis were stocked based on the volume of the bioremediation tank and optimization for light exposure.

In each cylindroconical tank, a flat base was placed mid-way to provide a horizontal surface area for the Palaemon prawns. Two cylindrical PVC baskets (80 mm height and 300 mm diameter) with a 2 mm mesh bottom were stacked in the tank and elevated with Bio-Net blocks in which aeration was fixed. The Bio-Net support consisted of small crevices, providing shelter places for the prawns. Each tank was stocked with 25g (0.28g/L) of Palaemon sp. and 115g (1.28g/L) of C. gigas, the oyster biomass being distributed equally over the two baskets in each tank. All culture tanks received 2% of oyster wet weight in microalgae dry weight in a 1:1:1 ratio of Tetraselmis chuii, Chaetoceros muellertii and Isochrysis galbana. All microalgae were obtained from Proviron (Hemiksem, Belgium). Palaemon prawns are fed with 1.5-2 mm shrimp pellets.

The total biomass of each trophic level was kept constant in all systems by removing the excess biomass produced over the course of a week. Microbial samples were taken weekly from each nutrient bioremediation tank. Water quality and nutrients (TAN, nitrite, nitrate, phosphate, calcium, and alkalinity) were measured three times per week in each bioremediation tank prior to the administration of feed. Temperature, pH and dissolved oxygen were assessed daily in each nutrient bioremediation tank and all culture tanks. The wet weight of all trophic levels was recorded weekly, as well as the dry weight and ash weight of P. umbilicalis and C. gigas, and the shell length and width of C. gigas.

(Continued on next page)
Results
This experiment represents pioneer research into co-cultivation of multiple trophic levels in a closed RAS. Despite this being the first time *P. umbilicalis*, *C. gigas*, and *Palaemon* sp. have been reared in such a system, there have been no detrimental effects on the health and welfare of the organisms. Furthermore, preliminary results indicate no significant differences in growth for *C. gigas* and *Palaemon* sp. between the three systems, and the different forms of nutrient bioremediation tested in this experiment have effectively kept all water quality parameters within a biologically suitable range.

Conclusion
Initial data from this innovative research suggests that conventional recirculating aquaculture farm designs may be effectively modified by replacing the traditional biofilter unit with macroalgae, reducing the upfront costs associated RAS production while contributing value-added biomass.

Introduction
The Scottish farmed salmon industry continues to expand and there is a requirement to reduce the level of finite marine origin raw materials used in traditional feed formulations. One alternative is to produce feeds with higher proportions of plant-derived oils and proteins, but these diets can lead to reduced feed utilization and also have lower levels of essential omega-3 long-chain polyunsaturated fatty acids (n-3 LC-PUFA), eicosapentaenoic acid (EPA; 20:5n-3) and docosahexaenoic acid (DHA; 22:6n-3). A novel solution to this problem is a concept referred to as “nutritional programming”. This involves applying an early nutritional intervention or “stimulus” where fish are fed a predominantly vegetable-based diet for a short period, to induce more efficient uptake and utilization of nutrients from a similar diet when fed later in life. Previously, it was demonstrated that Atlantic salmon (Salmo salar) fed such diets during a three-week stimulus phase from first exogenous feeding, resulted in significantly greater growth and nutrient retention efficiency during freshwater grow out, associated with upregulation in key pathways of intermediary metabolism (Clarkson et al. 2017; Vera et al. 2017). The current study aims to elucidate whether the effects of nutritional programming are sustained during post-smolt rearing in seawater at a transcriptomic level.

Materials and methods
Four experimental dietary groups were established in triplicated treatment tanks (Figure 1). Two treatments were fed an experimental vegetable-based diet for a three-week “stimulus” period from first feeding (V), while remaining tanks were fed a standard marine-based diet (M; Figure 1). Following stimulus, all groups were then fed a standard marine ingredient diet until week 36. Thereafter, two treatment groups were re-fed a vegetable-based diet for four weeks prior to sea transfer (MVV, VVV), while remaining tanks were maintained on marine-based feeds (MMV, VMV). Following a two-week acclimatization post- sea water (SW) transfer, when fish were fed a standard marine based diet, all fish were transferred to a vegetable-based diet for a 14-week period. Liver and pyloric caeca tissue were collected from six fish per tank immediately prior to SW transfer and at the start and end of SW challenge for molecular analysis. RNA was extracted from tissues, reverse transcribed and sequenced on an Illumina NovaSeq platform, producing an average on 49 million reads per sample, before quantifying expression based on read alignment to the S. salar genome.

Results & Discussion
Our hypothesis was that fish subjected to a vegetable-based stimulus diet would better utilize dietary nutrients in later development. Growth and retention results presented previously (McMillan et al. 2021) suggested no conclusive evidence, by those measures, that this was the case. However, there was evidence that groups fed a combination of both diets in FW adapted to the SW environment more rapidly. We also saw some evidence, from fish fed both diets in FW, that fish may better regulate their metabolism according to requirements when the n-3 LC-PUFA levels are running low. This study presents RNAseq results indicating whether there is evidence to support a continued nutritional programming effect at a transcriptomic level during the SW rearing phase. Furthermore, functional regulatory pathways will be discussed relating to the FW dietary regime, with primary focus on regulation of fatty acid metabolism at the end of FW and subsequent SW stages. Empirical evidence of nutritional programming regulating fatty acid biosynthesis to trigger endogenous production of essential EPA and DHA could determine how we formulate more resource-efficient aquafeeds and feeding strategies for Atlantic salmon in the future.

Introduction

Fish farming is striving to maximise sustainable production to meet the needs of a growing global human population, however, disease is a major barrier to achieving this (Stentiford et al., 2017). To address the problem of disease in aquaculture there has been, and continues to be, widespread use (and misuse) of antibiotics for both disease treatment and prevention (Cabello et al., 2016). Globally, antibiotic use is particularly prevalent in freshwater finfish culture (Schar et al., 2020) and per capita consumption is increasing faster than meat and dairy consumption. Reports have documented antimicrobial use in the rapidly expanding aquaculture industry, which may contribute to the rise of antimicrobial resistance, carrying potential consequences for animal-, human-, and ecosystem-health. However, quantitative antimicrobial use across a highly diversified aquaculture industry is not well characterized. Here, we estimate global trends in antimicrobial use in aquaculture in 2017 and 2030 to help target future surveillance efforts and antimicrobial stewardship policies. We estimate antimicrobial use intensity (mg kg⁻¹; however, it is unclear what influence antibiotic exposure may have on the fish microbiome under normal culture conditions, which is a critical component for maintaining health and resilience against disease. Here we assessed the effects of exposure to oxytetracycline (OTC) on the fish skin and pond water microbiomes; antibiotic residue fate; and development of antimicrobial resistance. This was performed as a mesocosm study in Khulna, Bangladesh to provide realistic environmental and microbial conditions that directly translate to aquaculture practices.

Materials and methods

Tilapia and carp (Oreochromis niloticus and Labeo rohita) were polycultured in earthen aquaculture ponds (3x control and 3x treatment ponds) and exposed to a typical medical treatment dose (100 mg/kg) of OTC via the diet for five days. Sampling of water and fish skin swabs were collected prior to treatment, and subsequently at 2, 9 and 23 days following the 5 day antibiotic exposure. To characterise the prokaryotic and microeukaryotic communities, amplicon sequencing libraries of pond water filters and fish skin swabs were prepared as previously described (McMurtrie et al., 2022). PCR-free metagenomes of pond water were also prepared to characterise the diversity of antimicrobial resistance genes selected in the resistome following antibiotic exposure. Sequencing of 16S V4 amplicons, metagenomes and 18S V9 amplicons was performed on the Illumina Novaseq SP-250, S1-150 and Illumina MiSeq V2-150 respectively. To assess antibiotic residue fate, pond water was concentrated by Solid Phase Extraction and quantified by the multi-residue UPLC-MS/MS validated methodology of Holton and Kasprzyk-Hordern (2021). Generalised linear mixed effects modelling was performed to statistically assess OTC residue fate and fish growth.

Results and discussion

Tilapia grew over the experimental period by 0.61 ± 0.31 g (95%-CI) p < 0.001 per day, with no observed difference between control and treatment groups p = 0.756, illustrating no toxic or beneficial effects of the antibiotic treatment on growth (Fig. 1A). Throughout the experimental period, concentrations of OTC in water of control ponds remained low at 0.045 ± 0.018 µg/L (95%-CI) (Fig 1B). Two days after the completion of exposure, OTC concentration reached 9.6 ± 2.11 µg/L (95%-CI) in dosed pond water, and the overall concentration of OTC in treatment ponds was significantly elevated compared to control ponds p < 0.001. At the final sampling point, 23 days post-exposure, the concentration of oxytetracycline in treatment ponds had returned to pre-exposure levels.

(Continued on next page)
Ultra-deep sequencing of 16S V4 amplicons for 384 samples of fish skin and pond water yielded a median sequencing depth of 168,440 paired-end reads per sample. Additionally, 104 samples of pond water were sequenced as 18S V9 amplicons, resulting in a median sequencing depth of 56,184 paired-end reads. We will report the impact of antibiotic exposure on fish skin microbiome community structure and will correlate specific taxonomic shifts to measured oxytetracycline concentrations. In parallel, to assess the development of antimicrobial resistance following therapeutic use of antibiotics in aquaculture we performed shotgun metagenomic sequencing on 12 pond water metagenomes of control and treatment ponds. Sequencing generated a total of 750 million paired-end reads. Ongoing analysis is exploring the diversity and abundance of antimicrobial resistance genes, in addition to mobile genetic elements selected in the resistome, that will be reported upon at the meeting.

By characterizing animal and environmental health, as well as the development and spread of antimicrobial disease resistance, these analyses aim to provide a comprehensive understanding of the implications for antibiotic (mis)use in aquaculture within the one health framework.

Tom Ole Nilsen: Tom.nilsen@uib.no

Introduction
The salmon farming industry has invested in larger and more technologically sophisticated RAS facilities over the last decade. Current practices favour constant high temperatures, use of continuous light and increased salinity in RAS to accelerate the growth of Atlantic salmon smolts from 50-80 grams a few years ago to approximately 500-600 grams today. The anadromous salmon goes through parr-smolt transformation (PST), which entails a series of morphological and physiological changes preparing them for seawater. However, industry reports several biological traits, such as increased silvering, elevated gill NKA activity and ability to ion regulate when challenged with SW, associated with PST to occur independent of applying standard photoperiod protocols. This have made it increasingly difficult to accurately time the “smolt window” and evaluate quality of large smolts (>250 gram). Thus, there is a need to better understand the physiological responses of larger smolts produced under intensive conditions in RAS.

Material and method
Here we present the effects of rearing protocols using four different photoperiod regimes on three different sized (150g, 350g, 800g) in freshwater or brackish water (12 ‰). The photoperiodic regimes were: No winter signal (NW), 6 weeks LD 12:12 winter signal given early (EW), 6 weeks LD 12:12 winter signal given late (LW) and 20 weeks LD 12:12 winter signal given late (LLW). We analysed how these protocols affect smolt development, measured as Na⁺; K⁺ -ATPase (NKA) enzyme activity in the three major osmoregulatory organs, gills, intestine, and kidney. Smolt development was also evaluated with a short-term seawater performance challenge test.

Results and discussion
Our findings suggest that a more holistic approach to evaluate overall smolt quality in modern aquaculture would be beneficial, in particular when producing large smolts and post-smolts. Our findings were also analysed in the context of long-term seawater performance, health and welfare.
EFFECT OF DIFFERENT TRANSFER TEMPERATURE SHIFT ON THE STRESS RESPONSE, NEURAL PLASTICITY AND ROBUSTNESS OF THE ATLANTIC SALMON (Salmo Salar)

Patrick Anthony Tang, Simon Menanteau-Ledouble*, Pradeep Lal, Naouel Gharbi

Fish Biology and Aquaculture (FBA) Group
Ocean and Environment Department
Norce, Nygårdsgaten 112
5008 Bergen, Norway
ptan@norceresearch.no

Introduction
The successful transfer of post-smolts depends on the fish’ abilities to mount good stress responses, initiate neural adaptations and maintain cognitive properties (neural plasticity) to sustain resilience during the sensitive SW phase. However, current year-round transfer strategies can expose farmed post-smolt Atlantic salmon (Salmo salar) to a broad range of thermal stressors that may challenge these functions, with negative implications regarding fish allostasis, health and welfare.

Material and methods
To investigate the effect of various transfer strategies, SW adapted post-smolts at 10-13°C were transferred to low (10°C, 7°C, and 4°C) and high temperatures (13°C, 16°C, and 18°C), with thermal differences consistent with off-(winter) and on- (summer) season transfer strategies. Differences in allostatic loads, altered physiological states, and capacities to overcome these thermal challenges were evaluated based on the stress response, neural plasticity and ability to withstand stress: Fish were examined for modulations in primary stress responses (plasma cortisol levels) and telencephalic neural plasticity genes important for cognition (neurod, bdnf, pcna, c-fos, mr, gr1, gr2 and hsd11b2) following the transfer, acclimation and in response to an acute challenge test (ACT) using confinement stress.

Results and discussion
Our findings show that elevated allostatic loads are present at both ends of the thermal profile, however, post-smolts clearly have a higher ability to withstand low temperatures compared to high ones. Accordingly, post-smolts retained robust abilities to maintain brain plasticity and initiate key neural adaptations against low thermal challenges. In contrast, post-smolt transfer to elevated temperatures adversely inhibited stress responses and neural functions, pointing to allostatic overload and poorer capacities to deal with increasing thermal challenges. In all, these findings demonstrate thermal differences in the production environment is associated with stresses that can alter key neural processes important for good stress management, abilities still conserved at low temperatures, but not at higher ones. This conforms to the natural life-history strategies of Atlantic salmon and highlights the importance of satisfying low thermal requirements of post-smolts during production, but also points to the potential future challenges of climate change.
EFFECTS OF MICROALGAE SUPPLEMENTATION IN THE DIET OF RAINBOW TROUT
(Oncorhynchus mykiss)

sime@norceresearch.no

Introduction
Microalgae are a large of diverse group of microorganisms producing a variety of valuable compounds: They are the richest source of polyunsaturated fatty acids in the environment and can harbour a wide array of other compounds with beneficial health properties, including antioxidant; anti-inflammatory, antimicrobial, or anti-virulence/quorum quenching. Despite these advantages, little is known about the application of microalgae as feed adjuvant in the diet of farmed fish.

Material and methods
To investigate the potential benefits of dietary microalgae, young rainbow trout (Oncorhynchus mykiss), of approximately 30 g; 15 cm length were allocated in between 6 feeding groups (fishmeal diet; diet enriched in soy protein; diet enriched with Chlorella sorokiniana; diet enriched with Tetradesmus obliquus; diet enriched with intact Haematococcus pluvialis; and diet enriched with leftover H. pluvialis following extraction of the astaxanthin). Each diet was represented in triplicates 3x15 fish per treatment. The fish were maintained that way for ten weeks. Afterwards, sera were harvested for metabolite analysis and the composition of the intestinal microbiota was analysed by amplicon sequencing using primers for the V1-V3 region of the 16S rRNA.

Results and discussion
No significant effect was found on the growth of the fish. However, the diets were associated in changes in the concentration of serum’s metabolite and in the composition of the fish’ intestinal microbiota. These results suggest that incorporation of microalgae can have potential health benefits as dietary supplement in the diet of farmed fish.
AQUAE STRENGTH, an International Cooperation Project for Promoting Sustainable Aquaculture

Email: vmenconi@izsvenezie.it

As the global population grows, the increasing food demand has boosted the search for sustainable and innovative food sources. Several countries worldwide rely on aquatic environments as a source of livelihood. Within this context, aquaculture is one of the fastest-growing livestock productions and holds a huge potential to meet the food demand. The AQUAE STRENGTH project, “Strengthening Capacity on Aquatic Animal Health and Epidemiological Surveillance,” is financed by the Italian Ministry of Health and supported by the World Organisation for Animal Health (WOAH). Aligned with WOAH priorities for the Aquatic Animal Health Strategy, the project seeks to elevate epidemiological surveillance and responses to aquatic animal diseases while advocating for sustainable practices such as the responsible use of veterinary medical products in aquaculture. Based on a multifaceted approach, it strives to foster capacity building and knowledge sharing among professionals, fortify the management of aquaculture production, and implement advanced Geographic Information System (GIS) techniques. Additionally, it aims to provide and refine diagnostic methods, thus strengthening mechanisms for detecting and controlling aquatic animal diseases. The project is implemented by a consortium that comprises seven Italian Governmental Institutions (Istituto Zooprofilattico Sperimentale), four beneficiary countries (Morocco, Tunisia, Israel, and Cambodia), and three advisory technical bodies from Norway, Denmark, and the UK. One of the primary tools used was the production of online Webinars, which were designed to provide theoretical insight into the project topics and level the background knowledge of the participants. To evaluate the state-of-the-art and identify areas that required intervention, the project employed assessment questionnaires addressed to beneficiaries. These questionnaires were customized and catered to the project’s topics and allowed a comprehensive understanding of existing conditions, thereby facilitating the interventions. The project highly values collaborative discussions and the engagement of each involved partner therefore several meetings and round tables were organized to foster collaboration. These events helped to outline project activities, aligned efforts and provided insights into the needs of beneficiaries. Regular field visits to the beneficiary countries were planned during the project as valuable opportunities to interact in person. Beyond facilitating questionnaire reviews and infrastructure evaluations, these visits created a space for interactions and allowed the project staff to better understand beneficiary needs. Furthermore, the project provides tailor-made training sessions to beneficiaries within consortium institutions and laboratories. While aquatic ecosystems substantially sustain populations, their swift degradation due to human activities mandates immediate action. The comprehensive approach of the AQUAE STRENGTH project tackles this challenge, aligning with responsible and sustainable practices. Empowering nations to advance their aquaculture and fishery sectors through optimal management of aquatic resources is essential in fortifying food security and promoting socioeconomic progress.
CANECO-EFFICIENT, CIRCULAR ECONOMY-DRIVEN AND ORGANIC FORMULATIONS IMPROVE THE PERFORMANCE AND ROBUSTNESS OF NILE TILAPIA?

Introduction

Aquaculture is facing challenges in terms of environmental sustainability of the feeds used and susceptibility of the farmed organisms to diseases. Fish meal and fish oil are still commonly used in farmed species' nutrition because of their nutritional value. Although most of these ingredients in the European Union are derived from well-regulated wild fish stocks and are certified, they are at the limit of sustainable exploitation. Moreover, particularly in some developing countries (e.g., China) with high levels of production, the use of these ingredients makes aquaculture practices associated with a high carbon emission. Given the high density in intensive farming systems, fish can be exposed to stress, which may have negative impacts on their immune system. Consequently, this effect will potentially deteriorate fish health and well-being, increasing the possibility of infection with pathogenic invaders, eventually leading to mortality. Functional ingredients possess bioactive compounds that regulate physiological processes and exhibit biological activities, which could improve weight gain, feed efficiency, and disease resistance in fish while reducing the environmental impacts of the sector. Accordingly, through the inclusion of novel functional ingredients in diets, such as the microalgae spirulina and the plant quinoa, may offer a potential solution to mitigate these issues.

This study aims to assess the effects of functional feeds on key growth performance indicators (e.g., weight gain, feed conversion ratio, feed intake), health (e.g., gut epithelium integrity, immune condition and oxidative status) of juvenile Nile tilapia (Oreochromis niloticus). Feeds were formulated with eco-efficient, circular economy-driven and organic frameworks.

Methods

Three experimental diets were formulated and produced by SPAROS Lda (Olhão, Portugal). A practical (PD) diet as control mimicking a commercial-type feed, without fish meal and fish oil. Organic (ORG) based on ingredients compatible with organic certification (including spirulina and quinoa). Eco-efficient (ALT) using circular economy-driven subproducts (e.g., poultry and feather meal) and emergent (e.g., spirulina, insect meal, quinoa) ingredients. Spirulina had inclusion levels of 10% and 2.5% and quinoa 5% and 2.5%, in ORG and ALT, respectively. All diets were formulated to be isonitrogenous (crude protein 39.4% wet weight (WW)) and isoenergetic (gross energy, 19.2 KJ/g WW). The trial was performed in 12 tanks of 300 L (3 diets x 4 replicates) with an average temperature of 24.4 ± 1.2 °C (mean ± SD). Each replicate tank contained 30 Nile tilapia with an initial mean weight of 31.0 ± 0.5 g. Fish were daily fed with the experimental diets until visual satiation for 61 days. Growth performance indicators were assessed, including weight gain, relative growth rate, feed conversion ratio (FCR) and voluntary feed intake (VFI). Fish were sampled for whole-body composition analysis and dissected for liver, anterior and posterior intestine for assessment of immune condition, oxidative status and gut health. Diet apparent digestibility was also determined. Statistical analyses were performed using SPSS version 23.0 by one-way ANOVA, followed by Tukey’s post-hoc.

Results

Although fish were fed until satiation, the VFI and FCR significantly differed across diets (Fig. 1 and 2; p<0.05). Both indicators were within normal values for PD and ALT, but not for ORG, showing that fish exhibited a negative response, which was reflected in the performance indicators.

Fish that were fed diet PD exhibited higher weight growth (3.5 – fold increase), ALT roughly doubled their initial body weight, while ORG almost did not show any growth (Fig. 3). Similarly, the final body weight of PD was also 1.7-fold and 3.3-fold higher than diet ALT and ORG (p<0.05), respectively.

(Continued on next page)
Conclusions
The three aquafeed formulations demonstrated significantly distinct impacts on juvenile Nile tilapia performance. Diets ALT and specifically diet ORG provided worse growth performance indicators than PD. The evaluation of the impacts of the diets on fish health (e.g., gut epithelium integrity, immune condition and oxidative status) is underway. In any case, this study reinforces the notion that novel formulations and ingredients need to be thoroughly evaluated.

Introduction
Farmed salmon will play a significant role in bridging the demand gap for high-quality food. However, salmon farming is faced with several challenges including access to high quality feed resources, and multi-stressor conditions such as suboptimal environmental conditions and diseases leading to mortalities and economic losses. Therefore, the need for sustainable novel feed resources to replace the conventional feed resources currently used in salmon feeds has never been more urgent. Novel aquafeed ingredients should be sustainable and address both nutritional and health related challenges in salmon farming. Microbial ingredients (MIs) such as yeast and fungi provide a viable alternative to address both challenges due to their high nutritional value [1] and bioactive components with proven health benefits [2]. Paecilomyces variotii (PEKILO®) is a filamentous fungus with high crude protein content (60-70%) and it contains bioactive components such as β-glucans, mannans and nucleic acids which induce health benefits for fish. Considering this, our study under the NordForsk-funded NordicFeed project was designed to characterize the immunomodulating effects of P. variotii in Atlantic salmon (Salmo salar) using in vitro and in vivo techniques. We hypothesized that the functional bioactive components in P. variotii will improve overall health and welfare in Atlantic salmon.

Materials and methods
The immunomodulatory effect of P. variotii fermented on sulphite stillage as substrate was characterized using adherent mononuclear leucocytes isolated from head kidney (HK) and spleen of Atlantic salmon (ca. 2 kg) and incubated for 6, 24 and 48 hours with or without the presence of heat inactivated Moritella viscosa (Figure 1, left panel). For the in vivo assessment, vaccinated Atlantic salmon pre-smolts were fed diets with P. variotii replacing 0, 5, 10, or 20% of crude protein from fishmeal and soy protein concentrates for 4 weeks in freshwater. Growth and health parameters were analyzed (Figure 1, right panel).

Results
Results from the in vitro studies (Figure 1, left panel) indicated that P. variotii induces a strong immune response in the HK of Atlantic salmon at all time-points evaluated, but most strongly after 6 h. Co-stimulation of the spleen and HK leucocytes with both P. variotii and M. viscosa induces an even stronger immune response, particularly in the HK. Upregulation of regulatory cytokine in the HK and downregulation in the spleen was observed when the bacteria alone or a combination with P. variotii was added to cell cultures. In addition, P. variotii enhanced the antimicrobial activity of leucocytes with higher transcript levels of β-glucan receptors, demonstrating recognition of this bioactive compound in the feed ingredient. Our results from the feeding trial (Figure 1, right panel) indicates that all inclusion levels of P. variotii resulted in feed intake, specific growth rate like the control diet and a dose-dependent linear decrease in the feed conversion ratio with increasing inclusion of the mycoprotein. The immune responses induced by P. variotii were systemic. Low and high doses of P. variotii modulated a strong T cell response, innate responses, and enhanced antimicrobial activity. Medium and high dosage also modulated a Th1 response as well as receptors and signaling molecules characteristic of β-glucan recognition (Figure 1). Further, inclusion of P. variotii in diets for Atlantic salmon increased specific antibody titres against V. anguillarum.

Conclusion
P. variotii can replace up to 20% of crude protein in the diet of Atlantic salmon without compromising growth performance of the fish. In addition, P. variotii has significant health benefits in Atlantic salmon beyond its nutritional value including enhancing the natural killer cells, the complement system, antimicrobial activity of leucocytes, modulated type 1 and type 2 responses and improved humoral responses.

Introduction
Innovative ingredients in fish diets are used to improve fish growth performance indicators and the ecological footprint of aquaculture activities with the benefits of improving fish health. Thus, the replacement of fishmeal and fish oil in fish diets with novel ingredients that can be sustainable produced is of much interest. It is widely accepted that under experimental rearing or aquaculture farming conditions, the fish gut microbiome can be manipulated by changes in the fish diet. Gut microbiota may play significant role in fish nutrition, producing enzymes (Ray et al. 2012) that promote host growth and health. However, the extent to which microbial function varies with host demand and the underlying mechanisms are largely unknown. The aim of this study was to investigate the effect of dietary inclusion of insect meal, tunicate meal and algae meal on Sparus aurata midgut microbiota.

Materials and methods
The experimental trial took place at the Department of Ichthyology and Aquatic Environment, University of Thessaly, Greece. Briefly, 1080 individuals S. aurata (initial mean weight 6.52±0.03g) were distributed randomly to eighteen 250l tanks. Six experimental diets were formulated to be isolipidic. The Control (26.55% fishmeal- FM), the 0%FMFO (total replacement of FM and fish oil with algae meal, Schizochytrium limacinum and Phaeodactylum tricornutum, insect meal Hermetia illucens and tunicate meal Ciona intestinalis), the IM (68.09% replacement of FM with insect meal H. illucens), the TM (45.91% replacement of FM with tunicate meal C. intestinalis), the PA ( 18.41% replacement of FM with P. tricornutum), and HA, ( 100% replacement of FO with S. limacinum) diet. Each diet was assigned to triplicate groups of 60 fish per group. The trial lasted 45 days, after 15 days of acclimatization. The fish fed three times per day at libitum. At the end of experiment, fish were starved for 24 hours and aseptically the midgut was dissected. After DNA extraction bacterial diversity was assessed by amplification of the V3-V4 region of the bacterial 16S rDNA gene using IlluminMiSeq with universal bacterial primers. Raw sequence reads were processed and analyzed, using the MOTHUR software (v. 1.45.3) and SILVA database was used to classify the operational taxonomic units (OTUs).

Results
Several bacterial Families were identified with different distribution in the midgut of fish fed with the different diets (Figure 1). The most abundant Family was LWQ8 in fish fed the control and IM dietary treatment and Burkholderiales was in fish fed the 0%FMFO dietary treatment. In the midgut of fish fed the TM and HA diets Rhodobacteraceae had an increased relative abundance and in midgut of those fed PA diet Bacillaceae was most abundant.

Figure 1: Relative abundance of bacterial Families in S. aurata midgut of different experimental dietary treatments.

(Continued on next page)
Discussion
Fish fed the TM diet had increased their bacterial Taxa in their midgut, an indicator of fish health, implying a normal gut physiology. Saccharimonadales, (LWQ8 bacteria) were found in all dietary treatments. It is associated with the degradation of sugars and glucose (Albertsen et al. 2013). Increased abundance of Burkholderiales in fish fed the 0%FMFO diet was related to immune and stress response (Sehnal et al. 2021). Rhodobacteraceae were a common family among the dietary treatments and were found to assist in the fermentation of complex polysaccharides (Gupta et al. 2019). Bacillaceae produce amylase, cellulase, phytase, protease, lipase, and chitinase (Askarian et al. 2012), enzymes that could contribute to better fish growth, performance. Bacterial Families that were beneficial to the host were found in the midgut of fish fed the six experimental diets associated with better growth performance.

Introduction

With the European Green Deal, the Farm-to-Fork Strategy and the Biodiversity Strategy, the EU has set targets of reaching at least 25% of the EU’s agricultural land under organic farming by 2030 and significantly increasing organic aquaculture. In the EU, the total organic aquaculture production is only accounting for 6.4% of the total production (EUMOFA, 2022). There is no concrete Farm-to-Fork target for organic aquaculture, but a three times growth rate as for farmland to a 5% share would require enormous efforts. Reaching these ambitious goals demands a balanced upscaling of both production and consumption, implying a huge transformation in farm structures and value chains. This transformation needs to be supported by research and innovation, strong advisory services, knowledge exchange and training opportunities for all organic operators and related professionals. The overall objective of OrganicTargets4EU (https://www.organictargets.eu/) Horizon Europe, research project is to support the achievement of the organic farm-to-Fork targets.

Materials and methods

OrganicsTarget4EU combines EU-level assessments for all Member States, with detailed analyses in selected focus countries: seven for agriculture (DE, HU; DK, IT, RO, AT, FR) and two for aquaculture (DE, GR covering freshwater and marine species respectively). While market data on organic aquaculture are not available, the share of organic aquaculture production was 21% and 1% (tonnes live weight) in 2018, in Germany and Greece respectively (https://ec.europa.eu/eurostat/databrowser/view/org_aqtspec/default/table?lang=en).

The project will identify the current and past developments of the organic sector by examining the institutional framework for organic farming and aquaculture and conduct a foresight based on scenario analysis. Participants will be recruited through interviews and a survey. These include knowledge providers, organic farmer organisations, organic aquaculture sector, certification bodies and policy makers. Workshops will be held aiming to: i) foster mutual learning processes and initiate transformation of existing advisory services; ii) stimulate the initiation of viable new conversion/organic advisory services in countries where they are not yet available, iii) explore possible funding mechanisms or public-private partnerships to develop or scale up advisory services, iv) foster relationships for a viable professional network beyond the project lifetime.

A recent review has shown that whilst availability of subsidies, environmental concerns, profitability, and uncertainties about the stability of the organic market are recurring as influential factors in the decision process of becoming organic, the most recurring factor is supportive social networks. The project will initiate Communities of Practice in which conventional farmers and aquaculture producers learn together what is involved in organic production and in conversion. Communities of practice are social learning groups of people, who share a concern and who deepen their expertise in this area by interacting on an ongoing basis (https://hbswk.hbs.edu/archive/cultivating-communities-of-practice-a-guide-to-managing-knowledge-seven-principles-for-cultivating-communities-of-practice).

The Community of Practice in Greece for aquaculture has been established. Group members in Greece for organic aquaculture are 5 conventional fishfarmers that farm sea bream, sea bass, rainbow trout and mussels.

Results/Discussion

OrganicTargets4EU supports the Farm-to-Fork Strategy in achieving the targets of at least 25% of the EU’s agricultural land under organic farming and significantly increasing organic aquaculture by 2030. To achieve these ambitious goals, 18 partners coordinated by IFOAM Organics Europe will set up a multi-actor process to create possible scenarios for reaching these targets and provide in-depth knowledge of the key drivers and lock-ins affecting the organic sector’s development. The Farm-to-Fork Strategy fully acknowledges the role of aquaculture in creating more sustainable food systems. Therefore, (Continued on next page)
it aims at a significant increase of organic aquaculture. The project will produce results that will support the growth of both marine and freshwater organic aquaculture. While organic farming has passed the niche phase, organic aquaculture is still in very early stages of development. Barriers exists at the technical, market and regulatory level. The project will address these for organic aquaculture. By helping to achieve the organic Farm to Fork targets, the project supports sustainable aquaculture systems, for marine and freshwater conditions, that are climate-resilient, environmentally-friendly and combine low impact on aquatic ecosystems with high animal welfare.

Preliminary results from the Community of Practise group in Greece for organic aquaculture have showed that the main obstacles for expansion of the organic aquaculture are the high cost of the organic feed production, the slower fish growth rates on the on-growing phase, the high cost of the certification and the luck of specialised advisory government service for organic aquaculture.

Introduction

Freshwater aquaculture contributes to 20% of the aquaculture production in EU, producing ca. 275’000 tonnes fish per year with a first sale value of 910 M€. Productivity in this sector must grow to contribute to the global demand for protein, expected to more than double by 2050 to 500 million tonnes (FAO, 2021). The sector employs 20626 people in 7582 companies (EUMOFA, 2021). The main production methods are extensive fishponds systems (33%) and intensive tank and raceways (65%). A small percentage (2%) of intensive systems are Recirculating Aquaculture Systems (RAS). Aquaponics is an integrated multitrophic aquaculture system involving farming fish and growing plants together. It requires no soil and uses water from fish production to support plant growth, which leads to a dramatic improvement in sustainability and efficiency of aquaculture practices. The practice of aquaponics in Europe is limited, with less than 50 commercial aquaponic enterprises (Turnsek et al., 2020). The aim of this study which is part of the AWARE (Horizon Europe, https://www.aware-eu.eu/about/) research project is to increase the circularity of fish waste and create fish species-specific diets for aquaponics.

Materials and methods

Fish waste produced in aquaponics will be used as substrate to produce nutrient-rich insect meal. The fish waste composition will be evaluated, particularly its fatty acid and amino acid profile, and investigation will take place on how it affects the nutritional value of the insects grown on it and the insect meal that will be produced in terms of crude protein, ash, moisture, fatty acids, amino acids, vitamin D content and minerals. The insects will then be used to produce insect meal, which will in turn be fed to the fish grown in aquaponics. New aquaponic fish species-specific diets will be formulated and tested in aquaponics systems to produce fish and vegetable for human consumption. The AWARE project will create a new farm-to-fork value chain and demonstrate technical solutions for efficient and sustainable aquaponics.

Results/Discussion

Aquaponics generally involves Recirculating Aquaculture Systems (RAS) recirculating more than 90% of the water. The fish production and hydroponics can be linked, or decoupled, with periodic water transfer between the two. Aquaponic systems benefit from high levels of production with extremely low land and water resource requirements, along with relative biological security and excellent direct access to urban markets. Aquaponic systems are currently limited by high capital cost, high energy requirements, and limitations in customer willingness to pay for ecosystem services. RAS and multitrophic aquaponics have been identified by The Strategic Working Group on Fisheries and Aquaculture of the Standing Committee on Agricultural Research (SCAR-Fish) as two of the issues that urgently need to be explored by research and addressed by innovation.

Aquaponic farming requires knowledge in geochemistry (nutrient cycling and other physico-chemical parameters), veterinary (animal welfare), fishery, horticulture and physiology (fish and plants farming), microbiology and biotechnology (study of the microbiome, pathogens and viruses). The AWARE project will innovate aquaculture practices in Europe by improving and increasing the uptake of RAS multitrophic aquaponics. This will be achieved by a) producing fish species-specific diets from fish waste, b) integrating aquaponics with wastewater treatment, using reclaimed wastewater as a water source; c) advancing the technology to improve resource efficiency; d) creating a regulatory and policy roadmap to facilitate its scale-up and market uptake. AWARE sets out to increase capacity to produce fish for human consumption at zero km in every European city, with no impact on natural habitats, no dependence from natural freshwater availability, and high resiliency to climate change. This goal could be met by farming fish locally using reclaimed water. Europe lacks the regulatory and policy framework to allow such a value chain to take root, due also to the absence of compelling scientific evidence of safety, quality, economic feasibility, and social acceptability.

Introduction
Forage legumes are considered to be promising candidates to fulfil the gap of the rapid growth in aquafeed production. In particular, lupin seed, with its diversity of species, high protein content and ability to be grown in different soil and climate types, can even be considered as a potential competitor to soya bean. Although lupin seeds contain moderately high levels of protein, calories, certain minerals and vitamins, their use in food and feed is still limited by the presence of several antinutritional factors that reduce enzyme activity and the absorption of minerals and other nutrients (Krogdahl et al., 2001). In animal nutrition, the digestibility and absorption of nutrients can be improved through biotechnological processes such as solid-state fermentation (SSF). The aim of this study was to improve the nutritional value of lupin meal (Lupinus albus) by using SSF with different microorganisms, conditions of humidity and temperature and by comparing it with a different biotechnological process such as the addition of exogenous enzymes.

Materials and methods
The whole seeds of Lupinus albus have been ground to produce lupin meal and have been analyzed for the level of phytic acid and free phosphorus. Then lupin meal was treated under different processes (moisture, temperature, time and pH) and enzyme combinations. Briefly, four commercial enzyme products were assessed i.e. xylanase, phytase and two multienzymes. Two different moisture levels (8 and 45%) and thermal treatments (25 and 50°C) were evaluated. Process duration was either 25 or 240 minutes and in cases pH was reduced citric acid was added. Three microorganisms were selected for SSF: Aspergillus niger, Saccharomyces cerevisiae and Bacillus subtilis. Each micro-organism was cultured on appropriate agar for optimal growth and inoculated on lupin meal under optimum humidity and temperature conditions for the number of days required to achieve optimal growth. Lupin meal products from both biotechnological processes were evaluated for levels of phytic acid and free phosphorus. Analysis was determined using Megazyme kits.

Results and discussion
Phytic acid hinders the activity of enzymes, which is necessary for protein degradation in the intestine and stomach (Kies et al., 2006). Phytic acid normally constitutes 0.2%–2% of the dry weight in cereals and legumes with 60%–90% of the total phosphorus present bound to phytate (Feizollahi et al., 2021). Biotechnological processes increase digestibility of nutrients and bioavailability. Additionally, cooking of pulses is a commonly used process that highly improved the nutritional value of foods by reducing their ANFs (Patterson et al. 2017). The results showed positive effects of microorganism SSF and exogenous enzyme treatment in the reduction of phytic acid and increase of free phosphorus. Lupin meal in combination with multienzyme product, high moisture content (45%) and higher thermal treatment (50°C) resulted in lower phytic acid content (0.23%) and increased free phosphorus levels from 0.08 to 0.34%. Fermentation by Aspergillus niger showed the greatest reduction in phytic acid content and increased free phosphorus levels compared to the other microorganisms. However, treatment with exogenous enzymes showed higher efficacy in phytic acid and free phosphorus in relation to fermentation with microorganisms.

The European flat oyster *Ostrea edulis* has been harvested for centuries but production continues to be significantly affected by stress and diseases impacting oyster growth and survival. Whilst production remains active in some areas, supplying a high-value product to a niche market, cultivation practices continue to be adapted to meet the demand. These include exploring sites further away from the shore as well as the potential for co-cultivation with other species groups such as shellfish and seaweeds.

This study explores the feasibility of growing oysters subtidally at an existing seaweed cultivation site in comparison to a traditional intertidal oyster monoculture. Juvenile *O. edulis* were deployed in baskets at either site and monitored for two years (Nov 2020 – Oct 2022) for their progression in growth, survival, and marketability (meat yield and condition index), respectively. Ultimately, the shelf life of the harvest-size oysters was determined, and sites tested for the presence/absence of the diseases-causing *Bonamia ostreae* using a qPCR approach.

Oyster growth was rapid in the first year of culture and progressively slowed, following different seasonal dynamics and average growth in shell height of 1.09 and 1.55mm mth$^{-1}$ in intertidal and subtidal culture, respectively. Meat yield and condition index varied throughout the study period and with season, being highest in early Summer and lowest in late Winter, and coinciding with the seasonality in oyster reproduction and environmental conditions (water temperature, food availability).

Most notably however, oyster survival differed dramatically across sites and seasons with re-occurring mass mortalities during hotter summer months at the intertidal but not the subtidal site. With mortality rates exceeding 70% compared to 1% in subtidal culture, and without confirmed presence of *B. ostreae* at either site, *O. edulis* appears to perform better in subtidal (i.e., suspended) culture.

This study provides long-term multi-parameter data on the conditions and performance of *O. edulis* in commercial culture. Our findings highlight that suspended culture can improve overall performance and most importantly survival, providing new opportunities for exploration of mono- as well as co-cultivation operations offshore.
EFFECTS OF TIRE PARTICLES AND ASSOCIATED-CHEMICALS ON THE PACIFIC OYSTER *Crassostrea gigas* PHYSIOLOGY, REPRODUCTION AND NEXT-GENERATION

**Introduction**

The mass of tire particles in the ocean is expected to represent 93% of the aquatic plastic contamination by 2040. This might have consequences on organisms, like physical injuries and health repercussions notably due to chemical risk following the leaching of tire-associated chemicals. In such context, it is pivotal to assess the risk posed by this stressor in marine living organisms and aquaculture activities in the context of long-term chronic exposure scenarios. In the present study, a multidisciplinary and multigenerational approach was implemented in the Pacific oyster *Crassostrea gigas*, a species having a high economic value and an important ecological role in the ecosystem functioning. To assess the effects of particles and leachates, several endpoints reflecting different organization levels were investigated.

**Material and Methods**

The effects of tire particles, tire leachates and natural particles were investigated at individual scale (generation G0) over a 6 weeks exposure in a flow-through system using endpoints reflecting different organization levels (e.g. transcriptomic analyses, gut microbiota, tissue alterations, feeding activity, growth, reproductive outputs) up to offspring performance (e.g. development, fertilization rate, larval growth). Secondly, the G1 offspring performance (development, survival and growth of larvae and juveniles) was monitored over one year up to their ability to reproduce (G2 larval progenies), providing unprecedented views about the potential long-term risks from exposure to tire particles at environmentally relevant concentrations for marine organisms.

**Results**

No significant differences in ecophysiological parameters and haemocytes features were observed between exposed parental conditions whereas molecular analyses revealed the disruption of energy metabolism and stress response following leachates exposure. Oocytes had the highest number of differentially expressed genes; among these, many were associated with endocrine disruption and demonstrated that oocytes are mostly targeted in case of prolonged exposures of the broodstock during gametogenesis. Microbiota analysis revealed the over-representation of *Tenacibaculum* spp., a gram-negative and motile bacterial genus often associated with mortality events of marine animals, which suggested the onset of dysbiosis following exposure to high concentration of both tire particles and leachates. Parental exposure had an impact on gamete quality with a 22% reduction of motile spermatozoa in the leachate conditions but had no consequences on the fertilization success nor lead to long-term effects on offspring growth and reproductive outputs. Considering the concept of energy-limited tolerance to stress, it would be of great interest to test tire risk in the context of harsher natural conditions (e.g. food limitation, water quality).

Overall, while our results bring a positive note on the apparent resilience of Pacific oysters to tire particles exposure, caution should be taken when extrapolating these results to other rubber materials or to natural – harsher – conditions occurring in coastal ecosystems, bearing in mind that the first answer to plastic pollution is to reduce its production and usages whenever possible and favor durable materials.
**MEDITERRANEAN AQUACULTURE: FUTURE DEVELOPMENTS MUST ADDRESS FARMED FISH WELFARE**

**Introduction**

Europe is one of the largest seafood markets and the second largest trader of seafood products. Regional consumption keeps increasing (estimated 24 kg per capita in 2019), with almost 60% of EU seafood’s total supply covered by imports, making it highly dependent on them, e.g., a noticeable amount of Turkish seafood exports end up in the EU market. Within the Union, aquaculture production mainly concentrates in four top countries (i.e., Spain, France, Greece and Italy) and three finfish species (i.e., European seabass, gilthead seabream and rainbow trout) (EC, 2022; STECF, 2023).

However, despite the relevance of these species, Mediterranean-basin aquaculture is frequently overshadowed by salmon farming, e.g., a large portion of scientific publications within the last decade were dedicated to Atlantic salmon. Therefore, the objectives of this presentation are: (i) to identify knowledge gaps concerning Mediterranean finfish welfare and link them to production levels and investments made by the EU, and (ii) to assess the current scientific knowledge on the welfare and farming practices of top predator species, planned to be intensively farmed on a large scale.

**Material and methods**

A thorough literature review was conducted on the available aquaculture scientific publications in Spain, France, Greece, Italy, and Turkey. Articles, reports, guides and manuals were analysed to gain knowledge on each aquaculture sector at a national level, the presence and definition of animal welfare in these documents, data related to species-specific good farming practices, and financial support available from the EU.

**Results**

The European Maritime, Fisheries and Aquaculture Fund (EMFAF) has allocated over €2,000M to fostering aquaculture during 2021-2027. However, welfare receives very little money, e.g., Spain (1.9%), Italy (1.2%), and Greece (0.6%), and the planned measures are mainly related to animal physical health. In the case of France, the funds allocated to animal welfare are unspecified. Also, despite the variety of EU projects working with finfish carnivorous species (e.g., FutureEU Aqua, Impaqt, MedAid, PerformFish, and Seafood Tomorrow), their welfare remains to be adequately addressed if compared with the available scientific knowledge.

Similarly, the reports, guides and manuals analysed follow the same trend (Mendeley, 2023), except for Canada, Ireland, and UK’s salmonids guides. Animal welfare is cited without a precise definition, and when defined, it references mainly to physical health (disregarding mental aspects). The lack of species-specific scientific knowledge and guidelines is also evident for those new large-scale intensive-rearing top predator farms (i.e., bluefin tuna, greater amberjack) which are planned in Spain, and expected to appear in other Mediterranean countries.

**Discussion and conclusions**

Aquaculture is quickly developing and evolving, and it is often portrayed as a sustainable alternative to wild fisheries and a means to achieve food security. However, it remains to be seen how further developments based on rearing current and new carnivorous species can be sustainable. Also, Mediterranean finfish species are usually neglected because most resources are allocated to salmon farming, mainly located in Norway and the UK.
The EU actively promotes aquaculture development and diversification in two opposite directions: a) by farming low-trophic species, integrating multitrophic systems and limiting the use of Fish Meal Fish Oil as fish feed (EC, 2023a, 2023b), and b) by rearing top predator species Mylonas et al. (2018). The latter has diverse animal welfare issues, including the lack of scientific knowledge and farming guidelines.

In this context, following a precautionary approach, more fish welfare research is needed before the sector further diversifies. The opening of large-scale intensive-rearing farms should be postponed unless high animal welfare standards are guaranteed, especially regarding all carnivorous species, of which little is known regarding good farming practices and welfare. By doing so, animal welfare would be at the core of aquaculture and in alignment with the EU Strategic Aquaculture Guidelines 2021-2030 (EC, 2021).

MULTI-OMICS INVESTIGATIONS OF THE ROLE PLAYED BY EMBRYONIC TEMPERATURE IN PROGRAMMING LONG-TERM IMMUNE FUNCTION IN ATLANTIC SALMON

C. Milton
Edinburgh University
S1533332@ed.ac.uk

Atlantic salmon represent a major component of the aquaculture industry with an annual production value of 16.7 billion USD in 2017, the largest for any finfish and the second highest of all marine species (Houston et al, 2020). This industry suffers from a high mortality rate. In Scottish aquaculture, salmon production losses remained stable at around 20% between 1990 and 2014 (Murray and Munro, 2018). However, this has increased in recent years with the latest smolt input to harvest loss rate standing at 25.6% (Munro, 2022). High mortality in farmed salmon production is not specific to UK aquaculture with approximately 20% of Norwegian farmed salmon also failing to reach the end of the production line (Directorate of Fisheries, 2019).

This is the result of low robustness, with viral diseases including cardiomyopathy syndrome and pancreas disease, bacterial diseases including tenacibaculosis, and parasites (especially salmon lice) accounting for much of this loss during the seawater production phase. The increased mortality among salmon is indicative of impaired immunity.

The environmental and production factors contributing to this effect are not properly understood. One potential cause of low robustness and impaired immunity may be attributed to suboptimal temperature during embryogenesis. As poikilothermic organisms, temperature influences essentially all biochemical and physiological processes of fishes like Atlantic salmon. It has been shown in many organisms including Atlantic salmon, that exposure to external stimuli such as temperature during early development may permanently alter metabolism and physiology, even long after the stimuli has been removed (Ziqiang et al., 2019). This phenomenon is known as metabolic programming. Higher embryonic temperature has been shown to accelerate growth of Atlantic salmon (Austreng et al, 1987) resulting in larger sized muscle fibres containing significantly more myofibrillar material. Muscle cell size increase was also found to proceed at a greater pace in higher embryonic temperature groups relative to lower temperature groups (Stickland et al, 1988). Additionally, higher embryonic temperature was linked to decreased promotor methylation in the Atlantic salmon myogenin gene, a transcription factor essential for muscle tissue development, which was in turn correlated with increased myogenin expression (Burgerhout et al, 2017).

However, growth of embryos at higher temperatures has been shown to result in greater rates of mortality and abnormal development (Gunnies, 1978). It is possible that metabolic programming of an embryo towards fast growth may impair energetic allocation into other functions and processes. For example, in coho salmon, fast-growing transgenic fish overexpressing growth hormone showed evidence of decreased immune function compared with wild-type fish (Alzaid et al, 2018). This suggests a fine balance is normally maintained between various physiological systems, which may become disrupted when the organism is pushed too strongly towards growth.

The COOLFISH project, in which my PhD is embedded, seeks to fully understand the effects of such metabolic programming by early rearing temperature on Atlantic salmon development and health throughout the production cycle. Three groups of Atlantic salmon were grown under different temperatures (4, 6 and 8°C) during embryogenesis (solely from fertilization to the eyed stage). After the embryos reached the eyed stage, these groups were reared under a common temperature for the rest of their life (until the parr stage, when a final disease challenge was performed using Yersinia ruckeri). Fish were sampled at start feeding, early in development and after the immune challenge.

My PhD aims to understand the functional mechanisms driving temperature differences in immune function, taking a multi-omics approach. At the conference single nucleus sequencing data of livers taken at start feeding sampling will be presented. Analysis is currently at an early stage but will be completed before September. Preliminary results show hundreds of differentially expressed genes found in hepatocytes and immune cell clusters between the temperature groups. This will be paired with freshly generated proteomics data (n=9 per temp group) from matched samples confirming the link between transcription levels and the actual abundance of proteins, strengthening the link between the cell-specific transcriptome and phenotype.
COCULTURE OF GRAZERS AND OYSTERS IN THE UNITED STATES: A LOCAL NATURE-BASED SOLUTION ADDRESSING FOOD SECURITY

Darien D. Mizuta*, William C. Walton
Virginia Institute of Marine Sciences (VIMS)
1370 Greate Rd
Gloucester Point, VA, 23062 United States
E-mail: ddmizuta@vims.edu

Introduction

Aquaculture can potentially adhere to the standards of the Nature-based Solutions (NbS) framework and contribute to the scaling up of NbS. Thus, this industry may take advantage of ideas that are both environmentally friendly and provide the best social-economic outcomes. The farming industry has recently been in search of added sustainable practices and new possible farming species, which have the potential to increase the availability of nutritious seafood and also promote higher food security. One such approach is the coculture of different species with a focus on positive socio-environmental outcomes, in addition to increased seafood provision.

The US is the top seafood importer in the world and a big consumer of shellfish. Given this opportunity for domestic production, growers, and related seafood businesses (e.g. restaurants) have expressed interest in innovative forms of aquaculture that bridge farming efficiency and marine conservation spheres (e.g. restorative aquaculture, regenerative aquaculture). At the same time, aquaculture management that increases shellfish quality, and is less time-consuming and less costly for biofouling control is required. Within that context, this work explores the feasibility of coculture of native grazers, Atlantic Purple Sea urchins (Arbacia punctulata), and the Common periwinkle (Littorina littorea), with suspension feeder Eastern oysters (Crassostrea virginica) as two separate projects, and discuss how the approach can fit the framework of NbS.

Methods

Using traditional bottom culture cages, and farming bags, different treatments were deployed in selected locations in the Chesapeake Bay area, where oyster culture is common, using a randomized design. Oyster stocking density in farming gear was maintained constant and similar to standard commercial densities in all treatments. Experimental designs involved the collection and use of two different sizes and stocking densities for urchins; whereas periwinkles were deployed in different coastal culture zones with varying stocking densities. Treatments within projects are being compared in terms of potential effects on farming efficiency, farming management improvement, and species’ conditions and survival. We additionally discuss how the design of grazer-oyster coculture can contribute directly or indirectly as a NbS based on IUCN’s ‘Global Standards for Nature-based Solutions’ (Fig.1).

Results

Preliminary results show positive effects of the coculture choice upon oyster production relative to the monoculture, such as less biofouling attached to farming gear (Fig. 2), and improved target bivalve species quality (e.g. higher condition index, shell cleanliness), with additional potential environmental outcomes (less use of freshwater in operations, energy).

Discussion

Although this research is ongoing and projects are still in the initial phase, grazers could potentially be a useful tool to improve shellfish farming management and bivalve shellfish product quality. Several technical aspects and economic considerations to bring grazers to the seafood market still need to be carefully assessed, but broadly, we expect the advantage of deploying cocultures to be at least two-fold for the farmer: coculture can increase the revenue of the farms with a secondary product and lower farming management costs; besides potentially being a suitable strategy to small-scale farmers. Moreover, coculture with these grazers uses the same in-use farming space and can be designed to link with marine conservation initiatives, resulting in additional positive environmental outcomes.

Introduction

Given the increasing demand for fish and fish products, it is necessary to determine the quality of fish fillets, as quality and nutritional value are considered as a major factor in fish sales and acceptance by consumers (Naeem and Ishtiaq, 2011; Naeem et al., 2016; Shirmohammadli and Mohammad Nejad, 2022). The amount of chemical composition in the aquatic body depends on the type of nutrition, living environment, age and sex of the living creature (Kochekian Sabour and Yasimi, 2011). Therefore, in the present study, changes in the composition of bighead carp meat, which is a valuable bone fish that is bred in many parts of the world, were studied at different weights.

Materials and Methods

For this research, 2 year old bighead carp were used in 4 weight groups as follows: Group A: Average weight 1000 gr, Group B: Average weight 2000 gr, Group C: Average weight 3000 gr and Group D: Average weight 4000 gr. To evaluate the quality of bighead carp meat, 5 fish were separated from each weight group after checking for health and abnormal symptoms and disease in the fish. After biometrics and measurement of fish length and weight, 100 grams of muscle was isolated from each fish sample to evaluate meat quality. The AOAC (1990) method was then used in the Food Analysis Laboratory to evaluate and analyze meat quality. SPSS 22 software was used for data analysis (Shirmohammadli and Mohammad Nejad, 2022).

Results and Discussion

Table 1 shows changes in protein, fat, ash and dry matter quality of bighead carp in different weight groups. The results showed that the amount of protein changed significantly in different groups and a significant difference was observed between different weight groups ($p<0.05$). So that the highest amount of protein was observed in 2000 gram fish. Changes in the fat of bighead carp showed that there are significant changes in fish with different weights ($p<0.05$). The lowest amount of fat was observed in the weight group of 2000 grams. But overall results showed that there was no statistically significant difference between different weight groups in dry matter and ash ($p>0.05$).

The results of this study showed that the change in fish weight has an effect on the quality of the fillet, so that the 2000 gram bighead fish had more fillet protein and less fat compared to other weights. The results of this study are not consistent with the study that was conducted on 500-1600 g silver carp and common carp. Their results showed that fish weight had no effect on fillet quality (Shirmohammadli and Mohammad Nejad, 2022). The reason for this difference can be physiological characteristics, species differences, nutritional conditions, etc. The results of this study showed that 2000 grams of bighead fish has more fillet protein than other weights. Therefore, it is suggested to present fish of this size to the consumption market and for consumers to use it.

</tbody>
</table>

*The small Latin letters show that there are significant differences among different weight

(Continued on next page)
Based on the results of this study, the average protein of bighead carp was 10.29 ± 0.89 %, which is much less than fish such as silver carp (14.18) (Shirmohammadli and Mohammad Nejad, 2022), *Liza auratus* (17.69%), *Clupea harengus* (18.45), *Tilapia zilli* (18.80 %) (Olagunju et al., 2012), *Orcynopsis unicolor* (22%), *Euthynnus affinis* (24%) (Aberomand, 2012), *Otolithes ruber* (19.64 %), *Scomberomorus guttatus* (19.9%), *Scomberomorus commerson* (19.5%) (Velayat-Zadeh and Askari Sari, 2013). Fat is a component of the chemical composition of the muscle that represents the largest difference in the amount of fish muscle (Askari Sari et al., 2016). The average fat of bighead carp in this study was 8.25 ± 0.67 %, which was higher than the amount of fat in *Liza auratus* (0.74%), *Liza dussmieri* (0.25%) (Aberoumand, 2012), *Otolithes ruber* (1.23 %), *Scomberomorus guttatus* (2.1%), *Scomberomorus commerson* (3.4 %) (Velayat-Zadeh and Askari Sari, 2013), as silver carp (14.18 %) (Shirmohammadli and Mohammad Nejad, 2022), and much less than fish such as as common carp (9.42 %) (Shirmohammadli and Mohammad Nejad, 2022), *Clupea harengus* (11.14 %), *Scomber scombrus* (12.33 %), *Tilapia zilli* (18.80%) (Olagunju et al., 2012), *Orcynopsis unicolor* (16 %), *Euthynnus affinis* (14 %) (Aberoumand, 2012).

According to the present study and its comparison with other studies, the bighead carp can be considered among the fish with medium protein and fat. In addition, due to the high value of protein, 2000 grams of bighead fish can be suggested as an acceptable weight for the consumer.

DIFFERENT METHODS OF OVULIN HORMONE INJECTION ON STRESS INDICES (GLUCOSE AND CORTISOL) OF Cyprinus carpio var. Sazan BROODSTOCKS

Majid Mohammad Nejad

Department of Fishery
Bandar Gaz Branch
Islamic Azad University
Bandar Gaz, Iran
P. O. Box: 48715-119
E-mail: majid_m_sh@bandargaziau.ac.ir

Introduction

Glucose and cortisol are important indicators in assessing the level of stress in living organisms. Blood glucose is the most variable index that is greatly affected by handling, transportation, environmental stress, seasonal changes, nutritional status and maturity (Hosseini Fard et al., 2013). Cortisol in bony fish affects reproductive function and gamete growth. Cortisol, an important corticosteroid produced during the spawning season, can suppress fish immunity (Odhiambo et al., 2020). Inducing sexual maturation in fish can be stressful and can have an adverse effect on fish reproduction. Hormone injections into fish for the purpose of inducing reproduction, in addition to affecting the levels of sex steroids, can cause changes in fish’s blood stress indices (Falahatkar et al., 2016). Therefore, it is important to use a method that puts the least stress on the fish. In this study, different methods of injecting the Ovulin hormone on glucose and cortisol of Cyprinus carpio var. Sazan were studied.

Materials and Methods

12 Cyprinus carpio var. Sazan were injected in three methods in one time: injection under the pectoral fin, injection under the dorsal fin and injection under the ventral fin at a dose of 0.6 ml / kg of Ovulin hormone. Blood samples were taken from male and female broodstocks with 5 cc syringes and from fish tail arteries in two stages (before hormone injection and 12 hours after hormone injection). In the hematology laboratory and after centrifugation at 5000 rpm, serum was isolated from blood cells for 5 minutes and glucose and cortisol levels were measured by automated devices. All statistical analyzes were performed using SPSS software version 26. Shapiro-Wilk test was used to investigate the normal distribution of data in groups and for all variables. One-way analysis of variance (Oneway ANOVA) was used for statistical comparison between groups, and after performing the Test of Homogeneity of Variances and Duncan test was used to compare groups with each other (Mohammad Nejad, 2022).

Results and Discussion

The results of glucose and cortisol analysis in male and female broodstocks of *Cyprinus carpio* var. Sazan showed that in both sexes and in all three injection methods, its amount increased after hormone injection (Tables 1 and 2). The amount of stress increase due to hormone injection in both male and female broodstocks in the method of pectoral fin and dorsal fin was more than the method of injection under the ventral fin. The comparison between the two broodstocks also showed that the increase in stress in the female broodstocks was more than the male broodstocks. These results were consistent with the study of changes in stress indices of *Cyprinus carpio* in different stages of artificial reproduction (Mohammad Nejad, 2022). The results of this study show that hormone injection is effective in increasing stress in Caspian carp. Consistent with the results of this study, injection of various hormones in artificial reproduction increased glucose and cortisol levels in some fish (Mohammad Nejad, 2022).

Almost any type of stress (physical and neurological) causes an immediate and pronounced increase in ACTH secretion and within minutes leads to a sharp increase in cortisol secretion from the cortical part of the adrenal glands. One of the many effects of cortisol is to increase the body’s resistance to stress by reducing glucose uptake, so as cortisol increases, blood glucose levels also increase rapidly (Saha et al., 2003), which was also proven in the current study. Due to the injection of Ovulin hormone in male and female broodstocks, the amount of cortisol increased due to stress and then the absorption of glucose from the blood decreased and as a result, the amount of glucose in the blood serum increased. However, the relationship between stress and reproductive hormones of Caspian carp was not investigated in the present study but, the relationship between stress and its indicators with sex hormones in fish has been proven. The effect of cortisol on reducing estradiol and testosterone has been reported in some fish (Falahatkar et al., 2016).

Therefore, using a method that can put the least stress on the fish during the breeding process is important and necessary. The results of the present study show that hormone injection by injection method under the dorsal fin can cause less stress to the *Cyprinus carpio* var. Sazan, so it is recommended compared to the other two methods in the reproduction of this fish.

Introduction

The diversification of species can be a good strategy for the economic success of the aquaculture industry. This strategy has been followed in Europe with international projects like DIVERSIFY, which highlights the role of some species, as *Seriola dumerili*, for its great potential, both taking biological and economic issues (Robles & Mylonas, 2017). For this purpose, it is necessary to determine optimal culture conditions for this species and one of these basic conditions is the stocking density. A first approach in this field was made by Jerez et al. (2017), who evaluated the effects of different stocking densities on this species. This study reached a maximum density of ~7 Kg/m³ for the high-density group, which showed a lower growth performance. However, our study was aimed to evaluate the metabolic orchestration, intestinal well-being and welfare reaching stocking densities higher than 30 Kg/m³ for the high-density group.

Material and Methods

Greater amberjacks were obtained from natural spawning at the Marine Scientific and Technological Park of ECOQUA Institute of the University of Las Palmas de Gran Canaria (Las Palmas, Canary Islands, Spain) and transferred to the Centro Tecnológico de la Acuicultura (CTAQUA, El Puerto de Santa María, Cádiz, Spain). Then, a total of 588 individuals (~24 g initial body mass) were distributed in a RAS system with 9 tanks of 400 L, which constituted the 3 experimental groups (in triplicate): i) Low Stocking Density (LSD), with a final estimated density of 8 Kg/m³; ii) Medium Stocking Density (MSD), with a final estimated density of 16 Kg/m³ and iii) High Stocking Density (HSD), with a final estimated density of 32 Kg/m³. After 72 days of an *ad libitum*-feeding trial, a biometric sampling was done, and samples from plasma, liver and muscle were taken. Somatic and zootechnical indices were calculated, and samples from each tissue were analysed.

Results and Discussion

No significant differences were observed in the final body mass of the fish in any experimental group. In addition, the Fulton’s condition factor (K) did not show any differences either, so fish in the three densities grew allometrically. Therefore, the results in terms of growth performance are positive and, moreover, parameters such as the specific growth rate (SGR) show normal values in all three groups (Jerez et al., 2017; Fernández·Montero et al., 2018; Monge·Ortiz et al., 2018). In terms of somatic indices, only the mesenteric index (MSI) showed significant differences, with an increase in perivisceral fat of the MSD group, concomitantly with i) higher lipid deposition in the liver, and ii) the lowest intestinal selectivity denoted by epithelial resistance (Rt). Finally, regarding intermediary metabolism, the results show a higher energy mobilisation with increasing density, which can be invested in growth performance. Interestingly, the MSD and HSD groups had significantly lower cortisol levels than the LSD group, which can be the cause or the consequence of the gregarious nature in juveniles of this species (Mazzola et al., 2000).

Results obtained in the present study, focussed on the combination of different analytical approaches, indicated that a higher stocking density than the highest currently used for *Seriola dumerili* herein is possible, since neither the growth performance nor the welfare of the individuals was negatively affected. Furthermore, these findings are highly transferable to the aquaculture sector, making the culture of this species more profitable, where the recommended stocking density could be set, at least, at 30 Kg/m³ without impact on fish performance parameters.

Introduction
Temperature is a key factor for achieving optimum fish growth and keep the welfare of the culture. Indeed, an incorrect temperature can affect ingestion, transit, digestion, assimilation and metabolism. Furthermore, this is magnified in a fast-growing fish such as the greater amberjack (*Seriola dumerili*). The culture of this species is becoming more and more important in the Mediterranean coasts mainly because of its fast development, its meat quality and its good acceptance in the market. For all these reasons, it is of utmost importance to establish a proper temperature, especially in RAS systems where this parameter can be modified quite easily, although its monitoring is especially important to avoid secondary artifacts that could compromise the metabolic and intestinal well-being of cultured fish. Taking all this into account, the aim of this study was to establish the consequences of water temperature on welfare, metabolic orchestration and intestinal integrity of greater amberjack juveniles accompanying the observed differences in growth performance (Yúfera et al., this conference).

Material and Methods
Greater amberjack juveniles (initial body mass 23.35 ± 5.07 g; mean ± SD) were randomly distributed in three independent RAS units set to 18, 22 and 26°C of temperature, each one with three 900-L tanks. Juveniles were reared for 58 days under a photoperiod of 12h-light/12h-dark and fed until apparent satiation 3 times per day with a commercial diet (Skretting). At the end of the experiment, 5 fish per tank were sampled to check their body weight and to obtain plasma and liver samples. These samples were analysed for determination of metabolites and circulant cortisol. Intestinal integrity, permeability and electrogenic amino acid transport were assessed in using chambers. Differences were checked by ANOVA followed by Tukey’s test.

Results and Discussion
In terms of growth performance, feed intake, final body weight and weight gain exhibited an increasing trend with the increase of temperature. Additionally, the feed conversion ratio was higher in the group maintained at 18°C, so low temperatures produce a lower feed efficiency in this species (Yúfera et al., this conference).

Following biochemical results, the parameters measured in plasma shown a higher energy mobilization through glucose, as well as a higher presence of circulating proteins probably due to a higher protein retention at higher temperatures (Fernández-Montero et al., 2018). Furthermore, decreased circulating cortisol levels has been observed in the 18°C group, probably due to the reduced metabolic rate associated with the low temperature, or even by a stimulatory effect of higher temperatures as a consequence of the anticipatory feeding activity. On the other hand, hepatic metabolites showed higher glycogen accumulation with increasing temperature, but lower triglyceride deposition in the 22 and 26°C group, indicating a temperature-dependent shift in energy substrate preference.

Intestinal health, evaluated by electrophysiological measurements, showed clear temperature-dependent variations. For example, an increase in mid gut transepithelial resistance (Rt, Fig. 2A) has been observed with increasing temperature. These results could also be associated with the higher transcellular transport in this section of the gut, as observed in the short-circuit current (Isc, Fig. 2B) for this group, as also confirmed the electrogenic amino acids transport in the mid intestine (ΔIsc, Fig. 2C). Both results could be indicative of increased gut integrity and selectivity, at least in the mid intestine, when fish are maintained at 26°C.

Considering all these results, it could be stated that optimal culture temperatures for *S. dumerili* could be set between 22 and 26°C, which agrees with the results obtained about growth performance and general health in previous studies with this species (Garcia-Gomez, 2000; Fernández-Montero et al., 2018).

Introduction

Vibrio vulnificus is an aquatic zoonotic pathogen whose distribution is expanding due to global warming. This pathogen causes a disease known as vibriosis in both aquatic animals and humans. The most severe form of vibriosis is a haemorrhagic septicaemia with a high probability of death. The species is subdivided into five potentially human-virulent lineages plus a polyphyletic pathovar with the ability to cause vibriosis in fish. Notably, this ability is associated to a series of genes encoding resistance to fish innate immunity. It has recently been shown that fish farms have played an important role in the evolution of this species as two of the five lineages emerged as human pathogenic variants in these sites after successive outbreaks of vibriosis in fish. Therefore, the control of this pathogen on farms is essential, not only to prevent animal and human infection but also to avoid the transference of this immunity system to other bacterial pathogens (1). This study is the first part of a larger project aiming at the development of a vaccine to protect any fish species not only from vibriosis caused by V. vulnificus but also from any other infection caused by a bacterium that had acquired this resistance system against fish immunity.

Materials and methods

Antigens. Selected genes (A1 and A2), related to fish immunity resistance, were cloned in pET28a (A1) and pET303a (A2), in frame with an N-terminal 6x-His tag. Recombinant protein expression was done in Escherichia coli BL21 (DE3) (A2) or E. coli BLR (DE3) (A1). Induced cells were suspended in lysis buffer, sonicated and centrifuged. Pellets were washed and sonicated several times with solubilization buffers (SB). Fractions containing the inclusion bodies were suspended in SB with 6M guanidine hydrochloride and solubilized by constant stirring overnight at 4ºC. Proteins were purified by nickel affinity chromatography (High Density Nickel, Agarose Bead Technologies) and quantified using the Pierce™ BCA Protein Assay kit (ThermoFisher Scientific).

Immunization. Four groups of 46 eels (Anguilla anguilla), selected as animal model, were intraperitoneally injected with 100 µl of purified proteins-based solutions according to Esteve-Gassent et al. (2). These formulations were prepared with A1, A2 or A1+A2 antigens (1:1 ratio) (0.75 µg protein/ml, in all cases), supplemented with Freund’s incomplete adjuvant in a 1:1 ratio. In addition, a control group immunized with a 1:1000 dilution of the V. vulnificus bacterin enriched with extracellular components (2) was included. Plasma samples were collected before and 0, 3, 10, 14 and 21 days after immunization.

Figure 1. Antibody response in plasma after eel immunization with purified antigens determined by ELISA. A) Groups immunized with A1 and A1+ A2 against antigen A1. B) Groups immunized with A2 and A1+ A2 against antigen A2. C) Group immunized with the bacterin against 1:100 diluted bacterin. *Significant differences in antibody production with respect to time 0.

(Continued on next page)
Immune response. Specific antibody titers in plasma were determined by ELISA according to Esteve-Gassent et al. (2). Briefly, plates were coated with 10 ng of purified proteins or 1:100 diluted bacterin. Serial 1:2 dilutions of plasma samples were done. Reaction development was performed using rabbit anti-eel IgM antiserum (1:2000) and HRP conjugated goat anti-rabbit antiserum (1:2000) (Bio-Rad). Titer was established as the inverse of the dilution giving an $A_{450}$ value twice greater than that of the blank (0.1% Bovine Serum Albumin in PBS).

Statistic. Two-factor ANOVA (p < 0.05), using R-Commaider V.2.8 (R V.4.3.1).

Results
Proteins were successfully purified with a yield of 12.5 mg/l for A1 and 20.55 mg/l for A2. Immunization of eels led to the production of specific antibodies overtime (Fig 1). A significant increase in plasma antibody titers was observed 14 days after immunization in all groups, reaching the highest value 14 days (19200, in group A1) (Fig 1A) or 22 days (12800 to A1 and 20800 to A2, in group A1+A2) (Fig 1A & B) post-immunization. Immunization with formulation A2 elicited similar response (Fig 1B) to that of the bacterin group, in terms of plasmatic antibody titer (Fig 1C). However, in groups immunized with A1 and A1+A2 formulations, antibody levels were higher (Figs 1A & 1B).

Discussion and conclusion
There is a patented vaccine against V. vulnificus that showed high efficacy in fish farm trials but was never licensed due to its high production costs and low commercial value. The increase in the number of both outbreaks of vibriosis in fish farms and human infections related to global warming has substantially changed the picture. This work is part of an ambitious project to develop a multispecies vaccine that avoids not only the transmission of vibriosis but also the expansion of virulence genes encoding the innate immune resistance system of fish. In this work, we have selected the antigens, produced them recombinantly in E. coli, purified them from inclusion bodies and tested their efficacy in terms of antibody production. The specific response in eel was stronger after vaccination with purified proteins-based formulation than with the bacterin. The results obtained are encouraging and promise protection against the pathogen. The next step will be to test the protective efficacy of the protein-based formulations using different fish species and different pathogens.

Introduction
Chub is an important gamefish in Hungary. There is a growing angling demand for this species (Borics et al. 2016). Several studies have already been carried out regarding the rearing of the chub larvae in a Recirculating Aquacultural System until the 30th day after hatching (Shiri Harzevili et al. 2003; Zarski et al. 2008; Crooks et al. 2013; Kupren et al. 2015). However, nowadays limited information is available on chub larvae rearing older than 30 days of age. Based on our previously experience, feeding with complete fish feed resulted high rate mortality and high rate of larval deformity compared to natural live food, for example Artemia nauplii (Bartucz 2020). One of the critical factors during rearing can be the lack of vitamin C (Berillis 2015). The study aimed to investigate the growth parameters on chub fries using different feeds.

Material and methods
The fries were reared for 28 days at a temperature of 25±0.5 °C and an oxygen level of 7.5±0.5 mg/L in Recirculating Aquacultural System (RAS). The lighting period was 12 h/day. Fish were stocked in tanks at the density of 10 individual/L. The effect of four different fish feed was examined in six repetition in each group. Fish were fed twice a day in a dosage of 2.5%/bodyweight.

Four different feeds were used:
- Artemia nauplii (A),
- Artemia nauplii with 1000 mg/kg Vitamin C (A+C),
- complete fish feed (Aller Infa EX GR 0.4 mm) (CF),
- complete fish feed (Aller Infa EX GR 0.4 mm) with 1000mg/kg Vitamin C (CF+C).

After 7 days of feed acclimatization period, wet body weight and standard length were recorded on the 0th, 14th and 28th days. Wet body weight and standard length were measured on 10 individuals/sampling occasion/tanks. Wet body weight was determined with a Mettler Toledo AB204-S analytical scale with an accuracy of ±1 mg. Standard length was measured with a Leica M205 FA type microscope and a Leica DFC 7000T camera mounted on it with an accuracy of ±1 mm. At the end of the experiment, the survival rate was determined.

Results
In wet body weight and standard length, no significant difference was observed as an effect of the addition of Vitamin C at any of the three measurements. On day 28, wet body weight and standard length were measured on 10 individuals/sampling occasion/tanks. Wet body weight was determined with a Mettler Toledo AB204-S analytical scale with an accuracy of ±1 mg. Standard length was measured with a Leica M205 FA type microscope and a Leica DFC 7000T camera mounted on it with an accuracy of ±1 mm. At the end of the experiment, the survival rate was determined.

Discussion and conclusion
We have successfully reared chub fry in a Recirculating Aquacultural System with artemia and a complete fish feed also. At the end of the experiment, between the two feed types, statistically verifiable higher wet body weight and standard length were recorded in the artemia groups, compared to the complete fish feed groups. The type of feed affected growth, but the addition of Vitamin C did not affect the offspring rearing period.

EFFECTS OF FUNCTIONAL BREWERS’ YEAST (*Saccharomyces cerevisiae*) ADDITIVES ON THE MUCOSAL HEALTH OF ATLANTIC SALMON PARR FED LOW MARINE CONTENT DIETS

Taofik Adeiza Momoh†, Nicola Pontefract†, Benjamin Eynon†, Holger Kühlwein‡, Victor Kuri†, Daniel L. Merrifield†

2. Leiber GmbH, Bramsche, Germany
Email: taofik.momoh@plymouth.ac.uk

Introduction
Premium Atlantic salmon diets have contained up to 30% fishmeal (FM) and 20% fish oil (FO). Sustainability concerns over raw materials such as those derived from forage fish has led to continuous research and refinement of aquafeeds. Despite the growth of novel ingredients (such as insect meals, algal meals and single cell proteins) as FM/FO replacements, maintaining a low Fish-in : Fish-out ratio (FiFo) for salmon aquaculture largely depends on the more readily available plant derived raw materials. However, the combination of low levels of marine ingredients with high levels of plant derived raw materials can lead to poor gut health and welfare.

Functional feed additives such as probiotics, prebiotics, enzymes, and phytobiotic compounds have been incorporated in aquaculture diets for their ability to improve intestinal health and enhance disease resistance. Particularly, cell wall components of *Saccharomyces cerevisiae* (rich in β-1,3 and -1,6-glucans and mannan oligosaccharides) have been demonstrated to confer immunomodulatory effects in fish. These benefits are at least partially induced by improvements of intestinal health. However, despite these reported benefits, many knowledge gaps exist with the exact mode of action of yeast cell wall derivatives.

Therefore, an experiment was conducted to investigate the efficacy of whole cell walls and highly purified β-glucans derived from brewer’s yeast on the intestinal health of Atlantic salmon fed low marine content (15% FM, 8% FO) diets.

Methodology
A total of 120 parr (ca. 20g) were randomly assigned into six experimental units (20 fish per tank) and fed either 1) control (no yeast additives), 2) PβG (0.02% Leiber® Beta-S) or 3) WYCW (0.2% Biolex® MB40) treatments for 4 weeks. All treatment groups were fed to the same percentage of biomass (av. 1.5% per day). At the end of the experiment, distal intestine and skin tissues were collected from 5 fish per tank (N = 10 per treatment) for histology, electron microscopy and gene expression analyses according to protocols described elsewhere (Merrifield et al., 2009; Rawling et al., 2021).

Results and Discussion
At the end of the experiment, there were no significant differences in zootechnical performance (weight gain, SGR and FCR) between fish fed the different diets. Histological appraisal (Figure 2) revealed that fish fed the WYCW treatment had a 39% increase ($P = 0.0422$) in goblet cell abundance in the distal intestine and that the PβG treatment-fed fish had a 49% increase ($P = 0.0459$) in goblet cell abundance in the skin when compared to the control group.

In addition, electron microscopy analysis (Figure 3) of the distal intestine revealed significantly different microvilli morphometrics. Fish fed the PβG treatment had 20% longer ($P < 0.0001$) and 34% denser ($P = 0.0001$) microvilli compared to the control group. Fish fed the WYCW treatment had 25% denser microvilli arrangement ($P = 0.0056$) than the control group.

Targeted gene expression analysis of immunomodulatory and barrier function genes is on-going, however, the available data show that both functional feed additives demonstrated the potential to enhance the epithelial barriers studied.

*Email: rowenamondonedo777@gmail.com

Introduction
Over the last two decades, there has been a growing acknowledgment of the significance of fisheries and aquaculture in providing global food security and nutrition. Seafood is essential to over 1.2 billion individuals, with approximately 700 million relying on fish as their main protein source (FAO 2022). However, the expansion of aquaculture has raised concerns regarding the production of enormous amounts of organic waste and the associated environmental impacts. *Salicornia ramosissima* known as pickleweed or glasswort, a salt-tolerant plant, has been investigated for its potential to bioremediate marine and brackish aquaculture effluents. Also, this species shows great potential for diverse applications in pharmaceuticals, nutraceuticals, culinary, and aquaculture industries (Buhmann and Papenbrock 2013; Patel 2016). Furthermore, the use of *S. ramosissima* in fish effluent treatment systems that integrate IMTA (Integrated Multi-trophic Aquaculture) and RAS (Recirculating Aquaculture System) is still in its early phases of development, and further study is required to evaluate its full potential. Also, the biochemical profiles of *S. ramosissima* in every stage of its life cycle, on the other, are scarcely understood. Thus, this study aimed to characterize the amount of lipid, fatty acid profile, and lipid classes in *S. ramosissima*, considering its productivity, nutrient uptake, and life stages in utilizing fish effluents from RAS.

Materials and methods
The plant was cultivated in an integrated multi-trophic aquaculture (IMTA) system with floating plant rafts and in a fish-recirculating aquaculture system (RAS). The four-month experiment examined the plants’ lipid, fatty acid content, and lipid classification considering their growth stages, biomass, and nutrient uptake.

![Graph](image)

**Figure 1.** Total Lipid content (%) of *S. ramosissima* (edible part) throughout the 4 months of study at various positions on a raft system utilizing fish effluents from RAS for growing. Error bars are denoted by the standard errors.

(Continued on next page)
**Results and discussions**

*S. ramosissima* yield was significantly higher in the first month and decreased progressively until the end of the trial. It also revealed a high capacity to remove nutrients such as nitrite (64%), nitrate (82%), ammonia (89%), and phosphate (73%). Moreover, lipid percentages varied significantly throughout the life cycle with values of 3.4%, 3.5%, 3.8%, and 3.2% every month (Figure 1). The most abundant fatty acids (FA) were the polyunsaturated 18:3n3 (ALA) and 18:2n6 (LA), and the saturated 16:0 (PA). ALA and LA showed contrary tendencies, remaining constant until the final month, where ALA decreased significantly and LA increased. This coincided with flowering and seed production, highlighting LA's relevance in the senescence period. Regarding lipid classes, plants mainly showed high content of pigments (chlorophyll and β-carotene), glycolipids (mainly monogalactosyldiacylglycerols or MGDG and digalactosyldiacylglycerols or DGDG), phospholipids (mainly phosphatidylcholine or PC), flavonoids, and sterols. Most of these compounds are associated with antioxidant activity and exhibit health benefits. Thus, the study showed that the lipid profile of *S. ramosissima* is influenced by its life cycle and cultivation conditions. Also, these findings emphasize the significance of *S. ramosissima* in promoting eco-friendly and sustainable aquaculture practices while also providing valuable resources for food, feed, medicines, cosmetics, and biofuel.

Introduction
The utilization of insect meal-based fish feed as substitute to conventional fish meal-based feed is considered as a promising innovative alternative to boost circularity in aquaculture and aquaponics (Shaw et al. 2022a). However, basic research on its use in aquaponics and particularly in decoupled aquaponics is limited. So far, no reports on the effects of fish waste water, derived from a recirculating aquaculture system using Black-Soldier-Fly (BSF) meal-based diets, on the growth performance of lettuce were available. Therefore, this study aimed to compare the effect of reusing fish waste water (as a base for the hydroponic nutrient solution) from tilapia culture fed with a fish meal-based diet (FM) and a black soldier fly meal-based diet (BSF) on lettuce growth and water nutrient profile in decoupled aquaponic systems.

Material & methods
The experiment was conducted in a controlled climate chamber in nine separate hydroponics units. A conventional hydroponics nutrient solution (HP, control) was compared to two different aquaponic treatments (FM & BSF), and inorganic fertilizers were added to all groups to reach comparable target concentrations. All treatment groups were tested in triplicates. Lettuce fresh and dry weight, number of leaves, SPAD values, water consumption, and the usage of inorganic fertilizers were measured. Abiotic parameters of the nutrient solutions, environmental conditions, and micro- and macronutrients in the nutrient solutions were monitored in time series.

Results
Similar lettuce yield was seen in all treatments, with no significant effects on fresh and dry weight, the number of leaves, and SPAD values. Water use per plant was also similar between treatments, while the amount of total inorganic fertilizer required for preparing the nutrient solutions was 32% lower in FM and BSF compared to HP (Fig. 1). For the water nutrient profile analysis, higher sodium concentrations were found in the FM-based nutrient solutions compared to BSF and HP.

Fig. 1. Average percentage difference between the two aquaponics and the control treatments for every macronutrient (NO₃-N, NH₄-N, K, P, Ca, Mg, and S) added in the form of inorganic fertilizer. The experiment tested lettuce production under three nutrient solution sources: conventional hydroponics solution (HP, control) and fish waste water solutions from tilapia culture fed with a fish meal-based diet (FM) and a black soldier fly meal-based diet (BSF).

(Continued on next page)
Discussion
The potential of using BSF-based feeds aquaponics for a combined production of fish and plants in a decoupled aquaponic approach was clearly shown in this study, as it was not negatively affecting lettuce growth. Nevertheless, also fish growth performance needs to be considered to evaluate the overall sustainability, since the use of BSF-meal-based diets might have a negative effect on the growth of Nile tilapia compared to a fish meal-based diet (Shaw et al. 2022b). In addition, BSF-based diets might be beneficial over FM-based diets in intensive, professional aquaponics applications due to the lower sodium concentration in the nutrient solution. This is especially important if the nutrient solution is recirculated in the hydroponics unit, as higher sodium concentrations might negatively influence plant growth (Hernández-Salinas et al. 2022).

The results confirm that BSF as ingredient for fish diets is a promising alternative to FM in aquaponics without any adverse effects on lettuce growth, but more research is needed to evaluate the overall applicability.

Introduction
The use of Virtual Reality (VR) for the training of different aspects in aquaculture can be a valuable tool to simulate different working environments and situations e.g. with regard to animal welfare. Animal welfare in aquaculture does not attract enough international attention and there are no adequate international animal welfare standards for the breeding of fish, shrimp or mollusca. Therefore, the Aquaculture Welfare Standards Initiative (AWSI) formulated minimum requirements that are both comprehensible and implementable for producers of a wide variety of aquaculture animal species in a wide variety of countries. And in this specific context VR is used to offer comprehensive and realistic VR-training modules to address five core issues in aquaculture production (Fig. 1).

Material & methods
VR-training modules are developed based on scientific recommendations, basic guidelines for the different core issues as well as on feedback from practitioners. The first training modules for the species-specific stunning and slaughter of carp and trout as well as on general aspects of water quality are available in English and German.

Results
The first practical tests were very promising and clearly demonstrated the advantages of VR as an additional tool for training purposes in aquaculture. With this technology we were able to bring different aquaculture production systems such as recirculating aquaculture systems (RAS), flow through systems as well as ponds to the classroom and the users had the unique opportunity to get to know these systems without the need of travelling for several days. Additionally, critical scenarios, as the failure of different filtrations units or the stop of the main waterflow, can be simulated without putting the real systems and the produced fish at any risk.

Fig. 1. The five aquaculture related topics which are particularly relevant for animal welfare. Specific VR-training modules are currently developed for these core issues.

(Continued on next page)
**Discussion**

There is a great potential for VR as a useful tool to improve the teaching and lifelong learning as well as to improve the awareness within the aquaculture sector. The topic animal welfare has been presented here with regard to the application of VR for training purposes but is of course not restricted to that. Many different use cases are possible, each one having their own challenges and beneficial effects. Next to the general development of further useful VR-training modules we would also like to scientifically study the effects of using VR as a training tool more in detail to further emphasize the potential benefits of this technology.

introduction

Microorganisms are omnipresent and key players in aquaculture, especially in recirculating aquaculture systems (RAS), where water is reused continuously. Monitoring and managing microorganisms in RAS rearing water is essential for optimal water quality, avoidance of microbial diseases, and sustainable fish production (1). Online sensors for multiple physicochemical parameters are standard in the industry; however, knowledge of microbial water quality has been hampered by the lack of tools available to fish farm managers.

Tracking and understanding microbial dynamics and the drivers of water microbiome disturbances requires fast-paced sampling and analysis, ideally in real-time, allowing for immediate reaction. Traditional methods have long time lags between water sampling and results and they are labor-intensive, time-consuming, and costly for implementation in a fish farm. onCyt Microbiology offers a real-time and fully automated microbial monitoring system based on flow cytometry that allows fast, accurate, and reproducible quantification and differentiation of total and intact microbial cells in aquaculture rearing water (2).

Materials and Methods

A fully automated flow cytometry monitoring system was used to monitor microbial concentration at multiple points across a European Perch RAS for 51 days. In the initial phase (biofilter start-up phase), water samples were drawn from the biofilter tank for 16 days every 30 minutes. In the second phase (fish farming phase), samples were drawn from up to 4 locations (2 fish tanks and their corresponding water inlets) for 35 consecutive days. Each water sample was automatically mixed with fluorescent stains, incubated, and then analyzed using flow cytometry. The resulting data sets (Approx. 4'000 data points) were batch-processed using onCyt proprietary software to determine total cell concentration (TCC) and intact cell concentration (ICC). Time series decomposition analysis was performed using R, version 4.21, and correlated with RAS operational and physicochemical sensor data.

Fig. 1. (A) Microbial concentration in a Perch RAS measured by automated flow cytometry. Total and intact cell concentrations (TCC and ICC) were measured every 30 minutes for 35 consecutive days at two fish RAS tanks at swimming phase (data from inlets to the tanks is not shown). (B) Time series-decomposition of selected 3 days for TCC of tank 1, pH, and oxygen.

(Continued on next page)
Results
The onCyt automated flow cytometry system successfully delivered meaningful information on the microbial dynamics of the RAS. In the first 6 days, during the biofilter start-up phase, TCC and ICC remained relatively stable with an average of $1.5 \times 10^6$ cells/ml and $1.1 \times 10^6$ cells/ml, respectively. Over the following 2 days, a considerable increase (62%) in microbial concentration was observed, reaching a maximum TCC value of $4.1 \times 10^6$ cells/ml, followed by a decrease and stabilization phase. Changes in microbial dynamics during this phase were attributed to operational changes, including the opening of the water recirculation and the start of water temperature regulation.

During the fish farming phase, measurements started one day after the perch entered the RAS. The first 10 days of this phase were highly dynamic and characterized by a massive increase in TCC and ICC at the three locations measured (two fish tanks and one water inlet), with tank 2 reaching up to $6.1 \times 10^6$ cells/ml TCC (Fig. 1A). This expansion event was followed by a quick and sharp decrease in concentration to the order of $10^5$ cells/ml (Fig. 1A). Thereafter, daily average microbial concentration remained relatively constant for the rest of the measurement period in all four locations, with water inlets showing similar trends but slightly lower concentration as the tanks they supply. Interestingly, a time series decomposition of selected 3 days revealed microbial trends linked to light and dark cycles, feeding times, and specific physicochemical parameters (oxygen and pH) (Fig. 1B).

Conclusions
Our findings provide strong evidence of the potential of advanced microbial monitoring for understanding the underlying mechanisms and operational consequences driving microbial dynamics in a RAS. The implementation of this tool in routine aquaculture operations can massively enhance microbial process management, improve operational efficiency, and reduce the risk of microbial infections.

Introduction
Selenium (Se) is a key essential trace mineral directly or indirectly involved in the maintenance of the body redox balance and antioxidant defense. Being a structural component of several selenoproteins, including glutathione peroxidase (GPx), Se helps to regulate lipid and protein oxidation processes, thereby enhancing the meat quality and its nutritional value. Traditionally, inorganic sources such as sodium selenite have been used to supplement Se in fish diets. However, in fish, research has shown that organic forms of Se have higher bioavailability and effectiveness in regulating oxidative stress and tissue retention rates than inorganic forms. The optimal levels of Se required to maximize fish performance may vary depending on the source, and further exploration in aquatic species is needed. The primary objective of this study was to compare the performance, product quality, and stress resistance of gilthead seabream (Sparus aurata) fed different sources of selenium (inorganic and two different organic sources) while meeting EFSA maximum allowed supplementation of organic Se as an additive of 0.2 mg kg⁻¹.

Materials and Methods
Three diets (CTRL, AVSe and ORGSe) were formulated to be isoproteic (48% DM), isolipidic (17% DM) and to vary in their Se source. Diets were supplemented with 0.2 ppm Se as selenite (CTRL), Zn-L-SeMet (AVSe) or OH-Se-Met (ORGSe). All experimental diets were extruded and hand fed to apparent satiety, three times a day (9h, 12h, and 16h) for 137 days, to quadruplicate groups of gilthead seabream juveniles (50 g initial body weight). The fish were subjected to a 12-h light/12-h dark photoperiod regime and kept in 250L fiberglass tanks in a recirculating saltwater system (salinity 35‰, 22 ± 1 ºC). At the end of the growth trial, all fish were individually weighed and measured, and sampled for whole-body composition (n=4), total lipid and mineral composition of dorsal muscle (n=12), evaluation of hepatic oxidative stress (n=12), shelf-life evaluation over a period of 14 days (n=8), muscle evaluation of pH, WHC, color, texture and lipid peroxidation (LPO) at days 7 and 14 (n=8), and for sensory analysis (n=20). In order to determine fish metabolic and oxidative status, 12 additional fish per treatment were subjected to overcrowding (100 kg m⁻³) for 5 min and air exposure for 1 min. After 1 hour of recovery, plasma and liver samples were collected from these fish.

Figure 1. Se muscle content of gilthead seabream fed the experimental diets for 137 days.

(Continued on next page)
Results
All dietary treatments were equally accepted by fish regarding growth performance. However, nutrient utilization and fish whole-body composition were significantly affected by the diets. Fish fed AVSe had significantly higher whole body protein content compared to those fed the CTRL diet. These fish were the leanest but did not differ significantly from the CTRL. In terms of mineral utilization, increased Se gain and retention in fish fed AVSe and ORGSe diets, resulted in higher whole body Se content in these fish compared to the CTRL. It must be highlighted that only AVSe diet was able to significantly increase Se deposition in the muscle (Figure 1). The flesh quality parameters analyzed did not reveal major differences among the tested diets. The only exception was hardness, which was higher in fish fed ORGSe diet in comparison to CTRL. This difference could not be organoleptically confirmed by the sensory panel that gave a positive evaluation to all fish. Concerning stress tolerance, antioxidant enzymes’ activity was either reduced (GR, GPx) or induced (GST) by the applied stress, although antioxidant enzymatic mechanisms did not differ significantly among dietary treatments. The source of Se supplemented to the diets has affected non-enzymatic antioxidant mechanisms. In fish exposed to the acute stress challenge, oxidized glutathione (GSSG) and oxidative stress index (OSI) were significantly higher with AVSe than with CTRL diet. Despite the increased levels of GSSG and OSI, no signs of oxidative damage were observed in the liver, as evidenced by similar LPO levels amongst dietary treatments and stress conditions.

Discussion and Conclusion
All the tested diets were equally effective in promoting the growth of fish and ensuring high feed efficiency. There were no significant differences in the overall consumer acceptance between the different muscle samples from the various diets. Stress exposure was shown to decrease GR and GPX activities which led to an increased level of oxidized glutathione (GSSG), particularly fish fed AVSe. This suggests a quicker response by these fish in challenging situations, by direct reaction of GSH with $\text{H}_2\text{O}_2$. The cause behind the lack of activation of the antioxidant enzyme response could not be completely addressed in the present study and should be considered and evaluated in future studies. The present study suggests that supplementation with organic Se, particularly from AVSe leads to leaner gilthead seabream fillets fortified in Se. The use of organic sources of Se, in particular of Zn-L-SeMet, could also have a positive environmental impact by improving Se gain and retention and therefore reducing Se emissions into the water bodies.

Introduction

Fish health and welfare are great concerns to the aquaculture industry [1]. In this regard, the search for sustainable feed compounds with bioactive properties, which contribute to maintaining fish health, is highly relevant. Seaweeds are important natural resources for the food and feed industry worldwide and volumes of cultivated seaweeds are increasing over the years [2]. Seaweeds contain bioactive compounds such as laminarin and fucoidan which have shown antioxidant, immunostimulant and anti-bacterial properties in several mammalian and fish cells [3]. Few studies have evaluated effects of laminarin in salmon cells, and so far, no studies have been done to evaluate laminarin as a bioactive compound in diets for salmon with the aim to improve/enhance immune responses.

To assess whether laminarin has immune-modulating activity on salmon cells, and to reduce the use of experimental animals, a “stepwise approach” was used. Step 1 involved an in vitro screening of differentially processed laminarin on the viability and on immune responses of salmon cells. Step 2 will involve an in vivo salmon trial evaluating the effects of different dietary inclusion levels of laminarin on growth performance and immune-related parameters. Together, this work will contribute to setting a basis for the inclusion of laminarin in salmon feed, with an overall aim to support and improve fish health and welfare.

Methods

*Laminaria hyperborea* biomass was processed by water extraction (50 °C, 4 h). A precipitate consisting of enriched laminarin was formed after storage of extract at 4 °C for several days. After extensive washing in 4 °C ion-free water and in 50% ethanol, three fractions were made by acid hydrolysis for further testing: L1, hydrolyzed 1 h, L2, hydrolyzed 3 h, and L3, control fraction without hydrolysis. To evaluate their effects in Atlantic salmon-isolated leukocytes from spleen and head kidney (HK), viability and bioactivity assays were performed using the three laminarin fractions. For the viability assay, 100, 250 and 500 µg mL⁻¹ were used, and the cell viability was measured after 6, 24, 48 and 72 h. For the bioactivity assay, spleen and HK cells were incubated with laminarin fractions at 250 µg mL⁻¹ for 6 and 24 h, and a panel of immune-related biomarkers were measured by qPCR.

Results and discussion

None of the fractions exhibited a toxic effect on spleen and head kidney (HK) cells; L1 even showed a positive effect on cell viability in cells from both organs at 250 µg mL⁻¹. Regarding bioactive properties on salmon leukocytes, L1 elicited an up-regulation of *tnfa, il1b, inos, ifng, cath-2, tgfb* and *sod* in both organs, which is similar to a mammalian macrophage type 1 profile (M1), evidencing a short-term inflammatory response that decreased 24 h after the exposure to laminarin. Moreover, in HK, L3 induced an up-regulation of *tgfb*, while no significant gene expression modulation was observed with L2. On the contrary, in spleen L2 and L3 showed an up-regulation of *ifng, il1b, inos* and *tgfb*, suggesting a differential response between these two organs.

Conclusions

Results show that laminarin from *L. hyperborea* has immuno-modulating capacity on salmon leukocytes. Therefore, laminarin could be a promising functional component for aquafeeds, especially when exposed to a low processing level such as in fraction L1. Further work is being carried out to elucidate whether laminarin may exert further immune effects on other salmon cells. Based on the promising results obtained in Step 1, Step 2, which will focus on including laminarin in salmon diets, is now being planned, with a future view to its application in novel functional feeds for the salmon aquaculture industry.

References
The present study evaluated the use of \textit{Arthrospira platensis} cyanobacterium and fish by-products as alternative protein sources in \textit{Liza aurata} larvae of 31 dph (days post-hatching) with an initial weight and length of 1.92±0.12 mg and 10.47±1.01 mm, respectively. Five microdiets were tested: Control diet, with 100% protein from squid meal; Arth10, Arth20 and Arth40 diets with 10%, 20% and 40% \textit{A. platensis} as partial substitution of squid meal; and Circular diet, with 100% squid meal substitution by fishery by-product. This research revealed that \textit{Spirulina} can be included in the microdiet of mullets up to 40% maximum selected replacement, reporting high growth rates in size and weight, as well as high survival rates and resistance to stress. The inclusion of aquafeed by-products, despite reflecting significantly lower growth, it presented similar survival rates and proximal composition in \textit{L. aurata} larvae. The skeletal anomalies analysis showed that mullet larvae do not present high percentages of severe deformities, except for the presence of stones in the urinary ducts. These results open a path towards sustainability for \textit{L. aurata} production and the use of fisheries by-product resources, giving rise to a circular economy necessary for the aquaculture sector.

**Introduction**

The continuous expansion of the aquaculture sector as well as the high demand of the population and the decreasing production of fishmeal and fish oils are speeding up the search processes for new raw materials and/or alternative protein and lipid ingredients to supply, effectively, proper feeding of cultured aquatic organisms. For this, the sector must focus on growing to offer products both in greater quantity and quality following the principle of sustainability of the environment and natural resources (FAO, 2022). Numerous scientific studies are directing their investigations towards the search for the highest percentage of fishmeal replacement by different routes and in a multitude of potential species for aquaculture industry (Yarnold \textit{et al.}, 2019). However, research on mugilids, candidate species for diversification, is scarce.

For this reason and taking into account that the exorbitant increase in prices will affect the composition of diets in the future and, therefore, the cultivation of species with high requirements, the species of \textit{Liza aurata} has been selected. Omnivorous organism with a low trophic level that presents a high potential in terms of the use of alternative ingredients and by-products of low added value, as well as the potential that its cultivation presents in different environments and even extreme conditions, and the opportunity for introduction into the regional aquaculture production in a differentiated way from the rest (Crosetti and Blaber, 2016; Rosas \textit{et al.}, 2019a).

Therefore, the main objective of the work is to evaluate the effect and potential use of these ingredients as alternative protein sources to squid meals used in microdiets for weaning of \textit{Liza aurata} larvae.

**Material and methods**

The trial was carried out in the Parque Científico Tecnológico de Taliarte (PCTM) of the ECOAQUA University Institute of the University of Las Palmas de Gran Canaria.

\textit{Liza aurata} larvae of 31 dpe (N=400) were randomly seeded in 15 200-L cylindrical tanks (5 treatments in triplicate). A co-feeding protocol was carried out with metanauplii of \textit{Artemia} sp. and 5 different experimental microdiets according to the percentage of inclusion and replacement of squid meal by the cyanobacteria \textit{Arthrospira platensis} in 10% (Arth10 Diet), 20% (Arth20 Diet) and 40% (Arth40 Diet) and by marine origin by-products not intended for human consumption (Sandach III) in 100% (Circular Diet). To evaluate the effect of the inclusion of the alternative ingredients, the larvae

(Continued on next page)
were measured (total length; mm) and weighed (wet weight; mg) to estimate parameters related to growth at 31, 40 and 52 dpe. Likewise, the proximal composition and fatty acids of the auxiliary cultures used during larval rearing, enrichers, experimental microdiets and larvae were analyzed following standardized chemical procedures (AOAC, 2005). In addition, larval quality was evaluated by performing a test of activity and resistance to an increase in salinity (38 to 70 ppt) and an analysis of identification and quantification of severe skeletal anomalies along the vertebral axis described by Boglione et al., (2014).

Results and discusión

The larvae fed with Arth10, Arth20 and Arth40 spirulina-based microdiets showed growth performance similar to the Control diet and significantly higher than the Circular diet. However, all treatments present high survival rates, greater than 90%, and similar values in the proximal composition as those found by Rosas et al. (2019a) in Mugil Liza. Larvae fed high levels of squid meal substitution exhibited a similar stress response as those fed the Control diet. On the other hand, the increasing inclusion of alternative ingredients to squid meal reflects a tendency to decrease the percentage of severe skeletal anomalies and, therefore, to increase the total percentage of high-quality larvae.

These results demonstrate the robustness of the larvae and the feasibility of producing juveniles with more sustainable diets, in addition to contributing to the promotion and growth of complementary industries, as well as the future development of the sector based on the sustainability of the environment and resources.

Introduction
The Sustainable Development Goals (SDGs) are seventeen interlinked objectives designed to serve as a guide for peace and prosperity for people and the planet, now and into the future (UN, 2015). Sustainability Indicators are variables defined to reflect the main features of sustainability in a simplified way (Valenti et al., 2018).

This work aims to achieve legal integration between the Sustainable Development Goals (SDGs) and available aquaculture sustainability indicators based on the legal principles of the Brazilian Constitution.

Materials and methods
An analysis of the Brazilian Federal Constitution was carried out from the perspective of constitutional principles related to environmental law to establish the correlation between these principles, the SDGs, and sustainability indicators of aquaculture.

It was defined 63 desirable states for sustainable aquaculture (DS) divided into 4 dimensions of sustainability. The SDGs were then associated with each of the desirable state characteristics. A hundred and eight six sustainability indicators were selected from the scientific literature and technical documents. They were associated with DS and SDGs.

The indicators must consider one or more of the SDGs to harmonize with the idea of sustainability in its most diverse aspects. The use of quantitative indicators is essential so that sustainability can be measured more accurately and that the intermediate stages of the process towards more sustainable systems can be evaluated and, consequently, the contribution of aquaculture to achieving the SDGs can be evaluated.

Results and Discussion
The analyses showed that aquaculture sustainability indicators make it possible to meet one or more of the SDGs of the United Nations 2030 Agenda (UN, 2015). These manage to relate to sustainability in its most diverse areas, as we can see in the figure below.

The use of quantitative indicators is fundamental so that sustainability can be measured more accurately and that the intermediate stages of the process towards more sustainable systems can be evaluated and, consequently, the contribution of aquaculture to achieving the SDGs. Even indicators based on qualitative variables should be transformed into a semi-quantitative scale to assess the degree of sustainability and the evolution after interventions by the public and private sector actions. (Valenti et al. 2018). This would allow public policies to be better evaluated and redirected to meet their purposes.

In addition to allowing the evaluation of the contributions of aquaculture to the achievement of the SDG targets, aquaculture sustainability indicators can serve as a tool to assist in the analysis of other sustainability measures such as the Corporate Sustainability Index or the ESG System – Environment, Social, and Governance.

Conclusions
This study showed that the Brazilian Federal constitution supports the four dimensions of sustainability; therefore, the concepts can be applied to national aquaculture and other economic activities.

The study also showed that the Desired States (DS) to achieve sustainable aquaculture are closely linked to the Sustainable Development Goals (SDGs). This means that achieving sustainability also contributes to achieving the SDGs.

(Continued on next page)
The sustainability indicators in aquaculture selected in this study can represent the desirable states, measuring their variation and evolution towards sustainable systems in the environmental, social, and economic dimensions. Therefore, they can also be used to assess the evolution of aquaculture as a driver of sustainable development for various purposes contained in the SDGs.

FEED PALATABILITY ENHANCER IMPROVES FEED INTAKE IN EUROPEAN SEABASS

Dicentrarchus labrax, ESPECIALLY UNDER STRESS

S. Morais1*, E. Leal2, J.M. Cerdá-Reverter2

1 Lucta S.A., Innovation Division, Animal Science Unit, UAB Research Park, Bellaterra, Spain
2 CSIC-IATS, Department of Fish Physiology and Biotechnology, Castellón, Spain
E-mail: sofia.morais@lucta.com

Introduction
Palatability of feed, associated to its chemical and sensory properties, determines its acceptability by fish and total feed intake. Some fishes are more demanding in this respect than others, but common stressors in captivity and farming conditions are known to severely accentuate feed intake problems in most species, especially when diet palatability is sub-optimal. A decrease in feed intake is normally the first sign of stress which, when repeated often or prolonged, leads to performance loss and disease susceptibility. Hence, maintaining the fishes’ motivation to eat during stressful events or production phases is key. A potential strategy to achieve this is to supplement feeds with chemosensory active substances that are quickly sensed by the fish and enhance attractive smell and taste cues of the feed, triggering fish appetite. In order to test a new palatability enhancer (PE) developed for European seabass, Dicentrarchus labrax, a trial was performed under both undisturbed and disturbed (induced stress) rearing conditions.

Materials and methods
The trial was performed in 16 indoor 250L tanks, equipped with a self-feeding system (activated by string sensors pulled by the fish) connected to a computer that registers and integrates the number of demands continuously (24/7). Feed demands are converted into grams, as feeders can be programed to deliver a set amount of feed, which is further corrected by weighing the amount added into each feeder and subtracting the feed remaining. Seabass juveniles were acclimated to the tanks (9 fish/tank, 8 tanks/treatment) and fed either a control feed (CTR: 42% CP, 18% CF; containing 12.5% fish meal, 4.8% fish oil and all remaining ingredients of plant origin) or the same basal formulation further supplemented (by vacuum coating with oil) with 0.1% of the PE. Fish average initial body weight (BW) was 146 ± 3.1 g (mean ± SEM) in the CTR and 154 ± 3.7 g in the PE group. The trial was divided in 2 phases: an undisturbed period lasting 35 days and a stressed period of 14 days, during which tanks were cleaned every day during the first 4 days and in alternate days afterwards, generating mechanical (brushing) and crowding (during 2 mins) stress. The trial was conducted from November to December 2022 under natural conditions of decreasing water temperature and photoperiod. Average water temperature during the undisturbed and stressed periods was 21.2°C and 16.4°C, respectively. The effect of treatment and stress were analyzed with a repeated measures ANOVA by the Proc MIXED (SAS), with tank as the experimental unit repeated through time (days), and differences between groups were assessed using the Tukey-Kramer test.

Results and discussion
During the 35 days undisturbed period only a non-significant trend (P=0.10) was observed, with the PE-fed fish showing 18% higher average daily feed intake (Fig. 1).

When stress was induced, a substantial decrease in feed intake was immediately observed in both treatments. Over the 14 days of the stress period, voluntary feed intake of the PE group gradually increased, although it never reached the level measured in the equivalent preceding undisturbed period (Fig. 2). It should be noted, however, that there was also a decrease in water temperature during this time, which might have contributed to the results. On the other hand, feed intake remained low during the whole stressed period in the CTR treatment. Interestingly, feed-demand peaks occurred in the CTR group in two of the days when no stress was imposed (it should be noted that on day 10 practically all feeding demands were recorded before 12h30, which is when cleaning of the tanks started), while feeding demands were more regular in the PE treatment.

Comparison of the average feed intake during an equivalent period of time (14 days) in the undisturbed and stressed phases (Fig. 3) revealed that stress induced a significant (P<0.05) decrease in both treatments, but the reduction was substantially lower in the PE than in the CTR treatment (43% versus 60%). Furthermore, feed intake in PE-fed fish was significantly (P<0.05) or nearly significant (P=0.057) higher than in the CTR in both the undisturbed and stressed periods, respectively.

In conclusion, present results suggest that the tested PE has the potential to increase feed intake in seabass fed diets containing low-moderate levels of marine ingredients (12.5% fish meal and 4.8% fish oil in this trial). Furthermore, and more significantly, results clearly indicate that the PE is effective in ameliorating the reduction in feed intake caused by stress.

(Continued on next page)
Fig. 1. Average voluntary daily feed intake (%BW/day) during the whole (35 days duration) undisturbed period.

Fig. 2. Average voluntary daily feed intake (%BW/day) during the stressed period. Red and grey bars indicate the average feed intake in the 14 days preceding the stress in the PE and CTR treatments, respectively. Black bars at the bottom mark the days in which tank cleaning was performed.

Fig. 3. Average voluntary feed intake percent reduction comparing the 14 days preceding (undisturbed) and the 14 days of the stressed period, in the CTR (grey) and PE (red) treatments. Columns containing different letters are significantly different (P<0.05), and a near significant difference between the CTR and PE treatments in the stressed period is indicated by an arrow.
NUTRITIONAL PROGRAMMING USING FUCOIDAN FROM SUGAR KELP AS A FEED ADDITIVE TO IMPROVE TRAINED IMMUNITY IN ATLANTIC SALMON AGAINST Tenacibaculum maritimum

Department of Animal and Aquacultural Sciences
Faculty of Biosciences
Norwegian University of Life Sciences (NMBU)
P. O. Box NO-1433, Aas (Norway)
E-mail: byron.maximiliano.morales.lange@nmbu.no

Introduction
Bacterial skin pathogens (e.g., Moritella viscota and Tenacibaculum spp) are affecting fish health and welfare in farmed salmon during seawater stage (Sommerset et al., 2022). Both bacteria can be the primary cause of an infection, or establish a “consortium of pathogens” together with others such as Aliivibrio wodanis (Karlsen et al., 2014), which increases fish mortality. To control this situation, fish-specific pathogen vaccines are used in salmon farming. However, the effectiveness of some of these immunological strategies still do not meet industry expectations, especially those associated with long-term protection (Figueroa et al., 2022). In addition, there is a lack of vaccines against emerging bacteria. Interestingly, Trained Immunity-based Vaccines (TlBVs) have been reported in higher vertebrates during recent years (Sánchez-Ramón et al., 2018). This approach focuses on the innate response and how the vaccines can provide immunological protection against challenges that are not related to the vaccine antigens (Sánchez-Ramón et al., 2018). Considering this, TlBVs could be relevant to explore in fish, since there are currently no specific vaccines available against Tenacibaculum spp.

In the Resilient Salmon project (RCN 294821), in coordination with Foods of Norway, a Centre for Research-based Innovation at the Norwegian University of Life Sciences (NMBU), we are exploring nutritional programming with novel aquafeeds containing fucoidan isolated from sugar kelp (Saccharina latissima) to modulate trained immunity-related responses against Tenacibaculum maritimum in vaccinated Atlantic salmon (Salmo salar).

Materials and methods
Atlantic salmon pre-smolts were maintained at the NMBU Center for Sustainable Aquaculture. Before the feeding trial, fish were vaccinated with ALPHA JECT micro 6 vaccine (PHARMAQ) which contained antigens from Aeromonas salmonicida, Listonella anguillarum O1 and O2a, Vibrio salmonicida, M. viscosa and infectious pancreatic necrosis virus. Later, fish were randomly distributed into six 300 L tanks (45 fish per tank) supplied with recirculated fresh water. Each tank was assigned one of three diets (CD: commercial-like diet; FD: CD + 0.2% fucoidan extract from sugar kelp; MG: CD + 0.2% MacroGard®) for four weeks.

After this period, 35 fish per tank were transferred to seawater at the Norwegian Institute for Water Research (Solbergstrand, Norway) and fed the CD for 4 weeks before being intraperitoneally injected with inactivated T. maritimum. Samples (e.g., distal intestine: DI and head kidney: HK) were taken from six fish per tank at different time points: at the end of freshwater stage, after four weeks in seawater, one day post-stimulation and seven days post-stimulation. Total RNA was extracted from the tissue samples, and qPCR was performed to determine the gene expression of specific immune-related biomarkers.

Results and Discussion
In the different dietary groups, an immunological profile that could be associated with trained immunity (up-regulation of type-1 immune biomarkers such as il-1b, il-8 and tnf-a at the end of the first stimulus, a decrease in their expression during rest time, and an enhanced response after the secondary stimulus) was detected in HK and DI of vaccinated Atlantic salmon. In higher vertebrates, there are reports showing similar results (Sánchez-Ramón et al., 2018), which have demonstrated the ability of vaccines to modulate the innate immunity against bacterial challenges that are not related to the vaccine antigens. This is interesting to explore in fish, since that there are no specific vaccines against T. maritimum, and because this bacterium is causing a higher number of natural outbreaks in salmon farms in recent years (Sommerset et al., 2022). Furthermore, the inclusion of fucoidan in novel aquafeeds as a bioactive additive showed up-regulation (one day post-stimulation with T. maritimum) of genes related to effector molecules such as antimicrobial peptides (e.g., hepcidin), which are crucial in the innate humoral response. Antimicrobial peptides are part of the first line of defence against a wide spectrum of pathogens and may contribute to a decrease in the use of antibiotics (Valero et al., 2020).

(Continued on next page)
Conclusion
Vaccines could induce the modulation of biomarkers associated with trained immunity against *T. maritimum* in HK and DI of Atlantic salmon. Moreover, nutritional programming using fucoidan may enhance the innate humoral response (e.g., antimicrobial peptides) related to TIbVs in immunological organs. This data supports the proposal to use fucoidan as a feed additive in novel aquafeeds for Atlantic salmon to improve fish health and welfare and to strengthen the sustainability of the aquaculture industry.

Introduction

The climate change has given the world an alarm to start making improvements in the way we exploit natural resources, specifically for animal and human diets. The actual problem found in aquaculture is directly associated with this natural resources shortage and its high demand, making substitutions in the bases of fish diets, from fish meals to vegetable ones. Although these changes show compatibility in carnivorous species, it may produce physiological alterations which can be modulated by nutraceutical compounds provided by macro and microalgae (Perera et al., 2020). In turn, the increase in global temperature as well as high stocking densities have triggered problems associated with oxygen demand, decreasing its concentration and availability in the environment. Therefore, this may be associated with internal changes leading to physiological stress (Martos-Sitcha et al., 2020). In addition, a strong relationship has been seen between the stressful effect and the intestinal microbiota, which can be attenuated through its maintenance and strengthening, where the addition of symbiotic nutraceuticals provides beneficial properties to the individual (Egerton et al., 2018). Moreover, it has shown the importance of gut enzymes and bacteria relationship, related to an appropriate digestibility along with better protein and energetic utilisation, in relation to the ammonia, nitrates and nitrites released to the aquatic environment (Hlordzi et al., 2020).

Materials and Methods

The experiment was carried out in Servicios Centrales de Investigación en Cultivos Marinos (SCI-CM, Universidad de Cádiz, Spain). A total of 180 gilthead seabream (Sparus aurata) juveniles (54.58±0.05 g average body mass) were distributed into 9 tanks (300 L, n=20 fish per tank), where three experimental groups were constituted to be fed with: i) a control diet (CTRL), or the same formulation supplemented with a ii) 1% and iii) 3.5% with the nutraceutical compound Prebiodo II produced by Biotechnology Biopolym S.A. (Granada, Spain). Feeding was performed ad libitum by twice daily meals for 91 days. Feed intake was controlled weekly and biometric samplings were performed every 4 weeks, allowing to obtain feed efficiency (FE) and weight evolution for each group. After the feeding period, a hypoxia challenge was performed on the 3 experimental groups, being subjected to moderate hypoxia (35-40% O₂ saturation) during 24 hours. Biological samples allowed analysis of plasma, muscle and hepatic metabolites (glucose, glycogen lactate, triglycerides, cholesterol and proteins) and plasma cortisol. In addition, water samples were taken for water quality analysis (ammonium and nitrite concentration).

Results and Discussion

In general, an effect on the parameters can be seen in relation to the Prebiodo II supplementation dose. Plasma cortisol levels showed a decrease in the supplemented groups both during normoxic and hypoxic conditions, while a lower lactate level was observed in these groups during a mid-hypoxia process, promoting a clear shift between aerobic and anaerobic metabolism, especially in those fish fed with supplemented diets (Fig. 1A, 1B). An inverse pattern was observed in hepatic glucose and glycogen values, responding to glucose mobilisation to maintain homeostasis. The good circulation, transport and energy use could be corroborated with the other parameters taken, showing an improvement in performance and metabolic status as a consequence of better nutritional absorption and water quality (Table 1, Fig. 1C).

Introduction
The use of plant proteins (PP) in fish feeds has considerably increased, at the expense of fishmeal (FM) inclusion, over the last decades to better cope with aquaculture sustainability. Nonetheless, after decades of research, 100% plant-based diets (PBD) still disturb fish physiology owing to multifactorial reasons among which an imbalance of PP amino acids (AA) profiles with some essential AA (EAA), mainly Methionine (Met), Lysine (Lys) and less frequently Arginine (Arg), being underrepresented in PP compared to FM. To overcome this issue, those EAA are usually added in free form to the PBD to fulfil requirements of fish determined previously using FM-based diets as standards. Although supplementation in these EAA improves fish growth, it does not rescue the full growing potential of fish fed FM-based diets. This could be explained, at least partially, by the fact that free AA are differentially absorbed compared to protein-bound AA, leading to differences in their bioavailabilities1. Interestingly, we noticed in two independent studies that some intestinal AA transporters (AAT), crucial for Arg, Lys and potentially Met absorption, and described in mammals to work by exchanging Arg and Lys with neutral AA2, were overexpressed in fish fed PBD3,4. Thus, we wondered if the difference in bioavailabilities of protein-bound neutral AA versus free Arg, Lys and Met added to PBD could compromise their absorption, leading to dysregulations of these AAT and subsequent negative outcomes on fish physiology and growth. Thus, our study aimed to challenge this hypothesis by i) identifying and characterising the whole sub-family of cationic AAT (in charge of Arg and Lys uptake) in response to cationic AA starvation, ii) studying the consequences of cationic AA starvation on two major AA-sensing dependent pathways called GCN2 (General Control Nonderepressible 2) and mTOR (mechanistic Target Of Rapamycin) pathways and iii) proposing, through fundamental knowledge gathered using rainbow trout (RT) cell lines as models to study AA absorption, a new formulation strategy that promotes the absorption of cationic AA supplemented in their free forms to 100% PBD in vivo to improve the zootechnical parameters of fish fed such PBD.

Materials and methods
Cell culture experiments were performed at 18°C using RTH-149 and RTgutGC cell lines. Cells lines were subjected to various nutritional challenge (e.g. AA starvation or specific cationic amino acid (CAA) starvations…) prior to determine cellular absorption of AA in cell lines, using UPLC-FL as well as the activation of AA-dependent signalling pathways, such as GCN2 and mTOR, involved in growth and stress through RT-qPCR and western blot analyses. For the presented in vivo results, RT were fed at libitum for 21 weeks with a full PBD supplemented with free Arg and Lys (RK) or the same PBD also supplemented with free Glycine (RKG). Plasma were sampled from the caudal vein 5 hours after the last meal (during the post-prandial amino academia peak) and AA levels were analysed by UPLC-FL to assess the effect of Gly supplementation on absorption of Arg and Lys.

Figure. Free glycine supplementation to plant-based diet improves free arginine and lysine absorption

(Continued on next page)
Results
Using in silico analysis we identified 42 orthologous genes of the 16 human cationic amino acid transporters (CAAT) in the rainbow trout (RT) genome. At least 28 of them are expressed in trout tissues. Both RTH-149 and RTgutGC cell lines express the same 16 CAAT which are also expressed in their tissues of origin, liver and intestine respectively. Of the 16 CAAT expressed in the cell lines, 6 of them were systematically shown to be-upregulated upon nutritional challenges in AA- and CAA-dependent manners, very likely through the activation of the GCN2 pathway. Interestingly, one of them, called y’LAT2 which is an important CAA exchanger (notably in the intestine) is one of the most upregulated by Arg and Lys starvation in cells while it was also shown to be upregulated in previous in vivo studies where fish were fed a 100% PBD supplemented with free CAA. Therefore we supposed that the y’LAT2 upregulation observed in fish fed PBD could be due to an activation of the GCN2 pathway caused by a compromised ability of fish to absorb the supplemented free CAAs and therefore leading to decrease fish growth performances. Knowing from our in vitro assays that part of the cellular absorption of CAAs relies on the presence of non-essential neutral AA, among which glycine certainly exchanged by y’LAT2, we therefore build a working hypothesis according which the known difference of bioavailability of free AA versus protein-bound AA, could considerably dampens the absorption of supplemented CAAs in PBD. Consequently, we challenged this hypothesis by comparing zootechnical parameters of fish fed a PBD supplemented with Arg and Lys (RK) to those fed with the same diet also supplemented with Gly (RKG). Following a 21 weeks feed trial, we first could observed that such Gly supplementation improves significantly the feeding efficiency (as already observed in broilers). Very strikingly, we could also noticed that such Gly supplementation allows a better absorption of CAA as demonstrated by the significant increase in post-prandial AA levels of Arg and Lys (see figure) while, with the exception of Gly and Serine, no other AA levels was observed to be significantly increased. These results demonstrate that free Gly supplementation increases free Arg and Lys absorption that in turns could improve feed efficiency.

Conclusion
In this study, we first identified the CAAT expressed in RT and showed with the use of RT cell lines that some of them are upregulated through activation of the GCN2 pathway during Arg and Lys starvation. One of them, y’LAT2, is also upregulated in fish fed with PBD supplemented with free Arg and Lys. Because y’LAT2 is 1) a strict exchanger of CAA against neutral AA and 2) an essential intestinal CAA transporter in mammals, we supposed that bioavailability difference between protein-bound neutral AA and free CAA affect absorption of the latter. Thus, we demonstrated with combined in vitro and in vivo approaches, that most of this working hypothesis was correct by showing that free CAA absorption can be improved by supplementing PBD with free neutral AA like Gly. Altogether, this study shed a new light on the importance considering AAT functions and activities in the biology of fish of agronomic interest and open new exciting avenues to develop new feed formulation that better meet the sustainable developmental goals of the aquaculture industry.

Introduction

Swimming capacity plays a crucial role in the fitness of fish, crucial for their survival and reproductive success. Origin and early life experiences may have important consequences for swimming capacity later in life (Zambonino-Infante et al., 2017; Vandeputte et al., 2019). In this study, we investigated the influence of origin and early life exercise training on the swimming economy and locomotory behaviour during later life in the European seabass (*Dicentrarchus labrax*).

Materials and methods

Experimental fish, originating from the Atlantic, Eastern Mediterranean, and Western Mediterranean, had been subjected to an early life exercise training consisting of swimming against an increased flow of 0.3 m.s⁻¹ from 92 to 162 dph at the facilities of Ifremer (Palavas-les-Flots, France) by M-L Bégout and colleagues. The controls had been reared at regular flow conditions of 0 - 0.1 m.s⁻¹ during this period. After training and PIT tagging, fish were reared in common garden until an average weight of about 20 g was reached. Fish were then transported to Wageningen University and Research experimental facilities (CARUS, Wageningen, The Netherlands). The fish (N= 36, with 3 origins x 2 training conditions is N= 6 fish per group) were grown until approximately 60 g in weight, when the swimming experiments were executed using a 30-L Loligo swim tunnel (Loligo systems, Viborg, Denmark) (Fig.1).

The flow in the swim-tunnel was set at five different speeds during the experiment, starting at the lowest speed of 0.1 m.s⁻¹ and then increasing stepwise with 0.1 m.s⁻¹ per hour up to a maximum speed of 0.5 m.s⁻¹. Oxygen consumption and locomotory behaviour were assessed at each interval using a galvanic oxygen probe and a Basler 2040-90um NIR USB3 high-speed camera, respectively (see also Arechavala-Lopez et al., 2021). From the experiment we obtained the following data thus far: oxygen consumption rates at each of the swimming speeds (MO₂ in mg.kg⁻¹.h⁻¹), optimal swimming speed (Uopt in m.s⁻¹), Cost of Transport at the optimal speed (COT in mg.kg⁻¹.km⁻¹) and critical swimming speed (Ucrit in m.s⁻¹). Locomotory behaviour parameters tail beat amplitude and frequency, and head width amplitude and frequency, are still being analysed.

Results and discussion

Our results provide valuable insights into the swimming economy of juvenile seabass. Group averages of MO₂ ranged from 206 to 231 mg.kg⁻¹.h⁻¹ when swimming at 0.1 m.s⁻¹; 174 to 218 mg.kg⁻¹.h⁻¹ at 0.2 m.s⁻¹; 190 to 232 mg.kg⁻¹.h⁻¹ at 0.3 m.s⁻¹ and 260 to 459 mg.kg⁻¹.h⁻¹ at 0.4 m.s⁻¹. Fish then started to fatigue at Ucrit values of 0.38 up to 0.43 m.s⁻¹ or 2.01 up to 2.48 BL.s⁻¹. Average Ucrit was calculated at 53-67% of Uopt as 0.30-0.33 m.s⁻¹ or 1.57-1.73 BL.s⁻¹. At Uopt, COT values were ~200 mg.kg⁻¹.km⁻¹. Uopt values were significantly lower than the 0.69 m.s⁻¹ reported for similar sized seabass swimming in Blazka-type swim-tunnels (Graziano et al., 2018) which may well be due to the longer swimming compartment in those tunnels allowing for burst-and-glide swimming behaviour. COT values at Uopt were similar.

Surprisingly, our results revealed no significant differences between fish from the three different origins, nor between trained fish and their controls. These findings suggest that origin and early life training do not have any relation with the swimming performance during later life. As we did observe that Atlantic fish were generally more active than fish from the Mediterranean sites, we expect to find differences in locomotory parameters between fish from different origin.

(Continued on next page)
Understanding the swimming economy of seabass has important implications for both scientific research and practical applications in aquaculture (McKenzie et al., 2020). By gaining a deeper understanding of the swimming economy, we can determine climate change impacts and optimize breeding programs, and develop more effective strategies for the cultivation and management of this economically significant fish species.

Introduction

To ensure sustainable production and maximize the efficiency of aquaculture, it is essential to implement strategies that maximize growth while minimizing the invested resources and the environmental impacts.

Our work aims to report one example of how bioenergetic modelling, and specifically the DEB theory, can link fish physiology with profits/impacts of the industry. Dynamic Energy Budget (DEB) theory (Kooijman, 2010) supports a fully mechanistic bioenergetic model that enables to predict individual growth under different scenarios of food and temperature. Interestingly for our matter, DEB theory assesses the energy and mass balance of an individual fish (or group of fish) at any moment of the life span, explicitly including, for example, the food and oxygen consumed and the waste produced at any time. All this information can be upscaled from the individual fish level to the cage or the farm level (Chary et al., 2022). Here, as a proof of concept, we aim to explore through computer simulation experiments the landscape of yield that emerges from several fish displaying different but realistic combinations of values for three key DEB parameters that have direct relation with the food assimilation and the energy mobilization processes: (1) digestion efficiency (kappa_X), (2) maximum assimilation rate (p_Am) and (3) energy conductance (v). Then, to enhance comprehension of the implications of different values of DEB parameters, we explored the emerging correlations between the three DEB parameters and 4 response variables: (1) final wet weight, (2) total food ingested, and two widely used efficiency indicators in aquaculture: (3) Specific Feeding Rate (SFR) and (4) Specific Growth Rate (SGR).

Methods

Sparus aurata (gilt-head seabream), a fish commonly cultivated in the Mediterranean Sea, was used as model species. Feeding (gr of ingested food) and growth (gr, gain in wet weight) were estimated using a DEB model for 200 simulated fish that only differ in the three DEB parameters above. The specific values of these parameters for a given fish were randomly sampled form a multinormal distribution. The means, variance and covariance of p_Am and v came from the actual values estimated for 69 gilt-head seabream male individuals (Moro-Martínez et al., 2023) reared at an aquaculture company (Aquicultura Balear, ABSA, S.A.U.). For kappa_X, we did not have yet empirical data because the challenge of quantifying the food ingested by each fish. In the meantime, the parameters for the distribution of kappa_X was approached as follows: the mean was taken from the add-my-pet database (Add-my-Pet, 2023) and a coefficient of variation of 12.5% was assumed for between-individual variability. We assume also no correlation between neither pAm nor v with kappa_X. Feeding and wet weight of each simulated fish was then used for estimating SFR and SGR.

Results and discussion

The simulation experiment supports two main findings. First, high interindividual variability in the feeding and growth rates was reported, which suggest that distinct individual feeding and growth strategies can coexist in aquaculture systems.

Second, concerning the emerging correlations between the three DEB parameters and 4 response variables, the main patterns found were: (1) Final wet weight is strongly, positively correlated with pAm and weakly, negatively correlated with v; (2) Total food consumed is weakly, positively correlated with pAm, and weakly, negatively correlated with kappa_X; (3) SFR is strongly, negatively correlated with kappa_X; and (4) SGR is weakly, positively correlated with pAm, and weakly, negatively correlated with v. The mechanistic explanations for all these emerging patterns will be discussed in detail.

(Continued on next page)
Overall, this preliminary simulation is aimed to be interpreted as a proof-of-concept, to demonstrate the potential of understanding how bioenergetic processes at the fish level scale up to aquaculture indicators. Finally, we aim to motivate discussion on the utility of DEB theory for bridging bioenergetics at the individual level to yield indicators at the aquaculture level, and eventually to be used as a tool to optimize resources in aquaculture and, consequently, make it more sustainable.

DANCE WITH SAMBA: AN INNOVATIVE APPROACH TO STUDY FISH GUT MICROBIOME USING BAYESIAN NETWORKS

F. Moroni*, F. Naya-Català, B. Soriano¹², A. I. Hafez², C. Llorens², J. Pérez-Sánchez

¹Institute of Aquaculture Torre de la Sal (IATS), Consejo Superior de Investigaciones Científicas (CSIC) Castellón, Spain. ²Biotechvana, Parc Científic Universitat de València, Paterna, Spain

Introduction

Gut microbiota creates a profound connection with the host, taking part in numerous essential aspects of its physiology (Naya-Català et al., 2022). Moreover, microbial populations build a mazy network of interconnections between species, characterized by cooperation or competition that can affect the whole microbiome (Yajima et al., 2023). It is well documented that several factors can affect the microbial composition, but the interpretation of the probabilistic factors that underlie these interactions are still unrevealed. Indeed, the current approaches in fish microbiota research are mainly focused on the comparison of bacterial abundances between experimental groups or meta-analyses matching different studies. In this context, to make a step forward in the understanding of the fish microbiome dynamics, we implemented SAMBA (Structure-Learning of Aquaculture Microbiomes using a Bayesian Approach), an open-source, web-based platform with a graphical user interface implemented with Shiny (Soriano et al., 2022). This tool uses probabilistic Bayesian Networks (BN) to evaluate the conditional dependencies within a set of experimental variables and taxa. The aim of this study is to show how the implementation of SAMBA works as a model of causal predictions in the gut microbiota of aquaculture species.

Materials and methods

Experimental data for training SAMBA were taken from Spanish national (ThinkInAzul) and H2020 EU projects (AquaIMPACT, AQUAEXCEL²⁰₂⁰, AQUAEXCEL3.0, and EATFISH). The experiments were carried out on gilthead sea bream (Sparus aurata) under specific experimental conditions such as changes in genetic background, diet composition, or feed additives supplementation, among others. To define how and which biotic and abiotic factors modulate the fish microbiota, and which causal relationships exist within microbial taxa, we set different goals in line with the potential of SAMBA. In a first approach, we combined the taxa abundances within one specific experiment with BN, identifying the positive and negative relationships among the most representative bacteria. In a second approach, we filtered, from the data of already published experiments, those taxa present in both trials that took part of the core microbiota in at least one experiment. The counts of the remaining taxa were introduced in SAMBA, and we built two separated models, aiming to detect common microbes’ causal relationships occurring in multiple experiences.

Figure 1. a Graphical representation of the relationships of the most abundant OTUs within the experiments (blue arrows= directional relationships from the OTUs, orange arrows= directional relationships to the OTUs, red diamonds=Experimental variables). b Graphical representation of the common relationships, shared between two different experiments (blue arrows=shared relationships, red diamonds=Experimental variables, dots=OTUs).

(Continued on next page)
Results and discussion
Both the intra-experiment and the inter-experiment approaches allowed us to obtain the hierarchical disposition of the experimental variables and the taxa within the data populations (Figure 1). Therefore, SAMBA tool can constitute a real step forward microbiomic studies, as it can take advantages from the taxa abundances to deeper understand the role and influence of each OTUs in the gut of livestock species. The directed acyclic graph (DAG) created in the intra-experiment approach (Figure 1a) disclosed the taxa primarily influenced by the experimental variables and the effect of these on other members of the microbial population. Interestingly, our results showed that the taxa affecting other taxa (i.e., parent taxa) are not always the most abundant, which are the ones usually reported in current 16S analyses. Regarding the inter-experiment approach, we obtained a total of 13 relationships present in both models (Figure 1b). From these results, it is feasible to draw a common structure, identifying which interconnections, shared by the two different experiments, and belonging to the core microbiota taxa, remain unaltered or are strictly linked with the variables that characterize the experiments. In addition, with the SAMBA implementation of the pipeline to infer metagenomes using PICRUSt2 (available with Metacyc and KEGG protocols), it is also possible to correlate the functional metabolic profiles of those taxa to better define their role in the specific relationships and in the total framework of the core microbiota (data not shown).

Concluding remarks
The implementation of SAMBA arises as an innovative approach, not yet exploited for aquaculture data (Ruiz-Pérez et al., 2021), to offer researchers relevant information beyond taxa abundances comparison when working with 16S metagenomics datasets. Although the tool is still being trained, when a sufficient amount of shared variables (i.e. mutual taxa, core microbiota) will be available, SAMBA will predict matching information of several experiments, discerning common associations between them that can be related with the experimental variables. In fact, future experimental designs are expected to be adapted to feed SAMBA. Moreover, as this tool is a constantly evolving project, SAMBA will soon include the integration of machine learning algorithms and new interfaces for different omics data, to be able to process complex and integrated results in an easy-to-use package.

HISTOPATHOLOGICAL CHANGES IN THE COMPACT MYOCARDIUM OF ATLANTIC SALMON (Salmo salar) DYING AFTER THERMAL DELOUSING TREATMENT

Introduction
The critical phase with regards to mortality of farmed Atlantic salmon during the sea stage used to be the shift from freshwater to seawater. However, in recent years substantial mortality is now also observed later in the sea stage. This late-stage loss is often connected to stressful events, such as delousing where mechanical and thermal salmon lice treatment appear to result in particularly high mortalities. While the reason for this increase in stress-related mortality is largely unknown, accumulating evidence points towards diseases of the heart and blood vessels (e.g., arteriosclerosis), which are becoming more common in farmed salmonids as farming practices intensify. These conditions are thought to make the fish’s heart less robust and able to handle stress, but few studies have directly examined the links between cardiovascular pathophysiological deviations and sudden stress-related mortality in farmed salmonids. Thus, the present study was designed to comprehensively evaluate salmon mortality in connection with thermal delousing treatment in the Faroe Islands. Here we present preliminary histological findings in the hearts of farmed Atlantic salmon that died in conjunction with treatment. As a comparison, hearts were also sampled from seemingly healthy salmon one week prior to the treatment at the same farming site.

Material and methods
Sampling was undertaken at a commercial farm in the Faroe Islands in late March 2022. The sampling was done approximately 10 months after sea transfer.

Prior to thermal delousing treatment, apparently healthy fish (N=20) were netted from the sea cage and euthanized with an overdose of anaesthetics (Tricaine methanesulfonate). The hearts were immediately dissected out and fixed in 4% formalin. Similarly, fish that died after delousing treatment (N=20) were pumped up from the sea cage and their hearts were sampled and fixed in the same way. After fixation the bulbous arteriosus and atrium were removed and the heart ventricle was longitudinally cut in half and routinely processed for histological examination. Sections (4 µm) were cut and stained with haematoxylin and eosin (HE) before being digitized and examined.

Fig. 1. Left: Normal histology of cardiomycocytes in the ventricular compactum from a salmon sampled prior to delousing (bar= 60 µm). Right: Degenerating cardiomycocytes in the ventricular compactum from a salmon that died after thermal delousing treatment. It shows multifocal areas with swollen, lighter stained cardiomycocytes, with granular (squares) or vacuolated (arrows) cytoplasm (bar= 60 µm).

(Continued on next page)
Results and discussion

In 14 out of the 20 ventricles sampled from fish that died in conjunction with the thermal delousing, there were changes indicating ischaemia (reduced oxygen supply) in the compact myocardium as previously described by Poppe et al (2021). Microscopic evaluation revealed multifocal areas in the compact myocardium with swollen, lighter stained cardiomyocytes (heart muscle cells), with granular or vacuolated cytoplasm (Fig.1). These histopathological changes are interpreted as cardiomyocyte degeneration due to ischaemia. None of the 20 ventricles sampled prior to delousing showed any histological changes consistent with ischaemia.

The ventricle of the salmonid heart consists of an outer compact myocardium, supplied by the coronary circulation with oxygen-rich blood, while the inner spongy myocardium receives oxygen from the oxygen-poor venous blood returning from the body. Thus, the ischaemic lesions in the compact myocardium observed here indicate that the coronary arterial blood flow is insufficient, and may have caused heart failure and possibly explaining why the fish died during the stressful and likely highly metabolically demanding delousing treatment.

A possible cause of the compact myocardial ischaemia is coronary arteriosclerosis, a condition in which coronary blood flow is partially or completely restricted. Coronary arteriosclerosis is becoming more frequent and severe in farmed Atlantic salmon.9,10 Another condition that can reduce the coronary blood supply to the myocardium, resulting in ischaemic lesions, is coronary artery spasm. Several factors can trigger coronary artery spasms, including stress and chronic inflammation.11 39 out of the 40 ventricles examined from both apparently healthy and dead fish exhibited mild to moderate inflammation in both spongy and compact myocardium that may be compatible with viral myocarditis, most likely heart and skeletal muscle inflammation (HSMI).

Conclusion

Ischaemic lesions were observed in the compact myocardium in the majority of the hearts sampled from fish that died in connection with delousing. No lesions consistent with ischaemia were observed in the hearts from fish sampled prior to treatment. We therefore argue that cardiac failure due to ischaemia was the most plausible cause of mortality.

The underlying cause(s) for the ischaemic lesions observed here are unknow and needs to be investigated further. To do this, we will now examine and quantify the severity of coronary arteriosclerosis in the collected hearts and relate that to the incidence of myocardial ischemic lesions reported here, as well as the overall mortality risk during thermal delousing treatment.

References

Introduction

Oyster farming is a major aquaculture industry worldwide, with the Pacific oyster being the most widely cultivated species. Controlled reproduction in hatcheries enables the production of genetically improved seed using polyploidy or selective breeding. Selective breeding programs have been applied successfully in different oyster species, including the Pacific oyster, using mass selection and pedigree-based approaches. Recent advances in genomics have led to the development of high-density SNP arrays for several bivalve species, including the Pacific oyster. Genomic selection can accelerate genetic gain by reducing the generation interval and increasing selection accuracy. However, the success of genomic selection relies on the availability of accurate and reliable phenotype and genotype data, as well as appropriate statistical models. The aim of our study was to assess the potential of genomic selection for growth and quality traits in two independent mixed-family breeding designs at commercial scale in *C. gigas* selected lines.

Material and Methods

The study used oysters from two French breeding companies, each from a population that underwent six to eight generations of mass selection, mostly for resistance to OsHV-1, growth, and morphology. The first population resulted from seven full-factorial crosses of ten males and ten females each, generating 700 full-sib families, while the second population resulted from six full-factorial crosses of ten males and eight females each, generating 480 full-sib families. The oysters were phenotyped at 36 and 31 months old for various traits, and their genetic variability was monitored with genetic markers. All parents and offspring were genotyped on the bi-species Axiom Affymetrix 57K oyster array, Axiom_Oyster02, comprising 40,625 markers for *C. gigas*, and quality control analyses were carried out to ensure the quality of the data.
Results & Discussion
LD (linkage disequilibrium) strongly decreased with distance between pairs of SNPs for both populations, and that P1 had higher LD than P2 throughout the genome. Parentage assignment rates were high in both populations, with P2 having a lower assignment rate due to missing genotypes for four parents. Effective population size (Ne) was estimated at 107 for P1 and 76 for P2. Heritability was estimated for each trait and population and ranged from 0.08 ± 0.04 to 0.56 ± 0.08 for a pedigree-based model and from 0.04 ± 0.02 to 0.69 ± 0.04 for a genomic-based model. Growth-related traits were generally highly genetically and positively correlated with each other, but weakly correlated with colour traits. Accuracy of prediction was generally higher with the genomic model (GBLUP) than with the classical BLUP model, with a maximum gain of accuracy (from 0.38 to 0.66) for flesh weight adjusted by total weight in P2. Accuracy of breeding values was slightly higher for colour traits for P2, with higher heritability estimates.

Conclusion
The study found that genomic selection and mixed-family designs can improve growth and color traits in Pacific oysters. Both breeding programs evaluated showed substantial genetic variation and good genetic diversity. However, better genomic tools are needed, and interactions between genotype and environment should be evaluated to optimize breeding programs for hatcheries.

Introduction
Vibrio spp. are Gram-negative, rod-shaped bacteria that are widely distributed in freshwater, estuarine, and marine environments. They have the potential to cause infections in animals and are frequently isolated from aquaculture farms, resulting in mss mortalities and significant economic losses. Vibrio bacterial pathogens may persist in aquaculture ponds in a biofilm form, a complex microbial structure, attached to a surface and integrated into an adhesive extracellular matrix. This matrix provides protection against environmental stressors, including cleaning and disinfection procedures used in aquaculture industry. Therefore, it is crucial for professionals to use effective disinfectants to eliminate these biofilms and prevent the transfer of Vibrio spp. cells from surfaces to food.

Objective
The aim of the present study was to assess the effectiveness of benzalkonium chloride, a commonly used disinfectant in aquaculture farms, against biofilms of Vibrio species that are frequently encountered in aquaculture and pose significant economic challenges.

Methods
Two strains of V. parahaemolyticus, two strains of V. alginolyticus, and one strain each of V. harveyi and V. cholerae were studied. Biofilms were grown in a 96-well microtiter plate at 23°C for 24 hours to simulate conditions encountered in aquaculture farms. Treatments with disinfectants or water (as control) were applied either before biofilm formation or on pre-formed 24-hour biofilms. The total biomass of the biofilms (matrix and bacterial population) was evaluated by crystal violet staining, the metabolic activity of cells within the biofilms was measured by 2,3,5-triphenyl tetrazolium chloride, a metabolic dye used as a mitochondrial redox potential indicator staining. The viability status of these bacterial populations was then evaluated by flow cytometry and epifluorescence microscopy coupled with a live/dead staining.

Results
Surprisingly, in four out of six strains of Vibrio studied, crystal violet quantification showed that benzalkonium chloride induced overproduction of Vibrio biofilm biomass. Metabolic activity was not always correlated with the overproduction of biofilm. Flow cytometry and microscopy data indicated that injured cells were responsible for this overproduction of biofilm.

Significance
This study demonstrates for the first time the ineffectiveness of benzalkonium chloride in removing biofilms formed by Vibrio species that pose significant economic problems in aquaculture. Worse still, this study shows that benzalkonium chloride induces overproduction of Vibrio biofilms, which represents a major risk in the resistance, dissemination and persistence of this pathogenic organism.
PREVENTATIVE CARE: CO-EXPOSURE WITH FUNGAL AND HERBAL STIMULANTS IN RAINBOW TROUT (Oncorhynchus mykiss) TO OPTIMISE BENEFICIAL IMMUNE EFFECTS

Introduction
Disease outbreaks are a major source of economic losses to the aquaculture industry. Preventive biological control strategies, using compounds that also meet food safety standards for subsequent human consumption, are urgently needed to improve animal health and welfare while reducing impacts from antibiotic use on human and environmental health. The addition of functional ingredients or immunostimulants in fish diets is a promising option with the ability to enhance the protective function of both humoral and cellular components of the immune system, increase host resilience and host resistance to pathogens and disease. The use of generally recognized as safe (GRAS) medicinal mushrooms already authorised for human consumption by the U.S. Food and Drug Administration (FDA), such as fungi belonging to Basidiomycetes, have significant potential as immunostimulants for farmed fish, as it was already proved in human or terrestrial animals. In addition, capsaicin, the principal pungent component in hot peppers, has received considerable interest for its implication into numerous biological activities with potential pharmacological application. Several studies have thus shown a correlation between the addition of capsaicin into the diets and increased nutrient uptake. In finfish, capsaicin has been implicated in having a modulating effect on the gastrointestinal mucosal barrier, enhancing the uptake of immunomodulatory compounds such as vaccine particles. While specific interactions within the microbiota remain unpredictable, it is clear that modifying the microbiome with the goal of optimising metabolite bioavailability is a promising approach to improve therapeutic efficacy.

Objective
In this study, we evaluated a holistic and cross-disciplinary pipeline to assess the immunostimulatory properties of two fungi: Trametes versicolor and Ganoderma lucidum; one herbal supplement, capsaicin in the form of Espelette pepper (Capsicum annuum), and a combination of these fungal and herbal additives on rainbow trout (Oncorhynchus mykiss).

Methods
After dietary exposure during a 7-week trial, fish were collected to investigate the effect of the feed additives on multiple parameters: growth, cellular and humoral immune parameters (blood samples), molecular immune parameters (spleen samples), and intestinal microbiota characteristics (intestinal samples). Fish cellular immune parameters (number of leucocytes and phagocytosis capacity) were then studied using flow cytometry, alongside with humoral immune parameter (alternative pathway of complement activities) using hemolytic assays, as well as gene expression patterns of specific immune organs (target genes il-1β, ifn-γ, tlr2, and tnf-α) using reverse-transcriptase quantitative polymerase chain reaction (RT-qPCR). In parallel, the response of the fish intestinal microbial community to these additives was conducted via metabarcording and predictive functional analyses. Ultimately, this study demonstrates the necessity for congruity between molecular, cellular, microbial, and humoral methods as a prerequisite to establish true changes in fish physiological state following the inclusion of novel feed ingredients.

(Continued on next page)
**Results**
Uptake of herbal and fungal compounds influenced the expression of immune related genes, without generating an inflammatory response. Significant differences were detected in the spleen-\(\text{thr2}\) gene expression. Supplementation with herbal additives correlated with structural changes in the fish intestinal microbiota and enhanced overall intestinal microbial diversity. Results demonstrated that the different treatments had no adverse effect on growth performance and survival, suggesting the safety of the different feed additives at the tested concentrations and their potential for application in aquaculture. While the mechanisms and multifactorial interactions driving the observed changes remain unclear, this study provides a holistic and cross-disciplinary investigation not only in regard to nutrition and safety, but also when considering potential mechanisms of action from a combined immune and gut microbiota perspective.

**Significance**
Novel fungal and herbal feed ingredients are on the crossroad between fish, human, and environmental health, with the potential to improve sustainability without compromising health outcomes. There is a pressing need in existing literature to apply a more holistic and integrative approach as part of the *One Health* concept to assess the impact of such functional additives. The use of compounds in aquaculture that are already authorized for human consumption - hence without environmental or public health concerns - is therefore a promising approach. This study provides a detailed cross-disciplinary investigation not only of the safety of these compounds for use in the target organism, but also provides insight into actual effectiveness in relation to combined immune and microbiological parameters.
MICROALGAL BIOFILMS AS A SOURCE OF UNEXPLORED BIOACTIVE COMPOUNDS: ANTI-ADHESIVE EFFECT AGAINST BACTERIAL PATHOGEN

Introduction

In food industry and aquaculture, successful bacterial pathogen colonisation and persistence begin with their adhesion to a surface, followed by the spatial development of mature biofilm of public health concern. A biofilm is a complex assemblage of cells embedded in a matrix of Extracellular Polymeric Substances (EPS), conferring bacteria increasing tolerance against antibiotics and disinfectants. Compromising bacterial adhesion with natural inhibitors is a promising alternative to conventional anti-fouling treatments typically based on chemical biocides or antibiotics that contribute to the growing burden of antimicrobial resistance.

An attractive alternative lies within the exploitation of marine microalgae and derivatives, which harbor a wide range of functionalities and bioactive components, such as proteins, lipids, pigments, or exopolysaccharides. Although polysaccharides from algae, bacteria and fungi have shown promising anti-biofilm activities against widespread pathogens, no studies have investigated microalgal EPS for applications in food-contact surfaces. Yet, their high biodegradability and expected non-toxicity, combined with the opportunity of large-scale production thanks to innovative biofilm-based microalgae cultivation technologies, make them ideal candidates for the development of natural and sustainable anti-adhesive surfaces, with promising applications in food industries. Indeed biofilm-based cultures have emerged lately to overcome the main drawbacks of conventional suspended microalgae cultures: low productivity and high operating costs. Especially, the two microalgae *Cylindrotheca closterium* and *Tetraselmis suecica*, are known to be able to develop photosynthetic biofilms and such a self-organized community might be a source of unexplored bioactive agents to tackle biofouling and bacterial biofilms of health concern.

Objective

The objective of this study was to investigate for the first time the bacterial anti-adhesive/antifouling potential of EPS fractions extracted from microalgae biofilms cultivated in innovative large-scale pilots, for application in food-contact materials.

Methods

Microalgal EPSs were extracted from biofilm cultures of *Cylindrotheca closterium* and *Tetraselmis suecica* resulting in the obtention of three fractions: fraction C from *C. closterium* and fractions Ta and Tb (cell-bound and insoluble EPSs respectively) from *T. suecica*. Early adhesion inhibition was tested using eight food-borne bacterial pathogens belonging to *Escherichia coli*, *Staphylococcus aureus*, *Salmonella enterica* subsp. *enterica*, and *Listeria monocytogenes* and quantified through Confocal Laser Scanning Microscopy (CLSM). In order, to better understand the mechanisms behind the modification of bacterial adhesion, the chemical composition of the different EPS fractions was characterized using analytical methods, including Attenuated Total Reflectance Fourier Transform Infrared (ATR-FTIR) spectroscopy and High-Performance Liquid Chromatography (HPLC).

(Continued on next page)
**Results**
The results showed that, among the three EPS fractions, the fraction Ta (*T. suecica*) significantly reduced adhesion of strains of *E. coli*, *S. aureus*, and *L. monocytogenes*. Overall EPSs coating on polystyrene surfaces of the different fractions increased the hydrophilic character of the support. Differences in bacterial adhesion could be explained by several dissimilarities in the structural and physicochemical EPSs composition, according to HPLC and ATR-FTIR analysis. Interestingly, while fractions Ta and Tb were extracted from the same microalgal culture, distinct adhesion patterns were observed, highlighting the importance of the extraction process. Overall, the findings showed that EPS extracted from microalgal photosynthetic biofilms can exhibit anti-adhesive effects against a wide range of food-borne pathogens and could help developing sustainable and non-toxic anti-adhesive surfaces for the food industry.

**Significance**
Biofilm and bio-fouling formation in food industry and aquaculture are major public health concerns, which represent reservoir of bacterial pathogens that could be armful for animals or human. In order to reduce the growing burden of antimicrobial resistance, the development of novel anti-fouling compounds is of paramount importance. As such, microalgal EPSs which are non-toxic and biodegradable represent a promising alternative for the development of sustainable anti-adhesive surfaces. Besides, such compounds may have inherent wide applications, ranging from marine, agricultural and industrial equipment and aquaculture sea-cages, to biomedical devices such as biosensors and implants.
MODE OF APPLICATION OF A FUNCTIONAL FEED DETERMINES THE IMMUNE RESPONSE OF ATLANTIC SALMON TOWARDS ACUTE OXIDATIVE STRESS

Introduction
It is widely recognized that stress has profound effects on the immune system of fish. Although actions are undertaken to minimize stress and adverse effects during aquaculture production mitigation strategies are necessary when stress cannot be avoided. A variety of stressors impact health and performance of Atlantic salmon produced in intensive land-based recirculating aquaculture systems (RAS). Among them oxidative stress occurs during the regular disinfection of RAS facilities and is induced by strong oxidants such as peracetic acid (PAA) [1]. Besides its beneficial effects PAA alters the stress and immune response of Atlantic salmon [2,3]. Dietary mitigation strategies may prove useful under these conditions in mitigating the effects of such oxidative acute stress. In this study we explored whether differently applied microalgae enriched functional feeds influence the immune and stress response of Atlantic salmon towards an acute oxidative stress (PAA treatment).

Material & Methods
Atlantic salmon smolts (20 per tank, initial weight ~ 126 g) were reared in triplicates in a recirculating aquaculture system. The fish were fed either a control diet (CD), a diet containing 2 % (CV2) or 14 % (CV14) of Chlorella vulgaris on a daily basis, or the diet containing 14 % Chlorella vulgaris once weekly (CV14w). Following eight weeks of feeding, all groups were subjected to an acute oxidative stress induced by treatment with peracetic acid (WOFA-steril, Kesla, Germany) at 2.5µl PAA / L water. We assessed growth performance plasma stress indicators as well as gene expression of stress- and immune-related genes in the head kidney and gill.

Introduction

Viral nervous necrosis (VNN) disease caused by the nervous necrosis virus (NNV) inflicts significant losses to seabass producers through mortalities and impaired growth of the infected fish (Barsøe et al. 2021). Genetics studies have demonstrated the potential for improving resistance to the disease through selective breeding in different seabass populations (Palaiokostas et al. 2018; Griot et al. 2021). Additionally, recent studies have identified genomic regions or markers with significant effect on VNN resistance in different European seabass populations (Palaiokostas et al. 2018; Griot et al. 2021; Vela-Avitúa et al. 2022). However, precise genetic basis of VNN resistance in European seabass remains unknown. Therefore, in the current study we employed multi-omics tools to identify and functionally characterize genomic components underpinning resistance to VNN in farmed European seabass.

Materials and Methods

Approximately 1,500 European seabass from a full factorial cross of 25 dams and 25 sires were challenged with NNV. Mortality of the challenged fish was then recorded twice a day for a period of 29 days and used as the primary phenotype for resistance to the virus (binary survival). Time of death (in days) of the challenged fish was also recorded. A total of 1,066 fish (including the 50 parents and 1016 NNV challenged fish) were genotyped on the MedFish SNP array for 30K SNPs. The 50 parents and 40 offspring were full genome sequenced, and used as references for full genome imputation of all the offspring. Additionally, 322 offspring from the same parents were recruited in a transcriptome challenge experiment where 110 and 212 fish were mock- and NNV-challenged respectively. Tissue samples for RNA sequencing were collected from brain and head kidney. Whole genome GWAS was performed for both binary survival and days to death using GCTA software. Additionally, correlation analyses between gene expression and VNN resistance breeding values were performed. We subsequently performed expression QTL analyses for the main candidate genes identified in the QTL region.

Figure 1: A) Manhattan plot summarizing whole genome GWAS results by P-value; B) Manhattan plot summarizing whole genome GWAS results by additive genetic variance explained; C) Plot showing the correlation between *IFI27L2A* expression and NNV resistance GEBV in the head kidney.
Results
Our results showed moderate heritability estimates for VNN resistance of 0.400 ± 0.058 and 0.451 ± 0.058, for binary survival and days to death respectively, indicating the potential of selective breeding to reduce the impact of the disease. Of the 8.5M variants, 48,787 were associated with VNN resistance, with a large majority (90%) located on LG12 (scaffold CAJNU010000003.1) as shown in Figure 1A. The most significant variant explained 37% of the total additive genetic variation in VNN resistance (Figure 1B) and showed a clear additive effect with individuals homozygous for the resistant allele showing 81% survival upon infection. This demonstrates the potential of utilizing marker assisted selection to enhance selective breeding for resistance against VNN. The eight most significant variants were located in the IFI27L2A gene, and our results revealed a significant correlation between IFI27L2A expression and VNN resistance (Figure 1C). Interestingly, variants with the strongest effect on VNN resistance also showed a clear association with the expression levels of IFI27L2A.

Conclusions
Our results provide a more refined insight into the genomic basis of resistance to VNN, which could be utilized for enhancing selective breeding or to design genome editing approaches to produce fish that are more resistant to the disease.

Funding
The study was conducted as part of the AQUA-FAANG project, which has received funding from the European Union’s Horizon 2020 research and innovation program under Grant Agreement No 817923.

OCCURRENCE OF MYCOTOXINS IN COMMON RAW INGREDIENTS USED IN AQUA FEED JAN-JUNE 2023

Müller1*, B. Behler-Woechtl1,

1 DSM Austria GmbH, Getzersdorf, Austria
* Anneliese.mueller@dsm.com

Introduction
Mycotoxins are secondary fungal metabolites which are frequently found in various plant-based ingredients and can negatively affect health and performance of aquatic species. The increasing inclusion of plant protein in aqua feed, leads to the introduction of mycotoxins in aqua diets. Mycotoxin occurrence in raw ingredients as well as finished feed is monitored within the DSM Mycotoxin Survey, the longest running global mycotoxin survey available. Global results between January-June 2023 of prevalence and concentrations of the six well known mycotoxins aflatoxins (Afla), zearalenone (ZEN), deoxynivalenol (DON), T-2 toxin (T-2), fumonisins (FUM) and ochratoxin A (OTA), in commonly used ingredients are presented.

Material and methods
Samples were analyzed with ELISA, HPLC and LC-MS/MS (liquid chromatography coupled to tandem mass spectrometry) based methods. For Asia, mainly the multi-mycotoxin method Spectrum Top® 50 developed by Romer Labs®, was used. This method allows the simultaneous detection of >50 different toxins and metabolites, including masked and “emerging” (unregulated) mycotoxins.

Results and discussion
Table 1 shows the number of samples analyzed, % of samples tested positive for each mycotoxin, average concentration of all positive samples (ppb), median concentration of all positive samples (ppb) as well as the maximum (ppb) detected.

Afla occurs most frequently in soybean, but at moderate levels. Wheat/-bran shows high abundance of DON. Corn is frequently contaminated with Fusarium toxins (ZEN, DON, FUM), but shows also an extreme Afla maximum. Corn gluten meal and corn DDGS are risky ingredients due to high contamination. Poster will also provide details on rice bran, cottonseed - and sunflower cake, rapeseed meal as well as cassava.

Conclusion
Prevalence and concentrations of the six well known mycotoxins underline the importance of a proper mycotoxin risk management including regular testing of ingredients as well as testing of aqua finished feed and inclusion of a mycotoxin deactivator.
RESPONSE TO SELECTION FOR CYTOGENETIC QUALITY IN *Mytilus edulis* AND *M. galloprovincialis*

Ajithkumar Munusamy*, Lionel Dégremont, Christophe Ledu, Abdellah Benabdelmouna

ASIM, Ifremer
La Tremblade
France
Email: ajithkumar.munusamy@ifremer.fr

Introduction
Mussel is one of the most cultured and high-value species in France. French mussel culture entirely depends on the wild spat collection. In the last decade, Abnormal Mass Mortality (AMM) has been observed in mussel farms along the Atlantic coasts, and the causes are not clearly established. Recent studies suggest that genetic factors are involved in mortality outbreaks, and poor cytogenetic quality is one among them (Degremont et al., 2019; Benabdelmouna et al., 2018). Abnormal mass mortality was shown to be strongly correlated to genomic abnormalities, in particular with a poor cytogenetic quality which is defined as a lower proportion of diploid to non-diploid cells in their haemolymph (Benabdelmouna and Ledu, 2016). The purpose of our study is to estimate the response to selection/realized heritability of cytogenetic quality using a divergent selection in the two main mussel species cultivated in France and to explore the relationship between the cytogenetic quality and the resistance to mortality using a cohabitation protocol with wild mussels sampled in site regularly impacted by AMM.

Materials and methods
Wild adult mussels were collected for *M. edulis* in Agnas and for *M. galloprovincialis* in Biarritz in January 2022. For each species, 420 mussels were phenotyped for cytogenetic quality after collecting haemolymph using flow cytometer analyses (FCM). For each species, a divergent selection was applied using an intensity of selection of 1.40 (i.e. 20% of the population selected for each group) producing a low and a high cytogenetic quality groups, respectively LCQ and HCQ, as well as a control group. In May 2022, five replicate spawns per group were produced for each species using two to five females and three to six males per spawning. Spawning, larval rearing and grow-out culture were carried out in our experimental hatchery at ASIM, Ifremer, La Tremblade, France. The cytogenetic quality of each replicate spawn will occur in summer 2023. Survival evaluation started on March 2023, using a cohabitation protocol between groups and wild mussels sampled in a mussel farm impacted by AMM. Thirty mussels per replicate spawns are tested in triplicate in a flow-through tanks, and mortality is recorded weekly until the summer 2023.

Results
The mean proportions of non-diploid cells were significantly higher for *M. edulis* (12%) than *M. galloprovincialis* (9%) (*p* <0.0001). The previous studies on non-diploid cells percentage of French mussels stocks varies between 2.44% to 21.37% (Sample size = 74-117) before mortality events (Benabdelmouna and Ledu, 2016). The mean proportions of non-diploid cells of LCQ, control and HCQ mussels were 28%, 12%, and 3% for *M. edulis*, and 26%, 9%, and 2% for *M. galloprovincialis*. HCQ has been found significant between the species (*p* <0.0001). However, LCQ have not showed any significant difference (*p* = 0.36) between species. The mean of non-diploid percentage of selected parents is shown in figure 1, and those of their progenies will be known during the summer, as well as their survival examined in the cohabitation experiment will be identified in summer. The mean mortality of the mussel species after 45 days was showed less than 1%.

Expected outcomes
It will be the first report on the possibility of selection for cytogenetic quality in shellfish. The previous results suggest that mortality level is significantly negatively correlated with the cytogenetic quality of the mussel. Selection for cytogenetic quality would not only improve the survival against the specific pathogen, but it should also improve the overall health status/fitness of the animal. If the cytogenetic character is heritable, it will give an important insight into the selection approach on the cytogenetic quality of the shellfish and will lead to new selection criteria for disease/survival/welfare traits of the shellfish.

Introduction
There is a growing use of plant ingredients in aquafeeds due to limited availability of marine protein sources (fishmeal). However, plant proteins included at high levels reduce fish growth, which can be partially explained by their lower digestibility (Krogdahl et al., 2022; Murashita et al., 2022). It is, therefore, important to understand the physiological mechanisms involved in the regulation of digestion, and how these are affected by nutrients and dietary ingredients. In mammals, the complex regulatory interaction between nutrient sensing and digestion involves the Calcium-sensing receptor (CaSR). However, the physiological roles of Casr in fish are still unclear. To explore the role of Casr in the regulatory mechanisms of fish digestion, this study described the tissue distribution of the \textit{casr} gene, generated a \textit{casr} knock-out (KO) model and analyzed its phenotype with focus on digestive enzyme secretion and growth, using medaka \textit{Oryzias latipes}.

Materials and methods
Tissue distribution of \textit{casr} gene in medaka: A Cab inbred strain of medaka was used in this study. The tissue distribution of medaka \textit{casr} gene was analyzed by real-time quantitative RT-PCR (qPCR) in sixteen different tissues (whole brain, pituitary, eye, tongue, gill, skin, muscle, heart, gallbladder, liver, spleen, kidney, gonad, foregut, midgut and hindgut) (\(n = 8\) fish).

Generation of \textit{casr} KO medaka: \textit{casr} gene was targeted and the gene-specific sgRNA was synthesized. A mixture of Cas9 protein and the synthesized sgRNA was injected into fertilized eggs before the first cleavage. The sgRNA activity (induction rate of somatic mutation) in the F0 embryo and its germ line transmission rate in the F1 fish (offspring of F0 founder and wild type (wt)) was estimated by High Resolution Melting analysis. The obtained F1 mutants were genotyped and heterozygous mutants (+/-) were selected. The selected F1 heterozygous mutants were incrossed to generate null F2 mutants (-/-). The population of null mutants was expanded by incrossing of the selected null mutants.

Phenotypic analysis of \textit{casr} KO medaka: To compare digestive enzymes secretion in wt and \textit{casr} KO fish, the same amount of commercial diet (2.5% body weight) was fed, and the intestinal content was collected. Activities of digestive enzymes (trypsin, chymotrypsin and lipase) of the collected intestinal contents were analyzed (\(n = 8\) fish). This can be regarded as the levels of secretion from the pancreas. To compare the growth rates between wt and \textit{casr} KO mutant, fish were fed with two isoenergetic (20.5 kJ/g) diets with different protein/lipid ratios, a high protein diet (HP; protein/lipid, 60%/11%) and low protein diet (LP; protein/lipid, 53%/15%) for seven weeks (from 3 to 10 weeks, triplicate tanks). Every week, the fish body weight, total length and Fulton’s condition factor were recorded until 10-week post hatch.

(Continued on next page)
Results and Discussion

Tissue distribution of casr gene in medaka: casr gene was highly expressed in the kidney and in all intestinal segments, suggesting the functions related to Ca²⁺ excretion and nutrient sensing, respectively, exist in medaka as seen in mammals (Hannan et al., 2018).

Generation of casr KO medaka: The induction rate of somatic mutations in the F0 embryo \((n = 24)\) and its germ line transmission rate in the F1 fish \((n = 46)\) were both 100%. The mutation in genotyped/isolated F1 mutant of casr gene showed a frameshift with 19-bp deletion, and the mutant allele yields a truncated protein due to an additional region of altered translation, in which a stop codon is generated before the functionally important domain of Casr. The homozygous mutant was successfully generated by increasing the selected heterozygous mutants and the population was expanded (Fig. 1).

Phenotypic analysis of casr KO medaka: Lower secretion levels of proteases (trypsin (Fig. 2) and chymotrypsin) were observed in the casr KO fish compared to the wt fish whereas no differences were found in the lipase secretion between the strains. Regarding the medaka growth performance, although no differences were found between the casr KO and wt strains for the fish fed the LP diet, casr KO fish fed the HP diet showed markedly lower growth performance compared to the other diet/strain groups.

The findings of this study indicate that fish with casr KO demonstrate a lower capacity for protein digestion, potentially due to a decrease in the intestinal nutrient (protein) sensing ability.

RESPONSIBLE CATFISH IS NEXT ON THE MENU! THE SCOPE EXTENSION PROJECT OF THE AQUACULTURE STEWARDSHIP COUNCIL (ASC)

Fabiola Mustafaj*, Kathrin Steinberg

Aquaculture Stewardship Council (ASC)
Daalseplein 101
3511 SX Utrecht, The Netherlands
E-mail: fabiola.mustafaj@asc-aqua.org

The Aquaculture Stewardship Council (ASC) is the world’s leading certification scheme for farmed seafood. In 2022, the total global production of ASC certified seafood amounted to more than 1.9 million tonnes, which corresponds to 1.55% of the global aquaculture production, while certified fish accounted for 1.4 million tonnes, meaning 2.4% of the total finfish global production. Our certification programme uses market-based approaches that incentivise famers to achieve strict standards of environmental and social performance. Compliance with the requirements of ASC Standards can help to reduce farm’s environmental footprint, conserve natural resources and contribute to worker’s well being.

Currently, the ASC covers 17 species groups under 11 standards, plus a joint ASC-MSC standard for seaweed. They all provide industry leading, robust, environmental and social requirements, but because they have been developed at different times, their requirements vary on some of the impacts that are common across aquaculture. Therefore, ASC is currently aligning all 11 standards into one ASC Farm Standard. This will cover all impact areas and all currently certifiable species in one rigorous standard. Additionally, it will also allow the ASC to more efficiently expand its reach (e.g. adding production systems or new species) and will facilitate the swifter update to specific metrics. The ASC Farm Standard will include a core set of indicators and will monitor legal, social and environmental impacts consistently across species and regions and set species-specific limits where necessary (e.g., mortality levels, feed conversion, etc.). New species will be added to the ASC portfolio by applying common management and system specific indicators form the ASC Farm Standard. Additional species-specific indicators will be evaluated for addition when the current indicators do not align cover major impacts of the new species. As a matter of fact, there is a huge potential for aquaculture volumes that are not within scope of the current 11 standards. This potential is explored by the ASC Species Scope Extension Project.

The next group of interest for the Scope Extension Project is catfish, including the following species: *Clarias gariepinus; Ictalurus punctatus; Hybrid of Heterobranchus Longifilis X Clarias Gariepinus*. The production of *Clarias gariepinus* has been exponentially increasing since the 1990s and peaked in 2015 with more than 250K tonnes of live weight produced in aquaculture (Food and Agriculture Organization of the United Nations, 2023). The genus *Clarias spp.* accounts for 2.3% of the total fish production in 2020, according to the FAO and it is a fish species with a remarkable potential for the development of freshwater aquaculture. They are air beathing species, meaning that they are highly adaptable, widely distributed geographically and tolerant to adverse conditions (Lisachov et al., 2023). *Ictalurus punctatus* is also a species of high commercial interest worldwide. It is a key aquaculture species especially in North America and Asia (Wen et al., 2023). It has a high economic importance in China due to its adaptability and resistance (Yu et al., 2023). Finally, catfish hybrids such as the “heteroclarrias” (*Heterobranchus Longifilis X Clarias Gariepinus*) have been widely used to select ideal parental features for breeding fast growing, efficient and healthy fish (Sobczak et al., 2022). Catfish and its hybrids are therefore gaining importance worldwide.

All these species seem to have competitive profit margins for large-scale production which is leading farmers to opt for more intensive aquaculture practices with associated social and environmental risk as well as risks for the fish welfare (Wise et al., 2023). These risks will be covered by the implementation of the ASC Farm Standard with species-specific indicators. Thus, the ASC sees an urgent need to include these species the portfolio to actively address major concerns and issues.

Our goal is to involve relevant stakeholders in the content development, especially in regard to metric setting. To set credible metrics, data from literature and real farm data will be used. Expanding ASC’s scope to include the potential for catfish certification expands accessibility to ASC standards and increased the environmental and social benefits awarded through certification. Farmers also benefit from this scope extension as ASC certification allows them to drive additional revenue and income through access to global market demand, demonstrate commitment to responsible farming practices, workers, communities and to have access to education in effective and efficient farming. This is the next step to bring responsible catfish on our consumers’ tables!

Introduction
The meagre (Argyrosomus regius) is an emerging species for the Mediterranean aquaculture industry and its reproductive dysfunctions have been resolved using gonadotropin releasing hormone agonist (GnRHa)-based spawning induction protocols. However, to eventually be able to obtain fertilized eggs spontaneously, more information on the environmental requirements of the species and its breeding behavior is needed. Although sound production has been described so far in little more than 1100 fish species, recent studies demonstrate that this communication modality is shared by nearly two-thirds of actinopterygian species. The meagre is a member of the Sciaenidae family -called “drums” or “croakers”- and has a wide vocal repertoire, emitting sounds made from a single pulse up to more than 100 pulses. The calling rate and sound temporal features have been suggested as indicative of reproductive events. The aim of this study was to describe the reproductive behavior and parental contribution of meagre in aquaculture conditions, after spawning induction with (GnRHa), and document sound production during spawning and investigate how sounds may relate with specific behaviors in aquaculture facilities.

Materials and Methods
Two meagre broodstocks (n=2 females and 3 males, each) were utilized for two consecutive years (2021 and 2022). At the expected spawning period, fish were induced to spawn with a GnRHa injection (15 μg kg⁻¹ for females) or implant (50 μg kg⁻¹ for males). Each breeder was externally tagged for individual identification, and their behavior was monitored using underwater cameras. Egg production and quality was evaluated in terms of fecundity, fertilization success, 24-h embryo survival, hatching and 5-d larval survival. A sub-sample of the eggs from each spawn was analyzed for parental contribution. In 2022 only, two HTI-96-Min hydrophones were also connected to the audio input of the cameras. Using Adobe Premiere, audio files were extracted from the videos before and after spawning induction (5–13 May, 2022). All audio files were analyzed by audio and visual assessment (Raven Pro 64 1.4). Sounds produced by the fish were manually labelled on the basis of the number of pulses as knocks (1-3 pulses), or short (4-7 pulses), intermediate (8-29 pulses) and long grunts (≥30 pulses). When a sound could be associated with one of the identified stereotype behaviors -such as “male(s) trailing a female”, “darting”, “male-to-male agonistic behavior” or “spawning” the occurrence was annotated from the video observations.

Results
Spawning induction led to three consecutive daily spawns, 2 days after GnRHa treatment, with maximum fecundity on day 3. Spawning usually took place with all three males following a female (Fig. 1), and after numerous male-to-male agonistic interactions. Mean daily fecundity (n=4 years x broodstock) was 159,743±23,315 eggs kg⁻¹, and mean fertilization success and 24-h embryo survival were 83-92% and 93-100%, respectively.

Of the eggs produced in both years, 77±3% were spawned by one of the females in each tank, while 77±9% of the eggs from each tank were fertilized by one of the three males in each broodstock. In broodstock 1 (Fig. 2), the larger male fertilized 68±9% of the eggs in both years and in broodstock 2, the most aggressive male fertilized 86±8% of the eggs.

After GnRHa treatment, the number of sounds produced increased significantly during spawning days, especially during the evening hours when spawning took place. Long grunts, in particular, were emitted only during spawning days. Knocks, on the other hand, were associated with all identified behaviors and were the only sound type associated with male-to-male agonistic behavior. Grunts, on the other hand, were associated with “male(s) trailing a female” during spawning days.

(Continued on next page)
Discussion

The study demonstrated that hierarchies developed within meagre broodstocks, and even after exogenous GnRHa stimulation of all individuals in the broodstock, spawning success was not equal among breeders. In both years, the same male and female dominated the produced progeny. It is not clear at this stage what factor contributes to dominance of the two sexes, especially in females, but in males it may be size or aggressiveness. The video and sound production results agree with previous studies that recorded long grunts during spawning nights, as well as with studies conducted in the wild, which reported long choruses of knocks. Knocks and long grunts are, therefore, suggested as “carriers of information” during spawning in meagre. In the future, we will examine the potential of sound “play-back” as an environmental inducer of spawning in cultured meagre and a disruptor of male hierarchies.

THE USE OF CHEMICAL AND BIOLOGICAL SETTLEMENT CUES IN ENHANCING THE LARVAL SETTLEMENT OF ABALONE Haliotis midae: IMPLICATIONS FOR HATCHERIES AND OCEAN RANCHING

Z. Mzozo1*, S. Hugo2 and NG. Vine1

Email: olonasanoluhle@gmail.com

Introduction
The seeding of abalone larvae has been considered as a viable alternative for stock enhancement programs due to high production costs of raising juvenile abalone for seeding (Preece et al., 1997). However, poor larval settlement and metamorphosis in the hatchery is one of the significant constraints with seed production on abalone farms, resulting in low post-larval survival (Gapasin and Polohan, 2004; Li et al., 2006). Improving settlement and metamorphosis of abalone larvae is critical to ensure that abalone larvae settle within the seeding site for ocean ranching or to increase production in hatcheries. This study investigated the effect of biological (planktonic Nitzschia sp.) and chemical (potassium chloride) cues in inducing settlement and metamorphosis of Haliotis midae larvae. Specifically, the effects of dilution of such cues upon release of the larvae into the ocean is imitated by removing the settlement cues after a certain time period.

Materials and Methods
Three potassium chloride concentrations (10, 15, and 20 mM) and a control (with no KCl) were used to determine the optimal concentration for potassium ions to induce larval settlement for Haliotis midae. The optimal concentration of KCl was used to determine the effect of longer exposure period (12- and 24-hours) on the larval settlement and metamorphosis with the treatments also include the combination of KCl optimal concentration and biological cues (Nitzschia). Larval settlement and metamorphosis was also determined after a brief exposure to chemical and biological cues and a combination of both using settlement sheets that were coated with diatoms.

Results
For larvae exposed to different KCl concentrations (10–20 mM), settlement was highest at 10 mM in the first 20 hours. Larval settlement exposed to KCl-12 hours and KCl and Nitzschia combined-24 hours was higher in the first 20 hours than larvae exposed to KCl-24 hours and the controls (Figure 1). However, in both experiments, larval settlement in the controls increased over time and surpassed other treatments after 20 hours. Finally, the settlement was very low on uncoated sheets, compared to diatom-coated sheets, regardless of exposure to different combinations of KCl and Nitzschia.

Discussion
Due to the dramatic decrease in the mean settlement post-exposure, these results should be interpreted with caution when drawing biological conclusions for field studies. We, therefore hypothesize that exposure of Haliotis midae larvae to 10 mM KCl and Nitzschia will not enhance settlement in the ocean, as the inducers are primarily effective when KCl concentration levels remain at 10 Mm. The level of K⁺ in the ocean are typically below 10 mM (Todd et al., 1991) and it does not improve settlement without adding extra KCl in the seawater. However, long-term exposure to both KCl and Nitzschia over 24 hours could be used in hatcheries to improve the settlement of Haliotis midae larvae.

Figure 1: Number of settled abalone (*Haliotis midae*) larvae during and post-exposure for 12 hr to 10 mM KCl, 24 hr to KCl, and exposure to a combination of 10 mM KCl and *Nitzschia* for 24 hr with control treatment for each exposure time. The vertical dashed line indicates exposure period for each treatment and no water flows for each control treatment.
Climate change with its heatwaves and water shortages has an impact on aquaculture. Aquaculture practice has a strong need to find ways on how to adapt to these changing conditions. One option to increase the resilience of the sector towards heatwaves is the application of shading material.

In order to investigate the effects of different shading materials, a 31-days summer experiment (28.06-28.07.2022) was conducted using twelve fish-free round tanks (Depth: 100cm, diameter: 158cm). Each unit had a total volume of 1.96m³ and was embedded in the ground at a depth of approx. 80cm. Tanks were randomly equipped with four different shading nets (0 (control), 40, 60 and 85% grade) in triplicates. The nets were installed 115cm above the top of the terrain. At the beginning of the experiment, the tanks were initially filled with water from Lake Sacrow to a level of 80cm. No exchange of water was conducted. Henceforth, water temperature (°C), oxygen concentration (mg/L), turbidity (FNU) and water level (cm) were monitored on daily basis by manual measurements. Furthermore, data loggers for air and water temperatures as well as light intensity (lx) were installed in and above the tanks. In order to determine the growth of periphyton (in g dry matter/m²), plastic stripes were placed in the tanks. In addition, a weather station was operated at the experimental site (Lat.: 52.449182, Lon.: 13.098415).

The shading nets had a significant effect on air and water temperatures. Mean air temperatures were reduced by 3.1 to 6.7 °C and water temperatures by 2.3 to 4.0 °C. Here, a significant decrease in water temperatures could already be reported in tanks with the installation of 40% shading material. Also, the increase of the water temperature (∆T) in the tanks between 10 a.m. and 2 p.m. was reduced when applying shading material. Hereby, an increase of 2.8°C was observed in the control, 1.6°C at 40% shading, 1.1°C at 60% shading and 0.6°C at 85% shading. Thus, shading nets can effectively reduce water temperatures and provide homogenization of rearing conditions. Illumination levels above and within the tanks were reduced according to the material properties of the nets, which also went along with a homogenization of the rearing environment.

Only the 85% shading grade significantly increased the water level. But, in addition to the reduction of evaporation, an increased collection of precipitation was observed when applying this particular material. This can have implications in practical applications, as this rainwater accumulation could affect the statics of shading units.

Shading had no significant effect on oxygen concentration and turbidity in the tanks, but it did influence periphyton growth. Compared to the periphyton biomass in the control (6.2g DM/m²), shading significantly increased the growth of periphyton (up to 15.9g DM/m²). Associated effects and arising consequences for tank cleanness, fish and product quality aspects need to be evaluated in future research.

In view of the results, the installation of shade material appears to be a simple, effective and relatively inexpensive measure for aquaculture practice that supports adapting to heatwaves and water shortages. Results will also be discussed with perspective on the use of floating photovoltaic in aquaculture.
DEVELOPMENT OF A LARGE-SCALE SPERM CRYOPRESERVATION METHOD AND TESTING ITS APPLICABILITY IN PROPAGATION OF CHUB (Squalius cephalus)

* E-mail: nagy.borbala.3@phd.uni-mate.hu

Introduction
Chub is a rheophilic species, preferring rapid rivers with gravelly bottoms. It is distributed in Europe and Asia Minor (Caffrey et al. 2008). Based on monitoring studies natural populations of chub have decreasing tendency due to overexploitation, loss of spawning habitat, water pollution, interspecific hybridization, remarkable angling demand and climate change (Cejko & Krejszef 2016). The improvement of applicable propagation technology, in which sperm cryopreservation plays a key role, is important for maintaining and stabilising the populations and for gene conservation. Cryopreserved sperm collected from farmed or natural populations is part of maintaining biological and genetic diversity. It can also contribute to increasing the natural abundance of fish species with high angling interest (Bernáth et al. 2021). The study aimed to compare the effects of two hormonal agents (Ovopel and carp pituitary extract) on chub sperm production, its cryopreservation and post-thaw storage time, moreover, the development of a novel large-scale cryopreservation procedure by testing various freezing methods.

Materials and methods
Experiment 1.
In the first experiment, 6-6 males were hormonally stimulated with two hormone preparations, carp pituitary extract and Ovopel. Sperm samples were frozen at a dilution ratio of 1:9 (sperm:diluent + protectant) in 0.5 mL straw in a Styrofoam box. Sperm motility assessment was carried out using Computer-Assisted Sperm Analysis (CASA) system. Sperm quality was determined by pMOT (progressive motility, %), VCL (curvilinear velocity, μm/s) and LIN (linearity, %). Motility parameters were recorded for fresh, cryopreserved and thawed chilled stored samples (at 0, 3, 6 h post-thawing).

Experiment 2.
In the second experiment, (N=5) sperm samples were cryopreserved in a Styrofoam box (dilution ratio: 1:9) using 5 mL straws and 4 mL cryotubes. Motility parameters of both fresh and thawed samples were recorded by CASA.

Experiment 3.
In our first propagation test, sperm samples (N=5) were pooled and filled into 4 mL cryotubes (dilution ratio: 1:9). The samples were frozen in a Styrofoam box and a Controlled-rate freezer (CRF). The kinetic parameters of fresh and frozen samples were recorded by CASA. In the experiment, 1-1 g of egg batches were fertilized with 10 µl of fresh and 100 µl of cryopreserved sperm. The control and cryopreserved groups were incubated separately at 19±0.8 °C using spawning nests. The hatching rate (hatched larvae per total egg number * 100) was determined for both groups (~100 larvae or eggs) at the moment of hatching (3 days post fertilization).

Experiment 4.
The second fertilization trial was carried out based on the results of the previous experiments (Ovopel, dilution ratio 1:1, 4 ml cryotube, Styrofoam box). Fertilization of 1-1 g egg batches was performed with fresh (10 µl) and frozen (20 µl) sperm. Kinetic parameters were recorded using CASA system in fresh samples, immediately before application (control, ~1 h post-collection) and after thawing. The hatching rate was determined for both fresh and frozen groups.

Results
Experiment 1.
No significant difference was measured between the carp pituitary extract and Ovopel treated groups for fresh and cryopreserved sperm samples (0, 3, 6 h post-thaw). Reduced pMOT values were also observed after 3 hours of chilled post-thaw storage in comparison to 0 h.

(Continued on next page)
Experiment 2.
There was no significant difference in the motility parameters tested between the groups frozen in a Styrofoam box using 5 ml straws and using 4 ml cryotubes.

Experiment 3.
No significant difference was observed between the efficacy of the two cryopreservation methods either in terms of kinetic parameters or in terms of hatching rates (Styrofoam box (35±7%) and CRF (25±9%)).

Experiment 4.
In the second fertilization trial, in pMOT and VCL parameters, a significant decrease was observed in the cryopreserved sperm in comparison to the fresh and control groups. Moreover, similar high (with no significant difference) hatching rates were observed in the control (72±19%) and cryopreserved (4 ml cryotube and Styrofoam box, 61±5%) groups.

Discussion and conclusion
Although there was no significant difference between the treatments. The chub sperm showed high sensitivity during 6 hours of chilled storage, the pMOT values were already significantly reduced after 3 hours. Before its implementation in common hatchery practices, it needs to be considered. Both the 5 mL straw and the 4 mL cryotube have been proven to be effective in freezing large-scale chub sperm. Both sperm frozen in a Styrofoam box and in a CRF seemed to be effective in propagation. For the first time, our study presents a novel and applicable method for the large-scale cryopreservation of chub sperm.

Szarvas, Hungary
*e-mail: nagy.zoltan84@uni-mate.hu

Introduction
In past decades, aquaculture production in the European Union has stagnated and even a slight decrease can be observed. In 2020, 89% of aquaculture production was used directly for human consumption while further growth of aquaculture industry is forecasted with increasing fish consumption and declining natural populations (FAO, 2022). However, the further growth of production can be slowed down by the lack of usable land, the increasingly scarce water resources, and the ecological carrying capacity of the surrounding areas. An intensification trend can be observed in the world aquaculture production, especially in Asia. These systems typically have high nutrient retention. Therefore, continuous monitoring of water quality plays a very important role in modern aquaculture production. The deterioration of water quality is caused by the inputs (fertilizer, complete feeds) used to increase production (Boyd, 2018). These substances result in greater production, on the other hand, it can lead to phytoplankton blooms and a decrease in dissolved oxygen (Boyd and Tucker, 1998). The aim of the study was to determine the effect of different rearing systems on water quality and on the growth of hybrid striped bass (Morone saxatilis x Morone chrysops).

Materials and Methods
The 13-week experiment was carried out at the Hungarian University of Agriculture and Life Sciences (MATE) Research Centre for Fisheries and Aquaculture (HAKI), Szarvas, Hungary. 1-year-old hybrid striped bass individuals with an average initial weight of 128.5±8.1 g were randomly distributed in two replicates to small ponds (treatment SP, surface 324 m²) and large ponds (treatment LP, surface 700 m²), in two replicates to cages in the small ponds (treatment SPC, 3x3x2 m, 18 m³) and in the large ponds (treatment LPC, 3x6x2 m, 36 m³). Common carp (Cyprinus carpio) were also stocked in the ponds containing the cages. Fish were fed with commercial floating feed for African catfish (Clarias gariepinus) (Aller Aqua Group, Denmark). The fish were fed 1-3% of the biomass. Water samples were collected twice per week from the outflow of each pond. At the beginning of the experiment, 32 randomly chosen specimens were measured for length (±1 cm) and weight (±1 g) individually. During the experiment, sample harvest was conducted every two weeks to monitor biomass growth.

Results and conclusions
Data of growth parameters and production traits determined at the end of the experiment are summarized in Table 1. After thirteen weeks of rearing significant differences were found between the groups in terms of growth (final weight, conditional factor, SGR and DGR). The final body weight was significantly affected by both the technology and the size of the ponds and the cages. The SGR and DGR were affected significantly by the technology. The parameters of water quality are summarized in Table 2. The technology had a significant effect on all parameters examined. NH₄-N and TN values were also affected by the size of the rearing environment. In term of water quality and production traits the most favourable result was achieved by monocultural rearing.

Introduction

In a context of rapid development of aquaculture, ecosystem responsible practices are a deep challenge. Aquaculture feeds have been traditionally based on fish meal (FM) and fish oil (FO) derived from fisheries of small pelagic species. Efficient alternatives to FM and FO are crucial to preserve wild fish populations. Another concern of aquaculture is the release of high amounts of wastewater into the environment. The excess of particulate and dissolved nutrients, i.e., uneaten feed and metabolic wastes of fish, induce the eutrophication of surrounding ecosystem. The generic concept of Integrated MultiTrophic Aquaculture (IMTA) covers a large set of practices but is based on the production of fed species (e.g., finfish fed sustainable commercial diets) with extractive species, which utilize the inorganic (e.g., seaweeds) and organic (e.g., suspension-feeders) excess nutrients from fed aquaculture for their growth (Chopin, 2013). IMTA have the principal advantages to decrease the dependence on external inputs, increase the system efficiency, diversify farm-products and decrease waste effluents. An important challenge, to increase the development of IMTA practices, is the understanding of trophic relationship between species co-habiting in the system. Carbon (δ13C) and nitrogen (δ15N) natural stable isotopes have proven to be a useful tool to characterize trophic interactions in aquatic ecosystem (Fry and Sherr, 1984). The use of stable isotopes is based on the assumption that isotope signatures of consumers reflect those of assimilated dietary sources. The δ13C signatures of consumer tissues are usually close to those of their diets, making possible an elucidation of the origin of food sources. In contrast, δ15N signatures are enriched by 3.5‰ between a consumer and its prey and thus are typically used to estimate the trophic position of a consumer.

In this study, seabream (Sparus aurata) was raised in one pond and feed with commercial pellets exclusively containing terrestrial plant ingredients. Unmarked batches of mussels were given to seabream as supplementary food to underbalanced deleterious effects of the total replacement of FM and FO in their diet. In three other ponds, filter-feeders (oyster and clam) and detritivores crustacean (shrimp) have been raised. The four ponds were only connected by water flow. The aim of our study was to determine the food sources used by seabream, shrimp, clam, and oyster raised in this IMTA system. The proportion of commercial diet and mussels used by seabream were quantified. We also evaluated the ability of shrimp, clam, and oyster to feed on fish detritus. The present study is part of SIMTAP (Self-sufficient Integrated Multi-Trophic AquaPonic systems) a PRIMA project aiming to improving food production sustainability and brackish water use and recycling.

Material and methods

From June 2020 to September 2020, experiment has been conducted in 4 ponds on the Atlantic French Coast at the “Lycée de la Mer et du Littoral, Bourcefranc le Chapus” (fig.1.). Seabream (Sparus aurata) were fed 5 a week with commercial pellets and once a week with mussels at a rate of 3.7 ± 1.3% of live weight day−1 and adjusted according to water temperature. Commercial feed and mussels were distributed to seabream as supplementary food to underbalanced deleterious effects of the total replacement of FM and FO in their diet. In three other ponds, filter-feeders (oyster and clam) and detritivores crustacean (shrimp) have been raised. The four ponds were only connected by water flow. The aim of our study was to determine the food sources used by seabream, shrimp, clam, and oyster raised in this IMTA system. The proportion of commercial diet and mussels used by seabream were quantified. We also evaluated the ability of shrimp, clam, and oyster to feed on fish detritus. The present study is part of SIMTAP (Self-sufficient Integrated Multi-Trophic AquaPonic systems) a PRIMA project aiming to improving food production sustainability and brackish water use and recycling.

(Continued on next page)
Results and discussion

Seabream, oyster, clam, and shrimp had significantly different δ13C and δ15N values (p < 0.05). Seabream were enriched by 5.5‰ and 5.49 ‰ in 13C and 15N respectively compared to commercial feed. Mixing model indicated that commercial feed contributes for 72.7% while mussels contribute for 27.3% to seabream diet. Proportion of mussel used by seabream was higher than those distributed (14%). Such difference is probably due to a better appetite and/or digestibility of mussel than plant-based diet. Oysters were enriched by 0.35 ‰ and 3.03 ‰ in 15N and 13C compared to SPOM that is consistent with a consumption of SPOM. Oyster did not directly ingest fish aquaculture waste. However, oyster helped to regulate the level of SPOM (i.e., bloom of phytoplankton and zooplankton) that is boosted by the release of nitrogen and phosphorus by fish. Mixing model indicated that clam consumed 67.3% of SPOM and 32.7% of SOM. Clams were in competition with oyster for SPOM but helped to reduce the level of organic matter in sediment. Shrimp had the higher δ13C and δ15N values suggesting that they not directly fed on organic matter from sediment but had a carnivorous diet feeding on naturally present organisms in sediment. The results of this study confirm that seabream, oyster, clam, and shrimp have complementary diets and can be raised together in IMTA ponds.

Examining the genome-wide regulatory response of Atlantic salmon to viral infection is central to understanding the control of antiviral immunity. This study investigated the epigenomic and transcriptomic response to stimulation with the viral mimic poly I:C in Atlantic salmon. We employed ATAC-seq and ChIP-seq in combination with RNA-seq analysis to comprehensively examine changes in chromatin accessibility, histone modifications and gene expression. We identified a core set of 197 interferon-stimulated genes (ISGs) that were epigenetically modulated and highly upregulated in response to poly I:C. Fifty-four of these genes were also ISGs in rainbow trout, zebrafish, and humans, highlighting their evolutionary conservation. Our analysis revealed key transcription factors involved in the interferon response, including IRF9, STAT1, and STAT2. Regulatory elements showing increased activity to poly I:C were enriched in conserved vertebrate binding sites for STAT6, PRDM1, IRF6, JDP2, NR2E1, and BCL6, suggesting their central roles in the antiviral immune response. Focused analysis of Interferon Stimulating Response Elements (ISRE) indicated that genomic regions containing ISREs were modulated in response to poly I:C stimulation. Finally, we investigated differences in response to poly I:C stimulation among key ISGs retained as salmonid-specific paralogues, including MX, RSAD2, IRF9, DHX58, STAT1, IRF7 and CD9. This revealed paralogue-specific enrichment of ISRE motifs in promoter regions. Overall, this study provides novel insights into the regulatory mechanisms underlying the antiviral response in Atlantic salmon and underscores the significance of the epigenetic landscape in transcriptional regulation.

Introduction
Grey mullet (*Mugil cephalus*) is a promising omnivorous species for the sustainable diversification of aquaculture due to its low dietary nutrients requirements and the broad market for its roe (bottarga). Bacterial single cell ingredients produced by fermenting industry by-products represent a sustainable alternative of fishmeal and soybean meal (Glencross et al., 2020). The application of bacterial single cell protein (SCP) ingredient was assessed on growth, digestive enzyme activity and on the gene expression of PepT-1 at three different time T0 (0h before feeding), T1 (0/6h after feeding), T2 (6/12h after feeding). To the best of our knowledge, this is the first characterisation of digestive enzymes at different times in grey mullet under captive conditions and different diets.

Materials and Methods
Three isonitrogenous, isolipidic and isoenergetic experimental diets were formulated to contain increasing inclusion levels of bacterial SCP (SCP0, 0%; SCP10, 10%; SCP20, 20%). Diets were tested on triplicate fish groups of 45 individuals (initial weight: 67.9 g) over a period of 113 days. During the trial, feed was provided to apparent satiation during a 6 hours meal once a day, temperature was kept at 26.8 ± 2.5 °C and oxygen above 7.5 mg L⁻¹. At the end of the trial final body weight (FBW), specific growth rate (SGR), feed intake (FI) and feed conversion rate (FCR) were calculated. Digestive enzyme activity (total alkaline protease, trypsin, chymotrypsin, leucine aminopeptidase, α-amylase, bile salt-activated lipase), anterior and posterior intestine of brush border (aminopeptidase and alkaline phosphatase) and gene expression of PepT-1 were performed in three different times T0 (0h before feeding), T1 (0/6h after feeding), T2 (6/12h after feeding). Differences among treatments were considered significant at P < 0.05.

Figure 1. SCP0, SCP10, SCP20 diets at different times for total alkaline proteases, α-amylase, bile salt activated lipase. Differences among each treatment and its timing (T0, T1, T2) were considered significant at P< 0.05 and are marked with letters. Different symbols (*) stand for significant differences at P< 0.05 between times for the same diet.

Figure 2. SCP0, SCP10, SCP20 diets at different times for gene expression. Differences among each treatment and its timing (T0, T1, T2) were considered significant at P< 0.05 and are marked with letters. Different symbols (*) stand for significant differences at P< 0.05 between times for the same diet.

(Continued on next page)
Results
At the end of the trial, fish fed SCP0 showed a significantly higher body weight and SGR and a significantly lower FI and FCR compared to SCP10 and SCP20 ($P < 0.05$). Temporal variation of digestive enzymes activity in different diet is reported in Fig.1. In fish fed SCP0, total alkaline proteases activities, trypsin and chymotrypsin increased significantly at T1 in comparison to T0, followed by a decreasing pattern at T2. No significant temporal variation for total alkaline protease, trypsin and chymotrypsin was detected in SCP10 and SCP20. On the other hand, in T0 and T1 the SCP0 diet was statistically different from SCP10 and SCP20. No significant differences were found in T2. In leucine aminopeptidase fish fed SCP0 showed an increase significantly in T2 compared to T0 and T1 which gave the same results. The same trend has been found for other diets. Fish fed with SCP10 and SCP20 in T2 exhibited significant differences from T1 and T0 that followed the same values. Comparison between time with diet, it turned out that in T1 the diet values SCP0 were different from SCP10 and SCP20 values. No differences in T0 and T2. In fish fed SCP0 diet, $\alpha$-amylase was significantly higher in T1 than T0. No differences were found in the comparison between time with diet. In bile salt-activated lipase, fish fed SCP0 diet in T2 showed a significantly high increase compared with fish fed SCP0 in the other two times. No differences in the comparison between time with diet. The results measured in the intestinal brush border (anterior and posterior intestine) were very similar to each other. Significantly higher differences of aminopeptidase were encountered in fish fed SCP0 diet in the anterior intestine at T1 than fish fed SCP0 at T0 and T2. No significant temporal variation for aminopeptidase was detected in SCP10 and SCP20. No differences in comparison of time with diet. No significant temporal variation for alkaline phosphatase were found. Instead there has been observed a significant difference in the time-diet interaction. In the posterior intestine, alkaline phosphatase displayed an increase in fish fed SCP10 diet at T1 from SCP0 diet at T1. In the results of gene expression of PepT-1 as shown in Fig. 2, there was a significant reduction in the anterior intestine in fish fed SCP0 diet at T0 than T1 and T2. No significant temporal variation was detected in SCP10 and SCP20. No differences in the comparison time with diet. There was a significant reduction in fish fed SCP0 diet in posterior intestine at T1 than T0 and T2. In the comparison time with diet, it turned out that in T2 in posterior intestine the diet values for SCP0 were higher from the SCP10 and SCP20 values.

Discussion and Conclusion
The lower performance of $C. glutamicum$ SCP as a protein source for grey mullet is probably due to a particular organisation of the digestive system because there was incomplete protein utilisation of SCP due to poor lysis of cell-wall components and also associated with the captive conditions (failure in the development of a functional gizzard). Analyses of enzyme activity showed the important key role in the physiology of the grey mullet digestive system. Proteases, in particular, played a key role but were negatively affected by diet. The temporal variation of grey mullet is similar to that found in the literature for other Mediterranean species of commercial interest. These are the first results concerning the enzymatic activity of the grey mullet. This highlights the extreme importance of analyses of the physiology of the species and the most adaptable diet.

Introduction
Gut microbial communities are highly dynamic and respond to factors such as diet and host metabolism. However, there is limited knowledge on gut microbiota changes during the daily cycle. In aquaculture, the characterization of gut microbiome dynamics is necessary to identify and understand the relationship it have on host physiology and fitness. To investigate how interactions between feeding and water temperature affected the diel dynamics and activity of the microbiota, we performed two experiments with water temperature and feeding regime as experimental variables, respectively. The qualitative and quantitative composition of the active bacterial community in feces was analyzed along a day cycle in greater amberjack (Seriola dumerili) juveniles.

Materials and methods
In the first experiment, with water temperature as experimental variable, fish were reared in three independent RAS systems set to 18, 22 and 26°C, under a light/dark photoperiod and fed ad libitum three times daily with a commercial diet. In the second experiment, the fish had two different feeding regimes, continuous feeding or intermittent feeding (three meals per day), both under continuous illumination. Water temperature was maintained at 22°C. Sampling was performed along a 24h cycle. For quantitative abundance and activity, we quantified copy numbers of total 16S rDNA genes and rRNA per gram of feces by quantitative PCR (qPCR), and used these data as a proxy of absolute bacterial density and protein synthesis, respectively. RNA:DNA ratio was used as an approximation for the specific activity of bacteria. The qualitative composition of the active bacterial community was analyzed by rRNA-based amplicon sequencing.

Results
Results from the first experiment identified feeding as the main driver modulating the diel variations in bacterial community activity. A peak in bacterial activity (based on RNA:DNA ratio) was observed at 6 h after first meal for the three temperatures (Fig. 1).

The composition of the active bacteria community in fish feces varied in relation to postprandial time. At the order level, feeding promoted a decrease in the relative abundance of active Spirochaetes and an increase in Vibrionales. Although the relative abundance of active Mycoplasmoidales was stable throughout the day in all treatments, the absolute abundance of active bacteria peaked at first postprandial sampling (6 h) for this order, being the order mainly responsible for the increase in absolute bacterial activity. At the lowest water temperature, the diel variations were slower.

Results from the second experiment confirmed the role of feeding as a synchronizer of the diel dynamics of the activity of the bacterial communities in the fish gut. Fish fed continuously did not have significant daily variations either in quantitative or qualitative composition of the active bacterial community. By contrast, and in agreement with the data shown above, intermittently fed-fish revealed a peak in specific bacterial activity after the first daily meal and postprandial changes in the relative abundance of active bacteria along the day. At the order level, the composition of the active bacterial community in continuously fed fish was dominated by Vibrionales during the whole day cycle, with minor fluctuations in its relative abundance (Fig. 2).

PERMANOVA based on the Sørensen similarity indicated that communities’ composition from the two feeding regimes, based on the ASV table, were different depending on sampling time. Active bacterial communities were significant different at the beginning of the day, before the first meal was offered to the intermittently fed-fish (0 h, p<0.05) and close to being different (p<0.08) at the end of the day cycle (8 and 12 h after the last meal for the intermittent fed-fish).

(Continued on next page)
Discussion

This is the first study assessing the quantitative and qualitative effects of water temperature and daily feeding rhythm on the gut microbiota dynamics in a poikilothermic animal. 16S rRNA:rDNA ratio revealed a postprandial increase in bacterial-specific activity, pointing to feeding as the main driver of the bacterial activity dynamics. The most noticeable change in the composition of the active bacteria community was a postprandial increase in the order Vibrionales, but for absolute abundance, Mycoplasmoidales was the most responsive order. Thus, the absolute abundance of active bacteria is more suitable for analyzing bacterial dynamics in a community. Low water temperature affected the timeline of the diel pattern in bacterial activity by slowing down the response, probably due to a lower maximum growth rate of the bacteria and a slower gut transit time in fish.

The composition of active bacteria community in continuously fed fish kept an “active-feeder” profile throughout the whole day, with Vibrionales as the dominant order in terms of both, relative and absolute abundances. Sørensen similarity indicated significant differences in active bacteria community between “pre-feeding” and “active-feeder” fish.

Introduction
Growth rate in farmed fish is the phenotypic trait of major relevance for the aquaculture industry. Several strategies have been followed to increase growth rate in fish such as genetic selection and improvements in diet formulation. Somatic growth in fish, as in other vertebrates, is mainly controlled by the growth hormone (GH) / insulin-like growth factor I (IGF-I) axis. The molecular and physiological features of this axis have been thoroughly studied in several vertebrates. In fish, GH/IGF-I axis functionality in fish depends on endogenous and environmental factors such as genetic polymorphisms and nutritional status. There are now several evidences that fish GH-IGF-I axis can be modulated also by epigenetic mechanisms such as DNA methylation. However, the role of epigenetics in regulating this axis in fish is far from being understood as results, in addition to sparse, are poorly consistent among species regarding genes affected. The present study aimed to evaluate ex-vivo models for epigenetic studies in Sparus aurata and to provide the first assessment in this species of the putative role of DNA methylation on the modulation of GH/IGF-I axis.

Materials and methods
Gilthead seabream (Sparus aurata) fish (body weight 37 ± 0.8 g; mean ± sem) were maintained in 120 L tanks under optimal conditions for the species. Fish were fed by hand to apparent satiety (approx. 5% of body weight) twice a day with a commercial diet (Skretting). Fish were euthanized with overdose of 2-phenoxethanol and decapitated. Pituitaries and liver explants were culture in microplates in sterile 80% (v/v) L15, pH 7.4, 10% FBS, 10 mM HEPES, 100 IU/ml penicillin, 100 μg/ml of streptomycin, 2.5 μg/mL amphotericin B, 5.5 mM D(+) -glucose, and 380 mOsm, for 48 h at 23°C under 95% O₂ and 5% CO₂. Viability and functionality of explants were evaluated by histology and measurements of LDH, GH, IGF-I and antioxidant response. In the case of liver, several conditions were evaluated until good results obtained. The effects of DNA methylation effectors; decitabine (5-Aza-2’-deoxycytidine; DAC) and genistein (GEN) as DNA methylation inhibitors and S-adenosylmethionine (SAM) as the main donor of methyl groups for DNA methylation, were evaluated on the expression of several GH-IGF-I related genes in liver explants after 24 h exposure.

Results
Both tissue explants retained the morphology of corresponding tissues in control fish for 48 h. Culture of pituitaries for 48 h did not increase LDH in the media and glands retained its LDH content, kept GH values into the media indicating that GH cells retained its secretory activity, and only presented slight signs of oxidative stress. Initial attempts to maintain liver explant failed, with more than 50% of LDH recovered in the media after 24 h. Thus, we went through a series of optimization steps (changing agitation, number of washing steps, volume of media, size of explants and temperature) until explants kept their LDH and IGF-I content, and showed no signs of oxidative stress. The exposure of liver explants to SAM for 24 h did not produce variations in the expression of the genes studied. Likewise, the exposure of liver explants to GEN or DAC did not alter igf1, igfbp1a, igfbp1b, and igfbp2b expressions. However, GEN and DAC enhanced significantly igfbp2a expression, and decreased significantly the expression of igfbp4, ghri, and ghrii (Figure 1). Experiments are being conducted to assess the effect of SAM, GEN and DAC on the gh expression in pituitary.

(Continued on next page)
Discussion
Our results support the use of pituitary and hepatic explants in short-term (i.e., 24-48 h) assays, which is an experimental window equal or longer than that used, for instance, in 78% of research with other \textit{in vitro} approaches such as precision cut liver slices. Given that \textit{igfbp-2a} has been related with reduction in fish growth, that \textit{igfbp4} seems to exert growth promoting effects in some fish, and that hepatic GH receptors are crucial for initiating GH signal transduction, the gene expression pattern obtained after a 24 h exposure to GEN and DAC is indicative of impaired growth. These results indicate that some genes involved in IGF-I production are directly or indirectly modulated by DNA methylation and that a methylation environment may increase growth in this fish or preclude negative impacts on growth of environmental stressors. Studies are ongoing to identify the genomic regions involved and the \textit{in vivo} effect of surplus methyl donors in diets. Collectively, these studies will shed light on the potential to foster growth in this species.

Introduction
The sustainable growth of modern aquaculture must rely in the production of healthy and robust fish fed with diets overcoming the dependence on fish meal (FM) and fish oil (FO). Selective breeding and functional feeds should be keystones towards this development, though most of their synergies remains mostly unexplored. Certainly, recent studies in gilthead sea bream highlighted that selection for growth co-selects for a plastic microbiota capable of exerting a wide nutritionally-mediated metabolic response with less community changes (Piazzon et al., 2020). Otherwise, the use of feed additives as boosters of overall fish performance has expanded rapidly as an alternative to antibiotics and chemotherapeutics, with also the capacity to modify the gut microbiota and host transcriptional associations. However, we are far from establishing the ultimate mode of action of each feed additive for a given genetic background. To bridge this gap, we investigated the effect of a battery of feed additives upon gut microbiota and host transcriptomics in reference (REF) gilthead sea bream and genetically improved fish for growth (GS) within the PROGENSA® selection program.

Material and methods
Estimated breeding values ranged between -159.14 for REF fish and +223.18 for GS fish. The basal diet (CTRL; no feed additive) was formulated by Skretting to be a low FM diet (7.5%), completely devoid of FO. Feed additives (INVE Technologies) added to CTRL diet by oil-coating included a phytobiotic based on natural plant extracts (PHY), a mixture of organic acids (OA), and a Bacillus-based probiotic (PROB). After an acclimation period of two weeks with the CTRL diet, fish continued to be fed with either CTRL, PHY, OA or PROB diets until the end of the trial (97 days). At this end-point, tissue portions of anterior intestine (AI) were taken for transcriptional (RNA-seq) and AI scrapped mucus for adherent microbiota analyses, using the Illumina platform and RDP database. Additionally, AI and posterior intestine (PI) sections were used for histological survey.

Results
The GS fish presented higher growth rates and condition factors, lower feed conversion ratios, and an enhanced homogeneity in terms of microbiota composition, regardless of the additive. The PHY effects were especially remarkable in the intestinal transcriptome of higher growth GS-PHY fish, with a particular up-regulation of markers of epithelial integrity (vil1, chmp2a-b, vps4b), sphingolipid metabolism (degs1, elovl1, sgpp1, plekha8), high-density lipoproteins secretion to vascular tissues (abcg8, abcal, nr1h3), and bile salt-activated lipase and receptor (cel, nr1h4). Facing OA, the gut adherent microbiota of REF fish shifted towards a less pathogenic profile, with a reduction in Staphylococcus, Streptococcus, and Neisseria genera correlated with neutrophil degranulation genes. This profile showed inferred bacterial processes involving organic acids, such as ABE fermentation and TCA cycle, and was prone to exert vitamin K biosynthesis. The Bacillus-based PROB diet affected both microbiome and transcriptome features. Bacillus genus was stablished in the fish gut regardless of the fish genotype, and anti-inflammatory histology patterns were increased in the AI and PI of PROB fish. GS-PROB showed an increased proportion of the nitrate reducer Kocuria, and a reduction of the pathogenic Photobacterium damsela, in parallel with a better feed efficiency of GS-PROB fish than the rest of the groups. This group also showed the up-regulation of markers of epithelial regeneration and integrity (ezr, ncsnt, plec, and neurog3) in concurrence with the down-regulation of markers of protein synthesis, that correlated with Chromohalobacter, Enhydrobacter, Vibrio, and Acinetobacter.

(Continued on next page)
Concluding remarks

As a general rule, it was confirmed that the gut microbiota variability among individuals was drastically reduced in GS fish (Naya-Català et al., 2022). The intensity and the specific effect of a given additive upon host transcriptomics and gut microbiota varied depending on the genetic background (Figure 1). Thus, PHY only shaped the transcriptome of GS fish. Conversely, OA shaped the gut microbiota of REF fish, whereas PROB triggered changes in both host transcriptome and gut microbiota of both GS and REF fish. Altogether, this work has generated a list of taxa and transcripts associated to a particular feed additive and fish genotype, which might help nutritionists, breeders and farmers to know which microbial and host elements are susceptible to be targeted in order to preserve and improve the gut function of PROGENSA® farmed fish.

EFFORTS TO ADDRESS BIODIVERSITY IMPACTS OF AQUACULTURE IN INDUSTRIAL SYMBIOSIS

Ulf Nermark*, Thomas Parker

WA3RM AB
Drottninggatan 34
211 41 Malmö, Sweden
Email: ulf@wa3rm.se

Today, the strongest driver of increased demand for fish is growth in affluence, specifically in China and Southeast Asia, where population is no longer growing, but consumption is, now that consumers can afford it. As the natural fish stocks are exploited to the maximum, the supply of this seafood demand can only be satisfied through increased aquaculture production. It is essential that this is done through best practices to ensure the sustainability of the industry. WA3RM has initiated partnerships with aquaculture projects with the intention to play an important role in the development of modern sustainable industrial scale food production systems. We initially looked at it from the point of efficient energy use. Industrial waste, such as surplus heat, as well as CO2 and sludge are most often seen as costly problems. We look at them as very valuable resources. What we have realized though is that sustainable aquaculture must address more than this. The understanding of how the industry affects biodiversity is a necessity if we should develop land-based RAS as an alternative and as a complement to commercial fishing and off-shore aquaculture.

By making use of huge waste heat streams from large scale industry we will be able to invite fish farm operators to establish land-based operations in geographical areas previously not considered suitable. This will enable an all-year optimal production of several warm water species even higher up in the colder parts of the Nordic countries. WA3RM intends to assess any potential operator of fish farms at any of our project sites through a biodiversity and sustainability screening. This is one way to direct the aquaculture industry to think in a more structured manner to address the different sustainability impacts from the production, including the impacts from up- and down-stream activities. Such an assessment must of course also address the biodiversity related issues.

One of the major negative impacts of fish farming on biodiversity is that which is caused away from the farm operations, in the fish feed sector. Most of the commercially farmed species use formulated feed produced by the big feed manufacturers. All fish feed must be a complete feed with low feed conversion ratio to support healthy fish with a fast growth, minimizing volumes needed and effluent volumes produced. Most of the fish species farmed are carnivorous species and a portion of their feed must be based on fishmeal. This fish meal is to a large extent dependent on fishing of smaller pelagic species by large commercial fishing vessels. Such fishing is negatively affecting the biodiversity, as it is exploiting the wild stocks of fish that is part of the food chain of larger wild fish species and marine mammals. An additional biodiversity issue is that of by-catch of non-targeted species. It can be a direct threat to those species, but it could also mean that it is taking away a resource that could be used directly for human consumption. By discussing with operators and feed manufacturers/suppliers we aim to support the continuous improvement in feed quality for best possible feed conversion ratio and trying to minimize the content of fishmeal-based ingredients.

We will also promote farming of alternative species for lower trophic level aquaculture, species that do not need the inclusion of feed ingredients from fish meal. This will need a change in consumer awareness and acceptance of non-traditional food-fish species, and it will only happen over time.

We know there will be different biodiversity consequences depending on what source the protein/oil will come from. By minimizing the need for fish meal in the diet the industry will create an increased demand for replacement ingredients from the terrestrial ecosystem. This necessary crop production will need huge areas under cultivation which might convert ecologically sensitive areas and farmland used for traditional agriculture into mono-crop environments with the use of pesticides. An article in Nature (A 20-year review global aquaculture, 24 March 2021), mentions that feed accounts for more than 90% of the environmental impact from fed aquaculture production.

With the aim to create a more circular economy that supports biodiversity, we will also seek opportunities for valorisation of generated waste streams from the fish farm projects (nutrient rich sludge and processing waste) by connecting with other production entities i.e., algae farming and insect farming aiming for an increased replacement of protein and oils in fish feed away from fishmeal.

(Continued on next page)
Another threat to biodiversity is the risk of farmed fish populations escaping and mixing with the natural populations, as is often the case with large cage farming operations. This will not be a risk with our projects as the operators will only farm in totally closed land-based systems. This means there will be no risk of introduction of new exotic species either. The operators will have their own breeding and hatchery operation, or alternatively will purchase egg/larvae/fingerlings from suppliers that are certified disease-free. Efficient filtration systems will remove almost all nutrients to minimize negative impacts to the receiving ecosystem and the biodiversity. Sterilization units will ensure that the effluent will not release any pathogens/parasites that can affect the natural fish stocks, and there will be no use of medication or hormones that could have a detrimental effect on the organisms in the recipient.

Our project for large-scale indoor RAS for shrimp culture will also address the stress on the natural environment. With the closed intensive systems, we will be able to minimize the physical footprint and we will not establish projects in any ecologically sensitive areas. In this way, we will help lessen some of the problematic land use issues in the tropical areas where the species is predominantly farmed, where it in many instances has led to physical habitat damage along large coastal areas.

WA3RM has created a novel business model that through industrial symbiosis can support operators that meet our sustainability criteria with investment finance based on their own production design needs. WA3RM will develop the project, finance, and build the infrastructure based on the operator’s specific requirements, including the infrastructure needed for the most efficient utilization of the waste streams from the project processes. The WA3RM Developer Fund will own the real assets being infrastructure and real estate, while the professional operator will take full responsibility for the operations and pay a monthly rent.
DIGIRAS - A COMPREHENSIVE PROJECT ON MONITORING AND IMPROVING WATER QUALITY AND FISH WELFARE IN COMMERCIAL RAS PRODUCING SEA- AND FRESHWATER FISH

Introduction

Land-based Recirculating Aquaculture System (RAS) technology has been recognized as a promising alternative for sustainable production of seafood and experienced a massive development in recent years. The technology also has the potential as an alternative to “capture fisheries production” since overfishing is a key driver of ecosystem collapse and biodiversity loss in aquatic environments. Such systems facilitate the production of fish in closed environments, which allows a high level of control on water quality and fish health, as well as recovery and refinery of valuable waste streams. Even though RAS technology has existed for over 65 years and experienced rapid development in technology and production volume, it is still considered to be in its infancy. Issues related to water quality and fish health prevent it from reaching its full potential.

DIGIRAS is a trans-European project funded by the BlueBio Cofund program, where six R&D institutions and five industry partners from five countries have joined forces to generate knowledge and develop new solutions for improving fish welfare, water quality and sustainability in land-based aquaculture. This goal is realized by systematic acquisition of biological, physico-chemical and operational data from different facilities, testing methods to remove unwanted compounds from rearing water, developing new sensors and water treatment techniques, conducting experiments to develop machine learning assisted fish behavior analysis and assessing fish welfare. Assessment and integration of the acquired data are conducted employing advanced statistics and artificial intelligence.

Main results so far

- Detailed monitoring of the microbiota in built rearing environments and the corresponding host allowed for RAS-specific spatio-temporal bacterial community mapping and detailed host-environment microbiota interaction analysis for Atlantic salmon, yellowtail kingfish, sea bream, sea bass and Arctic charr.
- Bioinformatic pipelines for standardized sequencing data processing and an aquaculture sequence database have been established, both for bacteria and protozoa. Full metagenomes from fish and built environments have been acquired using Oxford Nanopore Technologies (ONT) sequencing technology.
- Different H₂S and off-flavor compound analysis methods have been established and tested. A novel H₂S sensor prototype with high sensitivity has been developed. Covalent organic frameworks (COFs) have been demonstrated to be able to remove off-flavor compounds from water.
- A stereovision camera system has been developed and successfully tested. In addition, a surveillance camera system was successfully used to record and analyze fish behavior deviations related to stress.
- The histopathological studies made on samples of gilthead seabream and European seabass revealed no severe pathological observations. A comprehensive list of protozoa species present in seabream and seabass samples has been generated.

(Continued on next page)
• Microalgae have been demonstrated as potent alternatives for the removal of nitrogenous compounds from RAS wastewater. AOP technology was shown to improve the degradation of off-flavor compounds in RAS wastewater.
• Fish behavior deviation is statistically correlated with increasing H₂S concentrations. Supervised machine learning assisted camera vision can be used to assess fish welfare and water quality.

Impact

A major impact of DIGIRAS is to contribute to improving RAS technology towards sustainable production and improve fish welfare by parameterization of process ses and digitalization. So far, significant knowledge and microbiological, water quality and production data have been acquired in commercial RAS for the production of five commercially relevant fish species. In addition, experimental data on fish behavior and microbiota deviations in response to H₂S exposure has been acquired. Moreover, innovative water treatment technologies employing advanced oxidation processes and microalgae
AGRI BENCHMARK METHOD: TYPICAL FARM APPROACH REFERING TO DIFFERENT AQUATIC SHRIMP PRODUCTION SYSTEMS

M. Niemann* and T. Lasner

Thünen-Institute of Sea Fisheries
Herwigstr. 31
27572 Bremerhaven (Germany)
E-mail: melina.niemann@thuenen.de

Introduction
Agri benchmark is an international non-profit network coordinated by the Thünen-Institute in Germany. Since 2001 cooperating partners have used the Typical Farm Approach to collect and analyse economic data from agricultural farms. The method has been adopted to aquaculture farms since 2015 [1; 2]. In 2019, the first steps were undertaken to apply the typical farm approach towards German beam trawlers fishing brown shrimps in the North Sea [3]. After the standard procedure of data collection via focus groups, a detailed profit and loss account provides the base for further analysis. In doing so, the collected production systems can be compared regarding their profitability, efficiency and productivity. Moreover, the application of scenario techniques enables valuable evaluations for policymakers concerning altering markets and framework conditions. Our presentation describes the method and evaluates its potential using examples of modelled fisheries and aquaculture.

Materials and methods
In the typical farm approach, a standard operational procedure (SOP) consisting of 5 steps allows identical international implementation across sectors. First, relevant regions and typical production systems must be identified by scientists. Statistics can give a first indication regarding regions and production systems. In step 3, data from the typical farm are collected preferably by conducting a focus group consisting of one or two scientists, one local expert and four to six practitioners, whose production system should be similar to the previously identified characteristics. A standard questionnaire is discussed within the expert group, aiming for consensus on each figure discussed. These figures feed into the Technology Impact Policy Impact Calculations model (TIPI-CAL) to analyse the data (step 4). The calculation takes into account physical, economic and environmental parameters. This results on a whole-farm level in a profit and loss account and on the enterprise level in a total cost calculation, which divides costs into cash costs, depreciation and opportunity costs. The data are adjusted until it is agreed on the dataset’s realism, accuracy and consistency [4]. In step 5 all prices are updated annually, while the farm’s or the vessel’s basic characteristics are updated every three to five years [4; 2]. In 2015 the SOP was applied by scientific partner Le Thi Thanh Huyen to analyse the profitability of Vietnamese black tiger shrimp farms. Sulanke & Berkenhagen (2020) created a profitability time series for a German brown shrimp fishing vessel for the years 2014 and 2018 by using the typical farm approach [3]. The vessel model is currently being updated.

Figure 1: Profitability of a Vietnamese black tiger shrimp farm in 2015 (VN-GIT-3) and a German brown shrimp fishing vessel (DE-CSH-34) in 2014 and 2019.

(Continued on next page)
Results of different shrimp production systems
As an example, different studies of shrimp production systems applying SOP were chosen. Following the SOP brown shrimp was identified as the most valuable coastal fishery in Germany according to statistics. A focus group was conducted in 2020 to collect data for a typical brown shrimp fishing vessel in 2019 (DE-CSH-34) 2014 was considered a typical year by the participants so that prices and costs for this year were also recalled [3]. The costs and prices for the typical vessel were updated for 2022 (in validation) with almost the same participants from the first focus group. By the full cost analysis profitability can be represented over time (Figure 1).

When looking at the German brown shrimp fishing vessel (DE-CSH-34), all costs were covered by the revenues in 2014, which characterises long-term profitability. But just five years later, in 2019, the revenues did not cover the cash costs, which made the vessel not even temporarily profitable. Costs have increased over time, partly due to inflation. The data show that the varying catches and volatile prices are decisive factors in the profitability of the vessel. Another example where the typical farm approach has been applied is the black tiger shrimp farm in Vietnam (VN-GIT-3). The represented profitability results of the farm, which is located in Soc Trang, Vietnam, produces for the region typical in earthen ponds and encompasses 20,000m² (Le Thi Thanh Huyen). At first glance, the black tiger shrimp farm had a high profit margin in 2015. However, data for opportunity costs were not collected. Therefore, the farm was at least mid-term profitable. The data identify the cost of feed and the high black shrimp mortality rate as decisive factors for the farm’s profitability.

Conclusion
A realistic model is only created when the costs incurred are discussed and recorded in the focus group. The substantiated results allow not only a status quo analysis but also the benchmarking of similar production systems in different countries. Furthermore, the influence of the introduction of new production techniques as well as new political framework conditions or economic shocks like COVID-19 on the company’s profitability can be estimated if these are incorporated into the model [5]. This allows a before-after comparison regarding the farm-level results, but also an evaluation of the relative merits of different scenarios.

UNRAVELING THE CORE GILL MICROBIOME OF *Sparus aurata* BETWEEN WILD AND FARMED POPULATIONS

E. Nikouli*, E. Mente and K. Kormas

1Department of Ichthyology and Aquatic Environment, University of Thessaly, 384 46 Volos, Greece
2Agricultural Development Institute, University Research and Innovation Centre “IASON”
Argonafton & Filellinon, 38221 Volos, Greece
Email: elnikoul@uth.gr

Introduction
In teleosts, skin, gills and gut are the major mucosal surfaces (MS) which also act as host-microbiota interface, where they can form mutualistic relationships. To date, numerous studies have revealed the importance of host microbiomes and the various factors (host associated or environmental) affecting their dynamics (Egerton et al. 2018). Despite that there is progress in research on fish microbiome there is limited knowledge on the microbial structure of natural fish populations and any differences that may exist in the composition between wild and farmed fish species. Wild fish microbiota can be used as a fish health indicator to improve production through innovative applications of microbiomes-tailored products, but also for other interventional strategies, such as conservation practices. In this study, we analysed the gill microbiomes of 20 wild-caught and 32 farmed Mediterranean gilthead seabream (*S. aurata*) specimens by 16S rRNA gene sequencing to detect structural and inferred functional differences between the two different sets of individuals.

Materials and Methods
In total 52 tissue samples of gills were collected from *S. aurata* individuals. The specimens obtained by experimental/scientific fishing in the Ionian Sea (Wild: n = 20; weight = 147.2 g ± 44.7) and by a distantly located (Aegean Sea coast in central Greece) commercial aquaculture open-sea unit [Farmed n = 32; weight = 127.4 g ± 185.7 (average ± SD)]. The farmed fish species were collected in 4 different time points across the aquaculture production cycle (between ~100 to 500 days after their transfer in the sea cages). After dissection with sterilized equipment, and prior to their storage, samples were rinsed with sterile particle free seawater, to reduce surrounding environment associated bacteria. Water samples (n=8) were taken from the sea cages and filtered by using 0.2-μm isopore membrane filters to enable comparisons of the microbial communities in the water column with those present on the fish gill. Total DNA was isolated from the collected samples using the DNeasy PowerSoil Pro Kit (Qiagen) and 16S rRNA gene sequencing was applied for the identification of their bacterial targeting the V3–V4 regions of the 16S rRNA gene. Sequencing was performed on a MiSeq Illumina instrument (2×300 bp). Raw data were analyzed on the MOTHUR v.1.48.0 (Schloss et al. 2009). PICRUSt analysis (Douglas et al. 2020) was applied to predict the genetic functions of the detected bacterial taxa. Statistical analyses performed in Past4 software (Hamme et al. 2001).

Results & Discussion
A total of 52 gill samples, collected from both wild-caught and farmed populations, along with 8 water samples, were analyzed for this study. The bioinformatic analysis yielded 4678 operational taxonomic units (OTUs), after subsampling to the size (n = 10313) of the smallest group. The wild group microbiota presented the highest number of unique OTUs, while 254 (5.9% of the total OTUs) were shared among the microbiomes of the two *S. aurata* groups. Overall, OTUs represented 33 bacterial phyla. Proteobacteria and Bacteroidota accounting for 75.78% of the OTUs abundance. The most abundant OTUs were identified as unclassified Burkholderiales sp. (Gills) and *Synechococcus* sp. (Water). PERMANOVA analysis detected significant differences (PERMANOVA: p < 0.001 using Bray–Curtis dissimilarity indices, 9999 permutations) in community composition between the gill microbial communities of the two *S. aurata* groups (Wild and Farmed) but also between host (Gill) and environmental samples (Water). The clear separation between *S. aurata* samples and Sea water, supporting previous findings suggesting that *S. aurata* and other fish species harbours distinct microbial communities compared to those found in their surrounding environment (Legrand et al. 2018; Quero et al. 2022). According to SIMPER analysis the average dissimilarity between Wild and Farmed group was 83.86% with only 6 OTUs presenting a cumulative contribution of 49.9%. It is noteworthy that in ordination of samples, based on the same distance matrix, all samples from the farmed group (except of those obtained during the initial sampling, which had spent the minimum time in the sea) clustered closely with those of the Wild group. The relative abundance of the predicted MetaCyc pathways from PICRUSt analysis revealed that the two groups do not differ significantly (ANOSIM, p = 0.0611) and their most abundant (relative abundance ≥ 1%) pathways are involved in Aerobic Respiration, Fatty Acid, Lipid and Phospholipid Biosynthesis, suggesting that despite the structural differences of the Gill’s microbiota, these bacterial communities have no specific metabolic pathways. The same analysis revealed that the predicted metabolic pathways of the water samples shared similarities with the gill microbiota of the farmed group (ANOSIM, p = 0.12), but there were significant different when compared to the microbiota of the wild (ANOSIM, p = 0.0001).

(Continued on next page)
Conclusion
Knowing wild fish microbiota, could contribute to unravel the natural microbiome variation and enhance our knowledge on microbial diversity and host-microbe interactions. Our study revealed that gill microbial community composition differs significantly between Wild and Farmed populations. However, these differences tend to decrease as farmed populations spend more time in sea. These results suggest that host genetic background and the habitat status, due to human intervention, affect the bacterial dynamics in *S. aurata* gills. In addition, the existence of a core microbial community and the similarities in metagenomic functions strongly imply a coevolutionary relationship between *S. aurata* and its gill microbiome. These findings highlight the importance of thoroughly exploring these host-microbe interactions and taking them into account when developing conservation strategies and designing microbiome-based approaches.

CAN FRESHWATER TREATMENT POTENTIALLY REDUCE ULCER OUTBREAKS IN LAND-BASED SALMON AQUACULTURE?

Kristian Nordøy*1, Helle Hagenlund1, Vebjørn Ulvang1, Henry Thomassen2

1LetSea AS, Sandnessjøen, Norway
2Fishbase Group AS, Dønna, Norway
Email: Knordoy@letsea.no

Introduction
At low temperatures (<4 °C), ulcer formations cause welfare and economic issues in the production of Atlantic salmon. However, this problem also persists in land-based productions at higher temperatures, contrasting with what is established at sea production. Seawater flow-through systems in land-based production of salmon is gaining popularity, which escalates the issues of bacteria-mediated ulcers. This is especially true for smolt; the stage of fish which is more susceptible to bacterial infections. We hypothesize that the ulcer outbreak is related to the relative increase in surface area the fish is exposed to as well as a function of the higher density to water exchange rates in tanks compared to the traditional sea cages. Although susceptibility to marine bacteria such as Moritella viscosa and Tenacibaculum sp. may be increased in tank production, the self-contained nature of the production method may simplify treatment without pumping fish or using well boats or tarps.

This project aimed to establish a link between starting density, skin health, growth rates, and wound formation in the production of Atlantic Salmon in tanks using seawater. When wounds were observed in the experiment, we explored the potential of freshwater treatment to combat the pathogenic marine bacteria.

Material and Methods
The trial was conducted at LetSea’s R&D Land facility in Northern Norway between January 2023 and May 2023. Smolts used for the trial were obtained from Kvarøy Smolt, Norway. At the start of the trial and with a mean weight of 135 g, the fish were randomly distributed amongst eight trial tanks (2 m^3) at an abundance of fish per tank that reflected 15 kg/m^3 (four tanks) and 20 kg/m^3 (four tanks). All tanks were given a continuous light regime and a 20-hour feed regimen aimed at 12% overfeeding daily. The tanks were all equipped with cyclone feed collecting systems. The feed chosen was a commercially available feed designed for strengthened skin health and minimizing wound formation. Water for the trial was derived from the facility’s saltwater intake, located 140 m below the surface and 700 from the shore. The water was treated with UV before usage.

Five days after the start of the experiment, the first ulcer outbreak was observed, and a freshwater treatment was performed. All fish were starved 48 hours pre-treatment. On the day of treatment, 10 fish from each of the eight tanks were taken out and scored for ulcers on the body and fins and for the loss of scales (all scores 0-3 based on Fishwell welfare indicators)1. Samples were taken for bacteriology, and PCR on starting and open wounds were performed. After sampling, four tanks were randomly chosen for treatment (two high-density and two low-density tanks). 8 ml Aqui-S Vet. sedative (to a final concentration of 4 ml/m^3) was added to all four tanks. This was done to minimize the impact of the handling itself. Earlier trials also show Aqui-S reduce loss of blood chloride during freshwater treatments in Atlantic Salmon as well as reduces both cortisol and lactate formation during handling (results not published yet). The water column was reduced to 20 cm (20 % of the original volume), and 2 m^3 of fresh water was added. New salinity was measured, and the fish was kept under observation with continuous measurements of CO₂ and oxygen. The treatment lasted three hours. After the completed, treatment saltwater supply was turned back on, and new samples were taken from the handled fish.

Results and conclusions
Our results show that there were no clear differences in wound formation on the body or fins in tanks between low and high-density groups. It should be noted that body wound scores of 2 and 3 were only presented in high-density tanks. The freshwater treatment operations were successful, with little to no observable stress on the fish and only a drop in salinity to 2 ppt. PCRs taken from wounds before and after freshwater treatment showed little difference in CT values between pre-and post-treatment samples. Bacteriology showed positive results pre-treatment but no growth of either M. viscosa or Tenacibaculum sp. after treatment. No new wound formations were observed 30 days after treatment. The data on growth and FCR will be available in week 24, 2023, and will be presented at the conference. The current results suggest that freshwater treatments can potentially reduce marine bacteria-mediated ulcer formations and should be explored further.

TECHNICAL EFFICIENCY OF TILAPIA (*Oreochromis niloticus*) CAGE CULTURE IN BADAGRY, LAGOS STATE, NIGERIA

Nwanna, Lawrence*, Damian Ani and Mary Oloruntoba

Department of Fisheries and Aquaculture Technology
Federal University of Technology
Akure-Nigeria
Email: drlel@yahoo.com

Introduction
Cage fish culture is gaining more grounds in Nigeria as a means of augmenting total fish production and supply. This study investigated the technical efficiency of Tilapia cage farming in Lagos State, Nigeria.

Materials and methods
Data were collected from ten commercial fish farms in Afowo Community, Apa, Badagry, Lagos State with the coordinates (6° 25' 672” N, 2° 50' 809” E). The farms used net cages to raise Nile tilapia (*Oreochromis niloticus*). Each farm had different cycle lengths because the time to achieve the final average weight of the traded fish (~800 g) was different. The cycles were 6 months, 5 months and 8 months.

Sampling and analytical technique
Random sampling technique was used to select farms where the data were collected. This technique ensured representative sample, reduced sample error, increased generalizability and ethical considerations. Data were gotten using well-structured questionnaires and personal interviews. A stochastic frontier production model using the Battese and Coelli (1992) approach in R programming was applied in data analyses. The model decomposes total factor productivity into a technical efficiency component and an error component. The production function involves the use of one output and six inputs and farm, including stocking density, feed, labour, fuel (energy), utility (operational) and other relevant production costs, as presented in Table 1. The model is of the form: \( Y_i = f (X_{ik} ; \beta_k) + \varepsilon_i \ i = 1, 2, \ldots n. \)

**Introduction**

The Nile tilapia (Oreochromis niloticus) is one of the most common aquacultured species globally and is one of the most important farmed species in Nigeria. Despite the remarkable global growth of aquaculture, the sector still faces serious challenges in Nigeria and other sub-Saharan African countries (Barley, 2022), which undermines growth and sustainability. With this, there is a constant need to improve existing knowledge and develop new diets using sustainable additives such as yeast derivatives. Brewer’s yeast is rich in nutrients and bioactive substances such as β-glucans, mannan-oligosaccharides, and nucleotides which have been demonstrated to improve growth performance, health, and immune response of farmed fish (Merrifield and Ringø, 2014). The present study was conducted to evaluate the potential of dietary supplementation of autolysed brewer’s yeast (ABY) to improve the growth performance, intestinal health, and immune response of Nile tilapia fry.

**Materials and Methods**

A 35-day feeding trial was conducted in a freshwater recirculatory aquaculture system at the University of Plymouth with Nile tilapia fry (0.45 g). Four hundred and eighty tilapia fry were randomly distributed into twelve (15 L) tanks (40 fish/tank). Four diets were formulated to meet the known nutrient requirements (NRC, 2011) of Nile tilapia (Table 1). The control diet had no brewer’s yeast while the other 3 diets were supplemented with ABY (CeFi® Pro, Leiber GmbH) at 1 g/kg (ABY1), 2 g/kg (ABY2), or 4 g/kg (ABY4). All diets were isonitrogenous and isocaloric. The fish were fed one of the four diets (n = 3 tanks) at 5% of biomass per day. Water quality parameters were monitored throughout the trial (temp. 26.1±0.5 °C, pH 6.93±0.41, dissolved oxygen 7.64±0.24 mg/L, NH_4 0.20±0.38, NO_3 24.73±13.52, and NO_2 0.03±0.03). At the end of the feeding trial, intestinal samples were taken for histological analyses and gene expression.

Growth performance was assessed by final body weight (FBW), mean weight gain (MWG), feed conversion ratio (FCR), specific growth rate (SGR), and survival (SUR) as described by Rawling et al. (2021). Intestinal samples were taken for histological appraisal of morphometry as described by Rawling et al. (2021). Data were analysed with one-way ANOVA and post-hoc LSD using SPSS v25 (significance accepted at P < 0.05).

**Results**

Fish fed ABY1 showed significant improvements (P < 0.05) of MWG, SGR, and FCR compared to fish fed the control diet (Table 2). All treatments displayed normal intestinal physiology characterised by extensive mucosa folds with simple lamina propria and intact epithelial barriers. No statistically significant differences (P < 0.05) of fold height or goblet cell count were observed (Fig 1).

**Conclusion**

Results obtained so far indicate that ABY at a low dietary inclusion has the potential to improve the growth performance and feed utilization of Nile tilapia fry. Ongoing analysis is being undertaken to assess expression of immunoregulatory genes and further intestinal morphometric assessments are being undertaken using light microscopy.

WHAT INFLUENCES THE DEVELOPMENT OF NEW PRODUCTION SYSTEMS IN NORWEGIAN SALMON AQUACULTURE?

SINTEF Ocean
Postboks 4762 Torgarden
NO-7465 Trondheim, Norway
E-mail: Thealuras.oftebro@sintef.no

Introduction
Norway is a leading producer of Atlantic Salmon (Salmo salar) globally. Despite ambitions of growth, production in conventional sea-based fish farming is curbed by challenges such as salmon lice and escape of fish. Technological innovation is seen as key to solving these challenges, and policies to develop new concepts for aquaculture have also been initiated by the government (Føre et al. 2022). In 2023, the Norwegian salmon aquaculture industry is becoming more technologically diverse with several new production systems including land-based, floating closed and semi-closed, and open ocean aquaculture systems emerging.

The objective of this study is to provide knowledge of industry actors’ perceptions of key challenges and opportunities related to new aquaculture production systems in Norway. This knowledge is important for regulation and discussions of what influences the future development of the industry.

Materials and methods
To explore industry actors’ perceptions of variables that influence the development of the salmon aquaculture industry in Norway, Fuzzy Cognitive Mapping (FCM) was used as a key method. The first FCMs were set up by the research group based on Vensim diagrams created during interviews with a selection of industry representatives (fish farmers and organisations). Fish farmers represented different production systems, and the interviews focused on key challenges and opportunities for each system, as well as key challenges related to the regulation of new concepts. Following the interviews, the FCMs were made using the software Mental Modeler which was used in a series of workshops facilitated by the research group in the period 2021-2023. Representatives from the same companies as the interviewees participated in the workshops. The workshops aimed at identifying key variables and evaluating their relation to other variables in the map. Mental Modeler is a software that allows us to show how one variable directly affects another variable by drawing arrows between them during the discussions.

Results
This presentation will include the FCM of more than 30 variables seen as important by the industry actors, as well as insight into the participants’ reasoning as to why and how key variables would affect other variables.

In the initial workshops, some key variables were access to area, salmon lice, delousing, need for competent personnel and energy infrastructure. Discussions showed that all new production systems needed suitable areas to grow and that high salmon lice levels are driving the technological development towards solutions that may solve this issue such as land-based. Furthermore, all new technologies require competent personnel to operate the systems, and a solid infrastructure for energy.

Participants were concerned with geographical and seasonal differences in their discussions, for instance related to salmon lice levels and delousing that will vary in different parts of the country and at different times of the year. Variables such as delousing were seen as technology dependent, since there are several delousing methods that affect for instance fish welfare differently and new solutions are continuously being developed.

The workshops were spread out in time, which allowed participants to make changes to the maps during the project period. The predictability in framework conditions for the industry became highly relevant in September 2022, when the Norwegian government introduced a suggestion to a new resource rent tax (grunnrenteskatt) for sea-based aquaculture to be implemented from 2023. The variable taxes and fees, that was not part of the maps from 2021-2022 was thus introduced in a workshop in the spring of 2023. Furthermore, the variable political and regulatory predictability (both nationally and locally) was added. Both factors were seen as crucial for variables such as willingness to invest and economic results.

(Continued on next page)
Conclusion
The Norwegian aquaculture industry is becoming more technologically diverse. Using FCM, this study has identified relevant variables that industry actors think is important for the development of the salmon fish farming industry. Looking into the connections between different variables allows us to discuss different scenarios that can be useful for industry, regulators, and researchers moving forward.

Acknowledgements
The study is a part of the project “Compareit”, a collaborative project to meet societal and industry-related challenges conducted in close collaboration with key industry actors in the Norwegian aquaculture industry. The project is financed by the Research Council of Norway, grant number 319647.

Introduction

Two new projects will be presented - FishEUTrust: European integration of new technologies and socio-economic solutions for increasing consumer trust and engagement in seafood products and Sea2See: Innovative blockchain traceability technology and stakeholders’ engagement strategy for boosting sustainable seafood visibility, social acceptance and consumption in Europe.

The projects were approved in 2022 within the Horizon Europe call “Sea to fork transparency and consumer engagement”. More information about the projects can be found at https://fisheutrust.eu/ and http://www.sea2see.eu/.

Concept

A network of FishEUTrust co-creation living labs (CLL’s) will be created in three diverse aquaculture regions: The Mediterranean, Atlantic and North Sea. CLLs actors will cooperate in developing and testing new technologies, products, services, policy instruments, planning tools, organizational forms, and governance arrangements. The technological development includes: (i) suite of tools for determining seafood quality, safety and traceability (Farm-to-Fork) integrating metagenomics, genetic biomarkers and stable isotope approach; (ii) digital technologies for traceability based on Product Passport and/or Blockchain, unique identification and labelling of product instances; and (iii) integrated smart control systems based on sensor technologies to monitor freshness and presence of pathogens, antibiotics and biotoxins along the seafood supply chain. Further FishEUTrust innovation platform will be design in an open way to integrate technologies for seafood transparency and connect consumers and other seafood supply chain stakeholders. It will be connected with other relevant European infrastructures, in order to enable an easy access to harmonised and validated data, tools and services needed to identify any socio-economic and cultural barriers in respect to increase the uptake of seafood as well as to support FishEUTrust businesses and education. The gathered knowledge will serve for educating and nudging the producers and consumers through gamification. The platform will provide access through two portals, one aimed for consumers and another for aquaculture and food producers from the EU region to provide data and to enable the promotion of their activities and the growth of new businesses.

SEA2SEE is an innovative European project which main goal is to make actors with sustainable seafood practices more visible to consumers thus giving them a competitive advantage. The objectives include: (i) to develop a co-creation approach to sustainable seafood transparency and traceability; (ii) leverage a set of awareness raising and educational practices to increase sustainable seafood consumption; (iii) develop a blockchain deployment model for seafood industry-specific traceability data collection; (iv) demonstrate the feasibility and advantages of the Sea2See blockchain model; (v) develop a standardized Life Cycle Assessment framework for identifying and quantifying the major sources of environmental impact. SEA2SEE’s ambitious goal is pursued with the development, implementation and validation of a blockchain-based platform that consolidates and analyses data from the seafood value chain, in a system that is flexible enough to adapt to changes in the value chain. This will be completed with professional and consumer applications to increase trust and social acceptance of sustainably fished and farmed seafood. New strategies for stakeholders’ engagement organised around site-specific but also seafood product specific value chains have been developed. A co-creation approach based on early-stage involvement of intended end-users, needs identification and feedback collection on the proposed Sea2See traceability innovation is being applied. Two feasibility demonstrators will be carried out - one for fisheries with one demo site (traditional octopus fishery in the Algarve, Portugal) and one for aquaculture with 3 demo sites (in Portugal, Greece and Spain). The use of innovative technologies of water quality and cloud-based software production management systems allow the farms to directly upload farm data to the blockchain. To secure the uptake and exploitation of Sea2See results and innovation technologies, Life Cycle Sustainability Assessment (LCSA), seafood safety and evaluation of the presence of certain non-frequent or emerging contaminants is carried out for each of the 5 case studies. The Sea2See project will contribute to significantly increase Trust, Traceability and Transparency of the European Seafood Sector throughout the value chain.
GENOTYPE-BY-DIET INTERACTION (G×D) FOR FATTY ACIDS AND FILLET FAT IN EUROPEAN SEA BASS *Dicentrarchus labrax*

Introduction
The content of essential ω-3 long-chain polyunsaturated fatty acids (LC-PUFAs), eicosapentaenoic acid (EPA) and docosahexaenoic acid (DHA) has proven to have beneficial health effects in human diets (Horn et al., 2020). An issue of major concern in the aquaculture industry is the replacement of fish meal and fish oil in aquafeeds with sustainable protein sources such as those coming from plants due to the fluctuating cost and the declining percentage of world fisheries production (Luptasch et al., 2004). The purpose of the present study was to identify the presence/absence of genotype by diet interaction using a plant-based and a standard commercial diet for the fatty acids and fillet fat in European seabass.

Materials and Methods
In the Palairos area (Western Greece), 520 European seabass were divided randomly to be fed with two different diets, a plant-based (N=300) and a standard commercial one (N=220). From all the fish, fin-clips were collected and genotyped using the MedFISH SNP-array (Peñaloza et al., 2021) and the following fatty acids omega-3, EPA, DHA along with the fillet fat were recorded at 665 Days Post Hatching. The fillet fat was recorded using a Distell fat meter, (Distell FFM-692, Old Levenseat, Scotland, UK) and Fatty acid composition was measured using gas chromatography paired with flame ionisation detector (GC-FID, Variant 3800 GC, Agilent, California, USA). Genomic data were filtered using plink and a bivariate animal model for each possible pair of diets per trait (omega-3, EPA, DHA and Fillet fat) was performed in AIREMLF90. For each trait, two heritability estimates along with the genetic/genomic correlation between them were calculated,

\[ Y = \mu + Xa + Zu + e \]

where \( Y \) corresponds to the matrix of each pair, \( \mu \) is the mean of the above traits, \( Z \) and \( X \) are the incidence matrices, \( a \) is the tank, \( u \) is the additive genetic effect utilizing firstly, the Genomic Relationship Matrix (GRM) and it is illustrated as \( N(0, G\sigma^2) \) (\( G \) is the GRM and \( \sigma^2 \) is the additive variance), and secondly, the Pedigree Relationship Matrix (PRM) and it is illustrated as \( N(0, A\sigma^2) \) (\( A \) is the PRM and \( \sigma^2 \) is the additive variance), and lastly \( e \) is the residual. Then, the breeding values (EBVs) for each bivariate animal model using BLUPF90 were calculated and used to estimate the ranking correlation between them using R.

Results and Discussion
The correlation for the ω-3, EPA and DHA, between the two diets ranged from 0.94 to 0.99, which indicates a weak genotype-by-diet interaction independently of the relationship matrix. Albeit, for the fillet fat a strong genotype-by-diet interaction was detected since the genomic correlation was 0.83 and genetic correlation was 0.39. Additionally, only for the fillet fat, the ranking correlation firstly between Genomic EBVs for the plant-based diet and the standard commercial diet was 0.38 and secondly, between the EBVs was 0.16. Those findings indicate a strong re-ranking of selection candidates per diet for the fillet fat. In literature, the presence of genotype-by-diet interaction (from weak to moderate) has been identified for weight and fat in the European seabass (Le Boucher et al., 2013; Le Boucher, et al., 2011)"ISSN":"00448486","abstract":"In the last years, the increase of aquaculture production has led to the evolution of feed composition with an increasing...

(Continued on next page)
substitution of fish meal and fish oil with terrestrial plant products. In the meantime, selective breeding of fish has been widely developed. The ability to grow on plant-based diets has recently been proven to be genetically variable, pointing out the interest to increase knowledge on the potential consequences of substitution of fish meal and fish oil on current breeding programs. Moreover, heritabilities of major production traits other than growth also need to be estimated in this new environment. Experimental rainbow trouts (about 3000. In our study, a genotype-by-diet interaction for the fat has also been found and the estimated genomic correlation is within the reported range of Le Boucher et al. (2013; 2011).

**Introduction**

*Lernanthropus kroyeri* is an ectoparasite that attaches itself to the gills of the European sea bass *Dicentrarchus labrax*. In a W. Greece site, the inheritance of the parasite count was previously estimated at 0.28 and showed a moderate genetic correlation with the body weight for the European sea bass (Papapetrou et al., 2021). A selected subgroup of the above population was genotyped and the genomic correlation with the body weight was harmonized with the above findings. Additionally, a GWAS analysis was performed revealing two putative QTL in linkage group 7 associated with the resistance to *L. kroyeri* (Oikonomou et al., 2022). In the present study, the significant effect of those putative QTLs in farmed fish stocks was validated, by genotyping healthy and infected fish from another open-sea trial using 30K MedFISH array (Peñaloza et al., 2021).

**Materials and Methods**

Fin-clips were collected from 222 infected fish with *L. kroyeri* (randomly selected), and 110 healthy fish from the same site (Astakos). The infestation of the fish was performed through natural cohabitation. The following logistic regression model was used in R to validate any significant effect of the putative QTL on the parasite infestation,

\[
Outcome \sim AX_{373127007} + AX_{373218583} + \text{Origin} \quad \text{(Full Model)}
\]

Where *outcome* is the vector of the presence or absence of the *L. kroyeri*, the *AX*\textsubscript{373127007} is the genotype of the highest SNP, based on -log(*p*-value), with 3 levels (CC, CT, TT), the *AX*\textsubscript{373218583} is the genotype of the followed SNP with 3 levels (CC, TC, TT) (Oikonomou et al., 2022). Both were fitted as fixed effects in the model. Additionally, the *Origin* of the fish was used in the model as a fixed effect, since fish from two different genetic backgrounds were used (2 levels). Apart from the Full Model, Reduced ones were also utilized, in which each time one of the fixed effects was removed. In total, three Reduced Models were evaluated. For all the reduced models, the effect of the redundant fixed effect was estimated, and for all the evaluating models, the Akaike Information Criterion (AIC) was used in order to validate the goodness-of-fit.

*Statistically significant results with *p*-value < 0.05

(Continued on next page)
Results and Discussion
When removing the effect of AX_373127007 or AX_373218583 genotypes from the full model, the \( p \)-value was less than 0.05 (Table 1). Those findings indicate that both SNPs are important and significant factors to the model. Furthermore, the Full model showed the lowest AIC which means that this model showed the best goodness-of-fit compared to the reduced models (RM). Nevertheless, those SNPs could be considered to be linked to a putative QTL affecting the infestation with \( L. \) kroyeri, since both contributed significantly to the logistic regression which was performed using populations with different origin in the present analysis. Our next steps will be to calculate the probability to be, infected or healthy, for each SNP genotype as well as for the combined SNP genotype in order to identify the desirable “resistant” genotypes as well as their interaction.

Introduction
Caudal fin abnormalities have been reported in reared fish with a variety of phenotypes (e.g., fin stricture and lack of rays, lateral bending, duplication) (Koumoundouros et al., 1997). Their frequency has been shown to be affected mostly by the rearing environment and nutrition (Boglione et al., 2013). In a recent study on the genetic basis of caudal fin in gilthead seabream, moderate to low heritability estimations were detected for the lack of caudal fin rays (Fragoulis et al., 2020). In the present study, a subgroup of specimens (307) was selected from the data of Fragoulis et al. (2020) and used to identify any potential QTL link to the caudal fin abnormality.

Materials and methods
A de novo linkage map which was constructed and presented by Oikonomou et al., (2022) using 498 offspring who belonged to 153 full sib families (from 53 dams and 45 sires) was used. Out of the total fish, the 307 offspring (113 families) were used in the present analysis, in which the lower principal caudal ray (PCR\(_{\text{low}}\)_N) was recorded at 39 Days Post Hatching. Four categories were detected for the lower principal caudal ray (7, 8, 9, and 10). A Quantitative Trait Loci (QTL) analysis was performed in QXPAK 5.0 software (Pérez-Enciso and Misztal, 2011), to identify QTL related with the PCR\(_{\text{low}}\)_N, using a maximum likelihood Variance Component Analysis, the polygenic component (pedigree-based animal model) and the QTL effect.

![Graph showing QTL analysis](Fig 1 (a) Linkage groups 1 and 21 (Oikonomou et al., 2022) (b) Quantitative trait loci (QTL) analysis of PClow\(_N\) in LG1 and (c) Quantitative trait loci (QTL) analysis of PClow\(_N\) in LG21

(Continued on next page)
Results and Discussion
Two QTLs in LG1 and LG21 were revealed from the Quantitative Trait Loci (QTL) analysis explaining 13% of the phenotypic variation each. In LG1, the highest peak of the LOD score was close to the marker Cdn12p0003i0 and in LG21 the highest peak of the LOD score was close to the marker Id-13, with p-value <0.05. In LG1, a QTL related to jaw-deformation (Inwards bending (bMa)) was also detected and linked to Cdn14p0004o13 (Oikonomou et al., 2022). Even though the present findings are promising, further investigation must be done to the QTL linked to the caudal fin abnormality using a higher sample size before it can be used via Marker Assisted Selection in a production breeding program.

References
Offshore aquaculture production technology production is promising and sustainable; it has the potential for food production security related to the global demand, circular economy biomass feed stocks, and protect and thereby preserve fragile ecosystems in the future. The major challenges are that the structure and species cultivation are subject to extreme ocean environmental forces, and lack of adequate system design to mitigate this risk, but also resists the forces at the rough sea itself. There is a need to develop robust cost-effective technologies and tools to ensure sustainability in offshore aquaculture cultivation of aquaculture species. Simulation modelling and advanced risk analysis of offshore technologies are conducted to introduce an efficient and improved method of cultivation that will meet challenging safety requirements and improve production. Submersible tube is a sustainable solution for offshore aquaculture. Simulation software Orcaflex is used for numerical modelling the design of the submersible system for marine aquaculture cultivation, that can withstand harsh ocean environmental force. The system comprises of a submersible tube connected through pulley arrangement to counterweight buoyancy devise, the tube can be controlled hydraulically inner tubes that can be filled with air or water. The system configuration is set up in the marine environment and is simulated with North Sea metocean data of designated farm sites. First principle modelling to determine equivalent Morison force of the system components, that is suitable for typical system design and analysis, is carried out for required for validation of the simulation to optimal performance of the system. The estimated load parameter is used in size the design of a culture system that will reduce the risk of system failure, potential loss of crop, and costly repairs, or replacement of the system components. This work presents the response of the system under the specified weather conditions of the North Sea. The work also presents the analysis of hydrodynamic loads, under varying waves and currents acting on the cultivation system and species. The model accounts for various environmental factors that may impacts the systems performance Figure 1 shows the simulation model of submerged system and Figure 2 presents the effective tension at the end of the tube. Figure 3 shows tubes buoyancy and pulley effort needed.

Introduction
The aquaculture industry has been working to develop innovative aquafeeds that can enhance fish growth and health while ensuring aquaculture sustainability from social, economic, and environmental perspectives. Macroalgae have emerged as a plentiful source of bioactive compounds, such as antioxidants, polysaccharides, and pigments, which hold significant value for aquafeeds. Previous studies on several fish species showed the potential of macroalgae to provide essential nutrients for aquafeeds, leading to improved fish growth, immune response, and antioxidant capacity [1,2].

Oxidative stress occurs when there is an imbalance between the production of reactive oxygen species and their elimination, resulting in oxidative damage [3]. Fish possesses a robust antioxidant defense system to protect against oxidative damage. This system comprises both non-enzymatic components and enzymatic mechanisms. Enzymes such as superoxide dismutase (SOD), catalase (CAT), glutathione peroxidase (GPX), and glutathione reductase (GR) play vital roles in this antioxidant defense mechanism, neutralizing reactive oxygen species and maintaining overall cellular balance and health [4,5]. The ability of seaweeds to function as antioxidants arises primarily from the presence of dynamic biomolecules. These biomolecules have the potential to mitigate cellular damage caused by oxidative stress [6,7].

Extensive research has been conducted to investigate the antioxidant properties of water- and ethanol-based extracts derived from Palmaria palmata, along with their potential to serve as natural antioxidants. The bioactivity of extracts can be enhanced by applying different treatments, highlighting the potential of P. palmata and its derived products for use as functional ingredients [8].

Thus, this study aimed to evaluate the effect of dietary P. palmata inclusion level (0, 7.5, and 15%) and submitted or not to an alkaline pre-treatment on oxidative defense mechanisms of European seabass (Dicentrarchus labrax) juveniles.

Material and Methods
Palmaria palmata was subjected to an alkaline hydrothermal pre-treatment, briefly: P. palmata was incubated with a 1N of NaOH, solid-liquid ratio of 4:3 (w/v) solution and autoclavated (121°C) for 30 minutes. Triplicate groups of 16 European seabass (initial body weight of 38.0g) were fed five isoproteic (48% dry matter basis) and isolipidic (18% dry matter basis) diets, namely, a control diet, with no inclusion of P. palmata, and four other diets including 7.5% or 15% untreated or pre-treated P. palmata replacing a plant feedstuff mixture of the control diet. The trial lasted 11 weeks, and during the trial fish were hand-fed twice daily, 6 days a week, until apparent visual satiation. At the end of the growth trial, the liver and intestine from 3 fish per tank were collected and stored at -80°C until enzymatic analysis. The enzymatic activity of glucose-6-phosphate dehydrogenase (G6PDH; EC 1.1.1.49), superoxide dismutase (SOD; EC 1.15.1.1), catalase (CAT; EC 1.11.1.6), glutathione peroxidase (GPX; EC 1.11.1.9), and glutathione reductase (GR; EC 1.6.4.2) was determined. The concentration of malondialdehyde (MDA) was determined as a marker of lipid peroxidation (LPO) level.

Results
In the liver, G6PDH activity decreased with the inclusion of either 7.5%-treated or 15%-treated and untreated P. palmata compared to the control diet. Moreover, increasing dietary inclusion levels from 7.5 to 15% of untreated P. palmata decreased G6PDH activity. Regarding hepatic SOD, 15% of untreated P. palmata increased SOD activity compared with the control diet. At the 15% inclusion level, fish fed with treated P. palmata had lower SOD activity than fish fed the 15% untreated P. palmata diet.

In the intestine, G6PDH activity was lower in fish fed 15% treated P. palmata than in the control diet. Within the 15% P. palmata levels, the alkaline treatment promoted a reduction of G6PDH activity. Compared with the control diet, dietary inclusion of 7.5% P. palmata decreased intestinal GPX activity. Regardless of the dietary inclusion level, alkaline pre-treatment decreased GPX activity. LPO levels were increased by the dietary inclusion of 15% untreated P. palmata, while the pre-treated P. palmata promoted a decrease of LPO to levels similar to the control diet.

(Continued on next page)
In conclusion, the present results showed that dietary inclusion of *P. palmata* decreased G6PDH, SOD, and GPX activity in the liver and intestine of European sea bass. Additionally, dietary inclusion of 15% untreated *P. palmata* increased hepatic SOD activity and intestinal LPO levels, while the pre-treatment restored LPO levels. Overall, these results suggest that including 15% *P. palmata* could jeopardize the antioxidant response of European seabass juveniles, but *P. palmata* alkaline hydrothermal pre-treatment allowed the restoration of the antioxidant defense mechanisms to those of the control.

Introduction
Among finfish, the diadromous subgroup (mostly Atlantic salmon and rainbow trout) account for 29.7 % of the overall aquaculture production and 37.8 % of the total aquaculture value. European aquaculture is a highly specialised sector. With the exception of rainbow trout, for each of the 10 major species in the EU at least a quarter of the total volume is farmed in one EU country. Among the 10 major species, rainbow trout (*Oncorhynchus mykiss*) is the most widespread: it is grown in 24 EU countries, either in inland freshwaters (84.2 %) or in the saltwater of the Northeast Atlantic (15.8 %), and mainly in tanks (64.9 %). Three countries together accounted for more than half of the total weight: Italy (17.9 %), Denmark (17.3 %) and France (16.8 %). Most of the productive cycle of rainbow trout has been optimized over the last years; however, the very early embryonic development (from fertilization to eye development) still represents the most vulnerable phase during which entire egg batches loss can occur. In fact, during this early developmental phase, several factors, pertaining to eggs, environment and operational procedures can influence on the hatching rate of fish. Egg infections of ubiquitous Oomycete species, *Saprolegnia* sp., other pathogens, as well as poor egg management may cause annually great losses in production of rainbow trout, becoming a major contributing factor to economical loss in aquaculture worldwide. Several methods including UV sterilizers, formalin, hydroxide peroxide, and ozone have been used to contrast microbial spread; however, most of hatcheries still rely on the manual removal of the whitish eggs. The production of a technological automatic system, able to identify and quickly remove the infected eggs is thus necessary to reduce egg (-food) losses.

Materials and Methods
The present study is aimed at developing and validating an automatic system based on multi-spectral cameras to precociously identify, remove, and count dead trout embryos. Good and bad just-fertilized rainbow trout eggs, obtained from an Italian supplier, were immediately fixed in Formol, and stored at 4 °C until use. Preliminary acquisitions in the visible (VIS) and near infrared (NIR) spectrum were performed on batches composed by good and bad eggs. After placing the eggs on a net in a single layer, both VIS and NIR acquisitions were performed for each batch with or without water. Two multi-spectral cameras manufactured by XIMEA using the IMEC technology were used. The cameras were the MQ022HG-IM-SM5x5 (NIR) and MQ022HG-IM-SM4x4 (VIS). The NIR camera had 25 different spectral bands while the VIS one had 16 channels. Figure 1 shows the set-up we used to acquire preliminary data.

Results and Discussion
Images were acquired using the equipment described in the above section. The pipeline was based on several steps as: 1) image acquisition; 2) extraction of multi-spectral images for each channels with calibrated reflectance data; 3) manual labelling / annotation of images performed by an expert to draw bounding-boxes over each egg also assigning a class as good/bad/uncertain (training set); 4) AI algorithm to detect eggs and assign label based on reflectance data obtained from the training set. Figure 2 shows an example of VIS data.

Figure 3 shows an example of detection starting from collected data. The bad eggs have reflectance values higher than the good ones. The cost of a multi-spectral camera is a key aspect that should be considered. In a real scenario (production environment) the use of multi-spectral camera could be challenging considering the overall cost of the solution. The idea is to select a set of wavelengths that maximize the sensitivity of the detection of bad / good eggs. In this way a classical pass-band filter could be used on a monochrome or RGB sensor reducing the overall costs.

BIOLOGICAL PREMISES FOR ATLANTIC SALMON OFFSHORE FARMING.

Frode Oppedal*, Malthe Hvas & Ole Folkedal

Animal Welfare Research Group, Institute of Marine Research, 5984 Matredal, Norway
E-mail: frodeo@hi.no

Introduction

Parts of future increased production of Atlantic salmon (Salmo salar) may take place in offshore environments. Companies have sketched several potential technological solutions to be put out in the open, harsh, oceans with a range of connected service management tools. Within Norway, politicians are positive and legislation authorities have been steered to develop new regulations and review areas for offshore farming.

But will the salmon cope in offshore farming installation? What are the biological challenges for Atlantic salmon in offshore compared to less exposed cages? And do we have enough knowledge to produce salmon offshore? Can new farming technology be based on biological premises?

Materials and Methods

Over the last decades several projects have addressed biological challenges to the salmon in exposed farming and a review was presented by Hvas et al (2021). Since then, more sophisticated trial setups in swim tunnels, observations in the field, development of new tag technology and farming methods have been carried out together with variable advisory reports. This presentation will show and summarize some key recent findings.

Results and discussion

Atlantic salmon is an athletic fish species with a surprisingly high sustained swimming capacity that last for >72 hours at 80% of U_{crit} (critical swimming speed). In fluctuating water speeds mimicking wavy conditions, salmon unexpectedly display higher swimming capacities compared to constant speeds. Fasting seem to have negligible negative effects on swimming capacity and periods of non-available feed may not become problematic. From observations within a limited number of cages, salmon display deeper swimming during strong surface wave actions. Submerged farming technology with airdomes for swim bladder filling may be a future successful offshore technology. Three offshore areas for farming outside Norway is being reviewed based on distance from shore, wave and current characteristics, temperatures, pathogen spread, bottom characteristics, wildlife and other conflicting interests together with fish health and welfare. Typically, offshore installations are large and most sketched future farming technologies are longer and involves 5-10× the number of salmon per cage compared to present farming. It is debatably how large offshore cages can become and still provide adequate environmental conditions for the fish. Even in present cage technology low oxygen conditions are regularly seen. For some of the sketched enormous offshore cages, hypoxia might become a future challenge for the well-being of the fish. Offshore cage farming needs to be based on biological premises.

DIVERSITY AND ANTIBIOTIC RESISTANCE OF Splendidus CLADE (GENUS Vibrio) IN BIVALVE AQUACULTURE OF EASTERN ADRIATIC

K. Orlić*1, S. Kazazić1, D. Kapetanović1, I. Vardić-Smrzlić1, T. Buha1, A. Kolda1, J. Bolotin1, V. Kožul1, V. Nerlović4, S. Bobanović-Ćolić3, L. Perić1

E-mail: korlic@irb.hr

Introduction
Bivalves filter water as part of feeding process and accumulate large number of various particles and microorganisms, including the potential bacterial pathogens. One of the most relevant genera found in bivalve tissue is genus Vibrio, due to the fact that they cause mass mortality and huge economic losses in aquaculture. Among Vibrio pathogens, Splendidus clade is of particular concern due to numerus bivalve pathogens such as V. splendidus, V. crassostreae, V. tasmaniensis etc. (Destoumieux-Garzón et al., 2020). Additionally, one of the growing problems in marine environments is the emergence of antibiotic resistance due to the excessive use of antibiotics and anthropogenic discharges into the marine environment. However, antibiotic resistance in eastern Adriatic bivalve aquaculture has been poorly studied (Baralla et al, 2021).

Materials and methods
Focus of our research are two most important species in aquaculture in Croatia - European flat oyster, Ostrea edulis Linnaeus, 1758 and Mediterranean mussel, Mytilus galloprovincialis Lamarck, 1819. These species were sampled in two protected marine reserves – Lim Bay and Mali Ston Bay, locations which are known for bivalve aquaculture. We sampled seawater, sediment and bivalve tissue (hepatopancreas and gills) on both locations. For bacteria isolation, Vibrio selective medium was used (Tiosulphate Citrate Bile Salt Sucrose - TCBS). Subsequently, we identified Vibrio clades with MALDI-TOF mass spectrometry (Culot et al, 2021). Due to large number of isolates, we applied BOX-PCR genomic fingerprinting method as intermediate step for determination of differences between species and identification of clones (Canellas et al, 2021; Culot et al, 2021). As final step, we preformed Multilocus Sequence Analysis (MLSA) with three selected phylogenetic marker genes (gyrB, mreB and rpoD) for species identification (Pérez-Cataluña et al, 2016). Vibrio isolates belonging to Splendidus clade, were tested for antibiotic resistance via disk diffusion on Mueller Hinton agar for 13 selected antibiotics which are frequently used in aquaculture and medicine.

Results
MALDI-TOF MS results showed that more than half of all culturable Vibrio bacteria belonged to Splendidus clade. As we isolated large amount of Splendidus clade samples (n=688), we applied BOX-PCR genomic fingerprinting method as intermediate step for identification of clones which eliminated numerous isolates from further molecular analysis. Our final step of identification to species-level we preformed MLSA which resulted in phylogenetic tree, displaying clusters of two or three species, namely, V. splendidus-hemicentroti, V. tasmaniensis-atlanticus, V. crassostrea-gigantis-celticus, V. kanaloae-toranzoniae and V. chagasii-pomeroyi. Results of antibiotic resistance showed that more than 94% of all isolated bacteria belonging to Splendidus were resistant to one or more antibiotics. Furthermore, almost all isolates were resistant to vancomycin (96%). However, there is rising concern for antibiotics erythromycin, oxytetracycline and oxytetracycline due to intermediate resistance for around half of isolates. This study shows first report on the diversity and antibiotic resistance of Splendidus clade Vibrio species from bivalve aquaculture in Croatia and shows rising concern that on-going increasing anthropogenic pressures, might negatively affect bivalve aquaculture both with bigger susceptibility of farmed bivalves to colonization by Vibrio pathogens and with more resistant Vibrio bacteria.

DEVELOPMENT OF A QUALITY SCALE FOR THE PHENOTYPIC CATEGORISATION OF PUGHEADEDNESS IN GILTHEAD SEABREAM

P. Osaigbovo1*, R. Al Belbeisi1, G. Geladakis2, G. Koumoundouros1

1, Biology Department, University of Crete, Vasilika Vouton, 70013, Heraklion, Greece
2, Biology Department, University of Patras, 26504, Rion, Greece
Email: bio2p106@edu.biology.uoc.gr

Introduction
Skeletal abnormalities are a significant source of phenotypic variation in Gilthead seabream, which is mostly marketed whole (Fragkoulis et al. 2019). Deformities such as lordosis and pugheadedness exhibit a broad and continuous range of negative effects on external morphology, making the quality control and cull procedure cumbersome. This highlights the need for a precise and accurate quality scale linking the abnormalities' severity with changes in fish external morphology (Fragkoulis and Koumoundouros 2021). In the present study, a scale of quality was developed to quantify the effects of pugheadedness on the external morphology of Gilthead seabream.

Material and Methods
A total of 206 deformed and 70 normal fish (ca 400g mean weight) were selected from an unsorted experimental population, anaesthetized, and individually photographed. All deformed fish displayed pugheadedness that was not associated with severe malformations of the maxillaries and pre-maxillaries (Par type, Al Belbeisi et al. 2023). A geometric morphometric approach was employed to visualize and quantify shape differences among all fish. Specifically, Principal Component Analysis (PCA) was performed on the weight matrix (MorphoJ software package, version 1.07a) to study the deformity-induced body shape variation and test whether this variation could be related to Par severity.

Results & Discussion
Studied abnormality presented a continuous range of severity, mostly expressed as a distortion on the bending of the snout, without other obvious morpho-anatomical features (Fig. 1). The first principal component axis, PC1 (29.8% explained variation), contrasted between abnormal and normal fish, albeit with a slight overlap. Following their distribution along the PC1 axis, all the individuals were grouped into four classes and statistically compared. Differences in PC1 scores among the different classes were significant (p<0.05, Kruskal-Wallis and Mann-Whitney U tests), thus indicating the suitability of PC1 in classifying Par severity. Representative fish images for each of the Par severity classes are given in Fig. 1.

Fig 1. Left: Scatterplot of the first two principal component axes (PC1, PC2) depicting fish shape variation, including equal frequency ellipses. Spline diagrams demonstrate the components of shape change relative to the extreme values of PC1 axes (+3X). Right: Representative cases of the Par severity classes, as they were defined by PC1. Ab1, proximal part of PC1 range with only abnormal fish. Ab2, distal part of PC1 range with only abnormal fish. Mx, overlapping PC1 range of normal and abnormal fish. N, PC1 range with normal fish only. Par, Type I pugheadedness (Al Belbeisi et al. 2023). Scale bars equal to 1 cm.

(Continued on next page)
Deformities with similar phenotypic expressions but different ontogenetic and causative factors can develop in the same species, as is the case with pre-haemal and haemal lordosis. In Gilthead seabream, pugheadedness was shown to consist of two abnormality types, with significant differences with respect to their anatomy and recovery potential during the on-growing period (Al Belbeisi et al. 2023). The present study focused on the pugheadedness type that partially recovers (Par, Al Belbeisi et al. 2023) and developed a quality scale that classifies abnormal fish based on the severity of morphological deviation from the normal.

Our results could be applied by fish producers for the precise phenotypic scoring of pugheadedness in selective breeding programs and to improve precision for grading fish during packaging. In our next steps, we intend to test whether simpler morphometric indices (e.g., angles, bivariate ratios) could efficiently quantify the severity of Par abnormality.

SOLVING THE RAW MATERIAL CRISIS: A NORWEGIAN PERSPECTIVE ON DEVELOPING FUNCTIONAL INGREDIENTS FOR NOVEL AQUAFEEDS

Department of Animal and Aquacultural Sciences, Faculty of Biosciences
Norwegian University of Life Sciences (NMBU)
P. O. Box NO-1433, Aas (Norway)
E-mail: margareth.overland@nmbu.no

Introduction
Today, Atlantic salmon is Norway’s number two export in value, and the country wants to increase salmon production from 2 million tons today to 5 million tons by 2050. However, the industry faces multiple challenges, including a shortage of feed resources and high fish mortality due to exposure to multi-stressor conditions, such as sub-optimal nutrition, pathogens, environment, and handling stress, that need to be solved. To support further growth, we need to develop alternative feed ingredients from local underutilized natural resources that not only support high growth performance but also health and robustness of fish and that have low environmental impact. Microbial ingredients (MI) such as yeast and fungal proteins hold promise as alternatives; microbes have rapid growth rates, do not require agricultural land, use little fresh water, and can efficiently convert underutilized resources that do not compete with human food into high-quality proteins [1]. Thus, MI can meet the high protein demand of fish and they contain bioactive components with beneficial health effects. Foods of Norway, a Centre for Research-based Innovation at NMBU (foodsofnorway.net) and related projects, including NordicFeed, ForestFeed and Resilient Salmon are developing novel MI from local resources from forest by-products, animal by-products and food waste by biorefinery processing. Functions and applicability of these MI are evaluated during critical life stages of fish, such as during seawater transfer.

Results
Our results have shown that C. jadinii yeast produced from Norway spruce tree sugars contains about 50-58% crude protein and has a favorable amino acid composition. In general, diets based on C. jadinii supported high growth performance and improved health and robustness of Atlantic salmon [1-2]. We have also shown promising results on growth performance, health and product quality of C. jadinii-based diets under field conditions during the grow-out phase in seawater. In the Resilient Salmon project we have evaluated the use of hydrolysed Debaryomyces hansenii-based products (LAN4 and LAN6) in functional feeds during multi-stressor conditions to develop nutritional programming and to improve health and robustness of Atlantic salmon. Results showed that after exposure to an acute hypoxia, fish fed LAN4 were able to prevent the secretion of plasma cortisol and IL-10, which are both biomarkers associated with immunosuppression. In the gills, differential gene expression of metabolic pathways associated with stress tolerance and oxidative regulation were found. In the intestine, goblet cells maintained higher levels of mucin proteins, involved in the protection of the intestinal tract [3]. Interestingly, after the M. viscosa outbreak in seawater, plasma specific IgM levels against the bacteria increased in fish fed LAN6, in addition to an upregulation of genes related to humoral immune response and complement activation in liver.

Foods of Norway has developed a life-cycle analysis model on C. jadinii from Norway spruce tree sugars, which shows that this yeast has a low environmental footprint. However, a techno-economic analysis of yeast production shows that the price of the sugars has the largest impact on cost due to greater demand for biofuel. Considering this, we are developing a fungal protein Paecilomyces variotii (PEKILÓ®) that can be produced from a range of cheaper input factors to reduce cost. The fungal protein has a higher crude protein content of 60-70%. Our recent results suggest that P. variotii supports high growth performance and has immunomodulating properties.

Conclusion
To help solve the raw material crisis, we need to further develop biotechnology processing that enables the use of a broader range of cheaper input factors from various waste streams and gasses to produce MI. This will facilitate upscaling and reduce costs to meet requirements of the aquaculture industry.

SEASONAL STUDY ON THE REPRODUCTIVE STATUS OF MACROALGA *Codium tomentosum*

Teresa Pacheco*1,2, Maria Francisca Sál1,2, Isabel Sousa Pinto 1,2, Gonçalo Silva Marinho1,2
*corresponding author: p.teresa1310@gmail.com

1 Department of Biology, Faculty of Sciences of the University of Porto, Rua do Campo Alegre s/n, 4169-007 Porto, Portugal
2 Interdisciplinary Centre of Marine and Environmental Research, Terminal de Cruzeiros de Leixões 4450-208 Matosinhos, Portugal

**Introduction**

Macroalgae production has been gaining more support and recognition for its great potential, since these showed to have so many applications. However, the focus still remains in the same few species and diversification of seaweed production needs to happen, especially as other species have already been recognised for their potential.

*Codium tomentosum* is an important source of food and biomass with many bioactive properties [1;2]. This incites the interest of multiple industries, turning it into a highly desirable seaweed and consequently, raising the need for its cultivation. However, there’s a lack of knowledge when it comes to reproductive strategies and, therefore, cultivation approaches. This species experiences sexual reproduction as it releases gametes. Despite this, *C. tomentosum* is currently cultivated via fragmentation followed by vegetative propagation, which reduces the genetic diversity of the cultivated species.

In order to find alternative ways to produce this species, the gamete availability throughout the year should be studied. For this reason, this study focuses on the reproductive status of *C. tomentosum*.

**Material and methods**

Monthly, 20 specimens were collected in Praia da Paimó, Aguçadoura shore (41° 26′ N, 8° 47′ O), located in Póvoa de Varzim. The reproductive status was evaluated, through the observation (presence or absence) of reproductive structures, as well as their capability of developing to the next stages, gametes, zygotes, and early stages of development (germlings). These observations were followed through microscope. The specimens’ length was measured with a standard measuring tape and the mean was calculated.

**Results**

The samples were only considered reproductive (fertile), when it was observed the release of gametes, germination, and development of germlings. From 2020 to 2022, *Codium tomentosum* individuals were fertile from August to March and infertile from May to September, implying that this species follows a seasonal pattern.

From September to November, there was a significant increase in length, reaching its highest peak in November followed by a gradual decrease through the following months. The lowest peak was observed in April, gradually increasing until August.

**Discussion**

The natural population of *Codium tomentosum* collected from the Northern Portuguese coast showed to be reproductive from August to March as gametangia was present and germination occurred. As of April, the specimens collected were no longer fertile as germination did not occur. This coincides with the moment when the older *Codium* specimens on the shore are being replaced by new seedlings, immature ones, thus possibly explaining the infertility from April to July. Interestingly, the infertile specimens collected between March and July also presented lower observed thalli length, corroborating our hypothesis that these are immature juvenile specimens.

The lengths of the specimens for each month differs in both years (2020-2021 and 2021-2022). However, when analysing the pattern of the growth, for the entirety of the two years, the periods of time for the increases (Sept-Nov; Apr-Aug) and decreases (Jan-Apr) in length coincide.

(Continued on next page)
The months where the specimens weren’t fertile and the smaller lengths were observed, (April to July), coincide with the spring and summer months. This suggest that the conditions that influence the reproductive status are, most likely, temperature and photoperiod. Excessive radiation can reduce photosynthetic activity, leading to reduction in growth. Many seaweeds can suffer photo-inhibition during times of strong sunlight [3]. These occurrences happen mostly during spring/summer when the days have more sunlight exposure and temperatures increase. Therefore, the fact that the older Codium specimens start being replaced by the new seedlings during this time leads to believe that this seaweed uses this pattern as a strategy to grow and mature during the more favourable months. Corroborating even more the theory that Codium tomentosum does indeed follow a reproductive pattern through the year.

BIOLOGICAL AND ECOLOGICAL FEATURE OF TILAPIA (*Oreochromis niloticus*) IN THE CHICKAN LAKE DISTRACT DADU

Zameer Ali Palh¹, Khalid Hussain Lashari¹

Department of Fresh Water Biology and Fisheries University of Sindh Jamshoro

E-mail: alizameer735@gmail.com

Tilapia (*Oreochromis niloticus*) is an invasive fish species in Indonesia. A study on biological feature is expected to be used as an assessment to implement fisheries mitigation, restoration, and enhancement. This study aimed to analyze the ecological conditions, biological feature of the sex ratio, total length-weight relationship, maturity stages, and tilapia fecundity in the Chickan lake. Fish samples were collected four times in April to Dec 2022 using gill nets (mesh size of 3 inches). The sampling sites were 4 stations located in Chickan lake. Ecological parameters were measured, including water temperature, pH, Salinity, dissolved oxygen. Fish were measured for total length, weighed for gonads, and total weight.

- Water temperature ranged from 18.0-30.9 °C,
- pH ranged from 6.51-7.70,
- Salinity ranged from 5.04-8.39 mg/l,
- Dissolved oxygen ranged from 7-12ppt respectively.

The sex ratio of tilapia was 2:1.5 (females: males). Total length ranged from 90 to 360 mm, and total weight ranged from 15 to 780 g. The growth pattern of tilapia was positive allometric. The condition factor of male and female fish was 0.94-1.16 and 0.95-1.21, respectively. 36.8% of the female fishes were ripe stage (IV), and 65.8% of the male fishes were immature stage (I). The fecundity ranged from 28 to 7,852 eggs.
DOES THE LIGHT COLOR MODULATE STRESS DURING OUT-OF-SEASON REPRODUCTION OF EURASIAN PERCH FEMALES – FIRST STEP TO UNDERSTANDING

Introduction
Since the 1990s, the Eurasian perch (Perca fluviatilis L.) has been considered one of the key species for diversifying aquaculture in Europe (Fontaine and Teletchea, 2019). Despite the fact that commercial production of this species began over 30 years ago and is already established in some countries, research on its biology, larviculture, and reproduction technology in controlled conditions is still being optimized and developed (Żarski et al., 2017; Palińska-Żarska et al., 2020). One aspect that still requires in-depth research is determining the optimal lighting conditions, especially during out-of-season reproduction in Eurasian perch. This is especially important when considering the modulation of light as a tool to reduce stress during this critical period. In the present study, selected genes related to stress and immune response were investigated in response to different light colors (white, blue, and red) used during the controlled out-of-season reproduction of this species.

Material and methods
Pond-reared Eurasian perch females, obtained in early November, were transferred to a recirculating aquaculture system (RAS). They were then subjected to a 40-day wintering period before spawning. Throughout this entire period, the fish were exposed to three different light colors: white (W), blue (B), and red (R). At five specific sampling points (S), the females were anesthetized, and their livers were collected for RNA extraction (n=6 for each S) (Fig. 1.). Subsequently, qPCR was conducted to assess the expression of selected genes: hif1α (hypoxia-inducible factor 1α), tnfα (tumor necrosis factor α), hsp70 (heat shock protein 70), hamp (hepcidin), and lyz (lysozyme). The obtained data were compared using a two-way ANOVA, and differences were further analyzed through Tukey’s post-hoc test (p<0.05). All statistical analyses were performed using Statistica software developed by StatSoft.

Results
Two-way analysis of variance (p < 0.05) indicated significant interactions between light color and the expression of the genes encoding tnfα, hsp70, and hif1α, while there was a lack of significant interactions (p > 0.05) between light color and the expression of the genes encoding hamp and lyz. Furthermore, Tukey’s post-hoc analysis revealed significant differences (p < 0.05) in the expression of hif1α at S2 for all tested light colors, as well as hsp70, but solely in the case of R light. Additionally, a higher expression of hif1α in S3 was observed, specifically in W light (Fig. 2).

Discussion
One of the factors that significantly impact the induction of stress reactions in fish is the light color during rearing conditions (e.g., Maia and Volpato 2013). Therefore, the aim of this study was to address the question: Can different applied light colors during the out-of-season reproduction of pond-origin Eurasian perch, kept in RAS, somehow influence their stress levels? The used light colors did not yield significant differences in the maturation of females. However, the analysis of selected genes related to fish reactions to stress and their immune responses indicated that the light colors in which the spawners were kept significantly affected the expression of the hif1α and hsp70 genes (see Fig. 2). It was revealed that these light colors stimulated stress reactions in fish at the beginning of the wintering phase, before reaching the final oocyte maturation. Importantly, just before spawning, the levels of all tested genes were comparable. The results obtained suggest that varying light colors indeed significantly influence stress reactions in fish during their adaptation to rearing conditions in RAS. However, these light colors do not directly impact the final reproductive outcome. Similar stress reactions to different colors were observed in goldfish (Carassius auratus), where B and R colors induced chronic stress and immunosuppression (Eslamlo et al. 2013). These preliminary observations need in-depth exploration of additional stress and immune-related parameters. Considering the distinct reactions of Eurasian perch females to different light colors and their welfare, it is advisable to employ W light to minimize stress associated with fish adaptation to RAS conditions, whenever possible.

**Introduction**

Ballan wrasse (*L. bergylta*) has become a popular choice of biological control against sea lice infestation in salmon farms in the UK and in other salmon-producing countries in Europe. They are stocked in cages with salmon where they stay throughout the ongrowing period of up to 2 years. This consequently subjects ballan wrasse to seasonal changes in environmental conditions specifically water temperature which affects their delousing performance and welfare (Brooker et al, 2018). During winter, ballan wrasse has been observed to enter dormancy, exhibiting stunted growth and increased susceptibility to diseases (Erkinharju et al 2020). However, the basic understanding of thermal tolerance limits and tolerance range of ballan wrasse is lacking. In the present study, we determined the thermal tolerance limits of ballan wrasse and analysed the molecular changes following acclimation to different temperature and exposure to their thermal limits.

**Materials and Methods**

Hatchery-bred juvenile ballan wrasse were acclimated at a range of water temperature (6°C, 10°C or 14°C) for one week. Critical Thermal Methodology (CTM) was then performed wherein ballan wrasse from each group were individually placed in a challenge container and subjected to either increasing or decreasing water temperature until fish exhibit loss of equilibrium, indicating their upper (CTMax) and lower (CTMin) thermal tolerance limits. Gill tissues were collected from fish before and after they were subjected to CTM and analyzed for changes in transcriptome and methylation analyses.

**Results and Discussions**

CTM has shown that thermal tolerance of ballan wrasse shifts depending on acclimation temperature (Fig. 1). CTMax and CTMin values are lowest in fish acclimated to 6°C and highest in those acclimated to 14°C. Consistently, the thermal tolerance range was positively correlated with acclimation temperature. No prior estimate is available for the thermal tolerance limits of ballan wrasse although it has been shown that decrease in temperature is associated with significant decline in metabolic performance and aerobic scope which limits their tolerance to environmental conditions (Yuen et al 2019).

Preliminary results from transcriptome analysis show that acclimation temperature has an effect on the overall gene expression profile in the gills of ballan wrasse. Differential gene expression analysis between fish exposed to CTMax and CTMin is ongoing. In addition, DNA methylation data is being analysed to determine the epigenetic effects of acclimation temperature and exposure to thermal tolerance limit to ballan wrasse. This study will provide relevant information to improve our understanding of the physiological responses associated to temperature changes in ballan wrasse.

Introduction

*Ruditapes decussatus*, commonly known as the grooved carpet shell clam, is a commercially important bivalve species distributed throughout the Mediterranean Sea and the NE Atlantic Ocean. Its production has declined due to the introduction of Manila clam (*R. philippinarum*) and to environmental factors such as heat waves, low salinity and ocean acidification, as well as to several diseases, such as perkinsosis, caused by the parasite *Perkinsus olseni*.

*P. olseni* outbreaks have produced significant economic losses in the shellfish industry due to reduced growth rates and increased mortality. Clams can acquire the parasite through ingestion of infected water or through contact with infected individuals. Once inside, the parasite replicates within different organs, including the digestive gland and gills (Choi & Park, 2010). Control and prevention of *P. olseni* infections in *R. decussatus* has relied on a combination of management strategies, including monitoring and surveillance of infected populations, proper handling and disposal of infected individuals, and minimizing stressors that may weaken the immune system of clams (Ramilo et al., 2016). Despite management and prevention strategies will continue to play a critical role in reducing the impact of perkinsosis on the shellfish industry, understanding the genetic basis of the resilience to perkinsosis can facilitate developing breeding programs to obtain resilient strains for its control.

The aim of this study was carrying out a populations genomic screening to analyse the genetic structure of the grooved carpet shell clam to know its genetic structure across the Atlantic and Mediterranean areas and to use this information to identify outlier loci pointing to specific genomic regions associated with perkinsosis resilience.

Materials and Methods

High molecular weight (HMW) DNA was obtained from abductor muscle of one individual from the Atlantic area. Long-read Nanopore (50x) and short read Illumina (150 bp pair-end; 120x) sequencing was carried out for genome assembly. Furthermore, RNA from digestive gland, gill, mantle, haemolymph, and muscle of five individuals was extracted and equimolecular pooled by tissue for RNA-seq for genome annotation.

The Ray’s fluid thioglycollate medium (RFTM) histological method was used to evaluate the degree of perkinsosis infection from 0 (non-infected) to 5 (heavily infected).

Seven shellfish beds (~30 clams / bed) distributed across the NE Atlantic (NO: Noia, PO: Pontevedra, ALG: Algarve) and the Mediterranean Sea (SAR: Sardinia, VEN: Venice, NAP: Naples, TU: Turkey) coasts were sampled (Fig. 1). One sample was never in contact with the parasite (naïve), while the other seven were long-term affected. 2b-RADseq genotyping was performed using STACKS program taking the assembled draft genome as reference. The whole genotyping data was used to ascertain genetic diversity and population structure considering the geographical hierarchy (GENEPOP, ARLEQUIN, STRUCTURE). Outliers showing signals of divergence over the neutral background were identified across the species distribution range (BAYESCAN, ARLEQUIN), but also considering the different degree of perkinsosis infection of samples estimated by histology.

(Continued on next page)
Results

The draft genome *R. decussatus* rendered a C-value of 1.77 Gb, assembled into 1,220 contigs (N50 = 1.83 Mb) and BUSCO annotation close to 95%.

A total of 23,968 consistent SNPs were identified after filtering using the reference genome. Genetic diversity was significantly lower in the Atlantic than in the Mediterranean Sea shellfish beds (He: 0.137 vs 0.179). Genetic structure analyses differentiated two main clusters including the Atlantic and the Mediterranean beds, respectively (Fig. 2). Within the Mediterranean cluster, the Venice sample seemed a population in-between the main clusters, suggesting restocking with seed of both origins. Using the neutral structure as background, 56 outliers showed consistent signals of divergent selection across different levels of infection, suggesting their potential for marker assisted selection programs.

Conclusions

Genomic resources are very valuable to manage and restore depleted beds of molluscs. Here we present a first draft genome of *R. decussatus* that was applied for RADseq genotyping across the distribution range of the species. Two main regions were identified to be considered in restoration programs and a set of outlier markers could potentially help in the production of strains with improved resistance to perkinsosis.

Introduction
The cockle shellfish beds of the Ría de Arousa (Galicia, NW Spain) were devastated in 2012 by the protozoan parasite Martellia cochillia responsible for marteliosis. The annual outbreak of this parasite threatens production and the ecosystem services provided by cockles. In 2018, Villalba et al. (2021) suggested the presence of naturally resilient stocks, when compared their survival to naive cockles (never in contact with the parasite) from a northern estuary (Ría la Noia).

Generating preventive measures against parasitic infection is complex due to the lack of knowledge of the parasite’s biology and the difficulty of fighting against a parasite in a natural open environment. Therefore, developing resilient strains against M. cochillia through breeding programmes is an appealing approach, previously applied in other molluscs to control the impact of the parasite and restore cockle beds.

This study aimed to identify candidate genetic markers, single nucleotide polymorphisms (SNPs), associated with resilience to marteliosis for developing and validating a cost-effective genomic tool to assist in the restoration of cockle beds and preventing economic losses due to parasite spreading to other areas. For this, a common garden experiment involving naive and long-affected cockle stocks was carried out in Ría de Arousa in 2021 using families founded at hatchery.

Materials and Methods
To identify markers associated with Martellia resilience we followed two complementary approaches: (i) population genomics (PGA) using 77 samples, 39 collected in 2018 from a long term affected shellfish bed in the Arousa estuary, Lombok de Ulla, before and after the annual outbreak of marteliosis, and 38 naive from 2012 before the first report of marteliosis in the area. Samples were genotyped using a 2b-RAD panel of 9.154 SNPs mapped on the cockle’s genome and used to identify outlier loci. (ii) transcriptomic (TA), where cockles sorted by infection degree were compared to identify SNPs associated with 767 differentially expressed genes (DEG) according to the infection status. SNPs from both approaches were filtered according to missing data, heterozygosity (He) and technical criteria, to select the most consistent SNPs to be genotyped using a MassARRAY platform.

For the common garden experiment, mature breeders (400 individuals) from naive and long-affected shellfish beds were used to produce families at hatchery. After a pre-growing stage in a raft, 300 cockles from each stock were settled in two shellfish beds in Ría de Arousa under marteliosis pressure. Prevalence and mortality were recorded through histopathology. Individuals were histologically classified according to the level of infection and genotyped with the SNPs panel selected (183 naïve, and 197 long affected).

Results and Discussion
From the TA, a total of 121 DEG-SNPs showed significant differentiation depending on the cockle’s infection degree and another 110 outlier SNPs from the PGA were selected and mapped in the cockle’s genome. Finally, a panel of 45 SNPs including both approaches were combined in two multiplexes to be genotyped in a MassARRAY platform. Results from the common garden experiment showed that the naive stock was fully depleted after four months in both shellfish beds, while

(Continued on next page)
the affected stock barely showed marteiliosis. Among the 45 selected SNPs, 28 showed significant divergence between naive and long affected beds (p value <0.0012; Bonferroni correction), despite no significant differentiation was detected with neutral markers, suggesting they were involved in directional selection after eight generations of marteiliosis pressure (long-term selection). Furthermore, 11 SNPs showed significative differentiation in the short period affecting the naive stock (short-term selection), most of them shared with those from the long-term comparison. Several SNPs were located within relevant immune genes pertaining to families such as proteasome, ubiquitine and glutation S-transferase.

Conclusions
Common cockle became resilient to marteiliosis after eight generations of selection. The genomic approach followed to identify SNP markers associated with resilience proved to be useful and a total of 28 SNPs are candidates to be applied in marker assisted selection programs to manage common cockle shellfish beds. Some of these markers are within genes involved in critical immune functions. A SNP panel can be applied to recover common cockle shellfish beds in Galicia.

Funding information
This study was possible in part due to funds granted by the European Union through the project COCKLES (EAPA_458/2016) and the Marine Science Programme for Galicia funded by the Resilience and Recovery Funds.

VALIDATION OF A METHODOLOGY FOR APPARENT NUTRIENT DIGESTIBILITY AND FAECAL COLLECTION BY SEDIMENTATION IN PIKEPERCH (Sander lucioperca)

E. Panana* and S. Teerlinck
Inagro, Practical Research Aquaculture Center
Ieperseweg 87 8800 Rumbek-Beitem (Belgium)
E-mail: edson.pananavillalobos@inagro.be

Introduction
In aquaculture, the evaluation of feed ingredients is essential for the development of high quality aquafeeds. The determination of nutrient digestibility is the first step in evaluating the potential of an ingredient for use in the diet of an aquaculture species. This information is very useful for formulation of diets that maximize the growth of fish, by providing appropriate amounts of available nutrients, but also to limit fish waste products.

Over the last decades, apparent digestibility coefficients (ADC) of dry matter, crude protein, crude lipid, gross energy and phosphorus of different ingredients have been determined for different aquaculture species. However, different methods of feces collection (dissection, stripping or sedimentation) and different inert markers (chromic oxides, celites or yttrium) have been used, which often makes it difficult to compare results. Moreover, there is a lack of information on the ADC of ingredient in emerging aquaculture species. To our knowledge, no reports are available for the ADC of nutrients in pikeperch (Sander lucioperca). The objective of this work was to validate feces collection by sedimentation for the determination of ADC in macronutrients and phosphorus in pikeperch using yttrium as inert market.

Material and methods
The trials were conducted in a recirculating aquaculture system (RAS) consisting of 12 circular tanks (750-L/tank), a drum filter, moving bed filter, UV filter and an oxygen tower. Each tank was connected to a 200-L settler for feces collection.

A practical diet, 52% crude protein, 17% crude fat, 20.5 MJ/kg gross energy and 0.02% Yttrium (Y₂O₃) as inert market, was used in two trials. In the first trial, fifty pikeperch (body weight: 109 ± 9.8 g) were stocked on each tank for ADC determination. For three weeks, pikeperch were fed once a day until apparent satiation. The feces were collected after 18 hours, in cold plastic tubes connected to the bottom of the settlers, and stored at -20°C until analysis. The feed and the feces were analyzed for proximal composition of macronutrients, phosphorus and yttrium. The ADC was calculated using the formulas described by Glencross BD et al. (2007).

In the second trial, feces collection using three different strategies was determined. 1) one feeding per day-feces collection after 18 hours; 2) one feeding per day-feces collection after 21 hours; 3) two feedings per day-two feces collection: after 6 hours and after 18 hours. The percentage of feces recovery; feces production and dry weight of feces were determined.

The results of both trials will be presented and discussed during the EAS2023 percid session.

**Introduction**

Sperm cryopreservation is one of the leading, yet sophisticated techniques to employ both in research purposes and aquaculture production. It has already been reported that sperm cryopreservation may affect the transcriptomic profile of the progeny (Wang et al., 2022). It is, therefore, justified to hypothesize that by implementation of cryopreservation technology, possibly modifying cell physiology and/or affect structure of the cells retaining fertilizing capacity, a paternal-effect genes – being poorly explored in Teleosts – can be identified. Such strategy has a potential to elucidate paternal contribution to progeny quality what may be used by aquaculturists to fine-tune the selective breeding operations.

This study aims to explore the transcriptomic and phenotypic consequences of progeny obtained following usage for fertilization either cryopreserved or fresh semen in Eurasian perch (*Perca fluviatilis*), our model of commercial interest, in order to identify paternal-effect genes in this species.

**Materials and methods**

The semen from wild males (n=6) were stripped, checked for their motility and concentration; divided a portion (~ 1.5 ml) of semen was cryopreserved as described by Judycka et al. (2021), and the second portion (~1.5 ml) was used as fresh semen. Fertilizations were done with eggs coming from each female (n=3) portioned equally, one for cryopreserved semen (group C) and the other with fresh semen from the same male (group F). Advanced larviculture was carried out as described by Palińska-Żarska et al. (2020) till 16 days post hatch (dph), while noting zootechnical parameters. Larvae at mouth opening (MO) stage and weaning stage were sampled for transcriptomic analysis.

Sequencing of RNA of larvae at MO from both groups were compared using RStudio (version 4.1.3) using the package DESeq2 (Love et al., 2014). Differences were considered significant when corrected p-values were inferior to α (α=0.05).

Quantitative real-time PCRs (qRT-PCR) were performed for the differentially expressed genes (DEGs), normalized using 5 housekeeping genes, to verify expression levels of those genes at MO stage and at the weaning stage.

**Figure 1:** Relative expression level of successfully qPCR-validated genes at mouth opening stage and their relative expression at the end of the rearing trial. * – p<0.05; ** – p<0.01; ns – non significant.

(Continued on next page)
Results

Embryonic survival rate was significantly lower in Group C than in Group F, and the Group C larvae had higher weight wise at their weaning stage. The remaining zootechnical parameters were similar in both groups. Transcriptomic analysis revealed 11 DEGs, out of which 3 genes were further successfully validated by qRT-PCR, namely pde6g, opn1lw1 and rbpl4 (Figure1). Interestingly, all the genes are responsible for the development of the eye and had higher expression at MO stage in Group C but later at weaning stage, the expression levels were similar in both groups.

Discussion

This experiment was done with the intent to not just check the effect of cryopreservation on progeny quality, but also to use the technique as a condition to reveal paternal-effect genes. Phosphodiesterase 6 Gamma (pde6g) is expressed in rod photoreceptors and functions in the phototransduction signaling cascade (Dvir et al., 2010). Long-wave sensitive Opsin (opn1lw1) codes for red opsins and are abundant in cone cells (Crespo et al., 2018). Retinol Binding protein 4 (rbp4l) has a role to play in retina development. Examples of signalling pathways for pde6g and opn1lw1 is G protein mediated phototransduction, for rod and cone cells (Zang n.d.). Abola et al., (2015) found rbp4l gene being important in pathways like retinoid signalling. Thus we may conclude that development of an eye and potentially other sensory capabilities as well as its functioning during the first days post-hatching is under the influence of paternal genome, probably via the methylene status of the sperm (Jiang et al., 2013).

References

The largest companies in salmon aquaculture are rapidly getting bigger due to organic growth as well as mergers and acquisitions, and the largest are now multi-national companies. There are two main explanations for this growth: 1) An attempt to become large enough to exploit market power, or 2) New technologies that increase the efficient scale. In this paper, we investigate the degree of concentration in each of the main production countries for Atlantic salmon, as well as globally for Atlantic salmon, all farmed salmon, and all salmon to account for the global nature of the market using Herfindahl-Hirschman Indexes. The results indicate a high degree of concentration in the smaller producer nations but not in Chile and Norway. Globally, the Atlantic salmon industry can be characterized as unconcentrated, and it becomes even more so when the supply of other farmed salmon and wild salmon is accounted for.
THE SAFE SOLUTION TO CAPTURE AND VALORISE WASTE STREAMS FROM COMMON CARP (*Cyprinus carpio* L.) POND FARMING

Introduction

Traditional pond aquaculture in CE Europe currently faces numerous challenges (e.g. water shortages, soaring production costs, subsidies-dependent production) that significantly affect profitability of the farms. To overcome this difficult situation farmers must use some ponds to secure production water when available in excess (e.g. heavy rains), diversify produced species or seek for solutions to use waste streams already available at a farm (SCAR-Fish 2020). A good example of a waste stream are suspended solids, widely available in discharged water when ponds are annually emptied to harvest market-size fish for the market or to transfer fish between the ponds for grading or wintering. Emptying the ponds is a traditional on-farm procedure. However, it releases a significant pulse of organic and inorganic matter to the creeks downstream the farm. One of the objectives of SAFE project is to reduce the environmental impact and improve the viability of the freshwater aquaculture by applying circular economy approaches to the valorisation of solid and liquid wastes from pond farms. Therefore, to reduce the impact of the farms on the river systems and to increase profitability of the farms the aim was to build a low-cost and low-tech system to capture suspended solids from the discharged water for further use in a production of beta-glucan-rich oyster mushroom (*Pleurotus ostreatus*).

Material and methods

To sequestrate solids suspended in the water discharged from drained ponds a multilayer barrier made of straw bricks (rye) was installed in the channel below the common carp farm (Fig. 1).

After 2 weeks of filtering out suspended solids, straw bricks were removed from the discharge channel and its suitability for oyster mushroom production was analysed (e.g. nitrogen content, organic matter, pH, fibres, pesticides). Subsequently, straw bricks with sediment were mixed with the conventional substrate for oyster mushroom production in ratios 25%/75% (A), 50%/50% (B) and 75%/25% (C). Additionally, two substrates made of 100% conventional medium for oyster mushroom production (CTR) and made of 100% of straw with captured suspended solids (D). Polypropylene bags with a gas exchange filter were filled with 3 kg of each substrate (10 replicates), and were sterilised at 121°C for 2 hours. Sterilized bags were inoculated with *P. ostreatus* H9 (Gurelan) spawn and incubated at 25°C. After 20 days, bags were placed in a cultivation room at 18°C. From each bag mushrooms were collected and weighed separately without removing stems.

Results and Conclusions

No pesticide residue was detected in the analysis of the straw bricks. Results of the physicochemical parameters and fibres are shown in table 1 and 2.

The mushrooms obtained from all the bags have been collected and the average kg of production of each bag has been calculated for the kg of substrate that each bag initially contains. The partial results obtained to date are those shown in Fig. 2.

As the freshwater ponds can accumulate from 0.76 to 3.2 t of sediments per hectare along the production season, the valorisation of suspended solids in mushroom production is a sound solution to curb release of sediments into river systems and at the same time increase profitability of the freshwater farms (Eymontt et al. 2017). Therefore, further studies should evaluate whether the oyster mushroom caps can be offered as safe and nutritious food items for human consumption. Whereas a typical by-product of *P. ostreatus* production, stalls, can be used as a beta-glucan rich ingredient of feed used to mitigate commercial fish production bottlenecks, such as increased mortality of young common carps during wintering.

Introduction

Tilapia lake virus (TiLV) is an emerging RNA virus posing a severe threat to global tilapia aquaculture and the food security of millions of people. The viral genome comprises 10 segments of negative-sense, single-stranded RNA, with segment 1 showing sequence similarity to PB1 of influenza C virus, while the remaining sequences show no sequence homology to any other known sequences. Due to its relatively recent identification, there is limited molecular characterisation of the viral proteins, with currently no specific treatments or commercial vaccines available to combat the infection. In this study, we aimed to characterise and elucidate functional properties of the TiLV proteome. Firstly, to confirm the presence of the major viral polypeptides and identify the protein composition of virus particles, samples prepared from infected cells and partially purified virus pellets were analysed by liquid chromatography and tandem mass spectrometry (LC-MS/MS). Secondly, we investigated the expression and cellular localisation of wild type and mutated TiLV proteins in vitro and in eukaryotic cells using synthetic cDNA constructs as a means of examining individual protein function and a platform for mutagenic assessment of potential functional domains. Overall, we identified 11 major TiLV polypeptides: one from each segment plus a potential accessory protein with a Crm1-dependent nuclear export signal. We identified the segment 5 (S5) polypeptide as likely to occur in multiple isoforms, at least one of which is a N-glycosylated membrane protein, and S4, S7, S8 and S10 polypeptides as likely structural components of the virion. We also identified a potentially secreted TiLV polypeptide, as well as a nuclear localisation signal in S2. Overall, our data provide a foundation for further functional characterisation of the TiLV proteome and the design of intervention strategies.

Introduction
The iFishIENCi project aims to demonstrate the viability of sustainable feeds that support the development of new production species with improved growth and feed utilization efficiencies. This involves the implementation of effective monitoring systems for fish health and welfare, as well as the adoption of efficient feeding practices that reduce the pressure on sources of fish-feed ingredients such as agricultural crops and wild-caught fish for fishmeal and oil. The project targeted several species, including Asian seabass (Lates calcarifer), rainbow trout (Onchorhyncus mykiss), and catfish (Clarias spp.), and employed a multidisciplinary and holistic approach at AquaBioTech group to develop feed and feeding technology in RAS.

Experiment 1
The Asian seabass, Lates calcarifer, is a popular farmed species with an established market, and its potential for expansion of barramundi farming worldwide has been noted (Lawley, 2010). However, the cultivation of this fish in a recirculating aquaculture system (RAS) needs further development (Larkin, 2000). The trial performed within the project compared the growth and body quality traits of Asian seabass reared at two different salinity levels in RAS, and tested the potential benefits of a microalgae extract (Nannochloropsis gaditana) for fish growth, health, and fillet traits. The study found no significant differences in weight, specific growth rate, and most body quality traits between the different treatments, but fish in higher salinity (S1) had a significantly higher visceral-somatic index (VSI) compared to those in lower salinity (S2). The microalgae extract did not have a significant effect on the growth, health, or fillet traits of the fish. These findings suggest that further research is needed to optimize the RAS culture of Asian seabass and to determine the potential benefits of microalgae extracts in improving fish growth and health.

Experiment 2
Catfish is one of the fastest-growing sectors in the aquaculture industry, and its production has increased significantly over the past few years (FAO 2020). Clarias is one of the most popular types of catfish, and its hybridization has been studied to improve growth and disease resistance (Rahman et al., 2018). Sustainable aquaculture production is crucial, and aquaculture sustainability requires reducing dependence on traditional raw materials (Shah et al., 2018). The experiment compared the growth performance, morphometric indexes and body colour intensity of hybrid catfish (Clarias gariepinus ♀ x Heterobranchus longifilis ♂) fed with a control diet consisting primarily of land-based and animal-based ingredients with two experimental diets containing Candida utilis at 10% and 20% inclusion levels. The results showed no significant difference in growth performance among the treatments. The bio-morphometric indexes also showed no significant difference. However, the red/green coordinate in the body colour intensity of the 20% inclusion diet was significantly higher than the control diet. The inclusion of C. utilis reduced the plant-based ingredients in the diets by about 14% and 28% but did not affect growth performance. The study demonstrates the potential of C. utilis as a novel and sustainable alternative protein source for the aquafeed industry. Although the results are promising, further investigation is required to evaluate the interaction among the ingredients in formulated diets and the relative effect on digestibility and gut impact in hybrid catfish. The study suggests that catfish farming is a valuable candidate for further investigation due to its growing interest worldwide and the development of related technology.

Experiment 3
To ensure economic benefits and efficient growth in aquaculture, appropriate feeding management is crucial. Inadequate feeding strategies can lead to low growth and feed conversion efficiency, resulting in increased labour costs (Wu et al., 2004). Temperature is also a crucial factor affecting fish growth and survival, as it affects physiological and biochemical functions. The gastric evacuation rate (GER) in fish is a significant factor affecting feed intake and digestion and it can be estimated through the serial retrieval of gastric contents, and the optimal feeding frequency is closely related to GER conditions (Seymour, 1989). Overfeeding can lead to negative consequences such as gastrointestinal overload and reduced food utilization efficiency (Jobling, 1986).

(Continued on next page)
This study aimed to determine the optimal feeding strategies for rainbow trout (Onchorynchus mykiss) at different temperatures (16±1°C, 18±1°C, and 20±1°C) by conducting a gut transit study after starvation for various time frames. The digestive tract of the sampled fish was divided into three parts (stomach; anterior + mid intestine, and posterior intestine), and the collected gastric content was weighed and stored separately. The wet and dry weights obtained after drying the samples at 60°C for 24 hours were used to calibrate a digital twin model (FishMet) for rainbow trout under different temperature. The results will be presented as part of the project implementation.

Introduction

The development of new technologies has transformed aquaculture from a traditional labour-intensive farming to a mechanized production with a gradual evolvement to automated systems (Fore et al., 2018). However, automated production requires highly skilled workers, affecting cost-effectiveness and resources such as water and feed are still impacted (Engle et al., 2019). The integration of AI in the aquaculture industry represents a new business form of modern aquaculture development (Wang et al., 2021). AI in aquaculture involves aspects like monitoring and control; feeding optimization; disease detection and management; water quality management and predictive analysis to improve profitability and sustainability.

The study aimed to improve the production control and management in aquaculture to maximise feed utilisation through smart feeding, providing continuous monitoring of fish behaviour, health, and welfare through the iFishIENC Biology Online Steering System (iBOSS). The study was conducted in Atlantic salmon, Salmo salar in RAS at AquaBioTech Group.

Materials and Methods

The trial was performed in a 12 x 650L RAS system equipped with UV disinfection (TMC Pro Pond 110); Drum filter (BaseDrum 15, Ratz); Protein skimmer (Tornado, Aquosis); Automatic feeders (Arvo-Tec TD 2000); swirl separator and camera (JideTech P2R-20X).

The development of the technology, testing and monitoring of the fish lasted for 16 weeks in which three phases were conducted, each serving a specific purpose.

Phase 1 aimed to develop and calibrate the real-time detection, tracking, and monitoring of fish, using 400 juvenile Atlantic salmon (mean weight of 13.6±0.01g) allocated to one experimental tank for 10 weeks. The fish were fed four times a day (at 9:00, 11:30, 14:00, and 16:00) with commercial feed by automatic feeder until apparent satiation.

Phase 2 focused on the assessment of the fish activity under different feeding regimes and development of a scoring system ranging from 0 to 2 to measure it. Fish were fed four times a day with a fixed feeding rate using commercial feed. The experiment lasted for three weeks, and the feeding rate was changed weekly (WK1 FR of 1.5%; WK2 FR of 0.75%; WK3 FR of 3%).

Figure 1: Feed amount provided per feeding event during phase 3 of the trial.

(Continued on next page)
During phase 3 of the experiment, the technology developed was tested comparing two different feeding strategies. One based on fixed feeding at 1.5% of body weight and the second based on the scoring system developed in phase 2. 200 fish of 60.58 ± 0.92g were allocated into two experimental tanks. The fish were fed four times a day using automatic feeders, as previously described.

**Results**

In phase 1, the fish detection and tracking was carried out using YOLOv5, a deep learning object detection model implemented in Python, and Norfair, a Python library that implements a tracker using Kalman filters. During phase 1, around 100 out of 400 fish were detected while at rest, and between 20 and 40 fish were detected during feeding. However, since the goal was to estimate the behaviour of the entire fish group, the percentage of undetected fish did not impose a limitation on the technology’s development.

In phase 2, fish movement was estimated globally by comparing two successive frames of the video. The difference between the frames indicated the level of activity exhibited by the fish. The algorithm used for this purpose was relatively lightweight and capable of running in real-time throughout the day. The raw difference between successive frames was calibrated during the preliminary trial to ensure its value could be centred around 1. The measured movement was then averaged from the start of feeding until 15 minutes after it ended, taking into account the resting time after feeding. The resulting average value represented the feeding score.

In phase 3, the feeding based on the scoring system (T1) showed multiple daily fluctuation in the amount of feed provided, reflecting the variations in hunger exhibited by the fish as showed in the figure below. The growth performance showed a higher growth rate and a lower FCR of fish fed at 1.5% of body weight (T2) compared to the fish fed using the scoring system (T1).

Introduction
Fish and seafood represent an important source of protein to support the increasing world population, which is set to reach 9 billion in 2037 [1]. The expansion of fishery and aquaculture sectors will produce, along with the proteinaceous biomass, increasing quantities of side streams and residuals, such as skins, heads, viscera, and fillet cut-offs. These side streams account for approximately 70% of processed fish [2] and can be used as a source of fish oil and fishmeal [3] as well as other bio-compounds that can be used by nutraceutical, pharmaceutical and cosmetic industry [4]. Some of the valuable fractions of fish side streams are collagen, enzymes, chitin, and minerals [5]. Fish side-streams are also used for biofuel production, and as a source of nutrients in fertilizers [6]. However, the utilization of this side streams is often hampered by logistical barriers. For example, the limited refrigerated space on the vessels is used for the fillets and the side-streams are stored at air temperature for several hours before being transported to a processing plant.

The aim of this study was to investigate the quality of different tuna side-streams derived from a tuna farm in Malta in the hours following the harvest. The oxidation state of the side-streams transported to a processing plant was assessed and the histamine content was predicted using a model based on temperature changes.

The study is part of the BlueBio-funded project PROFIUS that has the goal to valorise underutilized fish biomasses.

Materials and Methods
Samples of tuna side streams were collected during the tuna harvesting season, from October to December 2022. A temperature logger (Tinytag, Gemini Data Loggers, Chichester, UK) was inserted in multiple samples of side-streams immediately after being removed to monitor the temperature from harvest to processing (between 3 and 6 hours). The software FSSP [10] was used to predict histamine formation based on the temperature profile. Other samples of tuna side-streams were taken to evaluate the nutritional composition and the oxidative status. The samples were frozen at -20°C within five hours of collection. Three different tuna side streams were identified and separated (head, liver and mixed stream). A total of six samples, two for each type, were analysed for proximate compositional analyses, following the methodology indicated by AOAC International (2000)[6], for Dry Matter (DM) (AOAC #934.01), Crude Protein (CP) (AOAC #984.13), Ash (AOAC #942.05), Ether Extract (EE) (AOAC #2003.05). Additionally, the fatty acids profile was determined following the protocol described by Schmid et al. [7]. The oxidative status (Peroxide value and thiobarbituric acid reactive substances) were assessed using the methodology described in AOAC #965.33 and the modified Thiobarbituric acid (TBA) method according to procedure described by Witte et al.[8], respectively.

Results
The results of the temperature profile recorded, analysed with the FSSP software, predicted no histamine formation by *M. psychrotolerans* and *M. morganii*, in any of the samples collected.

The nutritional composition showed a variation of the DM content across the side streams ranging between 25.65% of the head to 53% of the liver; the latter with the highest CP content as it of approximately 16%, while head and mixed samples accounted for 2.8% and 11.5% as it respectively. In terms of crude fat expressed as Ether Extract (EE), the liver showed the highest concentration of 35.9%, while the head had the lowest at 20.04% as it.

The primary oxidation expressed as peroxide value showed the highest value in the liver (between 5.48 to 6.74 meq peroxide/kg oil), while the lowest value was found in the tuna head samples (1.45 meq peroxide/kg oil). Regarding the secondary oxidation, the TBARS levels ranged between 1.89 and 49.00 ng MDA/g, with the lowest value found in the tuna head and the highest in the liver. After 72 hours at -20°C, all the values of PV and TBARS increased, highlighting the occurrence of a slow oxidation.

Introduction

Plant proteins have been widely used in aquafeeds as a substitute for fish meal diets to support aquaculture development. However, contamination of plant ingredients with toxicogenic fungi is common and occurs in a wide range of these raw materials worldwide. Accidental mycotoxin consumption by fish, can result in various toxic actions and raise concern for both animal health and food safety. In aquaculture, diets contaminated with mycotoxins is a burden on health of cultured fish (Zhonghao et al., 2023). This study aimed to evaluate the impact of co-exposure to the emerging dietary mycotoxins including Aflatoxin B1 (AFB1), Fumonisin B1 (FB), and Deoxynivalenol (DON) in graded contamination levels, on zootechnical parameters and health indices of gilthead seabream (Sparus aurata).

Materials and Methods

Triplicate aquariums received five experimental diets: A (DON:500, FB:1000, AFB1:5 ppb), B (DON:150, FB:650, AFB1:2 ppb), C (DON:3000, FB:40, AFB1:2 ppb), D (DON:150, FB:40, AFB1:10 ppb), E (DON:150, FB:100, AFB1:2 ppb). The control group (CTRL) was fed with a marine-based, mycotoxin-free diet. The feeding trial lasted 12 weeks. Fish were hand-fed “ad libitum”, two meals per day, 6 days a week. Feed intake and mortalities were daily recorded. Water physiochemical parameters were maintained within the standard levels. Endpoint assessment included evaluation of haematological and immunological parameters, energy utilization (feed-intake and growth) and induced genotoxicity by Single Cell Gel Electrophoresis assay. Liver samples were collected for the determination of hepatic lesions through histological analysis. One-way ANOVA was used to determine the variance among treatments, followed by Tukey’s post hoc test at a significance level of P < 0.05.

Results and Discussion

All treatments containing mycotoxins caused significantly lower food consumption compared to the control group. The group with the highest DON concentration (Group C) showed the lowest feed intake, followed by the group with the highest AFB1 concentration (Group D). Inferior growth (lower mean weight, length, and total biomass increase) was also recorded in group C, followed by groups D, E and B (Table 1.), as mentioned before in the case of rainbow trout after dietary exposure to DON (Koletsi et al., 2022). Significantly lower haematocrit was recorded in all groups compared to the CTRL, while the lowest value was estimated for the group with the highest FB concentration (group A). Significant decreases in the erythrocytes, leucocytes, and the haematocrit values were previously observed in fish fed with diets with a mixture of FB and AFB1 (Adeyemo et al., 2022). Diets C and D showed strong effects with significantly elevated Hb and reduced complement, trypsin inhibition and/or alkaline phosphatase activities. The inhibitory action of AFB1 was already shown in Indian major carp with a significant immunesuppressive effect including reduced serum total globulin and reduced bactericidal activities (Sahoo & Mukherjee, 2001). Diet A also showed significantly reduced trypsin inhibition. Concerning genotoxicity induced by the mycotoxins, no significant differences on DNA damage were confirmed between examined groups. Liver sections from all mycotoxin groups revealed pathological signs, such as focal to extensive degenerative changes in liver parenchyma and early necrotic changes in some hepatocytes, that showed pyknotic and shrunken nuclei (group C). Mild to extensive hepatocyte cytoplasmic vacuolation, indicating hydropic and fatty degeneration of liver cells was also detected in all mycotoxin groups. In contrast, histopathological examination of liver sections from the CTRL group showed normal hepatic parenchyma and hepatopancreas.

QUALITY AND SAFETY STANDARDS FOR READY-TO-EAT RAW CONSUMPTION OF FARmed GREEK FISH

L. Papaharisis

Technical Committee of the Hellenic Aquaculture Producers Organization (HAPO), https://fishfromgreece.com
l.papaharisis@avramar.eu

Introduction
The popularity of ready-to-eat raw fish (such as sushi and sashimi) has been significantly increased over the last decade. Raw fish is very appreciated worldwide and has become a major component of human diet because of its fine taste and nutritional properties. Possible hazards concerning fish safety and quality are classified as biological and chemical hazards. They may be contaminants (mainly bacteria and parasites) that often accumulate in edible tissue of fish and transmit to humans via the food chain affecting the consumer’s health (Lehen et al., 2020). The perception of health, quality and safety benefits is considered as one of the motivational factors that could explain fish consumption patterns; however, the issue of perceived convenience or discomfort of fish has often emerged as influential in consumer choice too (Masi et al., 2022).

The objective of the study was to establish a verification method for the absence of live parasites in farmed fish, to evaluate and define the quality and safety standards of whole fresh fish and fish fillets, and finally to design an efficient production and transportation/storage system for ready-to-eat raw fish obtained from the Greek aquacultures. The results were validated in actual fish production environment by implementing a standard production plan to control the potential risks (bacterial and parasitic infections) while retaining the high quality in terms of microbial spoilage and sensory profiling. The proposed protocol for the verification of absence of contaminants, expected to exclude farmed fish in Greece from the obligation of prior freezing fisheries products, intended to be consumed raw or undercooked according to Reg. (EEC) 853/2004. Currently the part of the assessment for bacterial contaminants and the validated self-life predictive model will be presented.

Materials and methods
Fish (gilthead seabream, European sea bass, red sea bream and meagre) was harvested from 6 different fish farms within the period November 2022-February 2023 from western Greece (Thesprotia and Kefallonia), central Greece (Phthiotida), northeastern Greece (Lesvos) and southeastern Greece (Rhodes). 80 fish from each batch was delivered to the Agricultural University of Athens (Department of Food Science and Human Nutrition, Laboratory of Food Process Engineering) for quality evaluation and shelf life modelling. Time and temperature was continuously monitored from harvesting upon receipt of samples at the laboratory for shelf life evaluation, using electronic data loggers (RC-5 USB temperature recorders, Elitech, London, United Kingdom). Quality evaluation was based on microbial spoilage (enumeration of total viable count, Pseudomonas spp. and Enterobacteriaceae) and sensory evaluation. Bacterial microbiota of fish flesh initially and during refrigerated storage was characterized by 16S metagenomic analysis. A sample of 600 fish (450 European sea bass and 150 Meagre) from 4 different fish farms was delivered to the Hellenic Centre for Marine Research for microscopic and molecular parasite examination.

Results
Initial microbial load of fish flesh (without skin - skinless) ranged 2.4-4.6 logCFU/g for total viable count (N=50). The required time from harvesting to the delivery of fish to the laboratory for shelf life evaluation was 2.5-52.5 hours and the effective temperature during harvesting and transportation ranged 0.2-1.6°C. A logarithmic equation was developed to describe the effect of time and temperature during harvesting and transportation of fish on the microbial load of fish flesh. Based on the shelf life experiments, the dominant spoilage microflora in fish stored at 2 and 4°C was Pseudomonas spp., in agreement with relevant studies on Mediterranean fish stored aerobically at refrigerated conditions (Gram and Huss, 1996; Papaharisis et al., 2019; Koutsoumanis and Nychas, 2000).

Discussion and conclusion
The definition of the dominant microflora and the development of a validated shelf-life predictive model is a prerequisite for the definition of the spoilage process and the quality and safety assurance of ready-to-eat raw fish products. A fish production system has been provided in the form of a detailed guide for fish farms and processing facilities, to ensure the availability of safe and high quality ready-to-eat raw farmed fish and develop distribution channels with focus on export market Mediterranean and the European region.

Introduction
The study of the gut microbiome has received great attention in the aquaculture sector as an indicator of productivity and fish health, although many interactions among gut microbiome and fish host are still unknown. The promotion of a healthy gut microbiome by dietary intervention is currently of relevant interest, especially in the context of circular ingredients such as single-cell protein, insect meal and marine by-products, which are candidates to replace fishmeal and vegetable protein. Indeed, besides their optimal nutritional values, these novel ingredients may promote gut health by favouring beneficial gut microbiota taxa. The aim of this study is to explore the gut microbiome modulation induced by circular aquafeed ingredients in gilthead sea bream and European sea bass by analysing several dose-response feeding trials. Implications on gut microbiome functions and correlation with fish welfare parameters are discussed.

Materials and methods
Three feeding trials in gilthead sea bream and two in European sea bass were conducted in a closed recirculation aquaculture system (RAS). Gilthead sea bream (initial weight 75, 25 and 98g for trial 1 to 3, respectively were fed: 1) dietary increasing level of bacterial single-cell protein (SCP) from Corynebacterium glutamicum (0%, SCP, 10% SCP, SPC10; 15% SCP, SCP15; 20% SCP, SCP20) to replace vegetal ingredients; 2) dietary SCP from Candida utilis to replace fish meal, FM (0% CTRL, 5% SCP5, 7.5% SCP7.5, and 10% SCP10) and 3) dietary Hermetia illucens (HI) larva meal (0% CTRL, 5% HI5, 10% HI10, and 15% HI15) in partial substitution of FM. European sea bass (initial weight, 75g) were fed dietary increasing levels of fishery and aquaculture by-products and microalgae to totally replace wild-caught FM and soy protein. At the end of each trial, distal intestine content was collected for 16S rRNA gut microbiota analysis on 15 individual fish per treatment. Sequencing was performed on the Illumina MiSeq platform. Growth, feed efficiency parameters and welfare parameters by plasma biochemistry were also assessed. Microbiota biostatistical analysis was produced using R software (https://www.r-project.org/)

Results and Discussion
At the end of the trials, gilthead sea bream fed SCP from Corynebacterium glutamicum and HI larva meal showed a significant (p<0.05) variation compared to their respective control group, in terms of overall gut microbiome composition (Fig.1A and B). In the first case, SCP, even at the lowest content, led to an increase in Bacillus and Oceanobacillus relative abundance, which were the most relevant taxa responsible for a significant separation in the PCoA analyses. Similarly, HI induced a general gut microbiome reconfiguration with significant enrichment of Bacillus, Oceanobacillus and Paenibacillus. As also observed for animals fed with Corynebacterium glutamicum, no dose-response was detected for the ability of both raw materials to shift the gut microbiome structure, which was evident from the lowest dietary inclusion level. In both trials (especially with HI) a general reduction (p<0.05) of alpha diversity indices (i.e., PD_whole_tree, number of ASV and Shannon index) was also detected. In gilthead sea bream fed SCP from Candida utilis and in European sea bass fed with by-products from fisheries and aquaculture (Fig.1C and D), no significant overall impact of diet on the gut microbiome was observed. A common feature of these latest growth trials was a slightly decreasing growth performance (in terms of FCR and SGR) observed at the highest dietary inclusion level of the circular ingredients tested.

Conclusion
The inclusion of novel circular ingredients, such as bacterial single-cell protein and insect meal, clearly modulated the gut microbiome of gilthead sea bream promoting bacteria taxa belonging to Bacillaceae, which may exert beneficial host functions. Specific compounds characterizing these ingredients such as nucleotide/nucleic acids in SCP and chitins in insect meal might induced this modulation. This data match literature on other fish species and confirm the potential role of these ingredients to exert functional properties on gut health besides being a valid alternative for FM and vegetal ingredients at nutritional level.

INTRODUCTION
The sea urchin *Paracentrotus lividus* is considered a delicacy seafood item in many countries and the wild population is suffering due to the overexploitation of the resource and inadequate fishery regulation. Pilot-scale hatcheries acquired adequate biotechnologies for their successful breeding in captivity to counterbalance the fishery pressure on wild populations and for restocking purposes (Giglioli et al., 2021). Nevertheless, it is necessary to acquire knowledge of their feeding behavior, aimed at formulating diets with higher palatability, and able to improve their growth under rearing conditions (Prato et al., 2018). The aim of this study is to shed light on the chemosensitivity of *P. lividus* and its behavioral response to different feeding stimuli. Here, we evaluate the chemical sensitivity of the sea urchin *P. lividus* to several stimuli possibly related to food, such as a few sugars and amino acids, the seaweed *Ulva* sp., compared to the blue-green algae.

Materials and methods
To explore the ability of sea urchins to detect the feeding stimuli we developed a simple, innovative method based on the recording of “urchinograms” estimating the movements of spines, pedicellariae, tube feet, and eventually of the whole sea urchin, in response to chemicals, while keeping both the whole animal and the stimulus in their natural environment, underwater (Solari et al., 2021; Addis et al., 2023). We considered *Ulva*- amino acids-, sugars-, and green-blue algae based experiments, using a defined concentration of each stimulus. The experimental setup consisted of a small rectangular Plexiglas tank containing about 350 mL seawater (SW), which was connected to two different channels of a peristaltic pump (Gilson, Minipuls Evolution) which ensured a constant flow within the tank. The inflow and outflow terminals allow the SW and chemical stimuli to be delivered into and removed from the tank. Trials were video-recorded for later analysis, using a digital camera (Samsung SMX-F34, Korea) mounted above the experimental tank. The behavioral response was determined by measuring the movement rate of spines, tube feet, and the fully coordinated locomotion, if any, by which the whole animal moves toward or away from the outlet of the stimulus supply.

Moreover, to define the attractiveness of the stimuli, we performed trials in an experimental arena consisting of ten circular plastic tanks (30 cm in diameter, 8 cm high) where sea urchins were individually exposed to fresh *Ulva*, whereas green-blue algae were supplied to the animals by using the polyvinyl chloride (PVC) dispenser technique. The animal movement in the tank was recorded by means of a color digital camera (Samsung SMX-F34, Samsung, Korea) positioned 60 cm above the tank. The attractiveness was estimated by taking into account the following measurable parameters: a) percentage of tested animals that found the micro-algae within 1 h and remained in contact with it for at least 10 min; b) distance and time (min) traveled (mm) to find it; c) mean speed (mm/min), determined as the ratio between the distance traveled to reach the microalgae and the time to the target and; d) tortuosity of the sea urchin’s route to the microalgae substrate, determined as the ratio between the distance (mm) traveled to find the item and the shortest distance (mm) from the center of the tank and the targeted item.

Results
Our results show that Spirulina is a highly stimulating compound for the sea urchin, by acting in a dose-dependent manner. The animals resulted also sensitive, even if to a lesser extent, to some sugars, such as the monosaccharide glucose, but not to its isomer fructose, while among disaccharides, they sensed cellobiose, but not sucrose or trehalose. The results showed that all forms of *Ulva* (fresh, defrosted, and fragmented) resulted in an effective stimulus, evoking in sea urchins strong responses with robust activation of spines and tube feet, where the defrosted one was the most stimulating. Among the amino acids tested, glycine, alanine, and glutamine produced a significant response, highlighting for the latter a concentration–response relationship. Sea urchins also displayed a sensitivity, even if to a lesser extent, to leucine, threonine, arginine, and proline.

(Continued on next page)
Discussion and conclusion

From an applied point of view, any insight into the chemical sensitivity of sea urchins toward potential food-related compounds may lead to the discovery of key chemicals that would help improve the efficiency and reduce the costs of dietary substrates for optimization of intensive rearing strategies. Although this method has been developed for *P. lividus*, it will be suitable to evaluate the chemical sensitivity of other echinoderms and other marine invertebrates characterized by low mobility.

Major results indicate the role of *Ulva* as a chemostimulant and strongly attractant for such herbivore species. From an applied point of view, the presence of potential *Ulva*’s feed-related compounds, acting as chemoattractants (to reduce food searching time) and/or feeding stimulants (to stimulate ingestion), would improve the several applications of *Ulva* in the formulation of the feeds for sustainable aquaculture. Besides, our results show that blue-green algae with high nutritional value, are very attractive for this sea urchin species. These findings gain further importance considering the commercial potential of echinoderms for human consumption and their growing importance in aquaculture. Moreover, green-blue algae combine high nutritional profiles with great stimulating and attractive effectiveness and may be considered as potential valuable feed supplements in aquaculture.

Introduction

Ulva sp. is a valuable seaweed with numerous recognised commercial applications, including food, feed, and ecosystem services. Ensuring a sustainable and consistent supply of biomass with targeted and desirable biochemical profiles, aligned with intended uses, is fundamental for the successful applications of this species (Mantri et al., 2020). This study investigates the cultivation by propagation of Ulva sp. in indoor cylindrical photobioreactors, considering different sources of nutrients (N, P) and their effect on the growth, composition and quality of the biomass.

Material and Methods

Wild Ulva sp. was collected in June 2023 from a coastal lagoon of South Sardinia, Italy (Santa Gilla, Lat 39°13›50.67»N, Long 9° 4›49.34»E) and transferred to laboratories for experiments. The collected seaweed was acclimated in indoor tanks for one week before the trials. On the day of the experiment, the biomass was rinsed with freshwater to remove attached organisms and biofouling. The central sections of the blades were cut into discs of 8-10 cm to ensure homogeneity of the cultured biomass. Approximately 20g of blotted dry weight per bioreactor was placed, resulting in a final density of 1g/L. Twelve 20L photobioreactors (plexiglass cylinders) were incubated in a controlled temperature room set at 20°C, under artificial light, and provided with aeration from the bottom. Each photobioreactor contained a 20 L volume of media. Four types of media were tested and compared in triplicate: lagoon water (LW), lagoon water enriched with F/2 (LF/2), lagoon water enriched with sea urchin wastewater (LU), and lagoon water enriched with cow digestate (LD). The experiment spanned a duration of one week. At the end of the experiment, the biomass was blotted dry and weighed to calculate the specific growth rate (SGR), expressed as percentage per day. In addition, the nitrogen content (nitrite, nitrate and ammonia expressed in ppm) and phosphorous (total, phosphate, and phosphorus pentoxide) in each treatment’s media were analysed both at the beginning and at the end of the experiment. The colorimetric analyses of Ulva sp. were conducted using a digital colorimeter (Chroma meter CR-400, Konica Minolta, Tokyo, Japan), which specified the color as L*=lightness, a*=red/green and b*=yellow/blue (CIELAB). Light absorption (calculated by subtracting the absorbed light and expressed as photosynthetically active radiation, PAR) were recorded for subsamples of each treatment using a quantum sensor, connected to a quantum/radiometer/photometer (Li-Cor Inc., Lincoln, NE, USA). Moreover, the biochemical composition of the produced Ulva sp. was compared across the different culture media used in the cultivation trial. This comparison encompassed proximate composition (ash, fiber, moisture, total carbohydrates, lipid, and protein) polyphenols and pigments. The goal was to understand the effect of the treatments on the overall morphology and biochemical profile.

Results

There were significant differences in SGR among treatments (P<0.001). The highest SGR was recorded for the biomass cultivated in LF/2, which was double (9.86 ±0.52 % day⁻¹, mean ± SE) compared to cultures grown in LD (4.53 ±0.74), followed by LU (4.25 ±1.04) and finally LW (3.74 ±0.29). At the end of the trial, there were no significant differences for the light absorbed by the blades (P=0.813). However, the highest value was reported for the biomass cultivated with lagoon water enriched with LD, followed by LF/2, LW, and LU. While a noticeable difference in colour was observed among the treatments, specifically, the L* and a* parameters were higher in samples cultivated with LF/2.

The biochemical analyses showed that the lipid content in Ulva sp. did not vary among treatments (2-3 % DW), whereas the protein content exhibited significant variation among treatments (P<0.001). LF/2 displayed the highest average, 21 % DW, followed by all other treatments (9-6 % DW). Conversely, carbohydrates and fiber content showed an opposite pattern, with significantly lower content in LF/2 (16% and 30% DW, respectively) compared to other treatments (27-34% and 41-48% DW, respectively). Carotenoid concentrations varied among treatments, being double in concentration in LF/2 and LU compared to LW. Moisture, ash, and polyphenols contents did not vary among treatments. Significant differences

(Continued on next page)
in nutrient concentration were observed between treatments and time (T0 vs Tfinal) for phosphorous (as Ptot, PO\text{4}^{-3}, and P\text{2O}_{5} in µg/L). Ptot exhibited an increase of up to 20-fold, while both PO\text{4}^{-3} and P\text{2O}_{5} doubled at T0 compared to T. Ammonia levels (in ppm) did not vary significantly, and nitrate levels (in ppm) varied over time but not between treatments, revealing a 7-fold decrease in the LF/2 treatment from T0 to Tfinal. Conversely, an opposite trend was reported for nitrite (in ppm), which was nearly 4 times higher at Tfinal in LF/2, with no observable differences in the other treatments.

**Discussion and conclusion**

Seaweeds belonging to the genus *Ulva* exhibit high plasticity and adaptability to environmental and growth conditions, which can significantly modify their quality (Simon et al., 2022). In this context, we assessed the quality of *Ulva* sp. produced using different culture media. At the end of the trials, *Ulva* sp. effectively reduced and absorbed the nutrients in all media given. In our experiment, the quality of *Ulva* sp. was affected by the culture medium. In detail, those produced using recycled sources of nutrients, such as sea urchin wastewater and cow digestate, showed similar overall quality and characteristics in terms of color and photosynthetic activity. Conversely, *Ulva* sp. produced with LF/2 showed greater protein content compared to other treatments and to previously reported values (Shuuluka et al., 2013). This was accompanied by reduced carbohydrate amounts, a darker green colour, and a higher SGR.

The growing interest in *Ulva* genus includes a multitude of applications such as human consumption and the food industries. These require a biomass with consistent nutritional qualities and reduced variability in product characteristics. Our study shows how different nutrient sources can change the nutritional composition and overall quality of biomass. *Ulva* cultivated under LF/2 exhibits characteristics better suitable for human consumption, although requiring a higher economic investment for production. On the other hand, biomass derived from an excess of nutrients, confirms as *Ulva* may have applications in wastewater treatment services and such potential biomass could be used for biodegradable (bioplastic) packaging production.

REPLACING VEGETABLE OIL IN THE FEED OF ARCTIC CHAR (Salvelinus alpinus) BY MICROBIAL OIL FROM THE OLEAGINOUS YEAST Rhodotorula toruloides GROWN ON LIGNOCELLULOSE HYDROLYSATE - CONSEQUENCES ON SAFETY, SENSORICAL OUTCOME AND ENERGY BALANCE OF THE PROCESS

Introduction
Aquaculture is the fastest growing food industry for decades, a large user of fish oil (FO) and fishmeal for fish feed production. FO resources are found in finite supplies, and partially replaced by vegetable oils (VO). The addition of VO to fish feed has limitations such as competition with food production, high carbon footprint and may indirectly result in rain forest cuttings (note that in most European aquaculture industries, rapeseed oil is used, rarely or not palm- or soya oil). Single cell oil produced by cultivation of oleaginous yeasts on lignocellulose sources has the potential to solve several of the problems related to VO. However, utilisation of lignocellulose for growth of oleaginous yeasts requires thermochemical pretreatment, which requires energy. Energy is also required for fermentation and other processes required for production of microbial oil. Moreover, pretreatment of lignocellulose may generate persistent organic pollutants (POPs) from the polyaromatic compound lignin. POPs can also be taken up by the plant from the environment. These compounds could be biomagnified through the food chain and result in metabolic changes/unwanted side effects. The aim of this study was to evaluate food safety aspects, as well as energy use, of a novel sustainable fish feed ingredient produced from yeast cultivation on lignocellulose (wheat straw) hydrolysate and to determine whether its use would be advantageous compared to using VO.

Materials and Methods
Cultivated yeast was screened for the presence of persistent organic compounds of concern by GC/MS. Analytical methods were optimized and validated. POPs quantification was performed by the isotope dilution method; isotopically labelled standards were used for each compound.

Arctic char (Salvelinus alpinus) was fed a diet in which VO and parts of the protein content were replaced by biomass of the oleaginous yeast Rhodotorula toruloides (Brunel et al. 2022). Growth of the fish was measured and the lipid composition of the fish was determined and compared to a control. Additionally, impact of new feed on fish was identified by measuring the catalytic activities of cytochromes 1A1 enzymes. Sensory analysis was performed with the triangle test method (Sinkinson, 2017) at the Swedish University of Agricultural Sciences (SLU) in November 2019 with 34 untrained volunteers.

In the system analysis, the outcome was a mass and energy balance for the yeast oil-producing biorefinery (Karlsson et al. 2016). The mass balance was represented by the yield of farmed salmon, yeast oil and other valuable outputs per tonne of straw input. The energy balance covered the fossil primary energy demand per tonne of salmon, per tonne of yeast oil produced and per tonne of wheat straw used, which was the sum of all non-renewable primary energy used for inputs in the manufacturing process. Four scenarios representing different process designs of the biorefinery were also tested and themass and energy balance modelling was carried out in Aspen Plus.

Results and Discussion
The investigated heavy metals and organic pollutants in the yeast biomass were below the limits of the regulations defined by the European Union. Moisture and ash contents, fatty acid profile and protein contents were similar between feed containing yeast oil and the control, confirming previous results with another oleaginous yeast species (Blomqvist et al. 2018). No significant differences were found in the hepatic activity of 7-ethoxyresorufin-O-deethylase. Sensory analysis did not reveal any perceptible sensory difference.

System analysis showed that production of 1 tonne of yeast oil would require 9.2 tonne of straw, 14.7 GJ in fossil primary energy demand, 14.6 GJ of process electricity and 13.3 GJ of process heat, while 21.5 GJ of biomethane (430 kg) and 6 GJ of excess power would be generated simultaneously. By applying economic allocation, the fossil primary energy demand was estimated to 11.9 GJ per tonne oil. In comparison with the commonly produced rapeseed oil, the primary energy demand of the oil among the scenarios tested, was 10-38% lower.

The results show that at least partial replacement of VO by oil from oleaginous yeasts grown on lignocellulose hydrolysate in aquaculture feed is safe and can be a sustainable alternative.

Introduction

The growth and development of farmed fish depends mostly on genetic, environmental and social factors, as well as on the production system and husbandry practices. Variation in growth rate between different populations of the same species and/or between different individuals of the same population is a challenge for scientists and producers. Farmed fish show great variability in size, ranging from 20-35% or even 40% in the early stages (Barki et al. 2000). Greater amberjack (Seriola dumerili) shows even greater size variability during pre-growing and on-growing stages, reaching 200 to 300% respectively, resulting in unreliable larval rearing and unpredictable production performance (Papandroulakis unpublished data). Water temperature is an important environmental factor that affects feed intake, food conversion efficiency and growth rate. The aim of the study was to investigate the impact of early life temperature on the molecular programming of growth rate in greater amberjack’s larvae.

Materials and Methods

To investigate the role of water temperature on the molecular programming of growth in greater amberjack larvae, we applied two different temperature conditions (20°C & 24°C) from the embryonic stage to first feeding. The growth rate was monitored during the whole larval period and mRNA expression of genes, involved in growth and appetite regulation, was determined at first feeding (FF, 4.0-4.5 mm), notochord flexion (FLX, 5-6 mm), and middle metamorphosis (MM, 15-20 mm). Hypothalamic-pituitary axis genes involved in growth-promoting and developmental effects were analysed: growth hormone-releasing hormone (GHRH) that stimulates growth hormone (GH) secretion, which in turn initiates insulin-like growth factor I and II (IGFs) secretion. In addition, we analyzed leptin (leptin) and neuropeptide Y (NPY) genes that are responsible for the regulation of appetite and long-term energy storage (i.e. fat deposits). Gene expression analysis was performed using real-time PCR quantitative technology and their expression levels were calculated and normalized to a reference gene (Glyceraldehyde 3-phosphate dehydrogenase (GAPDH) using the ΔΔCt method. Data were analyzed using the statistical package SigmaStat 3.1 (Systat Software, Inc., San Jose, CA, USA). Two-way ANOVA was used to estimate the effects of temperature on the three different developmental stages while Tukey’s multiple comparison test was used to confirm statistically significant differences.

Results & Discussion

Analyses showed variation in gene expression of the six analysed genes: growth hormone, growth hormone-releasing hormone, insulin-like growth factor I and II, leptin and neuropeptide Y, among the three developmental stages (Figure 1). The variation in gene expression was influenced by temperature, with increased expression at 20°C compared to 24°C. Results indicate that larvae maintained during the embryonic and autotrophic stages at 20°C show increased expression of both GH and NPY, a major appetite stimulator, at the FF stage where the exogenous feeding starts and leptin, which is a multifunctional hormone in fish and is involved in the food intake regulation and the body weight via anorexic actions presents increased expression for the same temperature regime. Results show that early life temperature affects the expression of genes implicated in the regulation of growth at subsequent stages of development, and that incubation of embryos and pre-larvae at 20°C is more prominent compared to incubation at higher water temperature (24°C).

Figure 1. Changes in mRNA expression levels of genes involved in the regulation of growth and appetite, during early ontogeny (FF: first feeding, FLX: notochord flexion, MM: middle metamorphosis) in larvae exposed to different incubation temperatures (20°C vs. 24°C) from embryos to FF. Different letters indicate statistically significant differences among the different incubation temperatures within each respective developmental stage. The asterisk denotes statistically significant differences among the different developmental stages within each respective incubation temperature.
EFFECTS OF ACUTE DISTRESS AND EUSTRESS ON EXPRESSION OF STRESS- AND IMMUNE-RELATED GENES IN THE PITUITARY AND HEAD KIDNEY OF JUVENILE KOI CARP (Cyprinus carpio L.)

P. Pawlak1,2*, J. Konrad1, C. Pietsch1

Email: *paulina.pawlak@bfh.ch

Introduction
The stress responses in teleost involve a variety of complex physiological processes in the organism, including alterations of immune functions [1]. Activation of hypothalamus-pituitary-interrenal (HPI) and hypothalamus-sympathetic-chromaffin (HSC) axes following acute stress plays a substantial role in adaptation to challenges fish encounter. Besides a clear role in stress responses, the head kidney has crucial functions in fish immunity, and due to its organization enables direct signaling between the endocrine and the immune system [2]. A more detailed knowledge about differential effects of acute stress on the immune system in fish is still scarce. The study intends to show that distress and eustress have different downstream effects on immune responses in koi carp.

Materials and methods
In total 60 juvenile koi carp trained to receive mosquito larvae as a daily feed reward were kept either in a group tank, from which they were sampled immediately, or kept in pairs in 50 L aquaria surrounded curtains, where they underwent experimental treatments after acclimatization. The treatments were as follows – opening curtains and lids of aquaria (C) as a control, receiving the feed reward (F) as a positive stressor, or netting the fish above the water surface for one minute (A) as a negative stressor. The fish were sampled 10, 30 or 60 minutes after each treatment. Each group consisted of 6 fish. During sampling, blood, brain (including pituitary) and head kidneys were collected. Blood analysis included measuring plasma glucocorticoid levels (cortisol, cortisone, corticosterone), as well as glucose and lactate. The plasma parameters were then analyzed using ANOVA. Gene expression analyses of HPI-related genes in the pituitary gland, immune-related genes, as well as genes related to isotocin and vasotocin signalling in the head kidney were analyzed by qPCR. Furthermore, the gene expression data was subjected to a principal component analysis (PCA), as well as bootstrapped (n=2000) and used for ElasticNet regression allowing treatment classification.

Results
The analysis of the plasma steroid values revealed that one minute air exposure caused a significant increase in cortisol levels in fish 30 min after treatment. The gene expression analysis of the pituitary gland suggests that both treatments, feed rewarding and air exposure, are perceived as stressors, however they are processed differently. The head kidney transcriptome profile shows that acute eustress and distress induce differential immune-related responses. The principal component analysis revealed that HPI-axis and immune genes have the highest impact on the outcome. Moreover, the ElasticNet regression analysis of the gene expression of both pituitary and head kidney was able, with high accuracy, to classify the different treatments and indicate genes with stronger association to certain treatments.

Introduction

Atlantic cod aquaculture is still faced with some production challenges which can be partially tackled through the optimization of rearing and feeding protocols. In particular, feeding and nutrition during early larval stages are paramount for ensuring the quality of juveniles. Although rotifers and Artemia are the most common protocols for cod larvae cultured by intensive methods, these have been shown to have lower growth rates and result in more severe and frequent skeletal deformities, than larvae fed on copepods in extensive and semi-extensive rearing systems. Barnacle nauplii have been proven to be suitable live prey for first-feeding cod larvae, being naturally high in essential polyunsaturated fatty acids, such as eicosapentaenoic acid (EPA) and docosahexaenoic acid (DHA) (Olivotto et al. 2010). And these have been identified to be a requirement for neural development, pigmentation, growth and survival of marine larvae (Puvanendran et al. 2021).

On the other hand, developing more suitable microdiets is also a relevant strategy to improve the quality of cod juveniles (Puvanendran et al. 2021) as it is for early weaning into inert diets. Although much progress has been made concerning feeding protocols for the intensive culture of cod larvae, further research is needed to optimise microdiets and a better combination with live feed. This work presents a trial conducted to evaluate the effect of two microdiets and one live feed protocol on Atlantic cod’s survival and growth performance.

Material and methods

Cod larvae at two days post-hatching (dph) were randomly distributed in 400 L tanks at Ode facilities (Stadsbygd, Norway). The light regime was 24 hours, and water parameters were monitored daily, maintaining oxygen saturation above 90 %, salinity at 35 psu and temperature at 8.8 ± 0.2 °C until 30 dph followed by 10.8 ± 0.2 °C until 66 dph.

Two experimental groups, in triplicate, were created differing on the feeding regime: 1) D1 group (D1) consisting of Cryo-micro (plankton eggs) and both small (Cryo-S) and large (Cryo-L) barnacle nauplii (Planktonic AS, Norway) co-fed with rotifers, followed by Diet 1; 2) D2 group (D2) consisting of Cryo-micro, Cryo-S and Cryo-L (Planktonic AS, Norway) co-fed with rotifers, followed by Diet 2.

Figure 1. Standard length (cm) and Dry weight (mg) of cod larvae fed with protocols D1 and D2. Results are expressed as means ± standard deviation.

(Continued on next page)
From 27 to 45 dph, the protocol consisted of co-feeding with two experimental formulated feeds provided by SPAROS Ld. (Olhão, Portugal) for D1 and D2. After this period, feeding was done exclusively with dry feed until the end of the trial (66 dph). The main ingredients of the two experimental diets were squid meal, krill meal, fish hydrolysate, lecithin and krill oil. D1 being lower in marine phospholipids and D2 richer in marine phospholipids and with higher content of n-3 PUFA, namely DHA and EPA.

Results

At day 66 ph no significant differences were found in dry weight or standard length between the treatments D1 and D2, despite the trend for increased parameters in D2 treatment (Figure 1). Moreover, larvae survival, FCR and RGR weren’t significantly affected by the different experimental diets.

Discussion and Conclusion

Overall, both protocols resulted in good growth performance and better survival rates, when compared to other studies (Puvanendran et al. 2023). Despite no significant differences between the two groups and although requiring further testing, at the end of the trial larvae from the D2 protocol showed a propensity for enhanced performance in terms of dry weight, standard length, RGR and FCR. This protocol included an experimental formulated feed richer in marine phospholipids, DHA and EPA which has been proven relevant for cod larval development and growth (Wold et al. 2007; Puvanendran et al. 2021). In future studies, there will be scope to test feeding protocols combining live feeds with novel microdiet formulations to further optimize the growth performance and survival of cod larvae.

Introduction
Currently, immune nutrition is used to enhance animal health by incorporating functional ingredients into aquafeeds. These ingredients are designed to stimulate or modulate fish immune system, and might serve as a complementary strategy alongside vaccination in aquaculture. In line with this, the objective of the present study was to investigate the connections between tryptophan nutrition and the complex network that regulates the bi-directional pathways between neuroendocrine and immune systems in European seabass.

Materials & Methods
European seabass juveniles (12.02 ± 2.77 g) were distributed in two independent recirculating seawater systems with a density of 5 kg/m³ (control) or a stress-inducing density (10 kg/m³). Fish were fed a control diet (CTRL) and a CTRL-based diet supplemented with tryptophan (0.3% DM basis; TRP) in quadruplicate for 15 days. Fish were sampled at the end of the feeding period and at 4, 24 and 72 hours post intraperitoneal injection with Photobacterium damsela piscicida. Plasma was used for the quantification of cortisol levels and the hypothalamus, pituitary gland and head-kidney were sampled for gene expression analysis.

Results & Discussion
Changes in transcription rates of several genes, including anti-inflammatory cytokines (il10) and others related to the HPI axis (gr1, htr2a, and tph1a) where observed in fish exposed to an ongoing stress response, that was translated into elevated plasma cortisol levels. When tryptophan was included as a dietary supplement, it played a key role in modulating the HPI axis response to stress, as observed by further alterations in expression levels of anti-inflammatory cytokine IL10 and glucocorticoid receptors 1 and 2. Additionally, tryptophan supplementation led to decreased pomcb mRNA levels, that was accompanied by a decrease in plasma cortisol levels in stressed fish. Moreover, when stress and inflammation were combined, tryptophan dietary supplementation attenuated suppressive effects of stress by modulating the neuroendocrine response, leading to a gene expression profile more similar to that of non-stressed fish. In particular, fish given a tryptophan surplus showed decreased expression of the anti-inflammatory cytokine IL10 compared to the control group. It also resulted in reduced stress-induced cortisol production and down-regulation of key components in the HPI axis, including serotonergic receptor (htr2a), tryptophan hydroxylase (tph1a), glucocorticoid receptor gr1, and pro-opiomelanocortin a-like (pomca). Such changes might have inhibited the release of ACTH and subsequent cortisol production.

Conclusion
Results unveil modulatory effects of tryptophan dietary intervention in central (brain) and peripheric (head-kidney) molecular patterns that might have sustained changes in cortisol release. These results highlight the importance of both this amino acid and serotonergic activity in pathways that orchestrate neuroendocrine-immune communication.

Introduction

In recent decades, with a growing world population, aquaculture has increased its activity to levels where environmental sustainability is compromised. In response to this problem, Biofloc technology has emerged. This technology consists of the use of microbial aggregates with the capacity to maintain water quality and provide food for cultured aquatic organisms. In this way, the toxic forms of nitrogen are reused while acting as a probiotic, providing a partial replacement of commercial food. The availability of stable mature Bioflocs for the reactivation of production tanks represents a clear competitive advantage. For this, it is essential to know the most appropriate cryopreservation technique for these microbial inoculums. Under this perspective, the present work has focused on the study of the microbiota of mature Biofloc subjected to 5 different cryopreservation methods.

Material and Methods

The effectiveness of refrigeration, freezing, freezing with addition of glycerol (10%), freezing with addition of glucose (10%) and lyophilization of the samples in skimmed milk was evaluated. First, samples of mature and concentrated Biofloc were generated. Subsequently, they were subjected to the different cryopreservation scenarios and analyzed by cultivar microbiological techniques. Total, heterotrophic and nitrifying bacterial populations were evaluated in this study. Total bacteria were measured with the Guava Muse® Cell Analyzer cytometer (Luminex Corporation, USA); Heterotrophic bacteria were cultured at 30 °C for 48 h in Marine Broth medium (Panreac AppliChem); Nitrifying bacteria, were cultured at room temperature for 14 days in a medium with specific components with a minimum mineral composition described by Rodriguez et al., 2017. Finally, we performed a metataxonomic analysis, in order to know the biodiversity and metataxome present in the Biofloc of each cryopreservation treatment. To know the uncultured microbiota of the samples, sequencing of the variable regions V3-V4 16S rRNA gene was carried out. DNA extraction was performed with the Power Soil Kit, Quiagen (Qiagen N.V., Hilden, Germany). After amplification of the genetic material by PCR, sequencing of the samples was performed with a MiSeq PE300 kit (Illumina Inc., San Diego, CA, United States). The quality of the demultiplexed FASTQ files was checked through FastQC software; and pairwise assembly of R1 and R2 reads was done with FLASH. Sequences were analyzed using QIIME2 software version 2021-04. Regarding biodiversity indices, two alpha biodiversity indices were calculated: the Chao1 index (richness of samples) and the Shannon index (diversity of samples).

Results and discussion

When analyzing the culture, it was observed that both freeze-drying and refrigeration resulted in a reduction of the microbial load, and, therefore, it was not an effective method when trying to preserve the viability of the microbiome (Figure 1). Freezing at -80 °C, both with the addition of 10% glucose and 10% glycerol, ensured the maintenance of a high microbial diversity, with a predominance of marine heterotrophic bacteria over nitrifying bacteria.

On the other hand, meta-taxonomic analysis revealed that the preservation methods that provided the highest richness to the biofloc were freeze-drying (Figure 2), followed by treatment with 10% glycerol. The result of the meta-taxonomic analysis coincided with the fact that refrigeration was not an optimal method for preserving the total microbiota, but also indicated that the use of 10% glucose generated a lower richness in the microbial community. The biodiversity present in the mature Biofloc was high, being constituted by a high number of diverse species. The Flavobacteriaceae family was the most representative microbial group, presenting a higher relative abundance in half of the preservation methods analyzed.

Introduction

Biofloc technology (BFT) is presented as a sustainable aquaculture method due to its low water exchange and increased stocking density compared to conventional methods. The bacteria population present at the biofloc is responsible of nitrogen recycling, maintaining the total nitrogen at safe levels for the cultured species. Furthermore, bacteria form protein-rich flocs, resulting in an improvement of growth rate and associated feed costs. On the other hand, microalgae are a source of beneficial fatty acids that improve the health and growth of cultivated species. Studies have demonstrated that continuous supplementation with different types of microalgae has enhanced BFT in different ways, such as increased survival rates and growth in *P. vannamei* (Dong et al., 2022). The main objective of this study is to find the ecological balance between the bacterial population and the inoculated microalgae. It is a known fact that microalgae require a light/dark regime for productive photosynthesis (specific photoperiod). Therefore, this experiment was conducted at different photoperiods to determine the most suitable for microalgal growth and *P. vannamei* in BFT.

Material and Methods

Two microalgae, *Chlorella sp.* (CH) and *Phaeodactylum tricornutum* (PH), with a final absorbance of 0.15 AU (λ= 680 nm) were added into a biofloc system (total suspended solids (TSS): 150 mg/L) under three different photoperiods (PP) (16:8, 12:12, and 8:16 light:dark). Additionally, a control group was included that consisted in a biofloc without microalgae inclusion and under darkness conditions (0:24). All groups had 3 replicates, with a total of 21 experimental units of 90 L. The experiment was carried out with a density of 123 animals/m², and an initial weight of 3.6 g and 5.1 g for CH and for PH, respectively. *P. vannamei* were fed twice a day with commercial feed (Le Gouguessant Aquaculture, France). The experiment had a duration of 14 days. Water parameters were monitored daily by the multiparametric HANNA equipment HI19829 Model, with salinity values of 19±4 g/L, temperature of 28 ºC, pH of 8-8.8, dissolved oxygen >5 mg/L, and alkalinity of 207 ± 40 mg/L. Ammonium, nitrite, nitrate, TSS < 500 mg/L values were measured twice a week. Microalgae population was quantified with total chlorophyll extraction and spectrophotometry (DLAB SP-UV1100). Finally, the animals were weighed at the end of the experiment. The results of the study were analyzed using multiparametric ANOVA and One-way ANOVA (p-value <0.05) with the Statgraphics 19 software.

Results and discussion

The concentration of chlorophyll showed different dynamics based on the PP, as can be seen in Figure 1. Using CH as microalgae, mostly, the control group showed lower levels of chlorophyll until 7th day. PH group showed significantly higher levels after microalgae inoculation respect to control, but only four days later decreased dramatically, remaining low the rest of the experiment. Except 16:8 group, which increased on day 14, showing differences with the rest of the groups. (Figure 1).

Regarding water quality, meanwhile CH group was able to maintain the ammonia, nitrite and nitrate concentration to non-toxic levels, in PH group, ammonium and nitrate concentration increased until the 11th day, to decrease later on, but never achieving toxic levels.

In relation to growth performance, no significant differences in weight gain were observed between PP within each experimental group (Table 1).

Nevertheless, when we compared PP and microalgae, generally, higher growth was obtained using *Chlorella spp* than *P. tricornutum*, with significant differences in the PP 12:12 and 8:16 PP. Thus, it seems that medium bacterial and microalgae growth are the best conditions for shrimp production using *Chlorella spp*. On the other hand, likely, due to the bad adaptation of PH to the BFT, the highest growth was obtained in the control group, without microalgae inoculation. The poorer adaptation of *P. tricornutum* could be due to being a diatom, it may face issues of insufficient silica for its growth.

(Continued on next page)
Therefore, we can conclude that based on the major stability of water parameters, minor decline in chlorophyll concentration and the greatest weight gain in animals indicates that *Chlorella sp.* may be the most optimal candidate to use under BFT. Similar effects were also found in the study by Ge et al. (2016), with better shrimp growths using microalgae. Longer experimental trials are necessary to confirm these results, but it is the first study under our knowledge that is able to maintain a stable microalgae population to produce *P. vannamei* under BFT.

Table 1: Weight increase of *P. vannamei*. Different letters indicate significant differences between rows (p-value < 0.05).

Introduction
Feeding is crucial in aquaculture, accounting for 60% of production costs. Reducing overfeeding and increasing efficiency is important for profitability and water quality in intensive aquaculture as general. Investigating feeding frequency preferences could improve growth performance and survival rate of pikeperch. This study aims to determine the optimal feeding frequency for sustainable and efficient aquaculture practices in pikeperch juvenile.

Material and methods
Juvenile pikeperch [n=750; total length (TL) = 239.5 ± 16.7 mm and body weight (BW) = 106.6 ± 24.8 g] were divided into five groups (with three replications each) and subjected to different feeding regimes over a 24-hour period: 12 feeds at 2-hour intervals, 6 feeds at 4-hour intervals, 4 feeds at 6-hour intervals, 3 feeds at 8-hour intervals, and 2 feeds at 12-hour intervals. Fish in all groups were fed with an Imetronic® self-feeding system (Pessac, France) that allowed for easy adjustment of feeding frequencies, actual batched feed, and controlled daily feeding rate (DFR). The DFR was set at 1% of the total biomass of fish per tank. After 28 days, each tank was weighed and the current daily feed intake for each group was recorded. Production parameters [TL, somatic length (SL), Fulton’s condition coefficient (FC), specific growth rate (SGR), feed conversion ratio (FCR), specific heterogeneity rate (SHR), survival rate (SR), ] and fin condition among tested groups were assessed at the beginning and end of the experiment. The pectoral, ventral, dorsal, caudal, and anal fins, and the level of fin damage rate were determined according to Policar et al. (2016). Blood samples were collected from 6 anesthetized fish per group at the beginning and end of the feeding trial for biochemical analysis, including plasma levels of total protein (TP), albumin (ALB), globulin (GLB), amylase (AMYL), lipase (LIPA), total cholesterol (TCHOL), glucose (GLU), ammonia (NH3), and triglyceride (TAG).

Figure 1. The cumulative survival rate course of groups with tested feeding frequencies of juvenile pikeperch (Sander lucioperca) during the 112-day feeding trial.

(Continued on next page)
Results
Following the 112-day feeding trial, there were no significant differences in fish biometric parameters (TL, SL, BW) among all tested groups. The group with an 8-hour feeding frequency had the highest values of FC (0.95) and SGR (0.95%.day⁻¹), while the group with a 4-hour feeding frequency had the lowest values (FC = 0.84, SGR = 0.82%.day⁻¹). No differences were observed in FCR (0.92–1.19), SHR (322.13–342.13‰.day⁻¹), and SR (98.69–100%) among all groups (Fig. 1). There was no cannibalism rate, ensuring high survival rates. Fin erosion was minimal in all groups, with juveniles with a 12-hour feeding frequency showing the most visible erosion effects. In contrast, the dorsal second and caudal fins in juveniles with an 8-hour feeding frequency were less affected (only 12%). No significant differences were found in selected biochemical parameters in all groups based on pikeperch blood plasma analysis after the 112-day feeding trial. Feeding interval 8-hour was evaluated as optimal for intensive juvenile pikeperch rearing, resulting with excellent and acceptable SGR (0.95%.d⁻¹) and FCR (0.95kg.kg⁻¹), high SR (100%) and minimal fin erosion, and well-maintained biochemical parameters in blood plasma.

Discussion
Higher feeding frequency led to smaller feed consumption, as observed in previous studies on other fish species (Gilannejad et al., 2021). However, some studies showed that juvenile carnivorous species grew better when fed to satiation (Booth et al., 2008; Enes et al., 2015). Fish size, species, and husbandry conditions may influence the optimal feeding frequency, as our study on pikeperch suggested. Nevertheless, all groups rapidly adapted to different feeding frequencies, indicating their flexible feeding behavior.

DELTA*, A DATABASE DEVELOPED FOR INDOOR SHRIMP FARMS

Supported by real-time monitoring, comprehensive data overview and evaluation

C. Peppler1, S. Bruns1

1Polyplan-Kreikenbaum Gruppe GmbH
Ueberseestraße 14
28217 Bremen, Germany
E-Mail: peppler@polyplan-kreikenbaum.eu

Background

The work presented here is part of a project funded by the “Deutsche Bundesstiftung Umwelt” and performed in cooperation with the University of Veterinary Medicine Hannover Foundation. The database part of the project was developed by our company, using a sub-contract for programming tasks. The resulting database “DeltA” has been implemented at the indoor shrimp farm in Germany “Damm Aquakultur” (www.die-landgarnele.de). DeltA signifies “Datenbank für europäische land- und technikbasierte Aquakultur, in English: “database for European land- and technique-based aquaculture”.

Indoor aquaculture is a growing sector of food production but still in a young and fragile stage of development that can be fostered by digital technologies, such as a specific database. Successful aquaculture is depending on rapid assessment and control of critical water quality parameters. Still, operators of aquaculture plants may rely on handwritten data protocols manually to be entered into computer-aided data processing. In case of critical developments the relevant data required for an immediate reaction is lacking in the very situation, or just coming too late. This may lead to notable decreases in production.

The solution we developed is a database for indoor aquaculture set up on the basic construction of DANA 2.0, an online database developed for public pools operated by biological water treatment, to date applied by more than 100 baths in several countries (DANA also received funding by the German DBU). The aim was to provide a tool designed for indoor shrimp aquaculture, rendering a comprehensive data overview and easy data evaluation in order to support the operator in rapid decision making and thereby substantially reducing the risks associated with aquaculture operation.

Results

DeltA is being employed at the shrimp farm “Damm Aquakultur”, all functions have been accomplished and are implemented. An essential module is the feed management tool, based on an assumed zootechnical performance (e.g. survival rate), adaptable to new findings. The tool for data entry lists groups of parameters corresponding with the working routine, and each entry is traceable via a ‘history’ protocol. Data evaluation by graphs and summary tables is selectable as tank-related or batch-specific. Finally and most crucial: alarm messages are integrated into DeltA via PLC and sensor data can be sent via LORAWAN, independent from WIFI or Ethernet. Furthermore, consultants can receive limited or full access to DeltA, as required. In conclusion, the database offers an easy and up-to-date access to any available data, supporting a deeper understanding of the complex processes and a more efficient control of all critical parameters. Development and implementation of a higher degree of automatisation, also supported by AI, are further objectives for the near future. Basically DeltA is adaptable to the culture of any aquaculture organism, thereby opening a broad field of applications.

E-Mail: peppler@polyplan-kreikenbaum.eu
²University of Veterinary Medicine Hannover Foundation

Background
The work presented here is part of a project funded by the “Deutsche Bundesstiftung Umwelt” and performed in cooperation with the University of Veterinary Medicine Hannover Foundation. The project was performed at the indoor shrimp farm in Germany “Damm Aquakultur” (www.die-landgarnele.de). At the project start in 11/2019 all PL were imported from the USA. Transport duration of more than 24h and poor transport conditions may impact the performance of shrimp during culture. One of the aims was to reveal a theoretical influence imposed by origin, i.e. transport duration. In 2020, despite pandemic-related shortening of PL availabilities, once three batches of *L. vannamei* (PL11-12) could be stocked in parallel. PL hatcheries were located in three countries: USA, Austria and Germany. No further parallel stocking was possible, but more cultures from different origin could be stocked during the observation period of ca. 18 months. In total we assessed: 3 batches from Germany, 4 from Austria and 7 from USA. Water quality and zootechnical data were acquired throughout the culture period. At three sampling dates during the culture period our cooperation partner examined the microbiome, its diversity and the relative abundances of bacteria phyla.

Results
In 3 simultaneously stocked batches PL from Germany (DE) grew much faster compared to PL from Austria (AT), followed by PL from USA (US) under comparable conditions of water quality and feeding regime. Harvest was highest for PL from Germany (at DOC 116), but this result was not comparable with harvest results from the other 2 batches due to much longer culture periods (>200 days of culture). Finally, comparing the average performance of 3 to 7 batches per origin growth curves showed high variability, independent of origin.

The microbiome differed at PL arrival and grew more diverse during culture, regardless of PL origin. Members of Nitrospirota increased in the biofilm on tank surface, a development observed in all sampled tanks.

In conclusion, zootechnical performance of *L. vannamei* cultured in a biofloc-based indoor shrimp farm could not be clearly related to the country of origin. The hatchery, i.e. the genetics employed, appear to be the more critical factor. More R&D in cooperation with shrimp producers seems to be needed to breed the optimum shrimp for indoor farming.

(Continued on next page)
Figures

**Introduction**

In aquaculture, recirculated aquaculture systems (RAS) show potential circularity due to their capacity to reutilize water and concentrate nutrient-rich effluents (Martins et al., 2010; European Commission, 2021). While successful implementation of circular production has been demonstrated in freshwater RAS with aquaponic systems (Joyce et al., 2019), effective nutrient recycling in marine RAS is challenging. The high salinity levels in marine RAS effluents exceed crop tolerance and municipal wastewater treatment limits.

In response to these challenges, algae emerge as a promising and cost-effective solution for capturing dissolved nutrients in marine aquaculture (Neori et al., 2004; Mohsenpour et al., 2021). Their efficient uptake and assimilation of key nutrients, including nitrogen, phosphorus, and carbon, align closely with the nutrient composition of RAS effluents (Bolton et al., 2009; Villar-Navarro et al., 2021). While nitrogen’s bioavailability for algae cultivation from RAS overflow water has been established (Ramli et al., 2020), the bioavailability of phosphorus, carbon and micronutrients in RAS sludge presents a significant hurdle. Although, carbon recovery from waste has been explored in diverse contexts, the recovery of dissolved phosphorus as not been fully elucidated. (Jung and Lovitt, 2011; Sarvajayakesavalu et al., 2018).

In this study, we examined the effect of oxygen on nutrient solubilization as part of a broader project aiming to the develop both a method and a biological reactor concept to enhance nutrient solubilization from marine RAS sludge.

**Materials and methods**

Marine sludge was taken after the denitrification tank in a commercial shrimp farm and subject to biological treatment. Treatments were conducted in duplicate within 2-liter bottles equipped with magnetic stirrers. The experimental encompassed four distinct oxygen regimens: complete aerobic, complete anaerobic, a combination of 30% aerobic followed by 70% anaerobic, and a combination of 70% aerobic and 30% anaerobic. During the study, the targeted parameters include pH, phosphorus, total phosphorus, iron, total iron, manganese, total manganese, and acetate. The outcomes of the study are currently undergoing analysis and will be showcased in the forthcoming poster presentation.

Introduction
Aquaculture is considered a sustainable solution for the growing food demand of this century¹. Within animal production, aquaculture is the sector that shows the fastest expansion rate, consistently increasing every year its share of the total seafood produced worldwide². Despite the major technological investments made towards maximizing farmed seafood production and value, aquaculture has always had to face the double challenge of developing cost-effective aquafeeds that meet fish species (particularly, marine carnivorous ones) metabolic and nutritional requirements, while reducing as much as possible the use of meals and oils derived from wild fish, which raise strong ecological concerns and compromise oceans’ sustainability³. During the last year, the sector was further defied by the limited availability and escalating prices of raw materials (such as cereal/vegetable meals and oils) that came along with the war in Ukrania (2022). Hence, this has recently called for the urgent discovery of new alternative sources of nutrients that suit the nutritional and energetic demands of farmed fish and, thus, can potentially be used in aquafeeds’ formulations.

The inclusion of seaweeds has been pointed out as an eco-friendly strategy to naturally enrich the aquafeeds with specific nutrients that are essential, though deficient, in the human diet⁴,⁵. Still, the current knowledge is very limited in what concerns their nutraceutical-functional potential, as well as, the effective doses necessary to improve the welfare of farmed animals, often compromised by captivity, high rearing densities and disease outbreaks.

Hence, the present study aimed to explore the effectiveness of aquafeeds biofortified with a brown (Laminaria digitata) and a red (Asparagopsis taxiformis) macroalgae (at three inclusion percentages) in improving the antioxidant, metabolic and digestive performance of two juvenile farmed fish ecologically and commercially relevant within the Mediterranean setting - Sparus aurata and Diplodus sargus.

Material and methods
S. aurata and D. sargus juveniles with ~8 g of body weight (BW) were kept in recirculation aquaculture systems (RAS) under optimal development conditions (20ºC, > 7 mg/L O₂). During the feeding trials, both fish species were fed ~2% of their BW with a commercial-based diet (CTR) and the S. aurata specimens with three experimental functional diets biofortified with 1.5%, 3% and 6% of L. digitata (whole, dried, and powdered) and the D. sargus specimens with three experimental diets supplemented with 1.5%, 3% and 6% of A. taxiformis (whole, dried, and powdered).

After 30 days of trial, 6 fish from each treatment and species were randomly collected and were euthanized for dissection and collection of muscle, gut and liver tissues.

To assess the effectiveness of biofortified aquafeeds to improve animal metabolism, digestive activity and overall welfare, the following physiological endpoints were assessed: oxidative stress (total antioxidant capacity [TAC], lipid peroxidation [LPO], superoxide dismutase activity [SOD], catalase activity [CAT] and glutathione S-transferases activity [GST]), metabolic enzymes activity (lactate dehydrogenase [LDH] and citrate synthase [CS]) and digestive enzymes activity (α-amylase, pepsin, trypsin and lipase)⁶. To normalize the results of each biomarker, total protein levels were also quantified according to the Bradford assay.

(Continued on next page)
Results and Discussion
Data are still currently being analysed. Yet, preliminary results showed that aquafeeds biofortified with both studied macroalgae significantly modulated farmed *S. aurata* and *D. sargus* antioxidant, metabolic and digestive performance, especially at the highest inclusion rate (6%). Contrasting previous studies using dried macroalgae as feed additives, the present results seem very promising, evidencing that *L. digitata* and, especially, *A. taxiformis* can have a positive effect on the antioxidant and metabolic activity of farmed marine juvenile fish.

Introduction

Aquaculture is the sector that shows the fastest expansion rate within animal production, consistently increasing its share of the total seafood produced worldwide every year. It plays a crucial role on food security, being responsible for more than 50% of global seafood production and, thus, contributing to end hunger and malnutrition of the world’s growing population1. The expansion of aquaculture and the consequent growing demand for aquafeeds has increased fish meal and fish oil prices and, although the proportion of meals and oils derived from wild fish within aquafeeds has been demonstrating a downward trend, they are still important feed components for many carnivorous fishes2,3. In addition, during the last year, the sector was further defied by the scarcity and escalating prices of raw materials (such as cereal/vegetable meals and oils) that came along with the war in Ukraine (2022). Therefore, it is of the utmost importance for aquaculture to find economical and sustainable alternative ingredients to be included in aquafeed formulations that not only meet fish species, especially marine carnivorous ones, metabolic and nutritional requirements, but also represent an asset for seafood consumers from the nutritional point of view3.

The inclusion of seaweeds has been suggested as an eco-friendly strategy to naturally enrich farmed fish diets with valuable sources of bioactive compounds that are not only essential for aquafeed formulations, but also lacking in the human diet (e.g. essential minerals and polyunsaturated fatty acids)4,5. However, the current knowledge is very limited regarding the nutraceutical/functional potential of macroalgae, as well as, the effective doses necessary to improve the quality of the final seafood product.

Thus, the present study aimed to evaluate the potential of aquafeeds biofortified with the red macroalgae Asparagopsis taxiformis (at three inclusion percentages) as an eco-innovative strategy to effectively upgrade the polyunsaturated fatty acids (PUFAs) and essential minerals contents in farmed white seabream (Diplodus sargus) fillets, as case study.

Material and methods

D. sargus juveniles with ~8 g body weight (BW) were kept in recirculation aquaculture systems (RAS) under optimal growing conditions (20°C, > 7 mg/L O2) during 60 days of feeding trial. During the trial, specimens were fed ~2% of their BW with either a commercial-based diet (CTR) or with experimental functional diets biofortified with 1.5%, 3% and 6% of A. taxiformis (dried powder), each in triplicate tanks.

At the beginning and end of the trial, six fish were randomly collected and euthanized for biometric data registration and dissection of muscle tissue. To assess the effectiveness of biofortified aquafeeds to improve nutritional value, fish muscle fillets were freeze-dried and analysed for proximate chemical composition (moisture, ash, free fat, carbohydrates and crude protein), fatty acid profile and essential elements (potassium, sodium, magnesium, iron, copper, zinc and manganese) content. Animal condition and growth performance were also assessed throughout the trial.

(Continued on next page)
Results and Discussion
Fish muscle proximate chemical composition, mineral and fatty acids profiles were significantly affected by the type of aquafeed. Overall, fat contents tended to increase with the addition of *A. taxiformis*, while carbohydrates and protein decreased at the highest macroalgae inclusion levels. Fish fillets biofortified with *A. taxiformis* showed higher contents of K and Fe, but lower contents of Zn, Mn, Mg and Cu, most likely due to the adjustments made in aquafeeds formulation necessary to maintain their digestibility and proximate chemical composition (i.e. replacement of some ingredients by dried *A. taxiformis*). The distinct percentage of algae used in each aquafeed dictated fish fillets fatty acids profiles, with fish fortified with 6% showing higher PUFA n-6 contents, mainly due to higher levels of linoleic acid (18:2 n-6) in those fish. Fish fed with 3% and 6% also revealed the highest contents of α-linolenic acid (18:3 n-3), which is an essential fatty acid precursor of EPA (20:5 n3) and DHA (22:6 n3). Overall, results evidenced that the use of seaweeds is an interesting and efficient way to tailor farmed fish nutritional value according to animal and consumers health requirements, though refining is necessary to optimize the biofortification of specific essential nutrients.

*tania.pereira@ciimar.up.pt

In order to strengthen CIIMAR’s research strength, amplify its innovative capabilities and secure its position as a dominant force within the aquaculture industry, GRINNAQUA is strategically aligned with the goals of the Farm to Fork Strategy. The partnership with well-known institutes in European aquaculture research, with extensive knowledge in relevant fields, will boost CIIMAR’s ascension to scientific preeminence and increased competitiveness. The Spanish institution INIA-CSIC is skilled at navigating vaccination procedures and has a deep understanding of the subtleties of fish acquired immunity. The University of Bergen (Norway) is highly competent in the area of animal health and the application of genetics, while the Roslin Institute at the University of Edinburgh (UEDIN, UK) has invaluable knowledge in the complex world of genetics and animal breeding.

To enhance the level of excellence of CIIMAR’s staff and raise their research profile, certain actions have been thoughtfully developed. To foster a culture of ongoing learning and innovation, the collaborating partners are putting into place specialized training sessions and immersive Summer schools. Senior researchers, technicians, and administrators are specifically targeted through planned visits by CIIMAR staff to partner institutions’ facilities to ensure an extensive exchange of knowledge and best practices.

A collaborative effort that makes use of the institutions’ combined scientific and technical resources is at the heart of the research agenda. The goal of this coordinated effort is to address urgent problems associated with economically significant virus and parasite outbreaks in the aquaculture industry. The project intends to bring insight into the preventive potential of functional foods for shielding rainbow trout against the haemorrhagic septicaemia virus and addressing the infestation of Atlantic salmon with sea lice parasites.

Beyond the scientific domain, this proposal casts a strategic vision for enhancing stakeholder engagement and mobilization, facilitating the alignment of CIIMAR’s objectives with tangible scientific accomplishments. This proactive approach reinforces CIIMAR’s position as a dynamic player in market-driven research and innovation, fostering an environment that heightens its competitive edge on both national and international platforms.

In essence, the GRINNAQUA project plays a crucial part in strengthening CIIMAR’s capacity for innovation, establishing the organization as a leader in bringing about the blue revolution in the aquaculture industry. This partnership is likely to be long lasting and to create synergies that significantly reinforce a more resilient and sustainable aquaculture landscape throughout Europe.

IGNITION (Improving Green Innovation for the Blue Revolution), a cutting-edge Horizon Europe project, aims to revolutionize the aquaculture sector by addressing the rising demand for high-quality animal protein while ensuring environmental sustainability and animal welfare in a changing climate. One of the main objectives of IGNITION is the development of effective antigen-based vaccines to combat major diseases, such as tenacibaculosis and infectious salmon anemia virus, which pose significant challenges to intensive aquaculture systems. These innovative vaccines will promote animal health, reduce disease susceptibility, and improve the overall sustainability of the aquaculture industry by relying less on antimicrobials. IGNITION will also focus on enhancing stress and disease resilience through the development of new feeds, formulated to provide essential nutrients and bioactive compounds that boost the immune system and mitigate stress factors in farmed aquatic animals. By bolstering stress and disease resistance, the project aims to improve animal welfare and enhance the sector’s overall productivity. To further support animal welfare, IGNITION will focus on the development of non-invasive stress and health biomarkers and biosensors and on defining operational welfare indicators. All these will offer real-time insights into animal welfare and health. Based on the data obtained, IGNITION will employ machine learning techniques and disease prediction software to improve decision-making and facilitate proactive management practices.

Overall, IGNITION’s visionary effort aims to transform aquaculture practices, fostering a sustainable, responsible, and thriving future for the industry by providing a wealth of knowledge and innovative solutions for the European aquaculture sector and beyond.
QUALITY OF FLESH AND LIPID DEPOSITION IN THE HEPATOCYTES OF ATLANTIC SALMON (Salmo salar) FED INSECT MEAL DIETS

Florence Perera Willora1*, Youngjin Park1, Abu Bakar Siddik1, Eyassu Ghebre1, Nathaniel W. Farris1, Kyla Zatti2, Saraswathy Bisa1, Viswanath Kiron1, Viviane Verlhac-Trichet1, Mette Sørensen1

1 Faculty of Biosciences and Aquaculture, Nord University, Bodø, Norway

Email: florence.w.perera@nord.no

Introduction
Insect meals have recently gained attention because of their suitability as feed ingredients in aquafeeds. These next-generation feed ingredients are produced through bio-circular methods and can uphold aquaculture sustainability. The effect of differently processed black soldier fly (BSF, Hermetia illucens) meals (full-fat, de-fatted, de-chitinised) or BSF paste in the diets of Atlantic salmon parr have been tested previously by Belghit et al., 2018; Fisher et al., 2020; Weththasinghe et al., 2021a, 2021b. In addition, a few studies examined the effect of diets with BSF meal throughout the full production cycle of Atlantic salmon (Belghit et al., 2019). However, the use of yellow mealworm (MW, Tenebrio molitor) meal as an ingredient in salmon feed is a novel approach. Therefore, in the current trial, we aimed to study the effects of insect meals on fillet composition, flesh quality, hepatocyte morphology, and lipid deposition in post-smolt Atlantic salmon.

Material & Methods
For the feeding trial, 520 fish (143 ± 12.8g) were randomly distributed into replicate tanks of the five dietary groups (26 fish/tank). The fish were fed either a control diet (CTRL) or one of four insect meal diets, at a rate of 1.6% body weight, using automatic feeders. The CTRL diet contained 20% SPC, 14% wheat gluten and 6.23% rapeseed oil, while the four test diets were prepared with BSF meal at 5% and 10% (BS5, BS10) inclusion and MW at 15% and 30% (MW15, MW30) inclusion. The study was conducted over a period of 103 days. After 74 days of feeding, the liver of 12 fish per group (441.3± 11.7g) were examined using imaging flow cytometry to elucidate any diet-caused changes in morphology and lipid accumulation. BODIPY™ 493/503 staining revealed the accumulation of neutral lipids. At the end of the trial (550.7 ± 12.5g), 24 fish per group were analyzed for fillet proximate and fatty acid composition as well as flesh quality parameters.

Results & Discussion
The tested insect meals did not affect the fillet proximate composition. The main dietary effects were linked to fillet fatty acid composition and flesh color. Fillets from fish fed 10% BS diet contained significantly higher levels of lauric acid compared to the fish fed the other experimental diets. This is due to the high levels of lauric acid present in the tested BSF meal, which is consistent with the reports by Liland et al., 2017; 2023. Moreover, alpha linoleic acid (C18:2n-6) and total n6 fatty acids were significantly higher in the fillet of the fish fed the 30% MW feed compared to the CTRL and 5% BS groups. Such a fatty acid profile of the fillet could be attributed to the dominance (33%) of alpha linoleic acid in MW. Although fillet texture was not affected by the insect meal inclusions, Minolta color measurements revealed significant differences in the skin and flesh color. The yellowness (b’) of the skin from the ventral region of the fish fed 30% MW meal was significantly higher compared to that of the CTRL fish. This is in line with the reports of Li et al., (2022) and Zhang et al (2022) that revealed a strong skin yellowness in mirror carp (Cyprinus carpio) and yellow croaker (Larimichthys crocea) fed MW, and the authors suggested that the pigmentation was caused by the carotenoids and riboflavin in the substrates fed to MW. A significantly lower redness (a’) value was found in flesh from the fish fed 30% MW diet in comparison to those fed the other diets except the 5% BS. Morphological analysis of the liver, based on cell diameter, circularity, and elongatedness, indicated that insect meal inclusion did not significantly affect these parameters in hepatocytes. Concerning the BODIPY analysis, fish fed higher levels of insect meals (BS15 and MW30) had significantly higher neutral lipids in the liver compared to those in the fish fed the lower insect meal, although the values were similar to that of the CTRL group.

Conclusion
Inclusion of black soldier fly larvae meal in salmon diet at 5% and meal worm at 15% did not compromise the fillet proximate composition, fillet texture, or liver cell morphology. However, the higher inclusion levels of the two insect meals (10% BS and 30% MW) resulted in unfavorable qualities to the produced fish, in terms of skin and fillet color and fillet fatty acid composition. Therefore, further studies are needed to determine the most appropriate levels of insect meals produced on side streams with required nutrient content.

ASSESSMENT OF IN VITRO POSTBIOTIC CAPABILITIES OF THE PROBIOTIC Shewanella putrefaciens PDP11 GROWING UNDER DIFFERENT CULTIVATION CONDITIONS CONTAINING MICROALGAE DIETARY SUPPLEMENTS WIDELY USED IN AQUACULTURE

(1) Departamento de Microbiología, Facultad de Ciencias, Universidad de Málaga

Introduction
Probiotics have been established as potential tools to improve host health and environmental quality in aquaculture. For example, Shewanella putrefaciens Pdp11 (SpPdp11), a strain described as a probiotic for use in aquaculture (reviewed by Cámara et al. 2020). Despite the proven health benefits of probiotics, recent evidence suggests that bacterial viability is not necessary to attain effects. Thus, postbiotics have emerged as potential opportunities in the field of functional foods. The International Scientific Association for Probiotics and Prebiotics (ISAPP) convened a panel that defined postbiotics as a “preparation of inanimate microorganisms and/or their components that confer a health benefit to the host”. Other natural dietary supplements, including microalgae, along with their extracted compounds, have also been studied as feed additives for several fish species, and have shown beneficial effects on fish health. Some of these important and well-characterized microalgae species are Chlorella, Arthrospira, Microchloropsis, and Tisochrysis, among others. These species are commonly used in fish diets and are known to improve health (Ansari et al., 2021).

Recent studies conducted by our group demonstrated how postbiotic production can be affected by different cultivation conditions of bacteria, especially the culture media (Domínguez-Maqueda et al., 2022). Information on this type of postbiotic activity is very scarce, especially in the case of aquaculture (Mora-Sánchez et al., 2020), and evaluation of the nutraceutical use of postbiotics to improve health management in fish and other cultivated aquatic organisms is an emerging area of research in aquaculture.

The present work evaluates the potential postbiotic, as extracellular products (ECPs), of SpPdp11 grown under different cultivation conditions. These included different culture media composed of a blend of microalgae, to observe a possible synergistic effect. The ECPs obtained were evaluated for their cytotoxicity against different fish cell lines, enzymatic and antibacterial activity, and their effect on biofilm formation by several fish pathogens

Material and methods
SpPdp11 was grown on tryptic soy agar supplemented with NaCl (1.5 %) (TSAs) at 23° C for 24 h. Then, one to two colonies were transferred to 50 mL of tryptic soy broth supplemented with NaCl (1.5%) (TSBs) at 23°C for 36 h (10⁹ CFU mL⁻¹, start of the stationary phase) with shaking at 80 rpm. Then, 1 mL of each culture was spread over sterile cellophane sheets placed on TSAs plates (T medium). Another 1 mL was spread on sterile cellophane sheets placed on plates containing an experimental aquafeed (160 g/L) agar (1.5 %) (F media), partial replacement of aquafeed with 25% of a blend of microalgae (Chlorella fusca, Tisochrysis galbana, Microchloropsis gaditana and Arthrospira platensis) (160g/L) and agar (1.5 %) (medium FM) and total blend of microalgae (50 g/L) (medium M). The plates were incubated at 23 °C and 15 °C for 24 h and 48 h. Samples were collected by adding 2 ml sterile saline phosphate buffer (PBS). The obtained suspension was centrifuged (10,000 x g, 20 min, 4°C) and the supernatant was filtered through membranes (0.22 μm, pore diameter), and kept at -80°C until use. Internal controls (ICs) and culture media without bacterial inoculation, were obtained under the same conditions.

The cytotoxicity of ECPs on European sea bass brain (DLB-1), hepatocellular carcinoma of Poeciliopsis lucida (PLHC-1), Fundulus heteroclitus brain (FuB-1) and fibroblast cell line of gilthead seabream (SAF-1), cells was verified by exposing the cells to different doses of ECPs. After exposure, cell viability was determined using the MTT assay. Then, using the agar-well diffusion assay, the ECPs were screened for nutritional (protease, collagenase, lipase and amylase) and

(Continued on next page)
anti-nutritional (phytase, tannase and cellulose) activities. As virulence factors, hemolytic and DNase activities was also determined. The antibacterial activities of the ECPs against pathogenic bacterial strains *Aeromonas hydrophila*, *Vibrio anguillarum* and *Tenacibaculum maritimum* were also evaluated. In all cases, 50 µL of ECPs was inoculated into 6 mm-diameter wells made in the plates and incubated at 23°C for 24-48h. Plates were observed in the presence of a clear zone around the wells. Finally, the effect by ECPs on biofilm formation of *A. hydrophila*, *V. anguillarum* and *T. maritimum* was evaluated according crystal violet (CV) technique.

**Results and discussion**

Only four ECP conditions were not cytotoxic at the protein concentration tested in any case against the different fish cell lines assayed, T2324, FM2324, FM1548 and M2324. In addition, three of these four ECP conditions are included in the best six that are capable of hydrolyzing more than three nutritional compounds (casein, lipids and gelatin), but none of the ECP conditions hydrolyze antinutritional compounds in any case. Although no antibacterial activity was observed on ECPs, the biofilms of *V. anguillarum* and *T. maritimum* were significantly reduced by several conditions, especially those from FM media (FM2324 and FM1548).

The results obtained demonstrate the influence of culture conditions on the production of postbiotics, which has been widely reported (Aggarwal et al., 2022), suggesting that the activity, quantity and type of these derived products are mainly related to the type of bacterial strain and culture medium. Because of the wide target points of postbiotics, their application could be very extensive for use in many industries, such as food, healthcare products, cosmetics, and nutraceuticals (Sudhakaran et al., 2022). In terms of the aquaculture industry, optimized growth conditions can allow us to obtain promising postbiotics, which may be of interest for future in vivo experiments as supplemental additives for improving fish health.

Introduction

Probiotics have been established as valuable tools for improving fish health and environmental quality in aquaculture such as *Shewanella putrefaciens* Pdp11 (SpPdp11) [1], which was extensively studied by our group. These probiotics have demonstrated important capacities for farmed fish species such as *Solea senegalensis* and *Sparus aurata* [2]. Among various natural dietary supplements, microalgae represent an effective and natural source [3]. We focused on four important and well-characterized microalgal species: *Chlorella*, *Spirulina*, *Nannochloropsis*, and *Isochrysis*. These species are commonly used in fish diets and are known to contribute to improved growth performance (in terms of size and weight gain), as well as immune system stimulation in fish.

The objective of this study was to evaluate the proteomic profile of potential postbiotics derived from extracellular products (ECPs) obtained from the bacterial strain SpPdp11 under different cultivation conditions of temperature (15 or 23°) and time (24 or 48h). For this, we formulated four different culture media: commercial media (T); aquafeed media (F); aquafeed media supplemented with a 25 % of blend of microalgae (FM); and a mixture of 25% of blend of microalgae (M). Based on their pathogenic and hydrolytic activities FM2324, FM1548 and M2324 were selected for proteomic analysis.

Materials and Methods

Each ECP condition was analyzed in the Proteomics Unit of the Central Research Support Services (SCAI) at University of Malaga. These samples were analyzed in triplicates, as the control condition (T2324) through tandem mass spectrometry using a quadrupole-orbitrap nano HPLC-ESI-MS/MS system. Mass spectrometry is based on the differential behavior of ionized molecules passing through the electric and magnetic fields. This technique allows ion separation based on the mass/charge ratio (m/z), which is subsequently detected. Mass spectrometry (MS)-based proteomics is the technology of choice for large-scale protein identification and quantification, interactions and post-translational modifications. The MS/MS spectra were obtained from the Uniprot protein database of *Shewanella baltica* BA175. Raw data were analyzed using the Proteome Discoverer 2.2 platform (Thermo Fisher Scientific) with the Sequest HT search using mass tolerances of 10 ppm and 0.02 Da for the precursor and fragment ions, respectively. Oxidation was established a as variable modification of methionine and N-terminal acetylation, whereas carbamidomethylation of cysteine residues wasestablished a fixed modification. The false positive rate (FDR) for consecutive peptide and protein assignments was determined using the Percolator software package, based on a target-decoy approach that uses an inverted protein database a decoy with a strict limit of 1% FDR. The results were filtered to accept only those proteins master (highest ranking protein of a group) with at least two peptide sequences. The protein COG annotation and interactions were developed by STRING database.

Results and Discussion

The comparative proteomic analysis revealed the frequency of proteins for each selected ECP condition (FM2324, FM1548 and M2324) compared the control (T2324), expressed as the log2 abundance ratio. At the same time, the principal coordinate analysis (PCoA) scores showed a higher similarity related to the temperature and growth phase, at 23 °C and 24 h, than the media FM or M. Based on log abundance ratio with threshold >=6, Venn diagram shows only three common proteins between FM1548 and M2324, followed by FM2324 and M2324 with 16 common proteins. The FM2324 and FM1548 share 7 proteins transporter and structural proteins, such as ABC-type transporter, DNA-binding protein, efflux transporter or proton channel, among others. Although M2324 also overexpressed these type of proteins, other interesting proteins related to bacterial tolerance and survival were present. Similarly, we observed proteins that were unique to each ECP condition.

(Continued on next page)
The interception among different culture conditions were analysed in order to deepen in proteomic composition and their variations. For score interaction value > 0.74, the FM2324 and FM1548 condition included two different relevant interaction among COG2804 and COG2165, COG4974 and COG0583. The COG2804 and COG2165 has been implicated in type II secretory system or pilus assembly pathway ATPase. By other hand, COG4974 and COG0583 were associated to site-specific recombinase XerD and DNA-binding transcriptional regulator (LysR family), respectively. The transcriptional regulation protein binding to specific DNA region were repressor or inductor of genes expression [4]. The XerD was a tyrosine recombinase which change the dimers to monomers in the end region of chromosome [5]. In the same score threshold, FM2324 and M2324 included the COG2863, COG2010 and COG0526 proteins with close interaction between them and which function was cytochrome c553, cytochrome c, mono- and diheme variants and thiol-disulfide isomerase or thioredoxin. The higher value of cytochrome protein on FM was release to increase the oxidative activity [6].

Introduction
Preservation of marine environment quality is of paramount importance for bivalve aquaculture. When it comes to the eastern Adriatic coast, recent drastic intensification of human activities, mainly urbanisation, touristification and marine transport, have raised concerns on intensification of anthropogenic pollutants’ input. Concomitantly, seawater surface temperature increase related to global warming has been considered as the most influential environmental stressor negatively affecting the health of bivalves. Consequently, negative impact of both anthropogenic and natural stressors on farmed bivalves and on seafood production success have been anticipated. Thus, the aim of the present study was to evaluate the performance of Mediterranean mussel Mytilus galloprovincialis and European flat oyster Ostrea edulis from two eastern Adriatic bivalve aquaculture sites. A set of well-established early warning biochemical biomarkers of sub-lethal stress were analysed, taking into account the spatio-temporal variations of seawater temperature, reproductive status and body burden of potentially toxic chemical pollutants.

Materials and methods
This work was carried out in two distinct and geographically distant ecosystems of the Eastern Adriatic, namely, Lim Bay (LB) and Mali Ston Bay (MSB), long been known for bivalve and fish farming, and both under legal protection as protected marine reserve. Sampling was carried out bimonthly from June 2020 to May 2021. Condition index (CI) of mussels and oysters as well as biochemical biomarkers of stress, namely, activities of acetylcholinesterase (AChE; neurotoxicity indicator) and glutathion S-transferase (GST; oxidative stress challenge indicator) in the gills, concentration of thiobarbituric acid reactive substances in the gills (TBARS; lipid membrane peroxidation indicator) and concentration of metallothioneins in the digestive gland (MTs; metal detoxification proteins) were determined by widely applied protocols (Davenport and Chen, 1987; Perić and Burić, 2019). Biomarker data were interpreted taking into account the seawater temperature, CI and concentrations of chemical pollutants (metals, PAHs) in the tissues. The latter were determined in accordance to previously reported protocols (Perić et al, 2017).

Results
Season dependent variations of all measured biochemical parameters were observed, but a link to temperature oscillations was not detected. While AChE activity annual trend was inconsistent, seasonality of GST activity was found for both species. Significant difference between sites occurred only sporadically for AChE activity, but almost regularly for GST activity of both species, albeit displaying an inconclusive pattern. Significantly higher MTs and TBARS concentrations were recorded in MSB oysters and mussels, respectively, for almost the whole sampling period, but seasonality of these parameters was less evident. For mussels, significant positive correlation was found between MTs and in particular TBARS concentration to the burden of potentially toxic metals (Cd, As, Hg) in the tissues (r=0.58-0.86). For oysters, association was detected between MTs concentration and As tissue concentration (r=0.63), while TBARS concentration was found to significantly correlate with condition index (r=0.82).

(Continued on next page)
Discussion and Conclusion
This study presents the first data on variability of biochemical performance of farmed bivalves across seasons and sampling sites as well as on susceptibility to different stressors within local farming environment. Mussel and oyster seem to be affected mostly by pro-oxidant conditions related to higher bioavailability of toxic metals and reproductive effort, respectively. The former may be more pronounced in MSB mussels, considering a consistently higher TBARS levels with respect to their LB counterparts. In conclusion, data reported here represent a valuable baseline information for future studies related to biochemical stress in farmed bivalves posed by natural and anthropogenic pressure along the coastline. Despite the lack of association with biochemical parameters measured in this study, temperature remains an important factor affecting the performance of bivalves in aquaculture due to its tight link to reproductive cycle dynamics, and in particular in the light of steady seawater warming trend recorded in the Adriatic over the last decades. Finally, the present study illustrates the utility of biomarker approach for assessment of farming habitats’ quality crucial for sustainability of eastern Adriatic bivalve aquaculture.

Introduction
As the aquaculture sector continues to expand rapidly, there is a growing emphasis on the implementation of sustainable methods in fishmeal preparation and waste management practices. In recent years, the pursuit of sustainable aquaculture practices has focused on alternatives to fisheries-derived ingredients, in order to reduce economic and environmental burdens. Low-trophic organisms, such as polychaetes (that may be fed on aquaculture side streams), could be a suitable partial alternative to fishmeal due to their high protein content. Furthermore, aquaculture side streams may be better exploited for enabling bioconversion processes yielding valuable bio-based chemicals, including astaxanthin as pigments with antioxidant properties, which is widely used in various industries, including food and pharmaceuticals. The demand for astaxanthin has led to the development of multiple production methods, including algal, bacterial, and synthetic approaches. In this work, we perform the environmental sustainability assessment of a multi-circular model. The analysis includes polychaete-based fishmeal (PM) production and seabass feeding trials compared with conventional best fish meal (FM) formulations, and a comparative analysis between two alternative bio-conversion methods to obtain astaxanthin: the bacterial bio-conversion process employing aquaculture side streams and the algal bio-conversion process. Both polychaetes-based diets and side streams fed bacteria bio-conversion process prove to be more sustainable alternatives with respect to current solutions relying on linear economy model, thus enabling a multi-circular value chain.

Materials, methods and results.
To address the sustainability issues associated with fishmeal, various alternatives have been investigated. One of these alternatives is polychaete meals (PM) that offer a well-balanced nutritional profile, high protein content, and omega-3 fatty acids.

In order to assess the environmental sustainability of using polychaete meal (PM) as a substitute for fishmeal (FM) in diets for European seabass, the Life Cycle Assessment (LCA) analysis has been performed for the production of 50kg of FM, considering four experimental diets, which were formulated with varying levels of PM, replacing 0%, 10%, 20%, and 40% of standard fishmeal, referred to as FM, PM2.5, PM5, PM10, respectively.

Environmental impacts have been normalised based on the result of the growth trials, which have been conducted by CIIMAR [1]. The assessment was performed referred to the diet functional key performance indicator represented by the Protein Efficiency Ratio defined as: (PER) = (Wf − Wi) / (total protein intake (g)), where W and W are the initial and final weights.

According to the trendline in Figure 1, which represents the average impacts per FU as a function of the PM rate (PM=0, corresponds to pure FM) indicates that an increasing inclusion of PM dramatically reduces the diet environmental impact profile. The feed trials through the addressed KPI prove that proposed PM diets are technically feasible, thus reinforcing the sustainability claim of the PM circular solution.

(Continued on next page)
Considering the significant increase in the consumption of aquatic foods, it is imperative, from environmental perspectives, to efficiently utilize by-products generated in the aquaculture sectors. Starting from this principle Schmitt(3) suggested an innovative bacterial astaxanthin production process by C.glutamicum employing aquaculture side streams. Our dedicated LCA provided the comparative assessment between the two main sources for producing natural astaxanthin: bacteria and algae bioconversion processes. Figure 2 shows that the bacterial astaxanthin production using renewable energy and aquaculture side stream looks to be a promising solution to enable multi-circular blue-economy schemes. This approach shows a dramatic decrease of environmental impacts on all represented categories compared to the algal production method, with the exception of the aquatic toxicity and eutrophication potentials, in which algae solution display negative values. Furthermore, this circularity framework for producing astaxanthin incorporates aquaculture side streams as a sustainable nutrient source, therefore the burden of waste management and its associated environmental consequences can be avoided, while supporting the astaxanthin production process within the circularity framework also may turns costs into economic exploitable valuable.

Introduction:

Bivalve aquaculture is currently considered among the most suitable activities to meet the ever-increasing protein demand of our population. Bivalves are not only a protein source, but provide also important ecosystem services. However, bivalve aquaculture is threatened by climate extreme events such as Heat Waves (HWs). In fact, it is predicted that by 2090 suitable areas for mollusc aquaculture will decrease globally by ~10%. These extreme events are globally increasing their frequency, intensity and duration and may result in massive mortality of benthic organisms. However, we recently showed how HWs may also trigger sublethal consequences in a bivalve mollusc, such as the onset of dysbiosis in the digestive gland microbiota, a significant reduction in energy reserves, impairment of the reproduction.

In shellfish farming the scope for contrasting the negative impact of HWs is limited, however a possible solution may lie in heat-priming, a process by which a plastic response of the phenotype is triggered (following sublethal stress) to mitigate the impact of a subsequent lethal stress. Our aim was to test the efficacy of heat-priming to improve the tolerance of Manila clam to HW.

Material and Methods:

To test the efficacy of thermal priming, we obtained a hatchery-produced population of Manila clam, *Ruditapes philippinarum*, from SATMAR, one of the biggest hatcheries in Europe, and acclimated them to summer conditions (25 °C) in the lab for 2 weeks. Then, half population was subjected to thermal priming (“P”) by exposing animals for 7 days to a constant temperature of 30 °C, while the remaining half was kept at 25 °C as non-primed control (“NP”). After this treatment, all animals were let recover for 2 weeks at 25 °C. Finally, each group (P and NP) was divided in two sub-groups: the first half was subject to HW conditions (i.e. daily thermal stress from 31 °C to 35 °C; sub-groups “P/HW”, “NP/HW”) while the remaining animals were kept at 25 °C as controls (sub-groups “P/noHW”; “NP/noHW”).

A large array of traits was recorded during the HW (and over the following 15 days). Burying behavior (percentage of burying animals, speed of burying) was tested and recorded at the end of heat-priming and after the HW. Physiological parameters (e.g. condition index, hepato-somatic index, enzymatic activity of SOD, GPx and Catalase, amount of lipid peroxidation) and functional genomic profiles (gene expression via RNA-seq and chromatin accessibility via ATAC-seq) were assessed 15 days after the exposure to HW, in order to reveal the effects of heat-priming on the physiology of the species. Mortality was recorded from all groups.

Results:

Overall, we observed a significant increase in the survival rate of “P/HW” clams in comparison to “NP/HW” clams. Further, our results indicated that, following priming, while the proportion of clams that successfully buried was equal among “P” and “NP” groups, “P” clams took longer to bury in contrast with “NP” clams. On the other hand, following HW, a significantly higher number of “P/HW” clams buried in contrast with “NP/HW” clams, suggesting that priming had an effect of the behavior of animals. Finally, condition index and hepato-somatic index were both decreased in “P/HW” clams compared to “NP/HW” clams, suggesting that priming is energetically demanding. However, the higher energetic cost imposed by priming is counterbalanced by the higher survival rate of primed animals following a lethal stress, suggesting that priming may be an effective tool to increase resistance of clams to extreme heat events.
PRODUCTION OF CAROTENOIDS FROM AQUACULTURE SIDESTREAMS AS FEEDSTOCK USING THE BACTERIUM Corynebacterium glutamicum

Introduction

Carotenoids are valuable secondary metabolites with important physiological functions as for instance being precursors in vitamin biosynthesis and high antioxidant potential. Especially astaxanthin is a high value fish feed supplement, already used in salmonid farming, mainly in chemical but also in natural form. Aquaculture is one of the fastest-growing food production systems, enabling to meet the rising consumer demand for healthy seafood, thus the expansion of the demand for natural astaxanthin alternatives is expected. To establish a flexible feedstock concept using aquaculture sidestreams (Wendisch et al. 2022; Fig. 1), the GRAS bacterium Corynebacterium glutamicum that naturally synthesizes the yellow C50 carotenoid decaprenoxanthin was metabolically engineered to produce a variety of different carotenoids including astaxanthin (Cankar et al. 2023; Henke et al. 2022). Preprocessed aquaculture sidestream (AQ) from a Norwegian aquaculture facility was tested for growth and production of these carotenoids. In a step towards a circular economy in aquaculture, the applicability of astaxanthin produced by C. glutamicum was demonstrated in a first trout feeding trial (Zeytin et al. 2022).

Material and Methods

The construction of metabolically engineered C. glutamicum was described elsewhere (Cankar et al. 2023; Henke et al. 2022). The aquaculture sidestream was collected from the sump of a post-smolt RAS for salmon operated by Lumarine AS (Tjeldbergodden, Norway) outside of Trondheim (Norway). Preprocessing of the liquid aquaculture sidestream in order to use it as a growth medium component was implemented by centrifugation and subsequent sterile filtration of the supernatant. The resulting AQ was supplemented in different amounts to a defined minimal salt medium and used in growth experiments performed with the different C. glutamicum strains at 30°C and 180 rpm in shake flasks. Fermentation of the astaxanthin producing C. glutamicum strain was performed in either 2 L glass or 19 L steel bioreactors using the same medium.

Preparation of astaxanthin containing biomass for the trout feed trial was performed as shown in Fig. 2.

Results and Discussion

Astaxanthin production by an engineered C. glutamicum producer strain was notably enhanced by addition of 20 % AQ in a mineral salts medium (Schmitt et al. 2023). The use of AQ as medium supplement was shown to be transferable to production of b-carotene, lycopene as well as zeaxanthin, canthaxanthin, sarkinaxanthin, BABR and C.P.450. Astaxanthin production was scaled up to the 2 L bioreactors. Fermentation of the astaxanthin producing C. glutamicum strain yielded 5.3 g biomass, containing 1 g natural glycosylated astaxanthin. This biomass was formulated into fish feed and this feed was compared in a trout feed trial to commercially available synthetic and natural astaxanthin sources resulting in a very promising pigmentation although lower growth of the trouts.

Here we could show for the first time a fully circular bioeconomy concept in aquaculture.

THE EFFECT OF LIGHT COLOUR AND INTENSITY ON THE STRESS OF THE PACIFIC WHITE SHRIMP *Litopenaeus vannamei* IN VIDEO TRACKING EXPERIMENTAL DESIGN

Pichon Charline*, Kersanté Pierrick, Le Reste Guillaume, Corbière Thierry, Jozet-Alves Christelle, Darmaillacq Anne-Sophie

cpichon@bcf-lifesciences.com

Introduction

*Litopenaeus vannamei* is one of the most bred crustaceans worldwide. In farms feed is, by far, the main expenditure. Thus, the objective of feed and premix manufacturers is to find affordable but attractive formula. Currently the methods for measuring the attractivity of a feed are poorly precise and reproductible. One option is to conceive a device and a procedure that will be able to track shrimp during a feeding process and evaluate their behaviour in relation with pellet attractivity. Light is an important environmental factor for animals living in water. It has significant effects on behaviour, feed intake and growth of aquatic animals (Giri et al., 2002). Light can also be a source of stress that can bias behavioural experiments. Thus, to determine which colour and intensity of light cause less stress for this species, three experiments were conducted. The first experiment aimed to find the less stressful colour. The second one aimed to find the less stressful light intensity. The last experiment aimed to determine which colours *L. vannamei* is able to perceive.

General protocol

For these three experiments, *L. vannamei* shrimp were purchased from a local Bulgarian farm and brought to the station Halieutica (France) during a 24h journey.

Experiment 1 – colour preferences. Protocol

Thirty PL20 *L. vannamei* shrimp were acclimatised for four weeks. After acclimatisation, six waiting tanks of 10 L with five shrimp were prepared.

Shrimp were tested in a random order in a closed structure and were enlightened and filmed once with each following colour: red, orange, yellow, green, blue, or purple for 15 min. Following Takahashi (2021), four motion behaviours were recorded to assess stress: swimming, freezing, time spent along the walls and time spent in the centre of the tank. In addition, the number of loops, tail flips, and eye beats were counted, as they are considered as stress markers in shrimp (Bardera et al., 2019; Takahashi, 2021) however to date there has been limited focus in this area. The Pacific white shrimp (*Litopenaeus vannamei*). Median speed was also analysed. We hypothesise that non-stressed shrimp will slowly explore their environment, leading to a low speed.

Experiment 1 – colour preferences. Results

Median speed and the number of loops and tail flips were significantly lower for red and orange light (p<0.05) suggesting that these colours are less stressful. We decided to choose orange for Experiment 2.

Experiment 2 – light intensity preferences. Protocol

Thirty PL20 *L. vannamei* shrimp were acclimatised for twelve weeks. Procedure and tested behaviour were the same as in Experiment 1.

For this experiment, shrimp were enlightened and filmed once with every following orange light intensity: 17, 64, 170 or 430 Lux for 15 min.

(Continued on next page)
Experiment 2 – light intensity preferences. Results

No effect of the light intensity was shown on any stress markers, meaning that orange is not stressful for shrimp, whatever the light intensity. One possible explanation is that shrimp do not perceive this colour. Thus, we studied *L. vannamei*’s colour vision in a third experiment.

Experiment 3 – *L. vannamei*’s colour vision. Protocol

Ten PL20 *L. vannamei* shrimp were acclimatised for twenty-two weeks. Shrimp were individually tested on an optomotor device. This device consists of a rotating cylinder (6 rpm), which inside walls were covered with a filter made of vertical stripes (6.28 cm) of grey, and one of the following colours: red, orange, yellow, green, blue, purple, and white (positive control). We also used a negative control (uniform grey). The shrimp was placed on a still platform in the middle of the cylinder. Each shrimp was tested once for each colour. The device turned 1 min clockwise, and 1 min counter clockwise, the percentage of time the shrimp spent turning in the same direction and at the same speed as the device was measured, this is called the optomotor response. We considered that the shrimp perceived the colour (and hence discriminated the stripes) when the percentages of rotation in the same direction as the cylinder was at least superior to 50%.

Experiment 3 – *L. vannamei*’s colour vision. Results

Shrimp showed an optomotor response to the green, blue, purple striped filters and to the positive control. Thus, *L. vannamei* might perceive green, blue, and purple, and not red, orange, and yellow.

Discussion

This study underlines that the less stressful colours for *L. vannamei* are red and orange, probably because they cannot perceive these colours. These results are in accordance with other studies held in crustaceans (crabs and crayfish mainly) (Goldsmith and Fernandez, 1968; Marshall et al., 2003) *Palaemonetes paludosus* (Everglades prawn. High intensity orange light can thus be used in a tracking device, as it will not stress shrimp and allow a good recognition of the animals by the tracking software. More generally, these colour and light intensity can be used for any experiment led in this shrimp species.

EFFECTS OF ACUTE AND CHRONIC STRESS ON CARP

Introduction
Different stressors can have diverse effects on fish. For fish in aquaculture, acute as well as chronic stressors are relevant. Distress interferes with the appetite and well-being of an animal, while eustress, e.g. a feeding event, also leads to increased locomotory activity and should be categorized as a stressor as well. It is assumed that fish are capable of distinguishing between different stressors to ensure that they react appropriately to their stressful environment. In our studies, the acute and chronic effects of stress on common carp (Cyprinus carpio) were investigated.

Material and methods
For the experiment investigating responses to acute stress, the fish were treated with air exposure, chasing or confinement for 1 min, were rewarded with a feed or left unfed for comparison. Control groups were reared in parallel and left untreated during the entire experiment. For the chronic experiment, the fish were treated with one 6 different stressors every day for 7 and 28 days in order to avoid habituation of the fish to the stressors, and were challenged on the sampling days with air exposure as an additional stressor. Control groups were reared in parallel and left untreated during the entire experiment or challenged with air exposure only on the sampling days. Physiological parameters were measured in each fish and gene expression and neurotransmitter analyses were used to analyze stress responses at the brain level.

Results and discussion
The mRNA expression patterns of genes belonging to the stress axis revealed that negative stress caused by exposure to air had broad-ranging effects on the gene regulation patterns in the fish brain, even if the fish were only treated for 1 min. This parallels the effects that have been observed on blood cortisol and glucose. In contrast, a limited number of genes allows discrimination of eustress and distress which indicates that further research is needed in the future. Furthermore, it is known that a complex brain network including different components of the stress axis interacts with mechanisms involved in the regulation of appetite and feed intake in fish. Our study indicated that social isolation, feed rewarding and distress are perceived differently in carp and differently affect the appetite regulation at the brain level. Finally, the chronic exposure to stress affected among other parameters the brain neurotransmitter levels and skin coloration of the fish.

A NOVEL APPROACH TO ESTIMATE WATER QUALITY OF INLAND AQUACULTURE PONDS USING SATELLITE DATA AND WQI MODEL

Rohit. P. P.
rohit.pingale@galaxeye.space

Assessment of the water quality in aquaculture ponds on land is essential for maintaining the wellbeing and productivity of aquatic ecosystems. A popular tool for thoroughly assessing the quality of surface water is the Water Quality Index (WQI) model. In order to assess water quality parameters in inland aquaculture ponds, this work introduces a novel method that integrates satellite data and the WQI model, improving the accuracy and effectiveness of water quality monitoring. The proposed approach integrates multispectral satellite imagery and machine learning techniques to predict key water quality parameters. The WQI model is used concurrently to combine various parameter predictions into a single index, offering a comprehensive evaluation of water quality. This hybrid methodology provides a solid framework for overcoming classic WQI models’ drawbacks, such as their region-specific applicability.

An extensive dataset of in-situ water quality measurements gathered from several aquaculture ponds is used to validate the methodology. Strong relationships between the predicted models for the individual parameters and the field measurements are shown. A machine learning model was explored to predict the water quality parameters and the outcomes are measured against ground truth values. This validation emphasises how accurate the suggested method is for calculating and assessing water quality conditions. In conclusion, the WQI model and the integration of satellite data offer an innovative approach for determining and assessing the water quality in inland aquaculture ponds. This methodology creates new opportunities for resource management, environmental preservation, and sustainable aquaculture practices by overcoming the constraints of conventional methods. The hybrid approach provided in this study has potential for redefining water quality evaluation across multiple water bodies and geographical contexts as remote sensing and modelling techniques continue to progress.

EFFECT OF THE USE OF FISH PROTEIN ISOLATED FROM SIDE STREAMS ON THE QUALITY AND STORAGE STABILITY OF AMBERJACK (Seriola dumerili) FISH BALLS

1 Department of Agricultural and Food Science, Campus of Food Science, Alma Mater Studiorum University of Bologna, Cesena, Italy
3 Interdepartmental Centre for Agri-Food Industrial Research, Alma Mater Studiorum, University of Bologna Via Quinto Bucci, 336, 47521 Cesena, FC, Italy

Introduction
The amberjack (Seriola dumerili) is an important commercial fish species in Europe. The farming of the amberjack has attracted great interest in the Mediterranean region and is now considered one of the most important species for the diversification of commercial fish production in Mediterranean countries (Corriero et al., 2021). In the fish processing sector, the further utilization of side streams and waste left after industrial production can contribute to the sustainability of raw materials, access to added value and higher profitability, and environmental protection by reducing the amount of by-products (Šilovs, 2018). Although fish by-products have a high potential for reuse and recycling, they are not yet sufficiently recovered to obtain high value-added products (Galanakis et al., 2015). In addition, fish by-products are an excellent source of bioactive compounds such as amino acids, proteins, peptides, enzymes, gelatin, collagen, long-chain omega-3 polyunsaturated fatty acids, chitin, and vitamins (Vázquez et al., 2019) which can be used both as raw materials and as functional ingredients for the production of value-added products (Suresh et al., 2018). The demand in the global market is shifting toward higher value-added processed seafood that features convenience, ease of preparation, and high nutritional value, and that can also satisfy the sensory-hedonic aspect. Fish protein hydrolysates (FPH) have great potential for use in food formulations because they possess several functional properties, including solubility, water-holding capacity, emulsifying, and foam-forming ability (Kristinsson and Rasco, 2000). Processing can strongly influence the nutritional value of fish products, with fatty acids being the most vulnerable nutrients from fish, as they can easily be subjected to oxidation reactions resulting in quality degradation. For the development of added value, ready-to-cook fish products, it is therefore important to evaluate modifications possibly occurring during processing and storage, and to carefully check whether innovative processing affects the quality and nutritional value of the final product. The aim of the present study was to evaluate the effect of the addition of a protein hydrolysate from fish side streams on the quality and stability of fish balls made from mechanically separated amberjack meat during cold storage.

Materials and methods
In this study, the minced meat of amberjack was obtained by mechanical separation from the by-products of fish filleting. Fish balls were prepared with amberjack meat and fish protein hydrolysate (FPH) was added to the base formulation at a concentration of 1.5% by replacing the same amount of amberjack meat; all other ingredients remained the same. The conventional product (control) was prepared using the basic formulation without fish protein hydrolysate. The fish balls were packed in polypropylene trays (PP) sealed with a high barrier film and packed in a modified atmosphere (MA)
with a gas mixture of 80% N2 and 20% CO2. After packaging, the control and the innovative products were stored at 4°C for a total of 20 days. Analytical determinations were carried out on the two groups of samples, the conventional product (control) and the innovative product, by taking samples for physicochemical analysis and microbiological analysis during storage. Experimental data were subjected to one-way analysis of variance (ANOVA) to determine the significant differences between samples. Tukey HSD (Honestly Significant Difference) multiple range test, with a significance level of p < 0.05 was applied.

**Results**
The results of this study showed that the presence of protein hydrolysate in fish balls significantly improved the microbiological shelf-life of the product (less than 12 days instead of less than 8 days). Moreover, the FPH delayed the accumulation of histamine by keeping its concentration below the EU limits throughout the shelf-life (12 days), contrarily to the conventional product where the limit was already exceeded after 8 days. During the shelf life, the innovative fish balls showed lower water activity than the conventional fish balls until the 12th day of storage (Fig. 1); this may have contributed to improved microbiological stability of the samples. Lightness (L*) was lower in the innovative samples than in the conventional samples, but during the storage period, L* values decreased in the conventional samples, while they remained almost constant in the innovative samples (Fig. 1). The addition of 1.5% of protein hydrolysate showed no effect in counteracting the phenomenon of lipid oxidation in the fish balls. The amberjack fish balls produced in this study can be considered as an interesting new fish product obtained through amberjack by-product (fish components remaining after filleting) valorization. At the same time, to extend fish balls shelf-life and make them safer, more stringent handling procedures must be implemented during by-products production since the starting material presented a high microbial load.

**Acknowledgements**
This research was conducted under the NewTechAqua project supported by the European Union’s Horizon 2020 Programme (grant agreement No 862658). The project aims to expand and diversify European aquaculture production by developing and validating technologically advanced, resilient, and sustainable applications for finfish, molluscs, and microalgae.

Introduction
Aquaponics is an innovative and sustainable production alternative. It combines aquaculture with hydroponics to use water and nutrients to promote the growth of aquatic organisms and plants in an integrated manner. The application of biofloc technology in aquaponic systems is relatively new. Recent studies demonstrate that, when compared to recirculating aquaculture systems (RAS), BFT can increase the plant and fish/shrimp yields and also improve the use of nutrients (e.g. nitrogen) in the culture system.

However, to apply this system to marine culture, it is necessary to use plants that have commercial value and are salinity tolerant so that they can develop in saline effluents. The species Plantago coronopus (known as Hirschhornwegerich) is a halophyte native to Europe that it grows in sand dunes, saline grasslands, and salt marshes. It is an edible plant with nutraceutical and antioxidant properties, and it has potential for a cash crop. In this context, this study aimed to assess the growth of P. coronopus when irrigated with three different nitrate sources: commercial fertilizer and water from marine shrimp culture (Penaeus vannamei) in RAS and BFT systems.

Material and methods
The study was conducted at the Center for Aquaculture Research from the Alfred Wegener Institute in Bremerhaven, Germany. The experiment was established in a tent inside of a glasshouse, with ventilation and air conditioning to keep the temperature in the tent around 20ºC.

The experimental units were based on the deep water system, where the roots are constantly in contact with the water, where the roots are constantly in contact with the water. They consisted of nine plastic boxes with lids and a useful volume of 10 L (40 x 30 x 12 cm, 0.12 m² of useful area), which were distributed on a 3-floor shelf (three boxes per floor). To evaluate nitrate sources (fertilizer, RAS, and BFT), three replicates per treatment were randomly assigned to each floor. The light intensity was 180 µmols photons.m⁻².s⁻¹, and the photoperiod was adjusted to 12h during the 4-week trial.

Table 1: Water quality variables of the different nitrate sources used to grow Plantago coronopus during four weeks. Mean ± standard deviation. Different letters in the same line indicate a significant difference by Tukey post-hoc test.

(Continued on next page)
The day before the experiment, the boxes were filled with water and 10 mL of garden fertilizer was added to 10 L of saline water for the Fertilizer treatment. In the RAS and BFT treatments, 10 L of water from each shrimp culture system was used, from the biofilter of a recirculation system and a biofloc tank, respectively. Once a week, half of the volume was replaced with new water, and freshwater was added to correct the salinity when necessary. Salinity, pH, and nitrate concentration of the water in the boxes were monitored once a week.

The seedlings were prepared four weeks prior to the start of the experiment. Seeds of *P. coronopus* were planted in a tray of organic medium (coconut fiber, Eazyplug) and irrigated with freshwater for two weeks. Then, they were slowly acclimatized with seawater for two weeks, until reaching the desired salinity in the experiment (around 25 ppt). To start the experiment, six seedlings (initial weight with substrate = 13.9 ± 1.7 g) were placed in each box, with a density of 50 plants/m². The seedlings were inserted into plastic baskets with 4cm diameter and 5cm height, which fit into 4cm holes on the box lids. At the end of the experiment, all plants were individually weighed and measured to calculate the growth indexes.

Results and discussion
The salinity remained within the range determined for the treatment (*p* > 0.05). The pH was significantly different among treatments (*p* < 0.001). Since the water in the boxes was replenished every week, the pH remained stable, as observed in the different water sources used in the experiment. The nitrate concentration was higher in the BFT treatment, followed by RAS and Fertilizer (*p* < 0.001). The RAS used as a water source in the experiment may not have had a fully established bacterial community since nitrate concentration did not accumulate as expected (Ray et al., 2017). In the Fertilizer treatment, the dose recommended by the manufacturer was used. However, the nitrogenous fraction of the fertilizer is composed of 2% urea, 3.7% ammonia and only 2.3% nitrate. This could explain the lower concentration of nitrate in this treatment (Table 1).

Reduced plant growth is one of the first and most general responses to stress. Plant growth was the same regardless of the nitrate source used (Table 2). The constant flooding of *P. coronopus* roots with saltwater, despite their ability to tolerate salinity up to 25 ppt as a halophyte, might have affected their growth in the used system (Al Hassan et al., 2016). In addition, a shoot growth inhibition was observed in all treatments, but the plant roots expressively increased in length. Under saline conditions, plants can have a rapid root elongation. Tolerant plants exhibit a larger and more extensive root system, enabling them to access deeper layers of soil for water and nutrients (Ltaeif et al., 2021).

Table 2: Production indexes of *Plantago coronopus* cultivated during four weeks under different nitrate sources. Mean ± standard deviation. The *p*-value is from one-way ANOVA.

### Conclusion
The results of this experiment suggest that, despite the low growth rate, the water from the cultivation of *Penaeus vannamei* can be used as a source of nitrate for the cultivation of *P. coronopus*, regardless of whether it comes from the RAS or the biofloc systems.

BODY SIZE OF MALE ATLANTIC SALMON INTERACTS WITH CHANGES IN PHOTOPERIOD UNDER AQUACULTURE CONDITIONS TO INFLUENCE THE DECISION TO MATURE OR SMOLTIFY

Introduction
Early maturation of male Atlantic salmon postsmolts represents an economic and welfare challenge for aquaculture producers, and occurs as a result of intensive manipulation of factors like temperature, photoperiod or diet among others (Good and Davidson, 2016). Light is often maintained constant to increase growth rate, but interrupted by a period of reduced daylength (“winter signal”) to induce smoltification (Björnsson et al., 2011). However, this light regime has also shown to synchronize early maturation (Pino Martinez et al., 2023b). The body size attained before the winter signal could affect the decision to mature, as larger fish may have more energy reserves and be driven to initiate maturation in response to photoperiod cues (Fraser et al., 2019). We report on an observation of out-of-season male Atlantic salmon initiating puberty as pre-smolts (jacks). This study assessed if a winter signal introduced at different sizes would impact the incidence of early maturation and the development of smoltification.

Materials and methods
900 parr (41.3 ± 3.7 g) were transferred to eight freshwater tanks (112/tank) in our flow-through facilities (Bergen). Temperature was always 12.5°C. Four photoperiod treatments (Fig. 1A) were established in duplicate: constant light (LL), a winter signal (5-week LD12:12) at 70.0 ± 8.4 g (70WS), a similar winter signal at 114 ± 9.9 g (110WS), and at 182.9 ± 35.7 g (180WS). After the winter signals, light returned to constant and the groups spent 7 weeks in freshwater to complete smoltification, followed by 2 weeks in seawater (35 ppt) (Fig. 1, left). A baseline and twelve main samplings (n ≥ 4 males per tank and sampling) were performed (N total = 396 males), measuring weight and length, and collecting plasma for cortisol analysis. Testes were excised and weighed to calculate GSI (%) = Gonad W (g) × 100/Body W (g), using this index to assess maturity status (Pino Martinez et al., 2023b, 2023a). Condition factor (K) was calculated as K = Body W(g) × 100/Length 3 (cm). Plasma cortisol was analyzed with a commercial ELISA kit (Demeditec Diagnostics GmbH). Differences in maturation among treatments were explored with Fisher’s exact test for count data. Differences in K and cortisol between treatments and over time were assessed with Linear Mixed Models. Statistical analyses were performed in Rstudio (α = 0.05).

Results
Maturing males were only observed after some weeks in constant light following the winter signal, and their proportion was higher in 180WS (6 males of 58) than in LL (2 of 142), 110WS (1 of 100) and 70WS (0) (p < 0.005). Condition factor in groups 70WS and 110WS decreased after the winter signal (both p < 0.001), but remained stable in 180WS and LL. Plasma cortisol (Fig. 1, right) peaked in the three groups that received winter signal some weeks after returning to constant light, but this peak was more remarkable in 180WS. After 2 weeks in seawater, plasma cortisol remained stable in 70WS and 110WS, while in contrast, displayed a large increase in 180WS and LL (both p < 0.001).

Figure 1. Experimental set up (left) and plasma cortisol in the four treatments (right). The experiment took place from 19 January to late August 2021. Red dots are samplings in freshwater, and white dots in seawater. Shadowed areas in both graphs with the same color of the treatment show the period in seawater. The double-ended arrows on the right graph show the duration of the winter signal in each treatment. Plasma cortisol is displayed as mean ± SE.

(Continued on next page)
Discussion and conclusions
Body size of male salmon at introduction of a winter signal influenced their decision to undergo maturation or smoltification. An early winter signal (70WS and 110WS) induced better signs of smoltification (reduced condition factor and less stress in seawater) and no tendency to mature early. In contrast, a late or no winter signal (180WS and LL) induced a strong stress response in seawater, poor morphological signs of smolting, and a higher tendency to mature early. The larger incidence of maturation in 180WS suggests that salmon of approximately 180 g may have accrued sufficient energy resources for early maturation, prioritizing this life strategy instead of smoltification in response to the photoperiod cue. In the LL group, however, the lack of light cue probably prevented more individuals to initiate the process despite being energetically ready, and only those highly determined initiated maturation driven by internal signals. These results evidence that increasing daylength when salmon is large enough to have accrued sufficient energy resources may pose high risk that a proportion of them prioritize sexual maturation over smoltification. Producers may take this into consideration when optimizing protocols for postsmolt production.

Introduction

The nasopharynx-associated lymphoid tissue (NALT) in the olfactory organ of teleost fish represents an ancient arm of mucosal immunity that has protected them from waterborne stimuli for millions of years. Many neurotrophic pathogens exploit the olfactory route to access the central nervous system. Despite the significant advances in understanding the neuro-immune interaction in fish in recent years, there is a considerable knowledge gap, especially of how this interaction is influenced by external factors such as temperature.

Atlantic salmon (Salmo salar) is one of the most economically important farmed fish species in the world. However, the industry is facing high mortality rates of up to 20%, largely caused by infectious diseases. In recent years, a significant body of evidence indicates that disease resistance, robustness and performance later in life could be influenced by stimuli, like temperature and oxygen, during the crucial stages of early development (Krasnov et al. 2021; Mateus et al. 2017). However, our understanding of how host immunity is shaped by exposure to these stimuli during early development is limited.

The present study explored the molecular and structural consequences in the brain and olfactory organ of Yersinia ruckeri infection in Atlantic salmon parr. We compared two groups of fish with different embryonic temperature histories to investigate if temperature stress during early development could reshape the responses to Y. ruckeri infection. Previous studies in rainbow trout (Oncorhynchus mykiss) revealed that Y. ruckeri is a neurotropic pathogen.

Materials and methods

Eggs were exposed to two different temperatures – 4ºC and 8ºC, from fertilization until the eyed stage (~320-day degrees). The latter was considered the commonly employed temperature in the industry. Thereafter, the fish were reared at 8ºC until they reached the parr stage. Fish (around 12 cm in length) were then exposed to Y. ruckeri serotype O1 by bath exposure. Disease development was followed for 2 weeks, and organs were sampled the day before infection and 1, 2, 3, 7, and 14 days after infection. Brain and olfactory organs were collected for qPCR, histopathology, and immunohistochemistry.

Results and Discussion

Infected fish showed the classic signs of Y. ruckeri infection, including exophthalmos, skin darkening and splenomegaly (Figure 1). The pathogen was detected in the brain and olfactory organs of infected fish by qPCR. This was further verified by the identification of the pathogen in the optic tectum in the brain and in the basal lamina of the olfactory lamella by immunohistochemistry (Figure 2).

Gene expression analysis in the brain showed an increase in the transcript level of microglia cell markers (e.g., aif1) in infected groups compared to the control group. The expression of microglia cell markers in infected brain increased over time, and there was a temporal delay in immune response tendency in the 8ºC group. The expression of cd4 also increased in infected groups, and a significant difference was observed between the two temperature groups at several time points, suggesting that embryonic temperature history affected the CD4-mediated response to infection.

In the olfactory organ, the expression of antimicrobial peptides (e.g., cathelicidin), was elevated in infected groups compared to the control group. This elevation increased over time in both temperature groups. Interleukin Iβ (il1β), an important pro-inflammatory cytokine, increased around 3 days after infection.

(Continued on next page)
Preliminary histopathology analysis shows mild signs of infection in both tissues. Significant differences were not found in the nasal morphometries, such as the thickness of mucosa and lamina propria of the olfactory lamella and the number of mucus cells present in the nasal wall and on the tip of the olfactory lamella.

**Conclusions**

The study confirms the neurotrophic nature of *Y. ruckeri* and further supports earlier evidence suggesting that it is taking the olfactory route to gain entry to the brain. The results indicate that the olfactory organ and brain could mount immune responses to the pathogenic infection. Both temperature groups were able to respond to infection, however, embryonic temperature history modulated the expression of some immune genes.

Introduction
In nature, animals must face challenges and adverse conditions that vary with different likelihood throughout the day, such as food availability, social competition or even human disturbances. These factors usually act as stressors for fish, resulting in physiological consequences that endanger their welfare and survival. Tench (*Tinca tinca*) is a freshwater species naturally distributed in most parts of Europe which has been identified as a promising species for diversifying the freshwater aquaculture industry (Celada et al., 2009). However, although this species can adapt and tolerate a wide range of rearing conditions, it is very sensitive to handling practices related to intensive aquaculture and its growth performance and productivity may remarkably depend on its welfare condition (Pula et al., 2018). Considering that tench has been described as a strictly nocturnal species, this study aimed to determine whether the time of day at which fish are exposed to stressors could affect their stress response.

Methodology
A total of 72 adult fish were reared for 1 month in community tanks subjected to a 12:12h light:dark (LD) cycle and fed once daily, during night-time, at 2% body-weight. After this acclimatisation phase, 12 independent fish were individually exposed to the novel tank test (NTt) every 4h during a 24h cycle (at ZT 2, 6, 10, 14, 18 and 22; n=12 fish/ZT). The NTt consisted of exposing fish to a novel environment (i.e., a 3L glass tank) for 10 minutes while fish anxiety-like behaviours (i.e., bottom-dwelling, freezing and angular velocity) and activity parameters (i.e., distance travelled) were recorded and quantified by the EthoVision XT software ®. The experimental arena was illuminated from above with a white LED strip which was only on during daytime (ZT0-12), and from its background with an infrared lighting panel. To evaluate the presence of daily rhythms on tench behaviour, Cosinor analyses were performed (p<0.05). Besides, one-way analyses of variance (ANOVA I, p<0.05) were conducted to determine the effect of the time of the day on each behaviour. When ANOVA I was significant, differences between ZTs were studied by the Tukey HSD test.

Results
All analysed behaviours exhibited significant daily rhythms (Cosinor p<0.05) along with remarkable day and night differences. The bottom-dwelling response indicated that tench spent significantly more time at the bottom of the arena during the day in comparison to the night (Fig. 1A; ANOVA I, p<0.01), showing maximum bottom-dwelling values around the middle of the light phase (time in bottom acrophase: ZT= 6.2). Besides, freezing behaviour showed significantly higher values during the day than at night (Fig. 1B; ANOVA I, p<0.01) with an acrophase close to the middle of the day (ZT= 6.64). In addition, angular velocity behaviour showed that tench movements were significantly more erratic during the day compared to the night (Fig. 1C; ANOVA I, p<0.01), with an acrophase found closer to the middle of the light phase (ZT= 7.03). Finally, as expected for a nocturnal species, tench exhibited a nocturnal activity pattern characterised by more distance travelled during the night (Fig. 1D; ANOVA, p<0.01) and an acrophase close to the middle of the dark phase (ZT 18.25).

Discussion and conclusion
This study showed that tench anxiety-like behaviours significantly varied throughout the day, suggesting that the time of day affects the behavioural stress response in this species. In the NTt, the innate aversion of the fish to explore new and potentially threatening areas is assessed. In our results, we observed that fish spent more time at the bottom of the tank and more time freezing during the day in comparison to the night. Considering both anxiety-like behaviours as the most used in the NTt paradigm, this result suggests the impact of the stressor was stronger during the resting phase of the species (day) than during its active phase (night). Consequently, tench displayed higher angular velocity values during the day, a parameter linked to erratic movements and pronounced anxiety-like states in fish. To conclude, this research provides relevant information on daily rhythms of stress response in fish, which might be useful to improve their welfare in captivity. Hence, our results suggest that fish handling during routine aquaculture procedures might be scheduled at those times of the day when the impact of stressors is reduced.

Introduction

During production in a biofloc system (Biofloc Technology - BFT) there is an accumulation of total suspended solids and an accumulation of nutrients (Krummenauer et al., 2011). Nitrate is accumulated in the system from the presence of chemoautotrophic bacteria that transform ammonia into nitrite and then into nitrate (Ferreira et al., 2021). Phosphorus, on the other hand, is accumulated due to feed degradation. According to Silva et al. (2003), only 22% of the nitrogen input is converted into shrimp biomass, 14% remains deposited in the sediment and 57% is discarded in the environment, suggesting little efficiency in the use of available nitrogen. To take advantage of these accumulated nutrients, macroalgae can be integrated into the crop, as a way of absorbing nitrogen to form biomass. This work aims to determine the best strategy for introducing macroalgae into the IMTA system, along with other cultivated organisms or after harvesting them.

Materials and methods

The first treatment consisted of integrated cultivation with the shrimp *Litopenaeus vannamei*, the fish *Oreochromis niloticus* and the macroalgae *U. lactuca* (All together - AT). This treatment was carried out in a greenhouse during 56 days of cultivation. Consisting of three systems, each system consisted of a 4 m³ tank with shrimp (350 shrimp m⁻²), where the water circulated by gravity to a 0.7 m³ tank with fish (7 fish m⁻³) and a pump submerged water circulated to a 300 L tank with macroalgae (100g of macroalgae m⁻³, relative to the total volume of the system), totaling 5 m³ each system.

The second treatment consists of treating the effluent from an integrated cultivation, with the introduction of algae after this period (After harvest - AH). At the end of 56 days of integrated shrimp and tilapia culture, the animals were removed from the system and the water stored. The macroalgae cultivation was carried out at a density of 100g of macroalgae m⁻³ (relative to the total volume of the system) in the effluent from the integrated cultivation.

![Figure 1. Average nitrate concentration over the weeks of cultivation in the treatment AT (All together). Percent values on the curve represent the nitrate removal rate for each week.](image1)

![Figure 2. Average phosphate concentration over the weeks of cultivation in the AT treatment. Percent values on the curve represent the phosphate removal rate for each week.](image2)

(Continued on next page)
The analysis of nutrients in the AT treatment was carried out twice a week, and the concentration of ammonia, nitrite, nitrate and phosphate was determined. And for the second experiment (AH) the nutrient analysis was daily. The nutrient removal rate was performed using the following formula: 

\[
\text{NRR} \, (\%) = 100 \times \left( \frac{\text{nutrient concentration at the initial time (mg L}^{-1}) - \text{nutrient concentration at the final time (mg L}^{-1})}{\text{concentration of nutrients in the initial time (mg L}^{-1})} \right).
\]

Data normality and homoscedasticity were verified using the Shapiro-Wilk and Levene tests, respectively. Once the assumptions were met, a t-test was performed to verify the difference between treatments. A minimum significance level of 5% \((p<0.05)\) was applied in all analyses.

**Partial results**

The AT treatment showed a mean removal rate of 56.48 ± 4.84% of nitrate, with a significant decrease up to the fourth week and in the last week of the experiment (Figure 1). For phosphate, there was an increase of 40.0 ± 36.1% in the final concentration of phosphate in relation to the initial one, with a significant decrease only in the first week and an increase in the last weeks (Figure 2).

Even with the constant production of nutrients in the AT treatment, the nitrate was still removed by the macroalgae. However, macroalgae did not show phosphorus removal values at the end of the experiment. Solid production is also constant in a biofloc culture (Gaona et al., 2017), which can also interfere with greater nutrient absorption. It is expected that in the AH system, as there will be no production of nutrients and solids, the macroalgae will maximize the absorption of nutrients.

EFFECT OF PARTIAL HARVESTING ON THE GROWTH OF THE MACROALGA *Ulva lactuca* INTEGRATED WITH SHRIMP AND FISH

L. Poersch, A, Carvalho, J, Tagliaferro, Alessandro Cardozo, Julio Zemor and Wilson Wasielesky

Universidade Federal do Rio Grande
Rio Grande
Rio Grande do Sul, Brasil
E-mail: lpoersch@gmail.com

Introduction

The integrated multitrophic culture allows the insertion of species of different trophic levels for the utilization of waste and increase the productivity of the system (Chopin, 2015). The availability of nitrate and phosphate in the integrated culture in biofloc system allows the cultivation of inorganic consumers, such as macroalgae, which absorb nutrients from the system. Alencar et al., (2010) showed that initial densities of 1g L⁻¹ allow for better macroalgae growth and nutrient uptake compared to higher densities of 2 and 3g L⁻¹. However, with the limited area and long-term cultivation, the increase in the biomass of macroalgae throughout the cultivation may interfere with their performance. Therefore, this study aimed to evaluate the effect of partial harvests on the final biomass gain of the macroalgae *Ulva lactuca* cultivated in biofloc system with the shrimp *Litopenaeus vannamei* and tilapia *Oreochromis niloticus*.

Materials and methods

The two experiments were conducted in the autumn period in a greenhouse, with 22°C, and constant aeration. Experiment 1 (EXP01) was 70 days of culture, with a recirculation of water in the shrimp tank at a density of 400 shrimp m⁻² (16 m³ of usable volume), to the fish tank at a density of 35 fish m⁻³ (4 m³ of usable volume), and to the macroalgae tank of 4 m³ of usable volume at a density of 0.1 kg m⁻³, considering 24 m³ of the entire system, with an initial average weight of 2.40 ± 1.64 kg.

The experiment 02 (EXP02) consisting of three systems, each system consisted of a 4 m³ tank with shrimp (350 shrimp m⁻²), where water circulated by gravity to a 0.7 m³ tank with fish (7 fish m⁻³) and a submerged pump circulated the water to a 300 L tank with macroalgae (0.1 kg m⁻³, considering 5 m³ of the entire system), with an initial average weight of 0.502 ± 0.05 kg.

Both experiments received a biofloc inoculum from an grow-out shrimp fattening culture. The macroalgae were maintained in structures made of polyethylene netting and PVC pipes, and the macroalgae were weighed every two weeks. For EXP01, the weighed macroalgae were returned to the culture structure. For EXP02, the macroalgae were weighed, and the biomass exceeding the initial weight of 0.502 kg was counted and removed, and the same weight was maintained at each weight measurement. The specific growth rate was calculated as follows: SGR (% d⁻¹): 100 × [ln (current weight (g)/ previous weight (g))/(final time − initial time)].

<table>
<thead>
<tr>
<th>Table 1. Mean and standard deviation of biomass gain at the end of each experiment.</th>

</tr>
</tbody>
</table>

![Figure 1. Specific growth rate (SGR) of EXP01 (without partial harvest of macroalgae), and EXP02 (with partial harvest of macroalgae) over the days of culture.](Continued on next page)
Data normality and homoscedasticity were verified using the Shapiro-Wilk and Levene tests, respectively. Once the assumptions were met, a t test was performed to verify the difference between treatments. A minimum significance level of 5% (p<0.05) was applied in all analyses.

**Results**
As a result, the biomass gains at the end of cultivation showed significant differences between the experiments. EXP02 with the use of partial harvest showed a higher biomass gain compared to EXP01 (Table 1).

Figure 1 shows the specific growth rate (SGR) in each experiment. The highest values were found in EXP02 (partial harvest), with a maximum of 3.2 ± 0.25 % day\(^{-1}\), compared to the maximum value of 0.95 ± 0.54 % day\(^{-1}\) found in EXP01.

**Discussion**
The increase in biomass during the culture cycle may allow for a maximization of nutrient uptake, however it may also interfere with macroalgae growth if it exceeds the load limit of the structure. The biomass loss seen between days 41 and 55 of EXP01 may be relative to the increase in biomass in the first two weeks. Viaroli et al., (1996), found that the increase in biomass caused the macroalgae to overlap and the stalks decompositio, which may have happened in EXP01. The use of partial harvesting in EXP02 showed a higher biomass production, being advantageous for the productivity of the integrated system.

**Conclusion**
The use of partial harvesting of macroalgae is feasible for production in closed system with integrated culture, generating higher biomass production and culture productivity.

INTRODUCTION

Bacterial cold-water disease (BCWD) and rainbow trout fry syndrome, caused by *Flavobacterium psychrophilum* (Fp), are among the most problematic diseases in rainbow trout (*Oncorhynchus mykiss*) farming. Trout farming often suffers substantial economic loss due to problems associated with BCWD outbreaks, including high mortality, increased susceptibility to other diseases and skeletal deformities resulting in quality reduction in recovering fish. The management of this disease is a significant cause of antibiotic use in rainbow trout farming which raises environmental concerns and issues about the emergence of antibiotic resistance. Therefore, there is a crucial need for other methods to control the disease. Selective breeding of resistance to BCWD is a promising approach to reducing the frequency and severity of BCWD outbreaks. Several Quantitative Trait Loci (QTLs) for BCWD resistance have been identified in previous studies (e.g., Fraslin et al., 2018, Vallejo et al., 2022). With the development of a new high-density Axiom™ Trout HD genotyping array (Bernard et al., 2022), the detection and mapping of QTLs can now be more precise. This work refines the description of genetic architecture of BCWD resistance in rainbow trout using waterborne experimental infection model and genome-wide association studies (GWAS) with high-density genotyping and imputation.

MATERIALS AND METHODS

Fish used in this experiment were from two French commercial breeding programs (pop. A and pop. B) and derived from partial factorial mating design plans from approx. 100 dams and 100 sires for each line. “Eyed” eggs were disinfected before entering the INRAE-IERP experimental unit (Jouy-en-Josas, France). After 4 months of breeding in flow water at 10°C, at an average weight of 3.9 g for pop. A and 3.3 g for pop. B, 1200 fish for each population were challenged with the virulent strain FRGDSA 1882/11 isolated in France from diseased rainbow trout. Briefly, bacteria were maintained in contact with fish at a concentration of 10^6 CFU mL^-1 by stopping the water flow for 24 h. Water was maintained at 10°C with vigorous aeration and physical parameters (NH4+, O2, ...) were monitored. Over a 29-d period, mortality was monitored twice a day, and live and dead fish were fin-clipped for DNA extraction and genotyping.

Challenged offspring and their sires were genotyped with the 57K Axiom™ Trout Genotyping array (Palti et al., 2015) at the INRAE genotyping Platform Gentiane. Their dams (96 for pop. A and 90 for pop. B) were genotyped with the high-density 675K Axiom™ Trout HD array. Offspring’s 57K genotypes were imputed to HD thanks to the dams reference HD genotypes using FIMPUTE3 software (Sargolzaei et al., 2014). After quality controls, 1148 individuals genotyped for 403,863 SNPs and 1038 individuals genotyped for 402,750 SNPs were kept for analysis in pop. A and pop. B, respectively. Variance components analysis was performed for each line considering a binary survival trait (dead or alive at 29 days) in a threshold mixed animal model using genomic relationship matrices with THRGIBBS1F90 from the BLUPF90 family of programs (Misztal et al., 2014). GWAS was then performed using the Bayesian sparse linear mixed model (BSLMM) implemented in the GEMMA software (Zhou et al., 2013). This model allows partitioning the genetic variance into two components: a polygenic small effect for all SNPs and a QTL large effect for a limited set of SNPs. GWAS have been performed either on each line or the two of them combined using phenotypes corrected for the line effect to capture shared QTL. The Bayes factor (BF) was calculated to quantify the degree of association between a SNP and the phenotype. Evidence for a QTL was provided by a value 2ln(BF) ≥ 14 at a SNP position. A credibility interval for the QTL was computed around the peak SNP including all SNPs for which 2ln(BF) ≥ 6 in a sliding window of 250 kb.

(Continued on next page)
Results and Discussion
Survival rate post immersion challenge was 49% and 29% and heritability of Fp resistance was estimated to be 0.57 (CI: 0.47-0.68) and 0.39 (CI: 0.25-0.53) for the pop. A and B, respectively, which is consistent with estimates in the literature. Overall, for the two lines, only 10 to 20 SNPs were jointly selected in the BSLMM model, but they explained ~60% and ~75% of the genetic variance of Fp resistance in pop. A and B, respectively. Such results suggest that Fp resistance is a polygenic trait but with a few genes having very large effects. In pop. A, we found 4 QTLs located in chromosomes (chr) 3, 17, 29 and 31 (Figure 1A), while 10 QTLs on chr 1, 2, 11, 13, 15, 16 and 24 were identified in pop. B (Figure 1B). The GWAS combining the two lines revealed only a few shared QTLs, suggesting distinct molecular pathways underlying host resistance. Some of the detected QTL have been reported in Troutlodge, Inc., May-spawning line (Vallejo et al., 2022) or French INRAE lines (Fraslin et al., 2018). Investigations are in progress to identify candidate genes.

Introduction
To expand the availability of marketable eyed-eggs, a common practice in rainbow trout aquaculture is to store eyed-eggs at low temperature (2-4°C) for periods of up to 2-3 weeks. Recent studies have shown that early exposure to environmental stimuli (such as hypoxia or temperature) could impact fish physiology, growth, metabolism and nutrition at mid- or long-term questioning about the potential effects of such breeder practice. This study aimed to test the impact of incubating rainbow trout eyed-eggs at low temperature (3°C instead of 11°C) for 15 days on resistance to later stresses (acute temperature and confinement). Two experimental lines divergent for muscle lipid content (Quillet et al. 2005) that have been shown to utilise feed differently and to possess a well-differentiated intermediary and energetic metabolism (Kolditz et al., 2008) have been used. Our hypothesis is that they will react differently to the cold exposure during incubation.

Materials and methods
At 17 days post fertilization (dpf), eyed-eggs from two experimental lines selected for high or low muscle lipid content, fat line (FL) and lean line (LL), were either incubated at standard temperature (11°C) or incubated at 3°C for 15 days in 12 tanks (2 lines x 2 incubation temperatures x 3 tanks). From hatching to the beginning of the experiments, consisting of confinement and temperature challenges, fish were kept at 11°C.

Confinement challenges were performed at 217-219 dpf (12 tests in total, one per tank), by increasing fish density to 200 kg/m³ for 4 minutes with no water renewal or oxygen supplementation. Four fish per tank were sampled for blood before the confinement stress (control condition) and 4 other fish per tank 1h after the confinement stress (stressed condition). Blood was taken from the caudal vein using heparinized syringes and then centrifuged. Plasma samples were stored at -20°C prior to analysis. Plasma cortisol was determined using the Neogen cortisol in saliva ELISA kit. Plasma glucose and lactate levels were assessed using Accu-Chek® Mobile (Roche) and The Edge™ Analyzer (Apexbio) systems, respectively. Chloride ions levels were assayed using a colorimetric method (Biolabo SAS). Statistical analyses were performed with linear mixed models using nlme package in R, with treatment (control or stressed), line and temperature as fixed effects and weight as a covariate when it significantly affected the response variable while tank was included as a random effect.

Figure 1. A) Plasma cortisol concentrations before (control) and 1H after (stressed) confinement challenges. B) Kaplan-Meir curves for acute temperature challenges.

(Continued on next page)
Acute temperature challenges were performed at 224-226 dpf. About one month before the challenges, fish were individually PIT-tagged and grouped into 3 separate tanks containing each 200 fish, i.e. 50 fish per line and per incubation temperature. The three temperature challenges (one per tank) were performed on three successive days. Fish were transferred into the challenge tank the day before the challenge for acclimation. Water temperature was increased progressively, about 0.7°C every 10 minutes until 22°C, then 0.1°C every 15 minutes. Water was oxygenated to keep oxygen levels near saturation. Fish were removed from the tank after the loss of equilibrium, weighed and their tag recorded alongside the time at loss of equilibrium. Kaplan-Meier curves and survival analysis were performed using the survival package in R, while differences between lines and temperature were assessed using linear mixed models fitted using nlme package, with line and temperature as fixed effects and weight as a covariate while tank was included as a random effect.

**Results**

As expected, there was a significant increase of plasma cortisol levels after confinement challenges (p<0.001); however, there was no significant effect of the genetic line or incubation temperature (Figure 1A). For plasma glucose and lactate levels, there was a significant effect of the confinement challenge (p<0.001); the genetic line had a significant effect only for glucose (p=0.015). There were no significant differences in chloride ion levels.

For acute temperature challenges, Kaplan-Meier curves are shown in Fig. 1B. There was a significant effect of the genetic line (p<0.001) and incubation temperature (p= 0.036), with FL line and fish incubated at 3°C resisting longer.

**Discussion**

Using two divergent lines for muscle fat content allowed for testing the impact of the genetic background on the observed responses. As expected, the two lines differently responded to the confinement and temperature challenges. Preliminary results suggest that the incubation temperature did not impair the responses of the two genetic lines to confinement and temperature challenges performed on 7-month-old juveniles. Based on this information, the practice of cold storage of eyed eggs does not appear to be detrimental to subsequent rearing. This study will contribute to the use of early programming as a lever to improve the long-term performances of animals.

WILD VERSUS F1 BROODSTOCK: COMPARISON OF SEMEN QUALITY, INCUBATION RATES, LARVAL REARING AND SETTLEMENT SUCCESS IN PURPLE SEA URCHIN (Paracentrotus lividus) PRODUCTION

João Araújo, Ana Candeias-Mendes, Daniel Rodrigues, Elsa Cabrita, Florbela Soares and P. Pousão-Ferreira*

Introduction
The gonads (also known as “roe”) of the sea urchin Paracentrotus lividus are a lucrative fishing resource since they are highly valued as a delicacy in Europe, where local populations have been intensively fished. In the past 20 years, interest in echinoid aquaculture has grown. There is now a considerable effort to develop and improve the different production techniques to optimize production and profitability. The quality of the broodstock is one issue that needs to be addressed in the aquaculture production of any marine species since the success of the many stages of development, from hatching to adulthood, will be influenced by the quality of the eggs. In the production of many marine species, using wild spawners to gather eggs is a standard practice, and in certain cases it is required due to the difficulties in locating natural spawners. The direct benefit of not disrupting natural populations may be a direct benefit of using captive broodstock. But another compelling argument in favor of using F1 broodstock is the potential for greater spawn quality and better acclimatization to life in captivity. In this work the quality of semen, eggs and larvae of sea urchins produced by wild broodstock and F1 generation captive-born broodstock was compared.

Materials and Methods
Wild sea urchin adults (Paracentrotus lividus) were collected in a rocky area on the south coast of Portugal. Captive-born animals aged about 4 years were used as F1 broodstock. The two groups of broodstock (wild and F1) were kept for 1 month under equal captive conditions: rectangular fiberglass tanks, 70 liters in volume, with open water circuit and aeration. All broodstock were fed ad libitum with macroalgae (Ulva spp.). Spawning inductions were performed by injecting a 0.5M KCl saline solution through the peristomial membrane into the coelom in order to extract male and female gametes. Cell viability and motility metrics were used to compare the sperm quality of wild and F1 generations. About 30,000 pre-fertilized eggs were placed in 2-liter glass beakers to test the hatching rate of sea urchin eggs. After 48h the percentage of hatched larvae was estimated by microscopic counting. After assessing the hatching rate, about 16,500 larvae were placed in 6-liter glass flasks. Three replicates were used for each treatment (wild and F1). Partial water renewals (30%) of each glass flask were performed every 2 days, using reverse filtration with a mesh size of 50 microns. After each renewal, a microalgae mixture composed of Phaeodactylum crostaum, Isochrysis galbana and Nannochloropsis oculata was provided. Survival of each replicate was monitored for 22 days and periodic observations were made to assess larval development by counting larvae at each developmental stage (4, 6 and 8 arms). At the end of the larval stage, a group of competent larvae was taken to test the success of settlement for both groups (wild-type and F1 offspring). To analyze the settlement rate, 6 petri dishes with agar substrate inoculated with microalgae Phaeodactylum tricornutum were prepared in advance, where 50 ml of sterilized seawater was added. In each petri dish 20 sea urchin larvae were placed, with 3 petri dishes for each treatment. Observations were made daily to count sea urchins’ post-larvae settled on the substrate.

Results and Discussion
It was possible to confirm that there were no significant changes in the cell viability of sperm produced by the two types of breeders (wild and F1) by examining the semen quality. However, it was found that F1 sperm had higher motility both at 5 and 10 min after activation (wild: 6.8 ± 6.0 % [5 min] and 0.8 ± 0.6 % [10 min]; F1: 33.2 ± 17.1 % [5 min] and 40.4 ± 16.2 % [10 min]. Regarding egg quality, there was a significantly higher hatch rate for eggs produced by F1 breeders compared to wild ones (58.3 ± 5.6 and 30.4 ± 3.4 % respectively) (P=0.008). The larval stage was monitored for 22 days, until a considerable presence of larvae in the pre-settlement and metamorphosis stages was verified. After 4 days of rearing, a higher mortality of larvae descended from F1 broodstock was observed. At the end of the larval stage, there was a higher mean survival rate of larvae from wild progenitors than from F1 (38.1 ± 18.7 and 23.4 ± 18.9), however the differences were not considered statistically significant (P=0.395). Regarding larval development, it was found that larvae descended from F1 broodstock showed faster development than larvae from wild type, this difference being more marked after 18 DAH. At the end of the trial 71.0 % of the larvae from the F1 treatment were at the 8-arm stage. For larvae hatched

(Continued on next page)
from wild broodstock, this percentage was 54.5%. The settlement experiment began on DAH 24 in petri dishes with agar substrate inoculated with microalgae. Settlement started in individuals descended from the F1 generation on day 26 DAH. On that day, a settlement rate of 31.7± 19.2% was recorded. This value grew to 44.4 ± 13.7% on the last day of the test. On this day, 2.8 ± 2.7% of sea-urchins descended from wild progeny were likewise settled, representing the ultimate value for both treatments.

Conclusions
Through this study, sea urchin (Paracentrotus lividus) production stages were analyzed, from the quality of male gametes to the settlement stage, with the aim of comparing the use of wild and captive-born broodstock (F1 generation). In general, it was found that production of this species is feasible and potentially better when using captive-born broodstock. This may be due to a genetic advantage of F1 individuals that allows them to better adapt to the captive environment and consequently a better quality of their offspring. In future work, a genetic study would be interesting to try to understand this phenomenon.

The Portuguese Institute for the Ocean and Atmosphere (IPMA, I.P.) is a public research institute and act as a counselor to the national authorities on the sea and atmosphere. IPMA, I.P., possesses a strong cluster of competences for the ocean and marine resources related to research, carried out by different groups, particularly dedicated to aquaculture and fisheries.

The Aquaculture Research Station of Olhão (EPPO, figure 1) stands out for the unique experimental conditions on aquaculture at the national and international levels. This marine core facility is equipped to carry out production studies at every scale from bench-top laboratory work to a much larger semi-industrial level. EPPO has an area of about 7ha with more than 250 tanks, including an hatchery fully equipped for research and experimental production with different rearing circuits (for broodstock, larvae, juvenile production, research with live animals and recirculation systems), a support building (with rooms for trophic chain production, daily routines and biological sampling), three RAS systems for research purposes, several analytical laboratories (biochemical, histological, molecular, microbiological and fish pathology), an unit for seafood packing, an area for pre-fattening (for earthen ponds and sea cages production) and 17 earthen ponds. It holds breeders of several marine fish species (e.g. meagre, gilthead seabream, seabass, Senegalese sole and sardine among others), microalgae and invertebrates as well as the know-how on the production of these species.

Production of new species, nutrition, welfare, environmentally friendly production systems and assessment of onshore and offshore and production systems for fish grow-out are some of research lines developed at EPPO (figure 2).

Acknowledgments: The research lines are partially funded by AQUARAS (Mar-02.05.01-FEAMP-0223).

Introduction
Skeletal anomalies affect fish growth, welfare and health, increase mortality and decrease product marketability (Boglione et al., 2013). Skeletal anomalies of early juveniles can be identified through an in toto double staining procedure, whose execution takes several days thus delaying diagnoses. Recently, a rapid microradiographic method to identify skeletal anomalies in early sea bream Sparus aurata juveniles (total length ≥ 25 mm) was proposed (Pousis et al., 2022). The aim of the present study was to assess the use of microradiography to identify skeletal anomalies in gilthead sea bream of younger age than previously reported and to extend the use of this method to the European sea bass Dicentrarchus labrax, the common carp Cyprinus carpio and the silver carp Hypophthalmichthys molitrix.

Material and Methods
Gilthead sea bream (N = 92; total length, TL, 18-31 mm), European sea bass (N = 145; TL 16-21 mm), common carp (N= 51; TL 18-31mm) and silver carp (N= 87; TL 17-23 mm) were sampled in fish farms operating in Italy and in Albania, anaesthetized, fixed in 10% buffered formalin and then stored in 50% ethanol. The fish were then micro-radiographed in latero-lateral projection. Since the high-resolution film is sensitive to water, a transparent polyethylene film was placed between the photographic film and the specimens. X-ray exposure was set up at 12 kV and 18 mA. The specimens <20 mm TL were subjected to 6500 X-ray shots, while the specimens ≥20 mm TL underwent 7500 shots. Films were then developed with Kodak HC-110, fixed in Kodak UNIFIX, and dried at room temperature. After microradiography, all the samples were stained with a routine in toto double staining procedure for bone and cartilage (Boglione et al., 2013).

Results and Discussion
In gilthead sea bream, the majority of the analyzed individuals (82.6%) showed at least one skeletal anomaly and most of them showed more than one anomaly (average: 3.3 ± 2.4). A total of 248 anomalies were recorded of which 21.4% were several anomalies such as haemal lordosis, vertebral body shape anomalies, vertebral body fusion and cephalic deformities. In European sea bass specimens, a total of 533 anomalies were recorded of which 10.3% were several anomalies such as cephalic deformities, kyphosis, lordosis and vertebral body fusion. The frequency of individuals with at least one (severe or slight) anomaly was found to be 93.1% while the average of anomalies per individual were 3.9 ± 3.1. In silver and common carp, a total of 1119 and 131 anomalies were respectively recorded. In silver carp 93.1% of the analyzed specimens showed almost one anomaly (average: 13.8 ± 15.4) while in common carp the frequency of deformed specimens was 78.4% (average: 3.5 ± 3.0). The most common severe anomalies in both species were vertebral body shape anomalies and vertebral body fusion, while no cephalic deformities were found. The frequency of specimens with almost one severe anomaly was 57.5% and 41.2%, respectively. In all the analyzed specimens the most common slight anomalies were deformed neural and haemal arches. All the skeletal anomalies observed after double staining method were also identified in the microradiographic plates (Fig. 1).

The present study suggests microradiography as a useful tool for the rapid identification of skeletal anomalies in early juveniles of different species, provided that X-ray exposure conditions appropriate to the size of the examined samples are set up.

**Introduction**

In 2022 *V. pectenicida* emerged as a serious pathogen, affecting the survival of larval cultures of the different species of bivalves cultured in CCM, in Galicia (NW Spain) [AqEu 2022]. The presence of the pathogen continues this year, compromising cultures of *Venerupis corrugata, Ensis magnus* and *Ruditapes decussatus*. *Vibrio ostreicida*, a close relative of *V. pectenicida*, also pathogenic to bivalve larvae has appeared this year, infecting currently cultured *Ruditapes decussatus* larvae.

The global analysis of samples from cultures affected by *V. pectenicida* and *V. ostreicida* showed an interesting fact: the co-occurrence of two marine bacterial taxa, *Pseudoalteromonas citrea-aurantia* (*Pca*) and/or *Phaeobacter inhibens-gallaeciensis*.

**Materials and methods**

The Centro de Cultivos Mariños-CIMA (Ribadeo. Xunta de Galicia) specialises in the development of bivalve molluscs from spawning to the appropriate size for outdoor cultivation. They have been diversifying the bivalve species, so that the facility is active throughout the year, combining clam and solenid cultures.

The USC-CIMA group has been developing microbiological control protocols for the facility, which include the transversal compartments (seawater circuit and microalgae cultures), as well as the larval, post-larval and spat cultures. The controls of the larval cultures are of particular relevance, and are mainly focused on detecting possible pathogens that may influence their development.

**Results and Discussion**

Recently, two pathogens, news to the installation, have been identified as responsible for mortalities in the cultures: *Vibrio pectenicida* and *V. ostreicida*. The review of the samples from a global point of view allowed us to observe the recurrent presence of two taxa in these episodes. The identification by 16S sequencing of the pigmented isolates showed that these bacteria are related to *Pseudoalteromonas citrea-aurantia* (*Pca*) and/or *Phaeobacter inhibens-gallaeciensis*.

*Pca* has been detected in most of the cultures suffering mortalities caused by *V. pectenicida-V. ostreicida*. Its presence were linked to the pathogens, over the year and independently of the bivalve species.

*Phaeobacter* was also associated to problems in the larval cultures. It was found together with *Pca*, but also alone. As with *Pca*, its proliferation does not seem to follow a seasonal pattern and is not related to bivalve species.

*Phaeobacter inhibens-gallaeciensis* has been proposed as probiotic for marine aquaculture. In fact, we have demonstrated the wide antibacterial spectrum of *Phaeobacter* PP-154, including aquaculture pathogens, especially members of the genus *Vibrio*, in solid medium as well as in seawater. In *vivo* studies in laboratory confirmed its ability to control the growth of vibrios (including *V. ostreicida*) in the water of larval cultures and in microalgal cultures. *Phaeobacter* PP-154 was also effective to combat bacterial infections, naturally produced or induced, with the condition of its use as preventive agent. However, its behaviour in scale-experiments in hatchery was not as expected. In addition, members of these species has been repeatedly isolated from specimens with problems, even caused by vibrios.

(Continued on next page)
Seyedsayamdost et al. (2011) have proposed two distinct phases in the Phaeobacter gallaeciensis-Emiliania huxleyi interaction. In the first phase, the bacteria contribute antibiotics that protect the algal host from bacterial pathogens, and substances that promotes algal growth. In the alternative phase, signals of high algal density and/or algal senescence led P. gallaeciensis to switches its metabolism to the production of algicide, converting the bacteria into an opportunistic pathogen. The findings presented here suggest that some similar could occur in Phaeobacter-larvae interaction, which would explain the risk of failure in scale-up experiments in vivo.

_Pseudoalteromonas citrea_ and _P. aurantia_ are known to produce antibiotic substances (Gauthier 1977, Gauthier and Breittmayer 1979, Holmström et al., 2002), with a broad range of antibacterial activity. However, there is scarce knowledge about their role in marine aquaculture systems and specific interactions with vibrios and/or bivalve larvae.

In summary, both pigmented bacteria share a high antibacterial activity, but in our observations their presence was related to larvae infected by _Vibrio pectenicida-V. ostreicida_, and they proliferated under these conditions without avoiding mortalities. These facts should be taken into account in their potential use as probiotics in aquaculture. Possible chemical signals in degraded larvae, that could trigger pathogenic behaviour in these bacteria, should be studied.

Introduction
Vibrio ostreicida is a pathogen for bivalve larvae isolated in a Galician hatchery (Prado, 2006, Prado et al., 2005) and posteriorly defined as a new species in genus Vibrio (Prado et al. 2014). In the continuous studies carried out in Galician hatcheries since its original detection, over the last two decades, Vibrio ostreicida had not been isolated.

Recently, this pathogen has suddenly emerged in different installations in Galicia, located in different environments, pointing to the seawater as source. Its entry has caused problems in the larval cultures and it seems able to remain in the installation.

Materials and methods
USC and Xunta de Galicia are presently collaborating in the monitoring of the microbiota in two different facilities, belonging to Consellería do Mar (Xunta de Galicia): Centro de Cultivos Mariños-CIMA de Ribadeo and Mini-hatchery at IGAFA.

Microbiological protocols have been implemented for both facilities, taking into account the particularities of each one. Routine samples include seawater and phytoplankton (food) circuits, as well as bivalve cultures. Initially, the bacteriological medium Thiosulphate-Citrate-Bile-Sucrose (TCBS medium) was mainly used as it is selective for vibrios, the main pathogens known in bivalve aquaculture. Further, Marine Agar (MA) was incorporated to obtain a broader view of the marine microbiota present.

Results and Discussion
The first episode of Vibrio ostreicida was recorded in 2022, at the Mini-hatchery in Ría de Arousa (W Galicia, NW Spain). It is a small facility with a light greenhouse-type structure for the cultivation of molluscs seed of commercial interest in Galicia. Routine microbiological controls of the seawater revealed its entry with the seawater in May and its circulation through the circuit of distribution.

It was recorded again in August, in an experience of pre-fattening of pulled carpet clam (Venerupis corrugata) at different densities, in cylindrical lanterns in a “batea” (raft) at Ría de Arousa. After one month at sea, mortalities recorded in the lantern with the highest density pointed to be related to V. ostreicida. Its presence was favoured by density and its pathogenicity by depth.

In 2023, V. ostreicida was detected in the seawater circuit of CIMA, in the Ría de Ribadeo (N Galicia, NW Spain), at least in two successive controls in May. Unfortunately, the pathogen reached the currently cultured larvae, of Ruditapes decussatus. Since the first detection, V. ostreicida has been repeatedly isolated in larval cultures.

This species was originally isolated from a Galician hatchery, with continuous mortalities of young spat of Ostrea edulis (<500 μm in size) (Prado, 2007). Microbiological samples were taken from spat, seawater and tank surfaces. Pathogenicity tests demonstrated that PP-203, isolated from the surfaces of nursery culture containers, caused severe mortalities within 24-48 h. In more recent experiments, we demonstrated the ability of PP-203 to form a biofilm on culture tanks surfaces under hatchery conditions (Prado et al. 2019).

(Continued on next page)
Regarding its source, in both installations seems to be linked to seawater from outside. So far, this pathogen has been found in summer, when the temperatures are rising. Hence, its recent reappearance, after so much years without detection, could be related to the environmental temperature, because in both places a worrying increase of this parameter is being recorded, regardless of their marked differences in their characteristics. Arousa, the biggest “ría” in Galicia, has a high density of population and it is the main aquaculture area, while Ribadeo is a small “ría”, with low human impact.

*Vibrio ostreicida* belongs to the same clade as *V. pectenicida*, within genus *Vibrio*. In fact, they share some special characteristics, such as their poor ability to grow in TCBS medium. Thus, although *V. ostreicida* grows in TCBS, it was mainly isolated from samples in MA medium, as observed with *V. pectenicida*. Both species, once they enter the installation, showed a high capacity of remain “under the radar”, causing continuous problems in the cultures. The demonstrated biofilm formation of *V. ostreicida* on the surface of the tanks under hatchery conditions clearly points to this persistence strategy.

In summary, the appearance of this pathogen in the seawater of Galicia coinciding with the observed increase in environmental temperatures, suggests that this could be a consequence of the climate change. Moreover, its persistence in the installations once it enters, causing mortalities in larval cultures of bivalves, could led to severe problems if it is not properly controlled.

Introduction
Waste management is a critical issue in aquaculture. Waste accumulating in the recirculating aquaculture system (RAS) is a function of amount of waste produced and their efficiency of removal. Since most solid waste is of faecal origin, manipulating the dietary factors may result in attributes desirable for their easy and efficient removal. In earlier studies, increasing the starch level in diet improved the faecal removal efficiency in Nile tilapia (*Oreochromis niloticus*; Amirkolaie et al., 2006), but reduced it in yellowtail kingfish (*Seriola lalandii*; Horstmann et al., 2023, under review), and African catfish (*Clarias gariepinus*; Phan et al., 2022). Similarly, NSP level in diet was shown to improve the faecal quality in Rainbow trout (*Oncorhynchus mykiss*; Meriac et al., 2014). Hence, in this study, we investigated the effect of starch and NSP levels in the diet and their interaction on nutrient digestibility, faecal waste production (digestibility), and faecal characteristics of rainbow trout.

Materials and Methods
Four diets were formulated according to a 2 × 2 factorial design. The first factor, starch was tested by including 0% gelatinized wheat flour (LS- low starch) or 20% gelatinized wheat flour (HS- high starch) in a plant based basal diet. The analysed starch content of the LS- and HS-diets was 40 and 240 g/kg respectively. The second factor, NSP was tested by adding 0% soya hull (LNSP- low NSP) or 10% soya hull (HNSP- high NSP). Tanks (experimental units) were stocked with 25 rainbow trout (initial weight, 81 grams) and the experiment was run for 6 weeks. Fish were fed restrictively (12 g/kg\textsuperscript{0.8}/d, expected FCR 0.9) twice a day. For each tank, faecal waste production and faecal removal efficiency was determined by sedimentation. To get insight into the faeces stability, part of the collected faeces (non-stressed) were exposed to mechanical stress and the PSD was measured.

Results
The amount of faecal waste produced was influenced by the interaction effect of starch and NSP supplementation (P<0.001; Figure 1). At low NSP levels, starch inclusion did not alter faecal waste production. Inclusion of NSP increased waste production, being the highest at the HS-HNSP diet (P<0.001). For most other faecal waste characteristics (faecal removal efficiency; PSD of non-stressed faeces; amount of non-removed faeces) the interactions effect was not significant. Increasing dietary starch content, reduced faecal removal efficiency by 11.3% (P<0.001). NSP inclusion in the diets increased the removal efficiency by 4.4% (P<0.05), which fully compensated for the increased faecal waste produced. The amount of non-removed faeces was unaffected by NSP inclusion (P>0.05), whereas dietary starch inclusion resulted in a doubling of the non-removed faeces (P<0.001). Both starch and NSP inclusion significantly altered PSD of non-stressed faeces (P<0.05). Starch inclusion reduced the size of faecal particles, while NSP inclusion increased it (Image 1). Exposing faeces to mechanical stress reduced the particle size, but this reduction seemed to be affected by an interaction effect between starch and NSP inclusion. After stress exposure, the amount of large faecal pellets (>1600 µm) was lower at the HS-diets, but the difference between LS and HS-diets was largest at the diets without NSP inclusion (P<0.05).

Conclusion
Non-removed faeces by settling is determined by dietary starch content and not by NSP. Dietary starch negatively affects faecal removal efficiency while NSP improves it. Dietary starch content reduces the faeces stability but this effect is dependent on the NSP content.

Introduction

The development of new technologies for aquaculture systems is essential to reach economic, social and environmental sustainability and allow the continuously growth of aquaculture production. In this scenario, the Biofloc Technology System (BFT) have been considered one of the possible solutions and opportunities to further develop aquaculture. However, one of the concerns in the BFT systems is the nitrate accumulation during the culture period, due to zero or low water exchange during the culture period and the constant reuse of water. Therefore, the present work aimed to evaluate the chronic stress of nitrate in *L. vannamei* and the possible recovery of growth rates when nitrate low levels are re-established through compensatory growth, which is defined as a physiological process where the organism goes through a rapid phase of growth after a restricted period of development.

Material and methods

The present work was divided in two experiments. Firstly, a Lethal Concentration 50 (LC50-96h) was conducted in clear water to define the nitrate safe level for *L. vannamei* in salinity 25 mg., calculated using the Trimmed Spearman-Karber Method. Therefore, Nine concentrations of nitrate were chosen to the lethal test: zero (control), 1000, 1500, 2000, 2500, 3000, 3500, 4000 and 4500 mg of N-NO₃.

From the result obtained from the lethal test, the chronic experiment was conducted in BFT. Thus, *L. vannamei* juveniles were stocked with an initial weight of 0.82 g (± 0.25 g) at a stocking density of 300 shrimps/m³. The experiment was performed using a 3 × 2 experimental design (two nitrate concentrations and three exposure times), plus the control (which the nitrate level was maintained lower than 20% of the safe level), totaling seven treatments (in triplicate) and lasted 58 days. The experiment was divided into two phases: (1) Stress and (2) Recovery. Two nitrate concentrations were chosen (safe level determined in the first experiment and half-safe level - 278.91 and 139.45, respectively) and three exposure times were established for each nitrate concentration (10, 20 and 30 days). After the stress period, which varied according to the treatment, the experimental units were exposed to optimum conditions until the experiment complete 58 days.

The treatments exposed to half of the safe level and the groups that were submitted to the nitrate safe level limit during 10, 20 and 30 days were named as 0.5*SL - 10, 0.5*SL - 20 and 0.5*SL - 30, 1.0*SL -10, 1.0*SL – 20 and 1.0*SL – 30, respectively.

Results and discussion

From the lethal test, the estimated LC50-96h was 2789.11, and safe level was determined through Sprague Factor (0.1 of the LC50-96h). Regarding the chronic experiment, survival did not present any difference among treatments over the experimental period. At the end of the stresses phases (day 10, 20 and 30), the weight, Weekly Growth Rate (WGR) and Specific Growth Rate (SGR), of the treatments submitted to 0.5 and 1.0 times of the nitrate safe level during 10 and 20 days (0.5*SL – 10, 0.5*SL - 20, 1.0*SL -10, 1.0*SL – 20) did not statistically differ from the control group. However, after 10 days (day 30) of recovery, in the treatments submitted to 20 days of stress (0.5*SL – 20, 1.0*SL – 20), a statistical difference was found between both treatments and the control. Regarding the treatment exposed to 0.5 times the safe level for 30 days (0.5*SL – 30), it did not present differences compared to the control treatment on day 30, while the treatment exposed to the safe limit level during 30 days (1.0*SL – 30) presented a lower weight compared to the control group. At day 40, the control statistically differ from the treatments stressed during 30 days (0.5*SL – 30, 1.0*SL – 30), which did not differ between them. The Apparent Feed Conversion Rate (AFCR) from the stressed groups during 10 and 20 days did not differ from the control group. Despite that, both 0.5*SL – 30 and 1.0*SL – 30 treatments presented higher AFCR compared to the control group.

(Continued on next page)
After the end of the recovery phase (day 58), no significant differences were found in the body mass among treatments. In addition, no differences were found in the WGR and SGR among treatments previous stressed during 10 and 20 days and the control group. The treatment 1.0*SL – 30 presented higher WGR compared to the control treatment and did not differ from the 0.5*SL – 30. SGR also had an also rate in the 1.0*SL – 30 treatment, followed the 0.5*SL – 30 group, while the control presented the lower SGR. AFCR did not present statistical differences among control and both groups exposed to high nitrate levels during 10 days. Regarding to treatments previous stressed during 20 and 30 days, the control group presented higher AFCE compared to the 0.5*SL – 20 and 0.5*SL-30 treatments, and did not differ from 1.0*SL – 20 and 1.0*SL – 30 groups.

Despite the depressed growth after the nitrate exposure in the treatments mentioned above, the animals were able to recovery the growth rates when exposed to lower levels of nitrate, characterizing total compensatory growth in all treatments previously affected by the high nitrate concentration.

CG is usually evaluated through the improvement of SGR and the feed conversion rate in the stressed treatments compared to the control after the recovery phase, which are both considered an adequate parameter to conclude the occurrence of CG. In the present study, the SGR at the end of the experiment of the 1*SL – 30 and 0.5*SL – 30 treatments, previous affected by the chronic exposition at day 30, was higher than the control, even though the feed conversion rate did not differ from the control. Therefore, since no survivor losses was identified and the final weight did not differ among treatments, it is possible to conclude the treatments previous affected by the nitrate toxicity reached the control treatment weight through CG.

Conclusion

Even though *L. vannamei* presents a great resistance to nitrate exposure, long expositions (more than 20 days) in high nitrate concentrations can negatively affect the growth rates. However, when nitrate lower values are re-established, the animals are capable to regrow in high rates and compensate the weight through compensatory growth.
GENETIC PARAMETERS OF FLESH COLOUR TRAITS IN MARKET SIZE AMUR MIRROR CARP AND THEIR RELATION TO PRODUCTION TRAITS

Introduction

Common carp is one of the most important freshwater fish species for world aquaculture, and its annual production is continuously increasing. Carp meat from pond aquaculture is a healthy product due to the highly nutritious protein, fat, minerals, and vitamins provided by natural food (Mráz et al., 2012). However, to reach sufficient productivity, carp pond aquaculture has to be supported by supplemental feeding, mainly by wheat grain, which might lead to decreased flesh quality in terms of fatty acids and potentially to a change in flesh colour (Mráz et al., 2012; Prchal et al., 2018). Colour and odour of raw fish flesh are important traits for consumers. Despite its affordability and high nutritional value, sometimes carp flesh is ignored at the market because of its unattractive look. In salmonids, it was shown that consumers prefer flesh products with richer red colour (Skonberg et al., 1998). Salmonids species present a moderate genetic variability of flesh colour which enables selective breeding for this trait (Norris and Cunningham, 2004; Blay et al., 2021). The aim of this study was to estimate genetic parameters of raw flesh colour traits in market size common carp and their relation to other economically important production traits (growth-related traits, muscle fat content, survival) to evaluate the possibility of improving carp flesh colour by selective breeding.

Materials and methods

The experimental stock was established by a partial factorial design of 20 dams and 40 sires of broodstock of Amur mirror carp (AMC). The stock was reared communally until the market size of an average of 1,910 g body weight under semi-intensive pond conditions, and 1,277 progenies were phenotyped and assigned to their parents using 12 microsatellites. The flesh colour traits were measured with a Minolta CR400 Chroma Meter and expressed in the L*, a* b* CIE system (Robertson, 1977) to obtain the mean value of the lightness, redness, and yellowness, respectively. Likewise, C* polar coordinate of the chromaticity (relative saturation) was also calculated as . Fish were also phenotyped for survival (Surv) during the last (third) growing season, body weight (BW), Fulton’s condition factor (FC), muscle fat content (%Fat) and slaughter yields (headless carcass: Res_Carss; fillets: Res_Fill). Heritability and genetic and phenotypic correlations were estimated with DMU software using an animal model with a fixed effect of sex.

Results

The mean values for flesh colour traits were typically low for “white-fleshed fish” – L* = 42.4, a* = 1.19, b* = 1.50, C* = 1.74 compared to salmonids. Heritability estimates differed significantly from zero and were low to moderate for flesh colour traits (0.16 – 0.39) and low to high (0.15 – 0.97) for production traits. A negative genetic correlation was observed between FC and a* (-0.44), FC and C* (-0.34) and headless carcass (Res_Carss) and a* (-0.33). Oppositely, a positive genetic correlation was estimated between %Fat and b* (0.50), %Fat and C* (0.47) and Res_Carss and L* (0.41). Moreover, a* was positively genetically correlated to b* ($r_g = 0.36$) and L* was negatively correlated to a* ($r_g = -0.64$).

(Continued on next page)
Discussion and conclusion

Heritability estimates for flesh colour traits in common carp were higher than in a previous study using the same CIE colour space in Atlantic salmon (Norris and Cunningham, 2004) but similar to flesh colour parameters in rainbow trout (Blay et al., 2021). It suggests that although the carp flesh colour is very different from that of salmonids, selective breeding might change these traits. FC, a trait related to body shape in AMC, was negatively genetically correlated to a* and C*. Thus, selecting fish for an elongated body shape might lead to more redness and generally more colourful flesh. We may hypothesize that in our study fish with an elongated shape, closer to that of the Amur wild carp, utilized more pond natural food (copepods, cladocerans and small zooplankton) rich in carotenoids with red pigmentation (Schneider et al., 2016). Conversely, selection for improved Res_Carss would indirectly lead to less redness and more lightness of flesh but also to higher fat content of muscle. Accordingly, muscle fat content was positively genetically associated with b* and C*, which could be explained by higher consumption of supplemental feed. Nevertheless, it might lead to a change in flesh colour and lower flesh quality in terms composition of fatty acids (Prchal et al., 2018). If this was the case, it would question how carp improved for flesh colour would valorise supplemental feed, and the impact on yield. However, further genetic correlations linked to other important performance traits recorded from fry to the market size might bring a better genetic picture of flesh colour traits in common carp and their relation to other traits.

FORCE MEASUREMENT ANALYSIS OF A FULL SCALE OFFSHORE SEAWEED CULTIVATION SYSTEM

A. B. K. Pribadi1*, M. Mansuy1, E. Lataire1

1Maritime Technology Division, Ghent University, Ghent (Belgium)
E-mail: ajiebramakrishna.pribadi@UGent.be

Introduction
As part of the Interreg Wier en Wind project, a full-scale offshore seaweed cultivation system was installed in the Dutch part of the North Sea, 12 km off the coast of Scheveningen. The system was installed in February 2022 and the seaweeds were harvested in June 2022. During this period, a storm of 5.01 m significant wave height was recorded at the location. This study focuses on the impact of environmental conditions of wave, current and tidal variation, as well as biomass, to the measured load in the full-scale seaweed cultivation system.

Materials and methods
The cultivation system consists of a 50 m x 2.1 m net structure on which the seaweeds grown. A 58-meter polyethylene (PE) pipe is utilized as a floatation device to provide buoyancy to the cultivation line. The distance between the two anchors is 230 m at a water depth of 18 m. A main rope is used to connect the net structure to a shackle that connects to the mooring chain. The main rope is connected to the PE tube using loops that are flexible to move along the pipe. As such, the PE tube does not act as a load bearing component. The general arrangement (GA) of the system is visualized in Fig 1. A force gauge with a sampling frequency of 0.2 Hz was fitted to measure the tension experienced by the main rope.

Results and discussions
During the measurement campaign, the highest peak tension was recorded during the harvesting activities. This value is 44% higher compared to the highest peak load during the system’s operational condition. The measured load compared to the water level variations, changes in current magnitudes and significant wave heights (Rijkswaterstaat 2023) is presented in Fig 3. The recorded highest and second highest tensions during operational condition occurred during ebb current and flood current, respectively. This indicates that the tidal variations have dominant influence to the measured peak tension. There are two time windows where the significant wave height is higher than 4.5 m. In those cases, the measured peak load is only up to 66% of the highest peak tension during operational condition (i.e., excluding harvesting). To analyse the influence of biomass, two time windows are compared to observe the mean measured force, presented in Fig 2. In the first time window (21/02/2022 – 25/02/2022) shown in blue dots, the net structure had just been installed, therefore, no biomass increase is present. This is the opposite for the second time window where the biomass has increased more than 1 month after it was installed. From Fig 2, no clear trend can be observed from the influence of the biomass on the mean measured force.

Conclusion
This analysis focuses only on the low frequency load because the influence of waves with a period shorter than 10 s cannot be clearly identified due to aliasing (Nyquist frequency of 0.1 Hz). A power spectral density (PSD) of the measured load reveals that the peak energy is found to be at the frequency of 2.24E-5 Hz or a period of 12.4 hours, which correlates to the cycle of a tidal current. The tidal variations found to be the biggest attribution to the measured peak tension, albeit high frequency forces were not clearly identified. During this measurement campaign, the increase in biomass does not have a significant influence to the measured low frequency load, albeit little biomass was found throughout this campaign.

EFFECT OF PEPTIDE DIETS ON SEA BASS (Dicentrarchus labrax) SKELETAL DEVELOPMENT

Introduction
Fish skeletal development is under the continuous influence of biotic and abiotic parameters (1). Being a valuable welfare index (2), skeletal abnormalities appearance undermines the quality of the experimental results and inevitably, the marketability of the aquaculture products. One of the most critical factors towards normal fish skeletal development is appropriate larval nutrition (3). Protein fraction, being the major component of fishmeal, has been proven advantageous for larval growth, survival and antioxidative response in the form of various sources and hydrolysis levels (4). Simultaneously, an effect of dietary peptides in harmonious skeletal development has been observed (5). Despite the well characterized beneficial effect of small dietary protein products on the normal development of fish skeletal elements, the molecular basis of these observations remains scarse.

The purpose of the present study is to evaluate the effect of three experimental diets with partial peptide incorporation on a) the skeletal development of sea bass larvae and b) the resistance of their vertebral column against swimming induced lordosis. A possible effect of the diets on gene markers of larval maturation (digestion, ossification, and mineralization) was also examined.

Materials and methods
Three isonitrogenous experimental diets were formulated by partial substitution of the total protein source with 0% (C, Control group), 6% (P6) and 12% (P12) shrimp di and tri-peptides. After a short Artemia inclusion (6-20dph), experimental diets were provided exclusively throughout the trials. Study of larval and juvenile quality was performed through means of whole mount staining, histology analysis and micro-ct scanning. To evaluate bones’ integrity against haemal lordosis induction, early juveniles with normal skeletal development were subjected to swimming challenge test (SCT, 6). Gene expression analysis on selected gene of interest was performed by means of rt-qPCR.

Results and Discussion
Results of the early skeletal development revealed an advantageous peptide-enhanced ossification in the case of P12 individuals (Fig. 1). Similarly, P12 had a beneficial effect in the frequency of exercise-induced lordosis after the SCT reducing the deformities rate in only 15.8% (Fig. 2a). RNA analyses confirmed a peptide-enhanced total larval maturation, in terms of their digestive function, bone mineralization and myogenesis in P12. After the exercise, a differential regulation of the genes in the affected haemal area confirmed the scenario about an early peptide nutritional programming of the post-larval musculoskeletal responses.

With the present project, we highlight the beneficial effect of the early peptide diets enhancing the total larval maturation in terms of digestive function and ossification in sea bass larvae. The limitations concerning the free amino acid participation should be taken into consideration. Potential incorporation of these small di- and tripeptides in inert larval but also post-larval diets could enhance larval and post-larval skeletal development.

AQUAPONICS OPTIMIZATION: ASSESSING SYSTEMS OF SUSTAINABLE PRODUCTION AND CONSUMPTION GLOBALLY

Gundula Proksch*
College of Built Environments, University of Washington
3950 University Way NE
Seattle, WA 98195
E-mail: proksch@uw.edu

Introduction
Sustainable food production depends on the recovery of water, energy, and nutrients from waste streams within existing supply chains. Aquaponics (AP) is a system composed of both hydroponic systems (HYP) and recirculating aquaculture systems (RAS) with biofilters in between where bacteria convert organic matter from RAS wastes into nutrients to fertilize HYP edible crops. Such systems are gaining the attention of entrepreneurs and policymakers globally because of their ability to meet local consumer demand for fresh produce from vegetable/fruit crops and high-quality protein from fish. The widespread adoption of aquaponics as a ‘green’ sustainable food production system needs further research and innovation to optimize system performance through enhancing biofilters, reducing reliance on fossil fuels, and assisting producers in transitioning to energy-efficient AP designs that fit their local human and natural resources while supporting them in management, marketing, and distribution decisions.

Globally, AP systems’ feasibility and environmental footprint depend on climate, technology adoption levels, and cultural contexts. To address these needs, “Aquaponics Optimization” leverages socioeconomic expertise and stakeholder knowledge to create a genuinely transdisciplinary team on five continents with core research partners in Sweden, Germany, Turkey, Taiwan, South Africa, Brazil, and the United States.

The partners aim to advance AP technology and implementation that supports regional environmental, economic, and social sustainability objectives. The project aims to enhance a climate-change-resilient food production system that:
1. Reduces, reuses, and recycles inputs while increasing nutrient and water efficiencies.
2. Reutilizes industrial and agricultural wastes to turn them into food, energy, and profit.
3. Provides ways to produce food that adapt to local climate change conditions.
4. Builds community capacity through skills development and knowledge exchange.

Methodology
In this study/poster, the Aquaponics Optimization team will share their overall interdisciplinary research design of connecting scientific advancement and optimization of the RAS and HYP system and required infrastructure while at the same time using social science methods to assess stakeholders’ best practices. The team will primarily collect data through semi-structured interviews.

Figure 1: Global network of core collaborators.

(Continued on next page)
As a first step, Aquaponics Optimization aims to identify active, commercially operating aquaponics farms (in addition to their database of over 600 aquaponics farms) globally and solicits self-registration through a form (docs. Google) and the snowball principle following takeaways from earlier AP surveys (Love et al. 2014; Pattillo et al. 2022).

Based on the directory, the team will identify a representative sample of operating aquaponics farms to conduct semi-structured interviews, following the methodology established in previous interdisciplinary research (Horn et al. 2023). As part of this study/poster, the team will share its framework for the questions and interview guide for its semi-structured interviews. The main topics that Aquaponics Optimization will address in stakeholder interviews include regional market analysis, consumer preferences, marketing strategies, supply chain issues, social benefits, food security advancement, and regulatory frameworks in selective cultural contexts across the world.

Commercial aquaponics producers from the global database of active commercial aquaponic farms will be recruited for semi-structured interviews. The interview guide will undergo an Institutional Review Board (IRB) review. Once the interviews have been conducted, their transcripts will be qualitatively content coded utilizing the established framework structure within the qualitative data analysis software Atlas.ti. The dissemination of the findings will be based on a collaborative analysis and review process of the interviews, combined with literature and policy data.

**Results**

The data collection about the emerging aquaponics industry globally will generate the following results: The directory entries will be consolidated and analyzed using Tableau Prep and Tableau by the Aquaponics Optimization team at the University of Washington. Results will indicate the current scale of aquaponic farming worldwide. Additionally, the team will use the data to create a searchable Global Aquaponic Directory for public use.

The results of the semi-structured interviews will be published in peer-reviewed journal articles. Five core questions will be addressed: (a) market analysis of AP operations around the world in different cultural contexts; (b) roadmap to increase marketability of AP; (c) assessment of social benefits and empowerment through AP; (d) opportunity map for AP to address food insecurity; and (e) regulatory barriers for the advancement of AP identified by stakeholders.

AQUAPONICS FOR FRONTLINE COMMUNITIES: SYNERGIES BETWEEN BENEFITS OF DIFFERENT OPERATION TYPES

Gundula Proksch

College of Built Environments
University of Washington
3950 University Way NE
Seattle, WA 98195
E-mail: prokschg@uw.edu

Introduction
Aquaponics (AP) has received much praise for its manifold environmental benefits as a system that recovers and reuses water, nutrients, and energy; economic potential for creating local healthy and safe food and jobs in the green economy; and potential to generate social community and educational benefits. This wide range of benefits is partly possible through the different types of AP that are typical in and around cities, such as large commercial production farms (Type 1), urban, commercial mixed-income AP (Type 2), community and educational operations (Type 3 a and b), and domestic AP (Type 5) (Proksch et al. 2022). While the benefits and types are well understood, more research needs to be conducted on how the different farm types could be integrated into specific neighborhoods. How would a mix of AP operations support a just transition towards a circular community?

This study investigates how the urban integration of AP operations helps to establish circular city principles in the frontline communities of South Park and Georgetown in Seattle, WA.

Methodology
Based on the speculative integration of different AP types in the same urban area, this investigation first establishes the (1) urban capacity of the two frontline neighborhoods for the integration of AP by identifying suitable sites and warehouse roofs for AP operations (Figure 1). It then assesses the (2) resources and infrastructure needed to operate the most common five types. An operating case study example for each type of AP has been identified (Figure 2), and their needs have been adjusted to the climate, geographic, and socioeconomic conditions in Seattle, WA. In the third step, (3) a representative available site is matched with an enclosure type most appropriate for each operation type. For example, Type 1, the large commercial production farm, will be assumed to occupy an on-grade greenhouse (Figure 3). Type 2, the urban, commercial mixed-income AP operation, will be co-located with an existing (food) business in a rooftop greenhouse. In the final step, the inputs, outputs, and benefits of the five types of operations will be compared. The inputs include data on start-up funding, potential funding sources, resources needed for operation, and the environmental footprint. As part of the outputs, yields, jobs, training opportunities, and non-monetary benefits are considered.

Figure 1: Suitable sites for AP operations in two frontline communities in Seattle, WA.

(Continued on next page)
Results
The assumptions and data collected for the five AP types will be compared in a graphic format. The main assessment criteria are the return on investment measured in different community benefits and the environmental footprint. The investigation concludes with a recommendation that a mix of aquaponics operations would make the most significant impact in transforming Seattle’s frontline communities, South Park and Georgetown, into a circular community.

CO-LOCATING AQUAPONICS GREENHOUSES AND BREWERIES: COMBINING FISH, HOPS, AND BEER PRODUCTION TO MITIGATE EFFECTS OF CLIMATE CHANGE

Gundula Proksch, Yixuan Eve Wang, Bella Septianti

College of Built Environments
University of Washington
3950 University Way NE
Seattle, WA 98195
E-mail: prokschg@uw.edu

Introduction
The growing interest in aquaponics (AP) reflects its positioning as a technology able to help advance the implementation of circular city principles (Proksch 2023) and support the sustainable development of food systems (Horn et al. 2023). The co-location of AP operations with other (food) industries further increases resource efficiency (Baganz et al. 2020). One promising co-location partner is breweries (Horn and Proksch 2020); a related one that has not received as much examination yet is hops production. Globally, hop production has decreased due to abnormally hot and dry growing seasons. Hops are grown in temperate climates; about 80 percent are produced in Germany and the United States. In Washington State, hops are commercially grown in the Yakima Valley, located in the eastern part of the state. This speculative investigation co-locates an AP production greenhouse with one of Washington State’s largest breweries and indoor hop production in Georgetown, an industrial neighborhood in South Seattle.

Methodology
Potential sites for AP facilities are identified adjacent to the five existing breweries in Georgetown. Locating vacant sites and warehouses reveal proximities and potentials for co-location. Each brewery facility is studied for greenhouses sites, and Elysian Brewery is identified as the primary case study.

The Elysian Brewing complex already offers an existing bar and restaurant and can be expanded with a rooftop greenhouse, outdoor growing, indoor growing, and a fish farm (Figure 2). This program accommodates community space and education facilities. With this co-location, the waste heat and spent grain from the brewery can be used as resources for the AP facility to produce nutritious food.

Results
The combination of all three production facilities for fish, hops, and beer in one complex (Figure 3) fosters resource and energy-efficient production of all three products, generates an urban, commercial mixed-income (Type 2) facility (Proksch et al. 2022), and helps to mitigate effects of climate change.

Introduction
Yeasts have been proved to be as functional nutritional supplements in fish diets with beneficial effects on growth, immune response and gut health (Agboola et al. 2021). This is mainly due to the high concentrations of mannooligosaccharides (MOS), β-glucan and chitin in their cell walls. Despite the importance of gilthead seabream (Sparus aurata) in aquaculture, there is limited relevant information and thus this study aimed at evaluating the effects of dietary supplementation with various yeast products on growth, immunology and histomorphology of the species.

Materials and Methods
S. aurata juveniles of 3.36 g initial mean weight were stocked at 12 tanks (125L) in a closed seawater recirculation system. Fish in triplicate groups (22 fish/tank, 3 tanks/dietary group) were fed to satiety, twice a day for 75 days, each of the six isonitrogenous (50%), isoenergetic (21.5 MJ/Kg) and isolipidic (15%) diets: a Control, three diets supplemented with 2% of either grain distillers dried yeast (GDY), brewery yeast (BY) or concentrated autolyzed yeast (AY), a diet (MOS) supplemented with 0.05% of a commercial premium yeast fraction from Saccharomyces cerevisiae containing mainly MOS, and a diet (LY) supplemented with 0.25% of a commercial live yeast product. At the end, fish were weighted to measure growth and feed utilization parameters. Blood samples from 18 fish per group were used for immunological analyses, while liver and foregut samples from 15 fish per group were used for histology.

Results and Discussion
The 2% supplementation with yeast products (GDY, BY, AY) significantly increased the feed intake, but that did not improve fish growth, while also decreased feed efficiency (Table 1). In fact, BY led to impaired (P<0.05) growth compared to the control group. MOS and LY did not exert any significant influence on fish growth and feed utilization compared to the control group. The histological analysis of seabream fed the experimental diets revealed a normal and similar histomorphological structure of liver and foregut among all dietary groups, but all yeast-based diets increased the intestinal epithelial brush border width with the highest values found in MOS and LY groups (results are not shown). GDY and BY increased the antibacterial activity against E.coli, but BY was slower to assemble the complement complexe. BY also tended to increase the trypsin inhibition and to decrease the ceruloplasmin activity, while LY tended to increase the alkaline phosphatase activity. MOS increased significantly the trypsin inhibition but reduced the antibacterial activity of the complement. The autolysed yeast did not show any significant effect on the immune system of the tested fish.

These results indicate that distiller grain yeast, brewery yeast and live yeast should be further studied as they may improve the immune system of S. aurata, despite the negative effect of the first two on feed efficiency. MOS may also be an efficient supplement showing some conflicting results with increased protection against pathogen evasion but decreased antibacterial activity, without affecting seabream’s growth performance. Several studies suggested that substantial dietary levels of yeast products did not have an adverse effect on growth and feed efficiency of S. aurata (Fronte et al. 2019, Reis et al. 2021, Nazzaro et al. 2021). Some gut morphological changes have been observed in the studies of Dimitroglou et al. (2010) and Fronte et al. (2019). Ortúño et al. (2002) reported that 1% S. cerevisiae yeast in the diet at 1% did not enhance the serum complement titres but did enhance the cellular innate immune response of S. aurata. Rodríguez et al. (2003) reported decreased serum peroxidases and complement activity and an increased lysozyme activity with 1% S. cerevisiae yeast dietary supplementation. When Reis at al. (2021) used a diet with 0.06% β-glucan dietary concentration extracted from yeast found no changes in plasma innate immune status. Further studies are needed to enlighten the effects of yeast products on S. aurata nutrition and immunology.

POPULATION STRUCTURE ANALYSIS OF BIVALVE SPECIES *Arca noae* FROM THE CENTRAL ADRIATIC SEA

S. Puljas* and N. Petrić

Faculty of science Split, Ruđera Boškovića 33, Split (Croatia)
E-mail: spuljas@pmfst.hr

Introduction
Along with the species *Pecten jacobaeus*, *Venus verrucosa*, *Mytilus galloprovincialis* and *Ostrea edulis*, the species *Arca noae* is one of the most important commercial bivalves overfished in the Adriatic Sea. Although much is known about the biology of the species, there is currently insufficient data on the intensity of fishing and the status of exploited populations on the east coast of the Adriatic. The minimum length of individuals (LML) allowed for fishing is 50 mm (Officiale Gazzete 63/2010), and the species reaches the indicated length at 3 to 7 years of age (Peharda et al., 2012). Although *A. noae* inhabits much of the eastern coast, recent studies indicate overfishing in certain areas. In the southern Adriatic basin (Maloston Bay), individuals below the legal minimum length accounted for 61% of commercial catches, and in the central Adriatic basin (Pašman Channel), the proportion exceeded 74% (Peharda et al. 2009). Therefore, the aim of this work was to determine the extent of fishing pressure on the population in Kaštela Bay in the central Adriatic Sea in order to gather information to assess the status of the population in this area.

Material and methods
The length composition of 50 individuals in the commercial catches was determined by the proportion of individuals shorter than the minimum length allowed for fishing (LML). In addition to describing the composition of individuals in terms of gender and size, the reproductive potential of the species and current selection pressure on individuals of a particular gender and length categories were analysed. Morphometric parameters were determined for all individuals and the gender of each individual was determined by histological methods.

![Fig. 1. Length frequency histogram of *Arca noae* individuals from the commercial catch in relation to the legal minimum length (LML)](image1)

![Fig. 2. Differences in mean length values of younger and older males and females from Kaštela Bay](image2)

![Fig. 3. Partially spawned male (A) and female (B) (scale bar: 300 µm)](image3)

(Continued on next page)
Results
Of the 50 individuals from the commercial catch, 12 (24%) were male, while 38 (76%) were female. 34% of all specimens were shorter than the legal minimum length (< 50 mm), of which 76.5% were female (Fig.1). Selection pressure was also observed on females with shell length between 50 and 60 mm. Analysis of the average length of captured males and females in both categories showed that captured males in the category above the legal minimum length were longer than females, while the lengths of males and females in the category below the legal minimum length were almost equal (Fig. 2). The reproductive potential of all individuals from both categories was 100% (Fig. 3).

Conclusion
Selection pressure was determined by gender analysis. The population is dominated by younger females, suggesting overexploitation of older females in the past and the current dominance of older males. The results also warn of the possibility of future overexploitation of individuals shorter than the legal minimum length and emphasize the importance of their role in maintaining population stability, as these individuals have the potential to participate in spawning, according to the reproductive potential analysis. The fact that Arca noae is not suitable for line-fish farming due to its low survival rate and slow growth (Župan et al., 2014) also contributes to concerns about overexploitation of this species.

Introduction

Bacterial presence in the water column can adversely impact fish health and, therefore, aquaculture production. For example, *Vibrio* spp. are ubiquitous heterotrophic bacteria found in aquatic and marine environments that can cause vibriosis, a potentially fatal disease in humans and aquatic animals (Baker-Austin et al, 2018). Pathogenic *Vibrio* spp. have already been causing mass fish die-offs, thus adversely affecting both farming and the environment; their impact is projected to increase due to climate change and other anthropogenic factors (Sampaio et al, 2022).

Water quality has generally been monitored using bacterial indicators such as heterotrophic plate counts, total coliforms, and fecal coliforms (Some et al, 2021). However, bacterial indicators such as *Vibrio* spp. have been ignored despite their potential importance in monitoring water quality in coastal areas. Although *Vibrio* spp. are regulated for food products (ISO 21872-1:2017), uniform guidelines and official regulations for monitoring their environmental presence in management strategies are still lacking.

Materials and methods

In this study, we examine the applicability of *Vibrio* spp. abundance as an additional indicator of water quality for informing science-based coastal management. To achieve this, we analyzed a three-year open dataset from Mali Ston Bay that included standard environmental and bacterial indicators, as well as *Vibrio* spp. abundance (Jug-Dujaković et al, 2022). To determine whether *Vibrio* spp. abundance provides additional information on water quality, we assessed the seasonal, spatial, and vertical variations of environmental and bacterial indicators such as HPC (heterotrophic plate counts), TC (total coliforms), *E. coli*, enterococci, and *Vibrio* spp. abundance, and their interrelationships. Specifically, we examined: (i) the extent of emissions from the fish farm, (ii) the environmental factors that impact *Vibrio* spp. abundance, and (iii) the variability of *Vibrio* spp. abundance in relation to other potential pathogens, including *E. coli*, enterococci, and heterotrophic bacteria overall. Differences between seasons (warm and cold), sites (fish farm and control) and depths (surface, 5m, 10m and bottom) for both environmental and bacterial indicators were investigated by permutational multivariate analysis of variance (PERMANOVA; Anderson, 2001). Relationships between environmental and bacterial indicators were assessed with Pearson’s correlation analysis and RDA (Legendre and Legendre, 2012). Finally, the distributions of pathogenic bacteria (*E. coli* and enterococci) in the water column was compared to that of *Vibrio* spp. by using water quality abundance categories (as defined in the Official Gazette of the Republic of Croatia 73/08). Official standards for *Vibrio* spp. for assessing water quality were not yet available, so we estimated one using a threshold of 100 CFU/ml reported to result in bacterial transmission into organisms after prolonged exposure to *Vibrio* spp. (Kim and Lee, 2017). We assumed the 100 CFU/ml critical value represents a threshold defining ‘sufficient’ water quality, and extrapolated the other thresholds using classification for enterococci, who share the same critical value for ‘sufficient’ water quality.

(Continued on next page)
Results

Our results show no differences between the fish farm and control site in terms of environmental conditions, organic enrichment, and bacterial abundance. However, the abundance of heterotrophic bacteria, enterococci, and *Vibrio* spp. was unexpectedly higher during the cold season. *E. coli* and total coliforms, in line with traditional patterns, were more abundant during the warm season. Temperature was found to be the best predictor of *Vibrio* spp. abundance when examining the correlation among explanatory variables in RDA, followed by total phosphorus. This finding reinforces the significance of temperature and the often restrictive nutrients in driving the dynamics of bacterial abundance. According to the thresholds from the Official Gazette 73/08, water quality was generally excellent. The best score was achieved by *E. coli*, with over 95% of samples collected at each site meeting the criteria for excellent quality. Enterococci showed excellent quality in more than 91% of the samples, while less than 64% of samples tested for *Vibrio* spp. fell into the excellent category. The notably lower result for *Vibrio* spp. suggests that either (i) there is a genuine concern regarding the prevalence of potentially pathogenic *Vibrio* spp., or (ii) the thresholds adopted from the enterococci regulations may not accurately reflect the risk of disease.

FEEDING RAINBOW TROUT (*Oncorhynchus mykiss*) WITH GUAR MEAL PROTEIN CONCENTRATE: WHICH IS THE BEST PERCENTAGE OF CONVENTIONAL PROTEIN SOURCE REPLACEMENT?

Quagliardi M.*, Galosi L., Di Cerbo A., Roncarati A.

School of Biosciences and Veterinary Medicine, Camerino University, Italy

E-mail: martina.quagliardi@unicam.it

Introduction

Since rainbow trout (*Oncorhynchus mykiss*) is one of the most significant freshwater fish species reared, efforts to improve this industry through genetic selection and sustainable diets are being made (Garcia-Ballesteros et al., 2021; D’Agaro et al., 2021).

Soy, rapeseed, wheat gluten and corn gluten are commonly used as protein concentrates in aquafeeds, due to their high digestibility (Parisi et al., 2020). Guar meal, deriving from the endosperm of an Indian cluster bean, the galactomannan polysaccharide Guar gum (*Cyamopsis tetragonolobus*), has already been used in aquafeed, increasing faecal stability (Janphirom et al., 2010). In the last years, it has been purified to reduce saponin, tannin, phytates and protease inhibitor concentration, that are considered to negatively affect growth of salmonids (Pach F. and Nagel F., 2017).

In this trial proprietary guar meal protein concentrate (MYCOPRIME®, Panghea SPA, Milan, Italy) replaced different percentages of conventional proteins in feed for rainbow trout, to investigate its effects on zootchnical performances during the fattening phase of rainbow trout.

Materials and Methods

A total of 2700 rainbow trout (mean body weight 50±1.4g) were reared at the initial stocking density of 15 kg/m³ in 12 concrete tanks (6x1x0.5m). The principal water physical-chemical parameters (temperature, dissolved oxygen and pH) were recorded daily. Total Ammonia Nitrogen (TAN), nitrates (NO₃-N) and nitrites (NO₂-N) were determined weekly using a spectrophotometer (Hach mod-2005, Hach Company, Loveland, USA) following the American Water Works Association and Water Pollution Control Federation of American Public Health Association (APHA) standard methods (1995).

Trout were fed twice a day *ad libitum*; each diet was administered to fish of three tanks. The Control diet (CD) was a growing feed available for trout with 43% of proteins and 25.3% of lipids (% as it is). The two experimental feeds (D5 and D15) were formulated isoproteic and isolipidic; a partial replacement with guar meal concentrate (5% in the D5 and 15% in the D15) of fish meal, chicken meal and soybean meal was applied.

The trial was performed during a standard zootechnical cycle and lasted 90 days. Final mean weight (g) and Final mean length (cm) were recorded and Palatability was calculated. Water physical-chemical parameters, fish biometric parameters and final productive traits were submitted to one-way analysis of variance (ANOVA) with *p*<0.05.

Results and discussion

The water physical-chemical parameters showed a very similar trend in terms of temperature, dissolved oxygen and pH during the whole trial. The nitrogen compounds demonstrated significant differences in TAN, having the highest ammonia concentration in D15 tank (0.44 ± 0.01 mg/L) compared to CD (0.24 ± 0.09 mg/L) and D5 (0.22 ± 0.06 mg/L). Nitrites ranged between 0.01 ± 0.001 mg/L (D15) and 0.02 ± 0.002 mg/L (CD). Nitrates varied between 0.9 ± 0.1 mg/L (D15) and 1.1 ± 0.4 mg/L (CD) without significant statistical differences. Brinker et al. observed negative effects on fine solid particles using diets with guar meal replacement, that clogged biofilters, in a recirculating water system (Brinker A. and Fredrich C., 2012); this condition occurred also in tank D15.

Concerning the biometric parameters, the final mean weight of trout receiving D5 (201.00 ± 3.7 g) and CD (198.8 ± 3.8 g) showed similar results, significantly major in comparison with D15 (171.2 ± 5.1 g). Final mean length didn’t show significant differences. Feed palatability resulted higher in CD and D5 diets in comparison to D15; in fact, presumably, trout fed with D15 reached the satiation before and this condition affected also the final zootechnical performances as shown by the lowest final mean body weight. This negative output could have been caused also by the reduction of the apparent digestibility of dry matter, crude protein, and crude lipid due to the highest inclusion of guar gum (Liu et al., 2022).

(Continued on next page)
Conclusions
Considering the zootechnical performances, the 5% inclusion of guar meal protein concentrate in fish feed resulted to be positive. Further analysis concerning fish welfare status and feed efficiency are going to be performed to confirm the satisfactory results.

Email: hferreira@ipma.pt

Introduction

Integrated Multi Trophic Aquaculture requires an equilibrium between farming different organisms in the same system. This requires an understanding of the biology and interactions between species. In earth ponds one of the main drivers of the dynamic of the system are microalgae and how the farmed species, either freshwater or seawater fish, bivalves and seaweeds, influence the population of microalgae. In Portugal since 2010 the EPPO has been studying the integrated culture of oysters in fishponds. From then EPPO has been building a larger database of technical, biological and water quality information to help create a model of IMTA for earth ponds. One key information for this database is the clearance rate of microalgae by oysters inside fishponds across a temperature gradient (reflecting the seasons). This poster will show the methodology to achieve this information in a reliable and affordable way.

Materials & Methods

All trials were performed in the earth ponds of the Aquaculture Research Station in Olhão, South of Portugal. The testing procedure involved using three acrylic cylinders: one served as a control, and the other two were replicas (Figure 1a). These cylinders were placed in the outlet of an earth pond fish culture, maintaining the typical environmental conditions of IMTA cultivation at EPPO (Cunha et al, 2019). The ponds used in all seasons comprised a total density of gilthead seabream (Sparus aurata) and European seabass (Dicentrarchus labrax) of 0.8 Kg/m³. To assess the filtration rates of oysters within the IMTA production system, specifically Crassostrea gigas, six individuals were selected for the assay. These individuals had dry weights ranging from 7.23 to 5.13 g.

Each of the three cylinders had a volume of 49.59 L, a water height of 1.75m, and a diameter of 0.19m. The cylinders were filled with water from the pond used and were continuously aerated to ensure constant water circulation and gas exchange with the atmosphere. Within each replica (C2 and C3 in Figure 1c), three oysters were placed in baskets suspended by ropes, approximately at the centre of the cylinders. The entire test spanned a duration of 3 hours, from 15:15 h to 18:15 h, during which environmental parameters within each cylinder were measured at 15-minute intervals.

Measurements included chlorophyll-a concentration (μg/L), pH, temperature (°C), and salinity, which were determined using a multiparameter system (model EXO 2, YSI/Xylem, USA). Additionally, the dissolved oxygen concentration (mg/L) was measured using a portable probe (model H9829, Hanna Instruments, USA) (refer to Figure 4, b). The dry weight and mineral content of the oysters, encompassing both meat and shells, were assessed by subjecting them to specific conditions in an oven (60°C for 24 hours) and muffle furnace (core: 525°C until white/grayish color, shell: 600°C for 2 hours), respectively.

Results & Discussion

Three different temperatures were test for oyster filtration rate: 16°C, 20°C and 26°C. At the start of each test, chlorophyll a mean concentration for the three cylinders used was, respectively, 4.5 ug/L, 49.5 ug/L and 9.6 ug/L.

At 16°C Chla concentration were not significantly different between control cylinder (without oysters) and both cylinders with oysters across the 3-hour period. At 20°C oysters manage to decrease the microalgae growth inside the test cylinders by up to 34% compared with the control. Final Chla concentration after 3 hours at this temperature were 94 ug/L for Control and only 71.7 ug/L in test cylinders. At 26°C, Chla concentrations in Control increase from 10.6 to 17.76 ug/L (an increase of 67%) and in test cylinders there was a decrease from 9.1 to 1.2 ug/L. This decrease shows that the oyster filtration rate was much higher than the microalgae growth, leading to a depletion of food for the oysters if the test continued a couple more hours.

(Continued on next page)
Although the initial microalgae concentrations for the three temperatures tested where significantly different as mentioned above, we could see that the filtration rate is higher at 20°C compared with 16 and 26°C ranges and similar to previous clearance rate tests of *Crassostrea gigas* (Bougrier *et al* 1995; Haurea *et al* 2003; Dupuy *et al* 2000; Nascimento *et al* 2022).

With this information on filtration rates for *Crassostrea gigas* we can see that temperature and microalgae concentration are key variables to estimate the oysters integration with fish and this varies substantially across seasons. Oyster density along the production cycle should be managed to avoid microalgae depletion at all seasons and especially when high oyster density and lower microalgae growth rates (usually below 18°C) occur at the same time. Managing microalgae population across all seasons in an IMTA pond with fish and oysters is the main key to allow for better oxygen levels, proper performance of oysters and fish and avoidance of stressful conditions for all farmed species. Knowing how much oyster filtration rates affect these dynamics is vital to application of IMTA principles to pond aquaculture of fish and bivalves.

**Introduction**

The greater amberjack (Seriola dumerili) is a marine fish with great consumer acceptance than can reach up to 2 kg in 18 months. However, seriola’s culture still face a series of bottlenecks that difficult a further expansion of this species aquaculture. Among them, the larval rearing phase faces great difficulties due to the limited bibliography of culture conditions and nutritional requirements, which produces a low quality of the juveniles, and therefore a limited market availability.

Taurine is an essential nutrient for larval development and growth, mainly in carnivorous marine fish such as the greater amberjack (Djellata et al., 2022). However, there are no available data on dietary taurine supplementation during the weaning period of this species.

**Materials and methods**

Four granulated microdiets containing 0.24 to 4.24 % of taurine levels were evaluated in 30 days post-hatching (dph) greater amberjack larvae until 44 dph. For that, 2700 larvae of 30 dph were handly distributed in twelve experimental tanks of 200 L volume in an open flow sea water system. During the first days the larvae were co-fed with enriched Artemia sp. metanaupli to be gradually weaned, and from day 39 until the end of the trial the larvae received only the microdiets. Each diet was offered in triplicate tanks from 8:00 am to 19:00 pm, and at 44 dph, survival, growth, the histology of liver and gut, the expression of growth and stress-related genes, and the incidence of skeletal anomalies were evaluated.

**Results**

There were no significant differences in survival because the administration of the different diets, however, regarding growth performance, the larvae fed 1.24% of taurine presented higher final weight and length, as well as higher total and daily weight gain.

Regarding the histological results, the level of vacuolization in liver was directly proportional to the level of taurine supplementation, with the highest levels reported for the larvae fed taurine at 4.24%. There were observed some intestinal lesions along the intestine without differences between treatments, however with the highest percentage of incidence (around 13%) in the larvae fed taurine at 4.24%.

Additionally, the larvae fed with 1.24 % taurine level had a higher expression of growth and stress-related genes (gh, igf-ii, crh and trh) at 44 dph.

The evaluation of skeletal anomalies revealed that treatment of taurine at 4.24 % also produced a higher incidence of total skeletal anomalies, followed by the treatment with the lowest taurine supplementation. The main anomalies founded were alterations in the vertebra of the pre-hemal and hemal regions, as compression or fusions of the vertebral bodies or kyphosis.

(Continued on next page)
Discussion and conclusions
The present results suggest the importance of adequate taurine supplementation in the weaning of the greater amberjack, as it impacts the growth, liver vacuolization, gene expression, and the incidence of skeletal anomalies in the fish. Despite including marine protein sources in the microdiets, a moderated level of taurine supplementation (1.24 g/100 g diet dry mass) is recommended for greater amberjack larvae. Additionally, excessive levels of dietary taurine (4.24 g/100 g diet dry mass) caused impairment in larval growth and quality.

**Introduction**

Parasitic infestations are a significant bottleneck for the further expansion of the culture of different aquaculture species as the greater amberjack (*Seriola dumerili*), producing mass mortalities and instability of the offer and production costs. *Neobenedenia girellae* is one of the main parasites which cause skin infection in carangids, feeding on their mucus and epithelial cells and causing haemorrhage, hyperproduction of mucus, inflammation, and epidermis thickening (Hirazawa *et al.*, 2013; Fernández-Montero *et al.*, 2019). Thus, an efficient approach for controlling these parasitic infestations is of great importance to developing the culture of *Seriola* sp., among them freshwater or formaldehyde baths and oral treatments with antiparasitic drugs (Hirazawa *et al.*, 2004; Hirazawa *et al.*, 2013). However, an integrated approach considering the local specificities is necessary to maximize the protocols’ effectiveness. For those reasons, the present study aimed to assess the local specificities of *Neobenedenia girellae* life cycle in the context of the last challenges for climate change resilience in the Canary Islands, Spain.

**Materials and methods**

From April to July 2023, juveniles of greater amberjack placed in open seawater system were monitored every two weeks to determine the presence of *Neobenedenia girellae*.

For that the animals were anesthesized with clove oil:ethanol 1:1, and subjected to a freshwater bath for 4 minutes (Hirazawa *et al.*, 2013). After the bath, the water was filtered through a 125 µm net, and the net was examined under a stereoscope to determine the presence of adults or eggs of *N. girellae*.

Once the presence of parasites was determined, alive specimens were carefully collected from the skin surface with a scalpel and placed in plastic dishes (10 cm diameter) filled with natural seawater. Additionally, white segments of polyester threads (around 50 cm length), were placed in the tanks and monitored every 24 h to check the presence of *N. girellae* eggs. Polyester threads when then placed in 300 ml buckets filled with natural seawater. Water from both plates and buckets was removed and replaced daily with clean seawater and temperature was monitored. The time to hatching was monitored through daily visualization of the eggs under a stereoscope. Additionally, measurements of adults and eggs (n=30) were made under the stereoscope with the program Leica Application Suite (Leica Microsystems Ltd., Heerbrugg, Switzerland).

(Continued on next page)
Results
The first detection of parasitation of *N. girellae* on the juveniles was determined in early July, with water temperatures rising from 23°C, and severe parasitation levels occurred from that moment in only two weeks between treatments with freshwater baths. Collected *N. girellae* adults placed in plates spawned in 24 h (25-27 °C). The mean fecundity was of 58.82±33.59 eggs per day and adult. Adults survived for a maximum of 72 h without a host. Egg hatching occurred from 4 to 8 days at mean temperatures of 26.5±2.38 °C and 24.8±2.86 °C, respectively. The oncomiracidia died in a maximum of 48 h without a host.

The mean area and perimeter of the eggs were 0.01±0.00 mm² and 0.44±0.04 mm, respectively, being the mean total length of adults of 3.96±0.68 mm.

Discussion and conclusions
In the context of climate change and ocean warming, adapting to new conditions and challenges will determine the success of sustainable aquaculture (Glencross *et al*., 2023). Moreover, as most aquatic species' life cycles are greatly affected by environmental conditions, microbial and parasitic infestations are expected to increase, so resilient and adapted protocols must be developed.

Although data obtained for *N. girellae* fecundity and adult size is lower than those reported by other authors (Hirazawa *et al*., 2013; Fernández-Montero *et al*., 2019), the record temperatures achieved in the North Atlantic in 2023, with 2 degrees higher than expected (Climate Change Institute, 2023), has aggravated the population densities of *N. girellae*, producing severe infestations in only two weeks between control treatments. Therefore, the periodicity of preventive procedures must be adapted, being recommended to be made weekly under the conditions described. In this context, establishing adequate oral treatments is a necessary tool to control the increasing prevalence of parasitic infestations.

Introduction

Senegalese sole (*Solea senegalensis*) is an emerging aquaculture species in Europe. However, despite large investments, bottlenecks in reproduction still curtail the expansion of this industry. This flatfish can reproduce in captivity when captured from the wild, but males reared in captivity (F1) fail to reproduce despite they produce viable sperm for fecundation. So reproduction is the main constraint in Senegalese sole aquaculture and consequently, the pursuit for potential solutions has been approached through different fields. It has been hypothesized that chemical communication might underlie sole courtship failure and that environmental factors associated with different life stories of F1 vs wild males may underlie the low performance of F1 males.

The fish olfactory organ, an essential player for chemical communication, is a multilamellar and rosette-shaped structure, composed of an epithelium embedded with olfactory sensory neurons expressing individual olfactory receptors. Despite its critical role in social relationships and individuals’ interaction with their environment, the olfactory system remains understudied. In particular, while its role in mammalian reproduction is well-established, its involvement in fish reproduction is poorly characterized. The aim of this work is to improve our knowledge of the fish olfactory system, and in particular, in the context of reproduction. To do so, we conducted a single-nuclei RNAseq (snRNAseq) analysis of the olfactory organ, enabling the characterization of transcriptomic profiles at the individual cell level featuring the different cell populations and their heterogeneity.

Material and Methods

The olfactory organ was collected from 3 different Senegalese sole fish (1 wild male, 1 wild female & 1 F1 male - born in captivity). A total of 6 samples, two samples per individual considering dorsal and ventral olfactory rosettes, were dissected and flash frozen separately. Nuclei were extracted using a modified protocol (REF) and processed using the Single-cell/nuclei RNA-seq Chromium 10X pipeline. Single-nuclei RNA-seq libraries were sequenced in a Novaseq 6000 as 150PE reads. Raw sequencing was aligned against the most recent Senegalese sole genome (GCA_919967415.2, de la Herrán et al. 2022) using STARSolo (Kaminow et al. 2021) and analysed using the R package Seurat (Stuart et al. 2019).

![Fig. 1: (A) UMAP of the clustering. (B) Dotplot of ORAs expression in each cluster.](Continued on next page)
Results
The six Senegalese sole single-nuclei libraries (wild female, wild male and F1 male x dorsal and ventral olfactory rosettes) were successfully sequenced, generating a total of 59,616 high-quality cells after filtering and quality controls. Cells were clustered according to their transcriptomic profile, resulting in the identification of 19 different cell populations present in the olfactory organ of Senegalese sole. A first inspection revealed no differences between the dorsal and ventral olfactory rosettes. The characterization of the different cell clusters showed a diverse set of cell types, including several groups of neuronal cells, immune cells, blood cells, secretory cells, ciliated cells, and fibroblasts, among others. This cell diversity along with the complex organization of the organ suggests that multiple biological processes are supported by the olfactory organ. In particular, we identified four ORA genes (ora1, ora2, ora3, ora4), which belong to an olfactory receptor (OR) family directly associated to chemical communication and pheromone perception. These genes exhibited low expression levels, which directly correlate to the rule ‘one receptor-one neuron’ applied to all ORs, and were concentrated in two clusters, cluster 9 (ora1, ora2), and cluster 10 (ora3, ora4). We characterized these clusters as neural cell types since ORs are always expressed in neurons (Fig. 1). Further analyses are in progress to functionally characterize the different cell populations, especially those neural subtypes potentially involved in reproduction.

Conclusions
The olfactory rosette of Senegalese sole is a complex and heterogeneous organ consisting of 19 cellular clusters with a diverse range of functions. The presence of different types of olfactory sensory neurons points to the importance of olfaction in fish, potentially underlying social behaviors such as reproduction.

FISHPOND SEDIMENT COMPOSITION AND ITS POTENTIAL USE IN AGRICULTURE IN THE CZECH REPUBLIC

Marija Radojičić, Radovan Kopp

Faculty of AgriSciences, Mendel University in Brno, Brno, Czech Republic
E-mail: radojicic.marija88@gmail.com

Introduction
At present, there are approximately 24,000 fishponds in the Czech Republic. Decades of inappropriate management of the water catchment area, excessive erosion of arable land and an increase in fish production have led to an accumulation of sediment in ponds. Consequences of this can be a reduction in depth, depletion of dissolved oxygen and accumulation of nutrients, thereby limiting biological and ecological functions and fish production. The removal of sediment from ponds is necessary for fishpond maintenance. Mechanical removal is one of the options. Sediments are rich in nutrients and contain high levels of organic matter, carbonates and calcium. At the beginning of the 20th century, sediments were considered to be quality soil, but today, due to the possible presence of pollutants, they are classified as waste by legislation. This limits the potential application of sediments on arable land. The aim of our study was to evaluate the sediment composition and to compare it with the content of agricultural soils in the Czech Republic and assess the possibility of improving the soil quality.

Material and methods
Sediments were analyzed in 34 fishponds in the Czech Republic. All monitored fishponds are characterized as typical shallow ponds with mainly muddy sediments. The trophic state of the ponds ranged from mesotrophic to hypertrophic. The surface layer (0–15 cm) of the sediment was collected using an Ekman-Birge grab when fishponds were full and with a spoon, during the harvesting/emptying of fishponds. Dry mass of the sediment samples was determined and aqueous leachates from the dry mass were prepared in accordance with the ČSN EN 12457-4 standard. From the dried samples of the sediment, soil extracts were prepared according to the Mehlich III procedure (Zbíral, 2016). Part of the sample was burnt (550 °C, at least 6 hours) for determination of the organic share, and the burnt sample was used for the preparation of a soil extract with aqua regia in accordance with the process set out by Zbíral (2011). Phosphorus (P) and calcium (Ca) were determined from aqueous leachates; available P, Ca, magnesium (Mg) and potassium (K) were determined from Mehlich III; and total P and Ca content from aqua regia. The results are expressed in weight units of dry mass of the sediments used.

Results and discussion
The results obtained show a significant difference between fishponds, but also between samples from the same pond. Dry mass varied between 25 and 45%. Phosphorus (P) values also varied widely. In aqueous leachates, the average value was 5.36 mg.kg⁻¹. Available P in Mehlich III, which is commonly used to test soil composition, ranged from 2.2 to 104.3 mg.kg⁻¹ with an average value of 25.1 mg.kg⁻¹. The average total P was 935.6 mg.kg⁻¹. The content of available P in sediment is lower than in arable soil, but the total P content in sediment is higher than in arable land. The average of available Ca was 21 g.kg⁻¹ and a total Ca was 48 g.kg⁻¹. Large differences in Ca are affected not only by bedrock type but also by fishery management and lime application. Calcium content is much higher in sediments than in soil. The values of available and total Mg are higher in sediment than in arable soils, while the values of K in sediments are similar to those in arable land. One of the most important indicators of the quality of agricultural soils is organic matter content. The share of organic matter in soils is most often expressed as a percentage of organic carbon. Long-term monitoring shows a wide range of organic carbon content of agricultural soils in the Czech Republic, from 0.6 to 3.2%. In monitored fishponds, the average content of organic matter was 6.12%. Despite the significant differences between the individual fishponds, a high proportion of organic matter is evident when compared to agricultural soils, where the organic matter content is continuously decreasing.

MODELING TROPHIC RELATIONSHIPS IN POLYCULTURE SYSTEMS FOR FRESHWATER FINFISH FARMING

P.R. Ralien*, M.S. Corson1 and J. Aubin1

1 INRAE, Institut Agro Rennes-Angers, SAS, F-35000 Rennes, France
E-mail: purco-ralaiarison.ralien@inrae.fr

Introduction
The increasing demand for aquaculture products requires increasing both the productivity and sustainability of fish farming systems (Thomas et al., 2021). Polyculture has shown potential to do so because it can (i) use food waste better and (ii) increase nutrient recycling in the system, which can (iii) optimize resource-use efficiency and (iv) reduce environmental impacts (Aubin et al., 2021). However, nearly all polyculture systems are built empirically through trial-and-error, which is time consuming and does not allow a range of solutions to be explored. In contrast, studies that attempt to design optimized polyculture systems are rare, and even fewer aim to improve the system’s productivity and sustainability simultaneously. Thus, the objective of this study was to develop a method to design more efficient and sustainable polyculture systems. To this end, we developed and modeled scenarios of species combinations using a food-web modeling tool and then selected the best scenarios as a function of performance indicators.

Materials and methods
The complementarity and compatibility of the species combined in this study had previously been assessed in experimental ponds in Le Rheu, France (SEPURE project). The ponds were 0.1 ha in area and 1 m deep. The species differed in feeding strategy: common carp Cyprinus carpio (omnivore), pike-perch Sander lucioperca (carnivore), roach Rutilus rutilus (zooplanktivore and detritivore) and tench Tinca tinca (benthivore). We developed 10 scenarios of polyculture (each with 10 trophic groups) with no external food supply that differed in each species’ percentage of total fish biomass at stocking. To assess the performance of these scenarios, we used Ecopath, a software package for modeling aquatic food webs (Christensen & Pauly, 2004). Biological parameters of these fish (e.g. specific growth rate, mortality rate, reproduction rate) and the productivity of macroinvertebrate, zooplankton, phytoplankton and detritus were extracted from the study of Aubin et al. (2021), which was conducted at the same study site. The individual weights of common carp, pike-perch, roach and tench used in the scenario were 10 g, 70 g, 150 g and 450 g respectively. The total stocking biomass was set to 87.5 kg/ha. Depending on the scenario, the percentage of fish species in the total biomass varied from 10-50% for carp, 5-10% for pike-perch, 22.5-48% for roach and 15-43% for tench. The duration of the rearing cycle was set to 270 days, which is sufficient for monitoring a temperate polyculture system. Each modeled scenario was assessed using indicators of agro-ecological performance that represented productivity, total system throughput (i.e. the amount of biomass flowing through the system over the rearing period), fish diversity, efficiency and recycling (Finn’s cycling index).

Results
Over the rearing cycle, the scenarios had a total system throughput of ca. 701±6 g/m$^2$. The ecotrophic efficiency of the zooplankton, phytoplankton and detritus, which supported food resources in these unfed systems, depended on the fish species composition, varying from 0.52-0.61, 0.23-0.24 and 0.43-0.48, respectively. The species composition also influenced the percentage of biomass fluxes recycled in the system. The percentage of common carp in the scenarios was strongly and negatively correlated with Finn’s cycling index ($r = -0.99$), unlike the percentage of other species such as roach ($r = 0.78$) and tench ($r = 0.87$), for which the correlation was positive. As the density of common carp decreased from 50% to 10%, the percentage of biomass fluxes recycled in the system increased from 17.8% to 18.1%.

Discussion
Ecopath food-web modeling seemed sufficient to assess scenarios of species composition. However, it has some limitations due to its use of linear equations (Christensen & Pauly, 2004), which may underestimate or overestimate the correlation between variables. In addition, the integration of environmental variables in the model is limited (Plagányi & Butterworth, 2004), which may limit its ability to explain certain parameters. Variations among performance indicators of the scenarios, especially ecotrophic efficiency and recycling, indicated relations among the trophic and functional roles of species in the system. When species have different feeding strategies, they do not compete with each other for food and share effects of their functional roles in the system (Wang & Lu, 2016). Differences in overall productivity among scenarios were small since the growth performance of fish and productivity of zooplankton, phytoplankton and detritus were extracted from another study (Aubin et al., 2021). However, the ecotrophic efficiency differed among scenarios, which allowed us

(Continued on next page)
to identify the most efficient scenario. The scenario with the best performance indicators had the lowest percentage of common carp (i.e. 10%), which was much lower than that in most polyculture experiments (i.e. usually more than 50%; Lin et al., 2022). Since these results come from a modeling exercise, experiments are needed to validate the productivity and sustainability of the recommended scenario.

**Conclusions**
Ecopath’s trophic network modeling allowed us to analyze multiple scenarios of species composition in a polyculture system. The scenario with the lowest percentage of carp (10%) appeared to be the most sustainable, based on ecotrophic efficiency and Finn’s cycling index.

Introduction

Turbot, *Scophthalmus maximus*, is an economically important flatfish species, produced in China, Iceland, Norway, and Southern European countries including Spain, France, and Portugal. This species still presents reproductive dysfunctions when held in captivity, namely the absence of spontaneous spawning. Breeders need to be hand-stripped when mature and eggs artificially fertilized. In routine procedures, photoperiod is manipulated to obtain eggs and sperm in a year-round basis. However, egg quality might differ across seasons, as well as the number of ovulating females. In this sense, diet may be an effective approach for improving and standardizing egg quality and ovulation success.

The incorporation of micro- and macroalgae in aquaculture feeds has been linked to immune system strengthening, antiviral and antibacterial action, improved gut function, and stress resistance, in addition to providing protein, amino acids, fatty acids, vitamins and minerals (Chiu et al., 2001). Thus, the objectives of this study were to evaluate both the effect of photoperiod manipulation and diet supplementation with an Algae Blend (Spirulina and Iodine-rich Macroalgae), in egg quality and ovulation success in turbot.

Materials and Methods

Captive-reared broodstocks (mean weight ~ 6 kg) from the company Flatlantic® were used, reared in 15 m³ tanks at a constant water temperature all year round (14.0 ± 0.5 °C) and under simulated natural photoperiod. Exp. 1: Each photoperiod simulated the natural seasonal oscillations, displaced to overlap the spawning period (15h of light) to the four seasons of the year: spring, summer, autumn and winter. In 2022, females from broodstocks corresponding to each season were checked for ovulation at the corresponding month of 15h light. These females were fed *ad libitum* on a commercial feed (Sparos Lda.). Exp. 2: In 2023, females from four tanks corresponding to the displaced photoperiod of spring season were checked at 15h of light -spawning season- and 15:30h of light -end of spawning season-. Each two tanks were fed a different diet: (1) on the same commercial feed (Control) and (2) on a diet supplemented with 5% Spirulina and 1% Iodine-rich Macroalgae, fortified with nutrients such as Astaxanthin, Vitamin C, and Vitamin E (Sparos Lda.) (Algae).

In ovulated females, eggs were hand-stripped and egg diameter, ovarian fluid pH and osmolarity were evaluated. The total antioxidant status and presence of enzymes with antioxidant activity in eggs, particularly of superoxide dismutase (SOD) and glutathione peroxidase (GPX), were measured using kits purchased from Randox Laboratories Ltd. (UK). Blood samples were also obtained, and plasma levels of 17β-estradiol (E₂) were analysed using commercially available ELISA kits (Cayman Chemical Company, USA).

Statistical analyses were carried out using SigmaPlot v14 (Systat Software Inc., Richmond, CA, USA). Data for all the broodstocks were compared using One-way ANOVA followed by Holm Sidák’s test or an Anova on Ranks followed by Dunn’s test (no normal distribution). Chi-square test was applied to compare ovulation rates. Data was expressed as means ± SD and significance was set at *P* < 0.05.

Results

The presence of ovulated eggs differed among broodstocks reared under different photoperiod displacements and feedings (*χ² = 27.523 with 7 degrees of freedom; *P* = <0.001). In exp. 1, the highest number of ovulated females was observed in the 15h light of the spring broodstock (100 %), followed by the summer (62.5 %) and winter (57.1 %) broodstocks, while no ovulated female was obtained in autumn. In exp. 2, the broodstock fed with the Algae diet had the same percentage of ovulated females as the summer broodstock, when sampled at 15h light, while control females did not ovulate. At 15:30h light, ovulation rate in Algae females decreased (25 %) while in control group there was an increase (12.5 %). E₂ levels (Continued on next page)
were significantly higher \((P < 0.05)\) in the control group \((2.8 \pm 1.1 \text{ ng mL}^{-1})\), when compared with Algae females \((1.0 \pm 1.2 \text{ ng mL}^{-1})\) at 15:30h.

No significant differences were observed in egg diameter, ovarian fluid pH and osmolarity, either in exp 1 or 2. The activity of SOD in eggs was lower \((P < 0.01)\) in Algae females \((1.9 \pm 0.7 \text{ units mL}^{-1})\) than in those from 2022 fed on the commercial diet \((3.2 \pm 1.1 \text{ units mL}^{-1})\). The activity of GPX was unaffected within groups. The total antioxidant status was higher \((P < 0.05)\) in Algae females eggs \((1.2 \pm 0.24 \text{ mmol L}^{-1})\).

**Discussion and Conclusion**

The present study showed a significant variation in female ovulation rates among broodstocks, which might compromise the success of larvae production throughout the year, even though egg quality appeared to be consistent. On the other hand, providing an Algae Blend supplemented diet clearly enhanced ovulation rates in comparison to the commercial diet, since control group appeared to have a delay in ovulation, only starting at end of the spawning season \((15:30h \text{ light})\). Higher \(E_2\) levels in this group also suggested a delay in concluding gonadal growth, considering \(E_2\) is present in high levels during vitellogenesis and diminishes at final oocyte maturation and ovulation.

Antioxidant enzymes provide a first line of defence against the effects of reactive oxygen species (ROS) that may damage cell membranes, and alter RNA and DNA (Félix et al., 2020). Fish eggs are rich in lipids, with relatively high levels of polyunsaturated fatty acids, which makes cellular membranes vulnerable to ROS. Therefore, adequate antioxidants, such as those found in micro and macroalgae, are expected to help protect cellular components. SOD was expected to exhibit increased activity in eggs from females fed the Algae diet, indicating greater protection against superoxide anion peroxydative action; nonetheless, the opposite was observed. On the other hand, total antioxidant status was significantly higher, which is more informative than individual enzymes, since a decrease in one may be compensated by an increase in another. In any case, although the Algae Blend used possesses antioxidant properties, its beneficial effects may not be restricted to these qualities.

As main conclusions we may say that (i) photoperiod manipulation affects ovulation differently when applied in different seasons, and (ii) the Algae diet guaranteed greater ovulation rates, coinciding with an accelerated ovulation, and improved the total antioxidant content of eggs. This suggests that diets supplementation can be a powerful tool to standardize egg production in turbot, counteracting its reproductive dysfunctions.

Introduction

The increasing global population and growing preference for healthy and natural dietary choices have increased the demand for fish for food, boosted the aquaculture production industry, and led to finding solutions to the limited availability of fishery-based products [1]. Modern aquafeeds have shifted from relying on fish meal as a primary ingredient to agricultural protein proteins such as soy, rapeseed, and corn gluten. However, these alternative proteins are often associated with increased land and water usage and a high carbon footprint in aquaculture. Thus, it is important to find new ingredients that ensure more environmental and economic sustainability of aquaculture.

Macroalgae have captured the attention of producers and fish nutritionists because production does not rely on land or freshwater and can be sustainably harvested from coastal regions with minimal environmental impact. Furthermore, macroalgae contain moderate protein levels and a high abundance of beneficial bioactive compounds, such as antioxidants, carotenoids, vitamins, and minerals [3]. These compounds could potentially benefit fish welfare and improve the nutritional value of fish fillets for human consumption. However, a high percentage of fiber hampers the digestibility of these ingredients in fish. Breakdown of the macroalgal cell wall could enhance nutrient bioavailability and access to digestive enzymes, leading to better nutrient absorption and fish growth [4,5].

The red macroalga *Palmaria palmata* is the most abundant red algae species in Northern Europe [6] and has been successfully cultivated as an extractive species in integrated multi-trophic aquaculture systems (IMTA). *P. palmata* has a relatively high protein content, around 20%; however, its potential as a feed ingredient for aquafeed has been little studied. The present study aimed to assess the effect of untreated and/or alkaline hydrothermally pretreated *P. palmata* on the growth performance and feed utilization of European seabass.

Material and Methods

Treatment of macroalgae

Samples of *P. palmata* provided by AlgaPlus (Aveiro, Portugal) were to alkaline hydrothermal pre-treatment (1N NaOH, solid-liquid ratio of 4:3, autoclavation at 121ºC for 30 minutes).

Growth trial

A plant-based practical diet (corn gluten, wheat gluten, soybean meal, pea protein concentrate, and wheat meal) was formulated to contain 48 % crude protein and 18 % crude lipids and was used as the control. Four other experimental diets were formulated similarly to the control but included 7.5 or 15 % of untreated or treated *P. palmata* at the expense of the plant feedstuffs mixture.

The growth trial was conducted in a RAS system with 15 tanks of 500 L water capacity, thermoregulated to 22 ºC. Groups of 16 European seabass juveniles (initial body weight of 38 g) were randomly distributed in each tank and triplicate groups of fish were fed each experimental diet twice a day until satiation, six days a week, for 11 weeks. Utmost care was taken to avoid feed waste and ensure all feed supplied was consumed. At the end of the growth trial, fish from each tank were weighed after a light anesthetized (2-phenoxyethanol; 0.3 ml l⁻¹) following 24h of feed deprivation to assess growth performance.

Statistical analysis

All data were checked for normality and homogeneity of variances and normalized when required. Specific non-orthogonal contrasts analyses were performed to compare the control diet vs. the *Palmaria palmata* treatment and inclusion level. All statistical analyzes were performed using the IBM SPSS Statistics software version 26 (IBM, NY, USA).
Results
At the end of the feeding trial, compared to the control diet, the dietary inclusion of 7.5% of untreated and 7.5 or 15% of treated *P. palmata* did not affect the growth performance, feed intake, and feed utilization efficiency of European seabass juveniles. However, including 15% of untreated *P. palmata* increased weight gain and daily growth index.

In conclusion, the alkaline hydrothermal treatment of *P. palmata* did not contribute to improve growth performance and feed utilization. The dietary inclusion of 15% untreated *P. palmata* replacing traditional agriculture feedstuffs improved the growth performance of European seabass. This preliminary study highlights the potential of *P. palmata* as an aquafeed ingredient contributing to the sustainable development of the aquaculture sector.

Introduction
Aquaculture is responsible for approximately half of the world’s supply of fish for human consumption. Therefore, it is important to guarantee the nutritional quality of the fish through aquafeeds capable of meeting the nutritional requirements of fish and ensuring the sustainable development of aquaculture. Thus, finding new suitable green alternatives to replace the traditional protein sources in aquatic feeds is of utmost importance. Plant feedstuffs are the most used alternative ingredients in aquafeeds. However, these ingredients increase the pressure on land-based feed production systems and are often associated with poor growth performance, feed utilization, and antioxidant status of fish.

Macroalgae emerge as an alternative to plant feedstuffs and are produced without needing arable land, freshwater, and the expensive fertilizers associated with terrestrial crop production [1,2]. Green seaweeds, the most abundant macroalgae, are an important marine biological resource. Their bioactive components may modulate several biological processes, such as antioxidant activity, immunoregulation, and anti-inflammatory response [3].

Fish have evolved a strong defense system against oxidative damage. This defense system includes non-enzymatic components, such as glutathione (GSH), and enzymatic mechanisms, including catalase (CAT), superoxide dismutase (SOD), glutathione peroxidase (GPX), and glutathione reductase (GR). Their primary function is to counteract the harmful effects of reactive oxygen species (ROS) and ensure overall oxi-redox cellular equilibrium and thus contributing to fish health and well-being [4, 5, 6]. In this study, we evaluated the impact of the dietary inclusion of 7.5% untreated or alkaline hydrothermal pre-treated Codium tomentosum on oxidative defense mechanisms in the liver and intestine of European seabass (Dicentrarchus labrax) juveniles.

Material and Methods
Alkaline hydrothermal pre-treatment of Codium tomentosum was performed using NaOH (solid-liquid ratio of 4:3), autoclaved (121°C) for 30 and 60 min. Four isoproteic (48% dry matter basis) and isolipidic (18% dry matter basis) diets were formulated: a control diet with no inclusion of macroalgae, and three other diets with the inclusion of 7.5% of Codium tomentosum untreated or treated for 30 or 60 min, as aforementioned.

The growth trial was run in a RAS system with 12 tanks. Triplicate homogenous groups of 16 European seabass (initial body weight of 38g) were fed the experimental diets by hand, twice daily, 6 days a week, until apparent visual satiation, for 11 weeks. At the end of the growth trial, the liver and intestine from 3 fish per tank were collected and stored at -80°C until enzymatic assay quantification. Oxidative stress biomarkers were determined in the liver and intestine after the homogenization in phosphate buffer (0.1 M pH 7.4). The activity of glucose-6-phosphate dehydrogenase (G6PDH; EC 1.1.1.49), superoxide dismutase (SOD; EC 1.15.1.1), catalase (CAT; EC 1.11.1.6), glutathione peroxidase (GPX; EC 1.11.1.9), and glutathione reductase (GR; EC 1.6.4.2) was measured. Lipid peroxidation (LPO) was determined in the liver and intestine as malondialdehyde concentration.

Results
In the liver, independently of the treatment, the dietary inclusion of C. tomentosum decreased CAT activity, compared to the control.

Intestinal SOD activity was lower in fish fed the pretreated C. tomentosum than in fish fed the control diet. Dietary inclusion of C. tomentosum pretreated for 60 minutes also decreased LPO levels compared to the control.

Overall, the current results indicate that dietary inclusion of 7.5% pre-treated C. tomentosum with 1N NaOH for 60 minutes may contribute to enhance the antioxidant responses of European seabass.

Introduction

Europe’s bioeconomy focuses on harnessing renewable resources from both terrestrial and marine environments to meet the increasing demands for food, animal feed, and bio-based products. The aquaculture sector, particularly marine aquaculture, has emerged as the fastest-growing food production sector globally, striving to ensure sustainable food security in response to the rising protein needs driven by a growing global population. However, despite its rapid growth, European aquaculture, including both marine and inland operations, faces challenges in keeping pace with global production growth, requiring the exploration of innovative solutions.

Among the flatfish species, turbot (Scophthalmus maximus) is highly valued for human consumption and produced mainly in Southern European countries like Spain, France, and Portugal, as well as in Iceland and Norway. Yet, turbot farming encounters obstacles, particularly in achieving high and consistent larval survival rates. This limitation is partly attributed to the quality of breeders, which can be improved through the supplementation of feeds during reproductive events using antioxidant and immune-stimulating raw ingredients. In line with the bioeconomy concept, this study focuses on developing new feeds for turbot breeders, incorporating sustainable marine compounds like microalgae and macroalgae.

Materials and methods

This study was conducted at the commercial aquaculture facility – Flatlantic, SA, where turbot breeders were fed two experimental diets for 4 months. The male breeders had an average weight of 5.24 ± 0.8 Kg, while the female breeders had an average weight of 7.49 ± 1.35 Kg. Briefly, the experiment involved four different broodstocks, where two broodstocks served as the control group, receiving the breeders’ baseline diet without any supplementation (Control). The other two broodstocks were fed an ALGAE diet, a specially formulated diet enriched with a blend of Macro- and Microalgae. The ALGAE diet included 5% Spirulina and 1% Iodine-rich Macroalgae (Laminaria digitata), fortified with additional nutrients such as Astaxanthin, Vitamin C, and Vitamin E. This dietary supplementation aimed to enhance the immune status of the turbot breeders and study the potential modulation of different diets during the breeding season.

Skin mucus and blood samples were collected from the breeders in two different dates at the end of the feeding period, coinciding with the breeding season. These samples were used to assess the immune status of the breeders and analyse the effects of the ALGAE diet on their immune status.

An overall multivariate analysis combining raw data from humoral parameters analysed in turbot skin mucus and blood plasma (using PCA-DA) was performed to discriminate the physiological effects caused by the experimental diets excluding the sampling times. Sampling time was excluded from this multivariate analysis for noise reduction.

(Continued on next page)
Results

The first two discriminant functions accounted for 98.84% of dataset variability. Group discrimination was significant (Wilks’s lambda = 0.0299, p <0.0001) highlighting the differences between experimental diets and gender. This discrimination was loaded by the expression of IgM in skin mucus, and peroxidase, bactericidal, and lysozyme activity measured in blood plasma.

Regarding plasma humoral parameters, no clear differences were observed. However, it was observed a tendency for higher lysozyme activity in fish fed the ALGAE diet, particularly in female breeders. And a tendency for a higher peroxidase activity in fish fed the CTRL diet. Overall, it was also observed a higher bactericidal activity in male breeders particularly those fed the CTRL diet.

Interestingly, IgM values in skin mucus increased in fish fed the ALGAE diet compared to those fed the CTRL diet, particularly in female breeders.

Discussion and conclusion

The present study adds valuable insights into the effects of incorporating a blend of micro- and macroalgae in the diets of turbot breeders. The findings from this trial indicate that the inclusion of the ALGAE blend does not have any adverse effects on the performance and survival of turbot broodstock. Moreover, it demonstrates a modulatory effect on the immune status of the breeders. Notably, one of the most affected humoral parameters by the ALGAE diet was the skin mucus IgM. This finding is of particular interest, as IgM in fish has been shown to possess neutralizing and agglutinating activities against viral and bacterial pathogens. Additionally, it activates the classical pathway of complement upon recognizing pathogens (Salinas, et al., 2021). Given the prevalence of IgM in coating a substantial portion of the microbiota on different mucosal surfaces, including the skin, it is plausible to say that IgM plays a relevant role in maintaining microbiota homeostasis at these sites. The observed modulation of immune parameters, especially IgM, in turbot breeders fed with the ALGAE blend seems to indicate a potential enhancement in their immune response. This finding suggests that dietary supplementation with micro- and macroalgae could contribute to improving the immune status of turbot breeders, which is crucial for their overall health and resilience against pathogens. Further research is planned using skin mucus proteomics to gain a comprehensive understanding of the immunomodulatory effects of the ALGAE blend on turbot breeders in commercial aquaculture settings. Skin mucus is a critical component of the fish’s immune system, serving as the first line of defence against pathogens. Analysing the skin mucus proteome can provide valuable insights into the specific proteins and peptides involved in the immune response and their interactions with the ALGAE blend.

Introduction

Amino acids, the foundational elements of proteins, transcend their conventional role in protein synthesis, acting as precursors to vital metabolites that shape various physiological processes. Tryptophan (Trp), an amino acid of notable significance, extends its impact beyond protein building, serving as a precursor for pivotal compounds such as serotonin and melatonin in fish. Serotonin, stemming from tryptophan metabolism, influences behavior, mood, and immune responses, introducing a novel dimension of amino acid functionality. Additionally, the conversion of tryptophan to melatonin holds implications for stress resilience and circadian rhythm regulation. This study explores the immunomodulatory potential of dietary tryptophan supplementation in gilthead seabream (Sparus aurata), aiming to unveil its multifaceted influence on immune response dynamics and broader physiological processes in fish.

Materials and methods

Triplicate groups of fish (6.28 ± 0.28 g) were either fed a control diet (CTRL) with a balanced AA profile, or the CTRL diet supplemented with graded levels of Trp (i.e. 0.5% and 1% of feed, TRP1 and TRP2, respectively) for a 4-week feeding period. After 2 and 4 weeks, fish were euthanized and blood was collected for blood smears, plasma for humoral immune parameters, whole gut for oxidative stress biomarkers, anterior gut and hypophysis for the measurement of transcripts. After the 4-week feeding period, fish were intraperitoneal injected with inactivated bacteria and the inflammatory insult was monitored with samplings at 4-, 24- and 48-hours post-injection.

Results

The study’s outcomes revealed that dietary treatments had no significant impact on growth performance, with no distinctions observed in final body weight, daily growth index, specific growth rate, voluntary feed intake, feed efficiency, or feed conversion ratio. Blood immune parameters during the feeding trial demonstrated a decrease in white blood cell count from 2 to 4 weeks, alongside increased hemoglobin at 2 weeks and reduced peripheral blood leukocytes at 4 weeks.

(Continued on next page)
In response to inflammation, blood cell dynamics and hemoglobin showed an increase. Plasma cortisol and humoral immune parameters exhibited variations, with no differences between dietary treatments. Gut oxidative stress markers remained steady during the feeding trial, while SOD increased and catalase and tGSH decreased during the inflammatory response. Gene expression analyses highlighted the modulation of csf1r in the gut by dietary treatments. In the brain, no significant differences were observed between dietary treatments, although variations were noted over sampling times. In the hypophysis, pomca1 was downregulated in fish fed TRP2 diet during the inflammatory response, while pomca2 was upregulated in fish fed tryptophan-supplemented diets, regardless of inclusion level.

Discussion and conclusion

Tryptophan, aside from its protein building role, holds significance as a precursor for metabolites influencing fish immune systems, including serotonin and those generated through the IDO pathway. While previous research has explored tryptophan’s potential as a growth modulator or nutraceutical ingredient, its functional role in challenging contexts remains less understood. In this context, the study aimed to elucidate its effects. Results showed that the inclusion of tryptophan did not significantly alter the hematological profile, general health biomarkers, or oxidative stress markers in the anterior gut. Similarly, no significant effects were observed in cortisol levels, a well-established stress marker, both during the feeding trial and post-injection immune stimulation. However, when immune mechanisms were activated by bacterial injection, an immune response was evident regardless of dietary treatments. An increase in lymphocytes and neutrophils highlighted the immune system’s response to acute stress and infection. Interestingly, an upregulation of the colony stimulating factor 1 receptor (csf1r), associated with macrophage differentiation, was noted in fish fed diets supplemented with tryptophan. Moreover, pomca1 expression significantly decreased after 48h post-insult in fish fed TRP2, suggesting mediation and regulation of the stress response.

While the results suggest a mild effect of the tested tryptophan inclusion levels without a stimulus, the study highlights the potential for tryptophan’s immunotolerance role, particularly under immune stimulation, as evidenced by its modulation of oxidative stress and health biomarkers in the anterior gut of gilthead seabream. Overall, the study sheds light on the intricate interplay between dietary tryptophan supplementation, immune response, and physiological processes in fish.

Introduction

In aquaculture, the body composition of fish is an important aspect to be measured or estimated, as it can affect the fish health, flesh quality and fish market value. Usually, fish body composition is measured through chemical analysis following standardized methods (e.g., AOAC 2005). However, these methods can be both time-consuming and expensive. In turn, mathematical models can be an alternative and complementary tool to estimate body composition since they are less time-consuming and less costly than chemical analysis.

SPAROS developed a free tool – ficoEst (https://webtools.sparos.pt/ficoest/) - to estimate the body composition of farmed fish, in terms of crude protein, crude lipids, water, phosphorus and energy content. This tool comprehends different types of models - BC1, relies on body weight as an input; BC2, uses body weight and water percentage as inputs; BC3, uses body weight, water and ash percentage as inputs - as a cost-effective alternative to chemical analysis.

In this study, we evaluated the performance of the model from Raposo et al. (2023) when calibrated for other species besides Nile tilapia (i.e., Atlantic salmon, gilthead seabream, European seabass and rainbow trout) against the estimates from ficoEst, to assess if including information on water and ash content improves the models’ accuracy in estimating other body composition components.

Materials and methods

The models from ficoEst tool (BC1 – only body weigh as input, BC2 – body weight and water as inputs and BC3 – body weight, water and ash as inputs) and Raposo et al. (2023) model (BCRA) were calibrated with data collected from literature and from trials developed in the framework of projects coordinated by SPAROS and its R&D partners. Regression analysis was performed for each body component and the models were evaluated both qualitatively, by visually observing model behaviour, and quantitatively, by calculating the mean absolute percentage error (MAPE) between observed and predicted values for each body composition component. Additionally, a method of cross-validation with 5-folds and 10 repetitions was used to assess model performance. Models were further validated using independent datasets (i.e., not used during the calibration process). Furthermore, to assess the uncertainty of the observed values, the mean percentage error (PE) was calculated based on the mean±sd values of the pairs that were used to calibrate and validate the models.

Results

Overall, the model that relies on body weight, water and ash as inputs (BC3) displayed lower validation errors when compared with other tested models. Particularly for Nile tilapia, BC3 model outperforms all others for all body composition components. However, regardless of the type of model, the validation errors were generally higher for Nile tilapia, specifically when predicting crude protein (MAPE ≈ 8%), crude lipids (MAPE ≈ 44%) and energy (MAPE ≈ 19%).

Discussion and Conclusion

The higher MAPEs observed in estimating the body composition of Nile tilapia may be related to the greater variability of strains used worldwide and due to different inclusion of males/females in the trials. Additionally, for the Nile tilapia published datasets the analysis of the sum of components shows greater deviations, and the correlation coefficients between crude protein and body weight and crude lipids and water are lower, when compared to other species. Furthermore, the ash estimates demonstrated higher MAPEs, potentially because of laboratory errors and renormalized data reported in
literature. The fact that the BC3 model was more accurate in predicting fish body composition, indicates that accounting for the abundance of water and ash can improve model performance.

Overall, the ficoEst tool is a valuable resource for estimating fish body composition, particularly when direct measurement is not feasible due to economical or logistical constrains.

Introduction

A wide range of species are produced in aquaculture, which implies a great variability among aquatic species in terms of nutritional requirements compared to what is seen in livestock production. This poses a great challenge for fish nutritionists and aquafeed producers. Objective criteria, based on the use of body composition and nutrient/energy budget modelling, can be used to explore similarity relationships between species and thus contribute to mitigate this challenge.

To predict the body composition in fish, usually isometric and/or allometric models are used. The isometric model assumes fish composition is proportional to their weight, while the allometric model accounts for a non-proportional relationship between the two variables. In nutrition studies, assumptions of isometric behaviour for protein and/or ash in fish may not hold for dynamic body composition evaluations.

Nutrient-based models, consider energy and protein intake to predict growth and body composition. These models assume that maintenance metabolic expenditure can be defined by exponents, which determine the change in metabolic rate as a function of body weight. However, there is a disagreement among authors regarding the definition of these exponents for the metabolic weight of fish, which makes it unclear whether the same exponents should be applied to different species.

In this work, commercial fish species such as, Atlantic salmon (Salmo salar), gilthead seabream (Sparus aurata), European seabass (Dicentrarchus labrax), Nile tilapia (Oreochromis niloticus), rainbow trout (Oncorhynchus mykiss), turbot (Scophthalmus maximus) and Senegalese sole (Solea senegalensis) were compared based on their body composition and growth analysis. The goal was to assess certain assumptions and hypotheses present in the literature, such as the use of isometric or allometric models to describe body composition, the application of “universal” or species-specific metabolic body weight exponents, the use of constant or non-constant protein/energy efficiency ratios, and the assumption of similarity between species with similar morphological and physiological traits (e.g., flatfish species).
Materials and methods

Data was collected from literature on the body composition and growth for the aforementioned species. For analysis of growth parameters, datasets on *in vivo* growth trials were used to estimate fasting maintenance and retention efficiency parameters, through linear regression techniques, for all species, except for sole due to limited data.

The study evaluated the similarity relationships between species in terms of body composition and protein/energy budgets using principal components analysis (PCA). The respective parameter estimates of the species were plotted along the first two principal components and scatter plots of the individual parameters were generated. Additionally, the predictions of the calibrated models (species-specific) were compared between different species.

Results

PCA analysis shows that seabream and sebass share similarities in their body composition parameters, as do salmon and trout. However, the flatfish species, turbot and sole, seem to have different body composition parameters. In turn, sole appears to be more similar to salmonids, whereas turbot displays certain similarities with tilapia.

In terms of general growth parameters, it seems that tilapia, seabream, salmon, and rainbow trout have some similarities, while sebass and turbot seem more different. Salmon and rainbow trout are closer to each other, while tilapia is closer to seabream. Turbot has the most distant estimations for fasting maintenance costs. Salmonids have higher retention efficiency for protein and energy, while Mediterranean species have lower retention efficiency for protein. Seabream has higher energy retention efficiency than sebass, but both have low protein retention efficiency.

Discussion and Conclusion

Results suggest that the similarity within salmonids and Mediterranean species are strong and consistent across parameters and thus clearer in the PCA projections. Despite having some differences in growth, Mediterranean species show similarities, especially in early life. However, flat species do not group as clearly. The variability observed between species in terms of model parameters and predictions may be related to taxonomy, physiological stages, ecological features, fish activity, body mass, as stated in previous studies. Results also suggest the metabolic body weight exponents for energy and protein are likely to be species-specific and differ between species, ranging from 0.6 to 0.9, which agrees with previous studies that challenge the theory of universal metabolic allometry.

This study enables the evaluation of certain assumptions in literature. Moreover, it shows that species belonging to the same family, geographical area, or with similar diets or body shapes may or may not exhibit similar body composition and growth patterns. Therefore, conducting the analysis of body composition and growth parameters between species is useful, as they complement each other, providing a full view of their developmental patterns, and allows to identify both similarities and differences between the species.

MULTIOMICS ANALYSIS OF GILTHEAD SEABREAM (Sparus aurata) LIVER MOLECULAR STRESS RESPONSE UNDER DIFFERENT AQUACULTURE CHALLENGES

Centre of Marine Sciences (CCMAR)
Universidade do Algarve
Faro, Portugal
csraposo@ualg.pt

Introduction

The ability of fish to respond to environmental challenges is critical for their survival and the maintenance of healthy populations. Therefore, to ensure a sustainable aquaculture while meeting the increasing demand for fish, it is essential to prioritize the welfare of farmed fish by minimizing the stress levels associated with aquaculture practices. The study of the molecular mechanisms of fish stress appraisal is paramount to achieving this goal and avoid negative impacts on fish health and ultimately on the aquaculture productivity. In this study, we performed an integrated multiomics characterization of the fish liver, a central organ during stress adaptation, to provide a holistic assessment of the molecular stress response at different organizational levels. Widening our understanding into the physiological changes occurring in the fish organism during stress adaptation can leverage the industry with valuable scientific knowledge for developing forthcoming species-specific welfare assessment protocols.

Methods

*Sparus aurata* adults were exposed to different suboptimal rearing conditions in three separate trials: overcrowding (45 kg/m³), repetitive net handling (4 times/week), and hypoxia (15% DO). A control group was also included, consisting of fish reared under optimal conditions for the species. By the end of the trials, fish were sampled (n = 6) and liver extracts were prepared for further transcriptomics (RNA-seq), proteomics (label-free shotgun) and metabolomics (untargeted LC-MS) analyses. In transcriptomics, after reference-guided transcriptome assembly, differential expression analysis was performed with DESeq2 (adjusted p-value < 0.01, log2|fold-change| >1). In proteomics and metabolomics, pairwise comparisons between identified proteins (protein FDR < 1%; peptide FDR < 0.1%) and metabolites, were achieved by a student’s t-test, p < 0.05; FDR controlled at 0.05. Gene set enrichment analysis (GSEA) and overrepresentation (ORA) analyses based on GO, KEGG and REACTOME databases were performed.

Results and conclusions

A total of 946 genes, 397 proteins and 121 metabolites were differentially regulated between challenged and control fish across the three trials. Integration and functional analysis of these selected features suggested a scenario of challenge-specific responses at the transcriptome, proteome, and metabolome levels. Net handling and hypoxia triggered a more impactful effect on hepatocytes than overcrowding, inducing an overall metabolism reprogramming to shift energy towards stress response processes and cell cycle arrest, mainly driven by ribosomal assembly stress, DNA replication stress, endoplasmic reticulum stress, and downregulation of insulin growth factor signalling. These results support the high phenotypic plasticity of this species and its differential responses to distinct challenging environments at different molecular levels. Additionally, the study provides valuable resources for characterizing and identifying potentially novel features essential for gilthead seabream resilience and aquaculture production efficiency concerning fish welfare.
Biomass production and reproduction of *Hediste diversicolor* fed with brewer’s spent grain.

Introduction

The “ragworm” *Hediste diversicolor* is a suitable species for industrial aquaculture because of its adaptability to wide environmental conditions, feeding flexibility and high growth rates. It is usually used as fishing bait or as feed supplements for farmed fish and crustaceans. The farming of this species is relatively simple and high yields can be obtained when using fishmeal and fish oil based feeds. However, this type of feed is expensive and unsustainable. Different low-cost feeds have been tested such as clam faeces, sludge from fish farming recirculation systems or biogas side stream. We propose a low cost product such brewer’s spent grain (BSG), the main by-product of the brewing industry. BSG is mainly composed of fibres and protein (Mussatto, 2014). Therefore, the aim of this work was to gain information on the growth and reproduction of *H. diversicolor* fed with BSG.

Material and methods

**Growth:** Experimental units (EU) consist on three polycarbonate trays (width: 0.35 m; height: 0.30 m; length: 0.54 m) provided with aeration, top water inlet (2.5 l/min), bottom drainage and a 12 cm high quarry sand substrate (0.25 - 1.0 mm grain size). Ragworms (N = 720, 4000 individuals / m²) of wet body weight (BW) 46.7 ± 5.5 mg, (mean ± SD), obtained from a captive population stock, were placed in the experimental units (biomass per tray = 33.7 g). Ragworms were fed with freshly produced BSG in an artisanal brewery, which was frozen until use (humidity 75%). Triturated BSG were distributed six days a week ad libitum. Bi-weekly, wet BW was estimated and the amount of food adjusted. At the end of the trial (culture day 79), all ragworms from each EU were harvested and the following indices were calculated as growth performance variables: Mean wet BW, percentage of ragworms larger than 500 mg, survival (%) and specific growth rate (SGR= (ln BWf- ln BWi)*100/ Tf-Ti). Dissolved oxygen (DO) were always > 90 %, and temperature, salinity and photoperiod were natural (13.8±1.0 ºC, salinity 36 ppm, 9 to 10.5 hours of light).

**Reproduction:** 400 ragworms larger than 500 mg from the previous trial were selected as broodstock and placed in two stocking tanks (height 0.5 m; area 1m², 20 cm high sand substrate) (Rasines et al. 2023). One tank was fed, *ad libitum*, with dried BSG (105ºC, 5 hours) and the other with fish feed. Samples were taken every two weeks from the top two cm of the substrate to detect and quantify the number of juveniles. Temperature, salinity and photoperiod were natural.

Results and Discussion

Ragworm body weight increased over time (Figure 1) but slowed between days 46 and 57 due to inadequate feeding management; BSG debris accumulated on the surface of the sand making it difficult for polychaetes to access fresh food. From that time onwards, BSG debris was removed periodically.

Although the SGR and production data were lower than those obtained with fish feed (Rasines et al. 2023, Nesto et al. 2012), they were quite promising because a significant biomass production per m² can be obtained with a low-cost feed (Table I).

There were reproduction processes with both types of feeding, so it is not necessary a change of feeding for the broodstock. The first juveniles were detected between 2 and 2.5 months. Both the time and the number of juveniles were in the range of those obtained when fish feed is used throughout the production process (Rasines et al. 2022) (Table II).

In conclusion, BSG is a suitable food for the growth and reproduction of *Hediste diversicolor*. Further studies are needed to characterise its nutritional profile and to advance in the optimisation of cultivation techniques.

Introduction

The synchronization of bivalve spawning involves chemical communication. Sperm carries a chemical signal that induces spawning in females: a spawn-inducing pheromone (SIP) (Galtsoff, 1938; Taylor et al., 2018). In the oyster *Pinctada maxima*, SIP has been characterized as proteinaceous and multicomponent, associated with sperm membrane (Taylor et al., 2018). Following this, the current study investigated the ‘olfactory’ and biological activity of male SIP in the Pacific oyster, *Magallana gigas*, through an electrophysiological technique and a bioassay, respectively. In addition, we also investigated the possible proteinaceous nature of SIP.

Material and methods

To isolate and chemically characterize oyster pheromones, sperm milt obtained by stripping the gonads was centrifuged to obtain different fractions. After centrifugation, the supernatant (supernatant 1) was carefully transferred to another vial and the pellet was resuspended in seawater: part was stored and used as a fraction - resuspended pellet- and the remaining part was homogenized with a glass Teflon homogenizer and centrifuged to obtain the supernatant of homogenized pellet (supernatant 2). Each fraction was assessed for olfactory activity using the electro-osphradiogram (EOsG) (Rato et al., 2023), to identify which fraction(s) contain the pheromone. The voltage signal of the EOsG was amplified (x5000) with the low-pass filter set at 30 Hz and then, the signal was digitised and recorded on a PC running Axoscope TM software. L-cysteine (10^{-3} M) was used as a positive control (or standard) whereas charcoal-filtered seawater was the blank or negative control. The EOsG peak amplitude was measured in millivolts. All recorded responses were blank-subtracted and normalized to the standard (10^{-3} M L-cysteine).

That a given compound can evoke an olfactory response does not necessarily mean that it has full biological activity, i.e., can induce spawning in conspecifics. To address this, a bioassay was performed in which oysters were exposed to the different sperm milt fractions, both singly and in combination, with exception of the resuspended pellet. Since chemical stimuli alone were not sufficient to induce spawning, oysters were induced to spawn by thermal shock (15°C - 30°C, at intervals of 1h) in combination with chemical stimulation, in which each of the fractions, plus fresh and frozen stripped sperm were used as chemical stimulus.

To investigate the possible proteinaceous nature of SIP, the protein profile of each sperm fraction and of an unfractionated sample (total) was analysed by SDS-PAGE electrophoresis (12% polyacrylamide), quantified by Bradford Protein Assay and the results correlated with EOsG and the bioassay.

Results

The olfactory responses did not reflect the biological activity. Although supernatant 1 evoked strong olfactory response, it failed to induce spawning on its own. Supernatant 2 alone, and in combination with supernatant 1, did induce spawning but not to the same extent as untreated milt. Frozen milt had similar biological activity to freshly stripped milt, inducing spawning in 87% of the oysters.

The SDS-PAGE revealed different protein profiles in each of the fractions, with supernatant 1 revealing a distinct band of ~35 kDa, whereas pellet and supernatant 2 fractions showed clear bands with a lower molecular weight of about 15 kDa. Each of these bands could also be seen in the unfractionated samples (total).

(Continued on next page)
Protein quantification revealed maximums of 0.42 mg.ml\(^{-1}\) and 0.34 mg.ml\(^{-1}\) in the supernatant of the frozen milt and in its unfractionated sample, respectively. The minimum protein concentration was seen in the supernatants 2 and 1 of fresh milt, varying between 0.08 mg.ml\(^{-1}\) and 0.09 mg.ml\(^{-1}\).

**Conclusions**

The chemical signal responsible for inducing spawning in conspecifics likely involves a low molecular weight protein (15 kDa) but is probably multi-component. It possibly includes peptides or proteins (by extrapolation from other molluscs).

The fact that a given fraction evoked a strong olfactory response is not indicative of its biological activity; two or more components are necessary to induce spawning.

That frozen sperm milt had a similar biological activity to fresh sperm milt may be useful and profitable for bivalve hatcheries as they can store it for use in a later spawning season.

The low protein concentrations may indicate that oysters are extremely sensitive to conspecific signals and, since oysters inhabit dense beds close to conspecifics, the concentration of such signals in the natural habitat may be relatively high. Future work will focus on the chemical isolation and identification of the male pheromone components and, if proteinaceous, on isolation and sequencing.

Introduction

YCWs are proven immune response modifiers holding an important position among multifarious paraprobiotics and, in fish, have been implicated in the maintenance of (intestinal) mucosal health and integrity, disease resilience and animal performance. The major structural components of YCWs are β-glucans and mannanoligosaccharides (MOS) which act as microbe-associated molecular patterns (MAMPs) that can be recognized by the pattern recognition receptors of the host immune system. YCW can vary in their biochemical composition and molecular structure due to the yeast species, strain, fermentation, and down-processing conditions. Such diversity of MAMPs structure and profile could elicit distinct host immune responses and to date has been under evaluated. The current investigation aimed to characterise the biochemical and molecular properties of four proprietary *S. cerevisiae* YCW fractions of discrete origin. Our hypothesis was that the biophysical characteristics of given *S. cerevisiae* will elicit distinct immune responses, which has not been previously addressed using a purposely designed comparative study.

Materials and Methods

A 5-week trial (Plymouth, UK) tested 5 dietary groups in triplicate using wild-type adult zebrafish (BW\(_i\) = 0.80 ± 0.02 g; 25 fish/tank) and a basal diet formulated to NRC requirements for cyprinids (36% protein, 8% lipid). Treatments consisted of 1) non-supplemented basal diet (Control), and basal diet supplemented with 2] YCW1, 3] YCW2, 4] YCW3, 5] YCW4. All YCW fractions were supplemented at 2.0 kg/T of feed and consisted of contrasted proprietary YCW strains provided by Lallemand SAS (France). YCW fractions were assessed by sulfuric acid method. Diets were fed at fixed rate of 4% biomass daily over 3 daily rations. At the end of the trial, intestinal and skin histomorphometry (n = 9 fish/treatment) as well as the intestinal gene expression analysis (n = 6 fish/treatment) was assessed. For gene expression analysis differences between control and experimental groups were assessed by non-parametric permutation test with significance accepted at \(p < 0.05\). All other data was analysed by One-way ANOVA and significance accepted at \(p < 0.05\).

Results

The biochemical analysis revealed significant differences in percentage composition of β-glucan and alpha-mannan polysaccharides in each YCW fraction (Fig 1; \(p < 0.05\)). Histological appraisal revealed significantly elevated GCD, IELs and acidomucins in YCW1, 2 and 3 groups containing higher levels of mannan content compared to YCW4 (Fig 2; \(p < 0.05\)). Gene expression analysis revealed differential modulation in markers for innate immune pattern recognition receptors (PRRs) and signal transduction factors, transcription and innate cytokines that suggest polarisation of responses to Th1, Th17, Tr1 and Foxp3+ Tregs according to each YCW group (Fig 3).

Conclusion

This study identifies marked intra-species variability in the molecular properties of *S. cerevisiae* yeast cell wall fraction. The α-mannan content was associated with GCD and IEL hyperplasia suggestive of fortifying intestinal barrier integrity and immune competence. The gene expression analysis revealed marked modification in the expression pattern of PRRs when fed contrasted YCW fractions. Furthermore, the gene expression patterns for transcription factors and cytokine responses suggest the preferential mobilisation of distinct T-helper cell subsets for Th1, Th17, TR1 and Foxp3+ Tregs, indicating a particular potential for each YCW fraction to confer protection against infectious agents and, or non-infectious pathologies. Accordingly, this study highlights the potential of considering the biophysical characteristics of the YCW to apprehend their specific immune properties and elicit targeted immune functionalities towards precision functional nutrition in Aquaculture.

Introduction

The rapid development of insect-derived feed materials production scale and quality increases the possibility and justification of their use in commercial diets for fish each year. For a number of species initial studies which assess the potential of fish meal replacement was performed. Fish tolerance for even high doses of insect meals was assessed with positive results for this novel group of feed ingredients. However, in most of the studies, there is a lack of calculations analyzing the sustainability of fish rearing based on combined feed composition and fish growth performance results.

Materials and method

900 juvenile Siberian sturgeons (5 g each) were used in the 60-day-long feeding trial. They were divided into 9 treatments using 5 tanks per group and 20 fish per tank. The control diet (CON) contained 300 g/kg of fish meal. In 8 following experimental treatments 75, 150, 225 and 300 g of *Hermetia illucens* partially defatted meal (BSFM) was introduced. In four diets (H75, H150, H225, H300) the level of crude protein in BSFM was based on nitrogen analysis with the assumption that crude protein = 6.25 x N. In another four diets (HK75, HK150, HK225, HK300) the BSFM protein content was calculated on the basis of amino acid levels using a modified conversion factor (Kp). After 60 days of feeding sustainability indexes including feed conversion efficiency and fish in – fish out ratio were calculated, and all the data were analysed using analysis of variance and post hoc Duncan’s test.

Results

The highest feed conversion efficiency (body weight gain/feed intake) was reached in HK75, HK150 and HK300 treatments in which efficiency was higher up to 300 g/kg of used feed than in CON treatment. The FIFO ratio was the lowest in diets containing 300 g/kg of BSFM with no difference among protein calculation methods.

Conclusions

Partially defatted Black Soldier Fly (*Hermetia illucens*) larvae meal is a feed resource which may not only meet the nutritional requirements of fish but also improve the sustainability of Siberian sturgeon production.

This study was carried out as part of the project entitled: Innovative application of Hermetia illucens protein and fat in Acipenseridae fish aquaculture (LIDER/2/0018/L-12/20/NCBR/2021) financed by The National Centre for Research and Development.
Animal density in indoor shrimp production is continuing to increase as producers seek to maximize production from their aquaculture systems. Increasing animal density and therefore feeding rates, results in faster accumulation of nitrogenous waste in systems with limited water exchange. Pacific white shrimp (*Litopenaeus vannamei*) are considered to be resilient to most forms of nitrogenous waste and have higher tolerances than many other aquatic species. Although shrimp may be tolerant to elevated levels of ammonia, nitrite, or nitrate individually, there is little information on the combined effects of these nitrogenous wastes on shrimp, particularly nitrite and nitrate. This study was designed to evaluate shrimp survival when subjected to elevated levels of both nitrite and nitrate.

In this experiment 36 64-L tanks were stocked with 10 shrimp each at a salinity of 15 ppt. Three different concentrations of nitrite-N (0, 10, 20 ppm) and four different concentrations of nitrate-N (0, 200, 400, 600 ppm) were used, resulting in a total of 12 treatments with three replicates each. The treatments were labeled based on the targeted amount of nitrite and nitrate in mg/L: 0/0, 0/200, 0/400, 0/600, 10/0, 10/200, 10/400, 10/600, 20/0, 20/200, 20/400, 20/600. The experiment was conducted for 11 days, at which point the total number of surviving shrimp were counted.

When examined individually, nitrite had a significant impact on survival at both the 10 and 20 ppm levels. By itself, nitrate levels of 600 ppm significantly decreased shrimp survival. Furthermore, the interaction between the two compounds was found to have a significant negative impact on shrimp survival. Combined levels of nitrite over 15 mg/L and nitrate over 400 mg/L showed mortality rates approaching 50%. This has important implications for shrimp producers, as many producers maintain high levels of nitrate and frequently experience fluctuations in nitrite levels. It seems that the two compounds should not only be considered as individually toxic, but in combination as well.
CAN BIOACTIVE PEPTIDES PRESENT IN PROTEIN HYDROLYSATES IMPROVE STRESS RESPONSE IN MEAGRE (*Argyrosomus regius*) JUVENILEs SUBMITTED TO ACUTE STRESS?

Introduction

Functional feeds are currently being proposed as a disease management tool under intensive farming conditions. These feeds, are designed not only to fulfill nutrient requirements for growth, but also strengthen immunity and stress resistance. The dietary inclusion of protein hydrolysates (PH) has been shown to improve fish growth, antioxidant activity and immunity. Protein hydrolysis can give rise to bioactive peptides with immune-modulatory effects. Low molecular weight peptides (< 3kDa) are described as having antimicrobial, immune-stimulating, anti-inflammatory and antioxidant properties. The present work aims to assess the effects of different PH on stress resilience, immune response and oxidative stress of meagre (*Argyrosomus regius*) juveniles prior and after acute stress.

Material & Methods

A practical commercial-like diet was used as control (CTR), whereas 3 other diets were formulated based on CTR to contain a 3% inclusion level of a short chain purified bioactive peptide in diet BPP, 3% shrimp PH in diet SPH and 3% feather meal PH in diet FMH. Diets were randomly assigned to triplicate groups of 90 fish (IBW approx. 9.5 g) that were hand fed to satiation 4 times a day for 14 days. After 2 weeks of feeding, fish were subjected to an acute stressful event (i.e., 5 min chasing with a net). Intestine samples were taken for gene expression, immune parameters and oxidative stress analysis, immediately prior to stress and one day following acute stress. Plasma samples were also taken for cortisol and glucose levels measurement, prior and one hour after stress.

Results & conclusion

Results demonstrate a stress induced response in the experimental animals. Thus, increased plasma glucose levels 1h after stress and increased gut lipid peroxidation 24h after stress were measured irrespective of the dietary treatment. Antioxidant functions in the gut were also affected by stress with a dietary modulation of the response. Both catalase (CAT) and superoxide dismutase (SOD), show a decrease in activity 24h post-stress, with SPH fed fish showing higher SOD and CAT activities than FMH group. In the case of SOD, enzyme activity is also higher than CTR and activity values are equivalent to those measured prior to the stimulus. This might indicate a positive effect exerted by SPH diet on meagre stress response. Further analysis on gut and plasma samples, namely immune response and gene transcription, are currently underway to obtain an overall picture of fish stress response and health status.

This work is part of project NOSTRESS_047122 supported by Portugal and the European Union through FEDER, LISBOA 2020, NORTE 2020 and CRESC Algarve 2020, in the framework of Portugal 2020.
DIETARY INCLUSION OF SARDINE COOKING WATERS: IMPACT ON APPETITE REGULATION, GROWTH AND SENSORY PROPERTIES OF EUROPEAN SEABASS

Introduction
Plant-based ingredients have been considered suitable options for replacing marine-based ones in aquafeeds (Naylor et al., 2021), but this may compromise diet palatability (Geurden et al., 2013), potentially affecting fish growth and flesh quality. To overcome this, feed attractants have been suggested. These compounds, like alcohols, aldehydes, and organic acids, were reported to stimulate intake in mammals (Chen et al., 2017; Takács et al., 2018). They can be obtained from agri-food by-products, within a circular economy framework. One example is the $9 m^3$ liquid waste generated by the canning industry per tonne of canned fish (Ferraro et al., 2013).

The objective of this work was to extract aromas from the effluent waters of a canning industry and incorporate them in plant-based diets for European seabass. The aim was to evaluate their potential to modulate intake, growth and fillet organoleptic characteristics.

Materials and methods
Sardine cooking wastewaters were collected and either used directly (CW-A) or after processing by vacuum distillation (VD-A) or liquid/liquid extraction with soybean oil (LLE-A). Although the resulting extracts had different chemical profiles, the most abundant compound in all fractions was the $1$-penten-$3$-ol. This was hence selected as marker and extracts containing $2 \mu g/g$ of this compound were incorporated in isolipidic and isoproteic diets (CW, VD and LLE) for European seabass. A non-supplemented diet was used as control (CTRL). Each diet was assigned to triplicate fish groups (initial weight $95.7 \pm 13.5$ g), hand-fed twice daily until apparent satiation in a recirculating saltwater system at $21$ °C. After 18 weeks, growth performance and nutrient utilisation were evaluated. Flesh colour and texture were assessed instrumentally and by sensory analysis using a consumer panel. Moreover, the expression of neuropeptides involved in feed intake regulation (neuropeptide y – npy, agouti-related peptide – agrp2, cocaine and amphetamine-related transcript – carpt2 and pro-opiomelanocortin – pomca) in the brain was analysed. Metabolites in plasma and liver of fish were also quantified.

Results and Conclusions
Fish fed LLE displayed a significantly higher voluntary feed intake than those fed the CW diet, although neither differed from CTRL. LLE also resulted in increased feed conversion ratio. Final weight, whole-body composition, and nutrient gain were similar among diets. The expression of intake-regulating neuropeptides was not significantly affected by diets, but a slight upregulation of the orexigenic npy was observed for the LLE diet. In addition, fish fed this diet displayed the lowest plasmatic glucose and highest hepatic glucose and triglycerides values, although the remaining metabolites (lactate, non-esterified fatty acids, cholesterol and glycogen) were unaffected. Thus, the changes in feed intake are probably due to a combined effect of the homeostatic (nutrient-driven) and hedonic (pleasure-driven) regulation. No differences were found in skin or muscle colour among treatments. Despite a lower hardness in fillets of fish fed LLE when compared to those fed CTRL, no significant differences were perceived by the sensory panel; global liking of samples was similar among treatments, being all generally well accepted. Additionally, the samples’ taste and odour were characterized as “characteristic fish” and “soft” for all treatments. Overall, results suggest that aromas from sardine cooking wastewaters can modulate feed intake, but further optimization of either the processing and/or incorporation levels seems required to maximize their effectiveness as feed intake stimulants for application in aquafeeds.

Introduction
In fish, feed intake regulation is mediated by an interaction between homeostatic and hedonic signals (Soengas et al., 2018). The homeostatic control relates to biological needs regarding nutrients and energy (Soengas, 2021). On the other hand, the hedonic control is associated with reward-based routes, which are triggered by highly palatable food (Díaz-Rúa et al., 2022). Hedonic control may override homeostatic and maintain a drive to eat, due to the sensory pleasure felt by eating. Increasing the palatability of diets, such as those with high levels of plant-based ingredients, is therefore an important matter in aquaculture, as to achieve the best growth performance of fish. In addition, to evaluate the potential of a diet to affect the hedonic regulation of feed intake, long-term growth trials may be inadequate, since the need to maintain nutrient and energy homeostasis becomes more relevant over time. In parallel, the habituation effect to the diets occurs and masks the impact of diet palatability. Thus, studying feed intake stimulants, preferably obtained from by-products (considering a circular economy approach), on short-term trials may shed light on their impact on diet palatability and hedonic regulation of feed intake. In this work, we evaluated aromatic extracts from sardine cooking wastewaters as feed intake stimulants in plant-based diets for European seabass, focusing on the first feeding response towards the experimental diets.

Materials and methods
Sardine cooking wastewaters were collected and either tested directly (CW-A) or after vacuum distillation (VD-A) or after liquid/liquid extraction with soybean oil (LLE-A), resulting in distinct chemical profiles. The most abundant compound in the three extracts was 1-penten-3-ol, being thus chosen as marker and included at 2 μg/g in isolipidic and isoproteic diets (CW, VD, LLE). A practical plant-based diet (12.5% fishmeal and 4% fish oil) without any supplementation was used as control. Each diet was assigned to six homogeneous groups of European seabass juveniles (96 g). Fish were sampled 2 and 6 hours after a single first meal distributed to apparent satiation. Metabolites including glucose, lactate, cholesterol and non-esterified fatty acids were quantified in the plasma. Additionally, the mRNA abundance of neuropeptides involved in the regulation of feed intake, namely neuropeptide Y (npy), agouti-related peptide (agrp2), cocaine and amphetamine-related transcript (carpt2) and pro-opiomelanocortin (pomca) was quantified in the hypothalamus and telencephalon.

Results and Conclusions
Feed intake after the first meal was significantly higher for the control diet than for the supplemented diets. No significant differences on plasma metabolites were observed. Although the expression of neuropeptides involved in feed intake regulation was statistically similar among diets and sampling points, LLE and VD diets displayed the lowest expression of the agrp2 in the telencephalon, whilst LLE diet led to the highest expression of pomca, 2 hours after feeding.

The similar profile of plasma metabolites among diets suggests that the regulation of feed intake in the tested fish was driven more by hedonic factors, such as reward or pleasure-driven, rather than homeostatic factors, such as nutrient-driven. The slightly lower expression of orexigenic (inducing feed intake) neuropeptide agrp2 in fish and higher expression of anorexigenic (supressing feed intake) neuropeptide pomca may be regulating factors associated with decreased feed intake observed in fish fed LLE and CW diets, but other factors might have also contributed to such results. Overall, the sardine cooking wastewaters extracts, in the tested concentration, had no positive effect on the short-term feed intake response of European seabass, which suggests that feed palatability was not enhanced. Further optimization of the extracts’ production process, and/or inclusion levels in diets should be considered in both short and long-term trials to improve effectiveness of the extracts as feed attractants.

Introduction

The Atlantic salmon (S. salar) industry covers approximately 90% of the total salmonid culture, with an annual worldwide production of ~1,000,000 tonnes. Chile is the second largest Atlantic salmon worldwide producer, representing its second most important economic activity. Among their challenges, the industry has to deal with sanitary issues, such as sea lice (C. rogercresseyi) infestations causing significant economic losses and social consequences for the aquaculture industry worldwide. Sea lice is an ectoparasite that infests the skin mucosa of Atlantic salmon in Chile. Despite its relevance, few studies have focused on evaluating the health status of the skin mucosa of Atlantic salmon reared in sea cage farms. In addition, environmental fluctuations such as temperature, a parameter of particular relevance in fish due to their poikilothermic characteristics, have not been considered either. For this reason, in this study, we evaluated the epithelial skin mucosa transcriptome in summer (at the maximum seawater surface temperature) and autumn (at the descending ramp temperature between the highest temperature and the lowest temperature) of Atlantic salmon infested with C. rogercresseyi.

Materials and methods

We performed a transcriptomic profile of the epithelial skin mucosa in Atlantic salmon infested and non-infested with sea lice sampled from the same seawater cage of a farm located in the fjords of the Aysén Region (Chile). We conducted the sampling in two different seasons: summer (during the peak of maximum water temperature; 10 weeks after seawater transfer) and autumn (at the half-descending ramp temperature; 23 weeks after seawater transfer). For transcriptomic analysis (RNA-Seq), total RNA was obtained from the epithelial skin tissue. We used a pooling strategy for the non-infested and infested fish group (n= 3 pools per condition; n= 5 fish per pool).

We verified the quality of each sequencing library with FastqQC (Andrews, 2010), a software package that estimates the number of uncallable and low-quality bases. We mapped the skin mucosa transcriptome to the Salmo salar reference genome (Ssal_v3.1) using STAR (Dobin, 2013), a high-performance community standard aligner. We used transcripts per million (TPM) values as gene expression levels for all the analyses. The differential gene expression analysis was based on the negative binomial distribution using the DESeq2 package (Love, 2014). Pathways enrichment analysis was performed using the Gene Ontology Consortium database (Gene Ontology Consortium, 2019) and STRING database (Szklarczyk, 2019).

Results

We mapped our data to a total of 14,831 genes. We observed a different expression profile between phenotypes (infested; non-infested) and seasons (summer; autumn). We identified only 19 differential expressed genes (DEGs) in the summer. By contrast, in autumn, the DEGs augmented to 102 DEGs. The representation of common DEGs between summer and autumn was minimal, with only 3 DEGs. For the exclusive DEGs, the summer showed 11 upregulated and 6 downregulated DEGs. On the other hand, the autumn showed 66 upregulated and 33 downregulated DEGs.

(Continued on next page)
We compared the functionality of the upregulated and downregulated DEGs between the infested and non-infested Atlantic salmon. The enrichment analysis showed the preference of the extracellular matrix process for the upregulated DEGs during summer. Conversely, the downregulated DEGs during summer showed no enrichment. In autumn, we observed upregulated DEGs associated with cellular response to corticotropin-releasing hormone stimulus, metabolic processes, cell proliferation, and nitric oxide biosynthetic process regulation, among others. On the other hand, the downregulated DEGs were associated with processes like riboflavin transport and mitochondrion organization.

Conclusions

Our analysis revealed that sea lice infestation does not appear to dominate the differential expression profile in summer, suggesting that both infested and non-infested samples are more concerned with seawater environmental adaptation. On the contrary, during autumn, the infested and non-infested Atlantic salmon show a differential expression profile and biological processes in response to sea lice. In this way, it stands out the physiological response to stress orchestrated by the cellular response to glucocorticoid stimulus.

Mysids play a vital role as a food source in aquaria and fisheries, and they are considered a valuable experimental model for studying crustacean biology due to their shrimp-like characteristics and favorable traits. However, our understanding of their physiology and biochemical responses in controlled culture systems is still limited. In this study, we focused on the marine mysid *Neomysis awatschensis* and reared them in a controlled laboratory system to investigate various parameters. We examined the growth, survival, molting, levels of 20-hydroxyecdysone (20E), and biochemical responses, such as antioxidant defense and cholinergic system, in response to consistent fluctuations in environmental factors across five generations. Our findings revealed that temperature fluctuations had a significant impact on growth parameters, including total length, antennal scale length, expod length, endopod length, and telson length. Specifically, the levels of 20E were significantly elevated during the postnauplioid stages when exposed to temperature changes. The number of newly hatched juveniles produced by the mysids was greatly influenced by temperature changes across generations. Furthermore, we observed that lower salinities below 15 practical salinity units (psu) negatively affected both growth and survival, while no significant modulation was observed at salinities above 25 psu. The combined effects of low temperature and salinity were identified as the most significant environmental factors impacting multigenerational mysid culture. It is worth noting that although the survival rate was slightly reduced at a pH of 7.0, it did not significantly affect the overall culture performance. The information obtained from this study is valuable for optimizing mass mysid culture in controlled systems. Understanding the specific environmental factors that influence mysid growth, survival, and reproduction can aid in the development of effective strategies for mysid aquaculture and enhance our knowledge of their physiology and responses to environmental conditions.
ARE CONSUMERS READY TO ACCEPT AQUACULTURE PRODUCTS?

Introduction
Aquaculture is a growing sector that plays a fundamental role as a healthy source of food and nutrients for the world’s population. Fish and aquatic foods are associated with numerous health benefits, not only as a source of protein, but also as an exceptional and diverse supplier of bioavailable fatty acids and micronutrients. Moreover, it is the main, and almost unique source of long-chain omega-3s, and its consumption is recommended by the World Health Organization1.

Consumers’ perception of food is evolving towards a greater awareness of the relationship between nutrition and health2. This is both a challenge and an opportunity for the agri-food industry, which must develop innovative products that meet consumers’ expectations, such as functional foods. Farmed fish can be considered an excellent candidate for a functional food since it combines the innovation of the sector with the possibility to tailor muscle composition with health beneficial compounds. It is, however, important that consumers understand and trust the benefits of consuming functional foods and know that the health claims are supported by scientific evidence3.

In order to assess consumer acceptance of differentiated aquaculture products a comprehensive survey was conducted internationally, as part of the OmegaPeixe Project.

Objectives
To carry out a comprehensive consumer survey, both nationally and in relevant European countries, a questionnaire was developed with the main purposes of:

1. Assess the level of consumer confidence in aquaculture products.
2. Identify trends in fish consumption.

Material and methods
An online questionnaire was designed, according to Hill4, to allow for the collection of information on the target audience - socio-economic characterization data, consumption data of fish and aquaculture products, level of trust and preference for aquaculture products. The questionnaire was disseminated by the project promoters, through their commercial and institutional contact networks, as well as through social networks. Additionally, relevant entities from the aquaculture sector and NGOs were invited to participate in the dissemination of the questionnaire to make it as comprehensive as possible. Responses were collected over a 5-month period from 16th September 2021 to 16th February 2022. The information collected was statistically treated in IBM SPSS Statistics 28.0 program. For comparison between groups, Pearson’s chi-square test ($\chi^2$) was performed to evaluate the association between nominal qualitative variables, with the following assumptions: sample number greater than 20; 80% of the categories with expected frequency greater than 5. To evaluate the strength of association of the chi-square test, Cramer’s V test was used for nominal variables and Eta test for ordinal variables.

Results
In this study 1349 valid questionnaires were obtained, with respondents aged 18-82 years, 61.7% living in Portugal and 30.9% living in Spain, 4% in the other countries of the European Union, 2% in the other countries of Europe, and almost 2% of the respondents were in other Countries Outside Europe. More than 80% of respondents were active and the average monthly household income was over 3000 € for 21.1% of the respondents, and 33.4% spend more than 400 € monthly on food. Additionally, 88.3% have never worked in the aquaculture sector and 97.4% were fish consumers. Moreover, in total, 41.9% consumers preferred wild fish, 41.3% showed no preference, while 7.2% preferred aquaculture fish, and 9.5% fish from organic aquaculture. Consumers in the age groups of 18-27 and 28-37 were less likely to choose wild fish, and more choose “no preference” answers as to how it was produced, than in the other age groups. On the other hand, the age group 58-67 years showed more preference for wild fish. Respondents with High School diploma consumed less aquaculture fish, while College degree respondents chose more “no preference” answers. Furthermore, results showed that working or having worked in the aquaculture sector significantly favoured fish from aquaculture production over wild fish.

(Continued on next page)
Conclusions
A low number of consumers showed preference for fish from aquaculture, indicating that consumers may not be ready to accept aquaculture products yet. Nonetheless, younger consumers, with higher levels of education showed higher level of acceptance towards eating fish from aquaculture. Moreover, consumers that work or have worked with the sector showed higher levels of consumption of aquaculture fish, suggesting that an increase in the dissemination and awareness of this industry could lead to an increase in acceptance and consumption of farmed fish by the general population.

Introduction
Fish in RAS is threatened by severe risks associated with the water quality, even though it is designed for optimizing growth conditions. Sudden mass mortality of fish is one of the major risks in RAS. In the past years, an increasing number of such incidents has been reported and most cases have been associated with H₂S. To-date monitoring of H₂S is not commonly implemented in RAS due to limitations in analytical methods to detect low concentrations relevant for fish health. This entails development of more precise analytical chemistry-based methods, or sophisticated methods for indirect detection of the hazardous gas. It has been shown across several fields that microbial communities and their composition can be an excellent proxy for predicting the state of a given environment. Data obtained by next generation sequencing (NGS) from environmental samples typically contains information on thousands of microbial taxa, which allows for the employment of supervised machine learning (SML) techniques. In the recently finished “MonMic” project, we have found that microbial communities are an excellent indicator for perturbations in RAS. Building upon that knowledge, we are exploring the potential of microbial communities as indicators for H₂S in RAS.

Material and methods
Atlantic salmon (Salmo salar) post-smolt were randomized and stocked into control and exposure groups, and acclimated for two weeks in RAS prior to the H₂S introduction. The control treatment comprised of one tank and one biofilter, while the exposure treatment included two tanks connected to one biofilter. The tanks and biofilters had a capacity of 0.8 m³ and 0.350 m³, respectively. The exposure group was stocked with two different densities of fish biomass, 10 and 30 kg/m³, and the control group was stocked with 30 kg/m³. After the acclimation period, both exposure tanks were exposed to artificially added H₂S for ten consecutive days. Sodium sulfide (Na₂S) was used to artificially introduce H₂S. The starting concentration of H₂S was 1,25 µg/L. Doubling concentrations of H₂S from previous exposure were used for subsequent exposures until a stress response in the fish was noticed. The final exposure of 160 µg/L was performed after nine days of the challenge. Different exposures were conducted after 24 hours, enabling fish recovery from the previous exposure. H₂S concentrations were monitored in real-time employing the SeaRAS AquaSense System (AQS).

Results
There was a difference in microbial communities at the start of the experiment between the two parallels (prior to H₂S exposure) (figure 1A). Communities of both treatments were also dynamic over time. Partial least square discriminant analysis (PLS-DA) and Random Forest (RF) SML have been used to attempt to classify H₂S exposed and non-exposed samples. Both approaches yielded excellent predictions, with PLS-DA classifying at 99%, while RF at 99.5% accuracy. Most prominent features contributing to the classification strength from both approaches were filtered out and classified (figure 1B).

Figure 1. Beta diversity analysis of all samples annotated on basis of different RAS and exposures (A). Most prominent features with mean relative abundances across two treatments contributing to classification of H₂S exposed samples for RF (B) approach.

(Continued on next page)
Discussion
Although the control and exposure RAS were identical from design, and the same water was used to fill the systems, communities between them were different (figure 1A). In fact, this is not uncommon for identical RAS, as very subtle differences in operations, water chemistry, etc. can lead to such contrasts. There was also a time component influencing community dynamics in both treatments which seemingly hinders clear conclusions to what extent H$_2$S has influenced community alterations in exposed RAS. Nevertheless, a larger time-wise spread of community dynamics in the exposure group compared to the control is an indication that these larger alterations of microbial community may be indeed influenced by the introduction of H$_2$S, rather than the standard community development. Application of supervised machine learning indicates that there is a pattern in microbial communities reflecting the presence of H$_2$S. Indeed, many of the prominent features are belonging to the taxa associated with sulfur oxidation, e.g., Marinicella, Pseudomonas, Hydrogenophaga, Ahrensia, Hoeflea, Phycisphaeraceae, or are associated with the metabolism byproducts of sulfur oxidation (e.g., Colwellia, Marinomonas). It has to be mentioned, however, that the experimental design was setup to simulate acute H$_2$S conditions, with short-lasting peakseasing off quickly. We may speculate that with a setup simulating chronic exposure, community shifts and signatures would be even more pronounced.

Conclusion
1) Two identical RAS show spatial and temporal differences in microbial communities. 2) Microbial community based SML model exhibits a potential for H$_2$S prediction in experimental RAS. 3) Features contributing to SML model distinction of H$_2$S exposed and non-exposed samples can be associated with sulfur metabolism.

Introduction
In recirculating aquaculture systems (RAS), an enclosed aquaculture system for cultivating animals in a controlled manner, microbial communities are critical for maintaining water quality and animal health (Rieder et al., 2023). Despite their systemic importance, the composition of the microbial communities within most RAS remains largely unknown. Establishing accurate, standardized, and user-friendly methods to study microbial communities in RAS may lead to better-designed RAS, improved management practices, and natural ways to prevent disease outbreaks, thereby securing sustainable food production (Moschos, Kormas and Karayanni, 2022).

Methods
This study investigated the effects of sampling, data generation, and analysis strategies on the inference of microbial community composition in RAS. To understand the key aspects of microbial community structure and dynamics, we collected water and biofilm samples (Fig 1A) from tanks (Farm A & B) and the biofilter compartment (Farm B) within two perch freshwater RAS (Fig 1B). Furthermore, to understand the advantages and disadvantages of different sequencing resolutions, we compared two amplicon sequencing approaches, short-read with Illumina Miseq and long-read with PacBio, and amplicon-free shotgun metagenomics with Illumina NovaSeq 6000 (Fig. 1D-F).

Results and Discussion
In the short-read dataset, the community composition varied between farms, the tank and biofilter compartment within farm A, the different sample types (biofilm vs. water), and between biofilms of different ages (> 1 week vs. < 1 week) (Fig 2). In the long-read dataset, in a semi-quantitative manner, we could identify the most abundant species in each farm and sample type and found complementary results to the Illumina amplicon sequencing concerning spatial patterns. For example, tank biofilm and tank water samples had the most considerable overlap of species, while between the biofilm sample groups, environmental farm conditions had a more substantial impact on shaping the communities than sample type (Fig. 3). The shotgun metagenomics sequencing yielded impressively comparable results to Illumina amplicon sequencing. Among the top 0.5% phyla, similar bacterial phyla appear. In addition, we can detect taxonomic groups that the short amplicon approach is blind to, such as Ascomycota (sac fungi) and Streptophyta (green algae) (Fig 4). The fungal signal will be interesting to study further and understand interactions between bacteria and fungi because the dynamics between these two groups play a role in animal health.

(Continued on next page)
Conclusion
The results show that microbial communities in RAS are highly dynamic and that management routines create a state of continuous succession and recolonization that can be detected with various sequencing methods. Also, different compartments feature unique microbial communities, despite the permanent water circulation, demonstrating the immense impact of environmental parameters on the community composition.

The results presented here contribute to the overall understanding of the microbial community and dynamic and complex interactions in RAS. They also indicate that further research of microbial communities in aquaculture will be helpful to farm management (e.g., biofilter start-up or disease prevention), to understand basic biological principles (e.g., the link between environmental stressors and microbiome dysbiosis), and to clarify medical relevant interactions (e.g., between host-microbiome-environment interaction and disease development).

Introduction
The sustainability of the aquafeed sector depends on an adequate and efficient response to the increasing demand for traditional fish-derived raw materials as aquaculture production increases. During the last decades, novel raw materials, including meals from terrestrial animal by-products, or oils from microalgae, have been proposed as alternatives to fishmeal (FM) and fish oil (FO). In parallel, great efforts have been spent for selective breeding to improve the productivity and sustainability of cultured fish species. Accordingly, the present study, in the frame of AquaIMPACT project (Horizon 2020), aimed to investigate in European sea bass (*Dicentrarchus labrax*), the genetic- and nutritionally-mediated effects upon gut mucosal health and microbiota. Different genetic stocks of fish fed with novel feed formulations completely devoid of FO and with low inclusion levels of FM, containing different additives, were tested.

Materials and methods
The feeding trials were carried out at the Parque Científico-Tecnológico Marino of the University of Las Palmas de Gran Canaria (Telde, Canary Island, Spain). Two batches of European sea bass populations: selected for high growth (HG), and wildtype (WT), produced at MARBEC-IFREMER, were used. In the first trial, as described in details by Montero et al. (2023), 294 dph sea bass larvae (t=0) were randomly distributed in cylinder-conical tanks (10 tanks for each genotype and dietary group, 500 L or 1000 L) at an initial density of 50 fish per tank. Fish were fed to apparent satiation with either a control or a “future” diet (Table 1), in which FO was totally replaced by a combination of poultry and DHA oil, and 50% of FM was replaced by poultry meal inclusion (Skretting ARC, Norway). Fish were sampled at t=0, and at the end of the feeding trial (609 dph).

In the second trial, HG and WT sea bass were fed the “future” diet until achieving the initial experimental size of 16 g. Then, fish were randomly distributed in 24 tanks of 500 L (34 fish/tank; 12 tanks for genotype) and fed diets supplemented with 3 different functional additives (INVE, Belgium) as follows: 2 weeks at high dose followed by 10 weeks at low dose. The functional additives used were a probiotic mixture (PROB), organic acids mixture (ORG), and a phytogenic (PHYTO). In this case, fish were sampled for the scheduled analyses only at the end of trial (after 12 weeks of feeding).

In both experimental trials, from each sampling point, 0.5 cm samples of proximal and distal intestine regions (n= 6 fish genotype/diet) were collected for GALT gene expression analysis by qPCR, whereas the mucosa associated microbiota was obtained by scraping the entire intestinal mucosa (n= 6 fish/ genotype/diet) with a sterile cotton swab. The high-throughput sequencing of 16S rRNA gene on MiSeq platform (Illumina) was performed to characterize the gut microbial communities as described in Rimoldi et al. (2019). The raw data obtained following sequencing were analyzed using the QIIME software. A Two-way ANOVA was applied to test for differences in gene expression and bacterial taxa relative abundances. Significance was set at $p < 0.05$.

(Continued on next page)
Results and discussion

Results from the first feeding trial showed differences in the expression of GALT-related genes in distal intestine. In particular, the expression of cytokines *il-1β*, *tnf-α*, and *il-10* was different, showing an interaction effect diet x genotype. With regard to gut microbiota, diet had a lower influence than genotype. Indeed, regardless of the diet, WT fish showed higher species richness than HG genotype. Furthermore, the gut microbiota of HG fish shared a reduced individual variability, indicating an enhanced capacity to cope with changes in diet composition. A significant genotype effect was found for specific bacterial taxa, such as *Paracoccus* genus and other genera belonging to Moraxellaceae family, which were more abundant in WT fish, regardless of the diet. Among them, the relative abundance of *Paracoccus* genus was positively correlated with the higher proinflammatory cytokine *il-1β* expression found in distal intestine of WT sea bass.

In terms of GALT-related gene expression, the second trial revealed a genotype x diet effect only for *il-1β* in distal intestine. In terms of gut microbiota, discriminant analysis did not show a clear separation between fish fed the future diet and fish fed additive supplemented diets. Despite that, relative abundances of specific taxa varied among experimental groups. Specifically, fish fed ORG diet presented higher relative abundance of *Streptococcus* in both genotypes, whereas fish fed PHYTO had higher abundance of Lactobacillales. Interestingly, *Bacillus*-based PROB had bactericidal activity on *Pseudomonas* and *Acinetobacter* genera. This result confirmed, our previous evidence, that the *Bacillus*-based probiotics have the capacity to modulate gut microbiota in European sea bass despite of a lack of colonization of the host’s intestinal mucosa (Moroni et al., 2021).

EFFECT OF STRESS ON DIFFERENT AGE GROUPS OF CULTURED *Labeo victorianus* CAUSED BY PHYSICO-CHEMICAL WATER QUALITY PARAMETERS

1Sheila Nyang’anyi Rioba*.

1Kenya Fisheries Service
*Corresponding Author: Sheila Nyang’anyi Rioba.: +254 704434297
Email; nyanganyis@gmail.com

Given the growth of the aquaculture industry and concerns over negative effects of stress on fish, it is important to research how cultured fish respond to stress. The duration and intensity of stress can lead to fish mortality, disease outbreaks, poor growth performance, and reproductive failure.

This study aims to investigate the impact of physico-chemical water quality parameters on the stress response of different age groups of *Labeo victorianus*, a cultured fish species. Four treatments will be conducted, each consisting of 100 fish of different age groups (5g, 20g, 50g, and 100g) housed in four tanks and replicated three times. The fish will be fed high-quality feeds with a crude protein content of 30% throughout the experimental period.

Blood samples will be collected from each age group every two days, and the cortisol, glucose, sodium, and chloride ion concentrations will be analyzed. This process will continue for 10 days, with subsequent blood samples taken every two days to monitor the effects of stress. Physico-chemical parameters of each experimental set-up will also be measured by taking three water samples from each setup before extracting blood samples from the experimental fish.

The analyzed blood and water samples from each treatment will be compared to evaluate the response of different age groups of *Labeo victorianus* to different water quality parameters. This study will contribute to a better understanding of how fish respond to stress and may inform strategies to mitigate negative impacts on cultured fish.
GENOMIC ANALYSIS OF AMOEBIC GILL DISEASE CAUSING Neoparamoeba perurans IN ATLANTIC SALMON AQUACULTURE

Introduction
Amoebic Gill Disease (AGD) is a severe infection of farmed Atlantic salmon (Salmo salar L.) with the first reported case in Tasmania-farmed salmonids in 1986. The causative agent was confirmed via in situ hybridization to be Neoparamoeba perurans. Since its emergence, AGD has continued to spread across the globe at an alarming rate with initially reported cases in Ireland in 1995, Norway and Scotland in 2006 and Chile in 2007. The spread is concerning, both in its speed and in the outsized impact it can have on the salmon farming industry due to the high financial costs associated with both treatment and losses. Over 40 years since its discovery, we still know little about how N. perurans spreads between farms, production cycles, regions and countries. An understanding of parasite transmission dynamics could inform fallowing and control in salmonid aquaculture. Any genomic analyses required to achieve N. perurans molecular epidemiology, however, are frustrated by characteristically high levels of intracellular bacterial contamination.

Currently, a handful of N. perurans genes have been successfully sequenced (18S rRNA, cytochrome oxidase I, ITS, etc) but with insufficient genetic resolution to be of use the farmer or regulator. A A draft genome of N. perurans has been generated at the Llewellyn lab, University of Glasgow, and has enabled hundreds of new sequencing markers to be developed. These markers can be sequenced directly from gill swabs at low cost to provide epidemiologically relevant information., A highly multiplexed testing strategy is under development with the intent to sequence a series of AGD samples from Ireland and Scotland 2019-2023 for molecular epidemiological analysis.

Method and Materials
Gill swabs were analysed from 2019 and 2022 from Atlantic salmon affected by AGD for qPCR barcoding that were provided from aquaculture industry partners in Scotland. Further non-invasive gill swabs from infected individuals were obtained from aquaculture industry partners in 2023 for additional qPCR barcoding. DNA extractions were conducted on all obtained gill swab samples and amplified through qPCR to determine the presence of the 18S rRNA gene of N. perurans.

A multiplex PCR was developed using up to >300 primer pairs per reaction to amplify genes across the nuclear, mitochondrial, and kinetoplast genome on samples that displayed a positive presence of N. perurans from qPCR. PCR products were barcoded and cleaned. Library preparation was conducted as per Nanopore specifications. PCR products were then sequenced using the Nanopore MinION system. Basecalling was completed per MinKNOW 23.04.3 protocol. Sequences were then aligned with phylogeny estimated and analysed in RStudio, MEGA, and Figtree.

Results
Extracted DNA of 149 gill swabs from Atlantic salmon in Scotland and Ireland revealed 108 (72.5%) to be positive for N. perurans presence at or before 30 amplification cycles of the 18S rRNA gene and quantified (ng/μl) as seen in Figure 1A & B. From this data, best candidates for DNA sequencing based on DNA quantity, and epidemiological considerations (location & time) were chosen to both maximise the success of genome sequencing and allow for phylogenetic investigation inclusive of spatiotemporal changes.

Sequence data is still being sequenced through Nanopore and awaiting results back to begin alignment and phylogeny estimates. Samples for sequencing based on qPCR results with a cut-off limit of 30cq are to be brought forward for sequencing to enhance the viability of genomic sequencing results.

(Continued on next page)
Discussion

To date, there is no effective means of attributing AGD infections to source. Although currently incomplete, this current work has taken important steps towards achieving this by demonstrating that high-resolution genetic information may be readily derived directly from gill swab samples to inform AGD treatment and control.

Figure 1: (A) Plot of gill swab samples with DNA quantities between 0-1 ng/µL per RT-PCR output. (B) Plot of gill swab samples with DNA quantities greater than 1 ng/µL per RT-PCR output.
HEALTH PROMOTING PHYTOADDITIVE FOR GUT HEALTH IMPROVEMENT ACROSS FISH SPECIES: GILTHEAD SEA BREAM *Sparus aurata* AND TILPIA *Oreochromis sp.*

Introduction

After the latest discoveries on how the gut health influences the general wellbeing in humans, the fish intestine is getting more and more attention. The gut acts as a selective barrier allowing nutrients in and blocking the entry to pathogens.

The inclusion of new ingredients in fish feed formulation represents a challenge for the correct functionality of the gut. Not only the formula has to be nutritionally balanced but it should also promote the health of the intestine.

Feed additives are designed to provide a benefit for the fish, helping in the transport, absorption and/or incorporation of nutrients. In order to evaluate such a benefit, the Ussing chamber has been used as diagnostic tool to assess the tissue electrical properties of the gut (electrophysiology). This technique allows the analysis of the intestine *ex-vivo* if the tissue is kept alive, and reflects its *in vivo* functionality.

In this work, electrophysiology and histology have been used to evaluate the impact of a feed additive on the gut health of a marine fish, gilthead seabream (*S. aurata*) and a freshwater fish, tilapia (*Oreochromis sp.*).

Material and methods

**Gilthead seabream**: fish of 98.07±1.02 g average individual body weight were distributed in 6 tanks of a marine (32 psu) recirculating aquaculture system (RAS) held at 23ºC. A group of 25 animals were stocked per tank. Fish were fed either a control diet (diet A) or the same diet to which a gut health promoting additive (Sanacore GM®, Adisseo) was added (diet B). Feeds contained 10% FM and the additive was included at 0.5%. Feeds were isoproteic and isolipidic (CP/CF = 45/18). Fish were fed manually twice per day 6 days per week. Trial lasted 8 weeks.

**Tilapia**: fingerlings of 9.95±1.02 g average individual body weight were stocked in 12 tanks of a freshwater RAS. Fish were fed a positive control diet (diet T+), a negative control diet (diet T-) and a diet S, containing the additive (Sanacore GM®, Adisseo). Diet T+ contains 10% FM and diets T- and S had 0% FM inclusion. Diets were isoproteic and isolipidic (CP/CF = 33/5). Fish were fed automatically distributing the daily ration during 12 hours per day. Trial lasted 8 weeks.

Epithelial electrophysiology in Ussing chambers

The anterior intestine, was isolated and mounted as previously described (Gregorio et al., 2013) with apical (luminal) and basolateral (blood side) sides of the tissue identified on a tissue holder of 0.25-0.30 cm² and positioned between two half-chambers containing 2 ml of physiological saline. Bioelectrical parameters for each tissue were recorded continuously during the *in vitro* period onto Labscribe3 running in a MacIntosh computer using IWorx188 and Lab-Trax-4 data acquisition systems, from the time of mounting for 90 min. Epithelial resistance (Rt, Ω.cm²) was manually calculated (using Ohm’s law) from the current deflections induced by a bilateral +2 mV pulse of 3 s every minute.

Results & conclusions

**Gilthead seabream**: diet A and B had a similar performance in terms of SGR and FCR as well as in somatic indexes. Significant difference was found in the transepithelial resistance of fish fed the two diets (Fig.1). Tissue resistance in the intestine of healthy seabream juveniles of this size is expected to be higher than 150 Ω cm². The time-response in vitro in the Ussing chamber experiment shows a typical progression to plateau values in groups A and B. Fish fed diet B showed a significantly higher average values of tissue electrical resistance than fish fed diet A.

**Tilapia**: there are very few reports on epithelial tissue resistance in the intestine of tilapia. Values obtained in previous experiments with tilapia species points to values between 45-75 Ω cm². Values barely changed during the time *in vitro*, and no significant differences between groups were observed after statistical analysis. However, fish fed with the diet S showed an increase of the epithelium resistance in tilapia although no significant difference was found between diet S and diet T+. Diet T- without additive inclusion showed the lowest Rt values (Fig.2).

FROM A CELL MODEL TO A FISH TRIAL: IMMUNOMODULATORY EFFECTS OF HEAT-KILLED *Lactiplantibacillus plantarum* AS FUNCTIONAL INGREDIENT IN AQUAFEEDS FOR SALMONIDS

Introduction

During fish farming, fish are exposed to several stressor conditions that can lead to reduced growth, increased mortalities and large economical losses. These problems can be mitigated by the use of functional feeds, leading to a more sustainable aquaculture and improved animal welfare. The use of functional novel aquafeeds containing paraprobiotics (dead/inactivated probiotics) can be an important solutions to these problems. *Lactiplantibacillus plantarum* strain L-137 is a common bacterium found in fermented Southeast Asian dish made from fish and rice. Use of the heat-killed form of this bacterium (HK L-137) in aquaculture species is associated with improved growth performance and immunoregulation, representing a cost-effective way to prevent mortality. The effects of Feed LP20™ (20% HK L-137) were already proven in species such as Nile Tilapia, striped catfish and bighead catfish. Thus functional feeds containing HK L-137 also have potential to improve growth performance and health in Atlantic salmon.

Materials and methods

For the *in vitro* model, we used an intestinal epithelium cell line from rainbow trout (RTgutGC) stimulated with pre-digested HK L-137 to mimic *in vivo* gastro-intestinal digestion. We consider the distal intestine as a good model to study the effect of functional feeds, since this is where the active compound is in contact with the mucosa-associated lymphoid tissue (MALT) in this organ (GALT), which can coordinate both local and systemic immune responses.

For the *in vivo* dietary trial with Atlantic salmon, pre-smolts (average weight 27.3g) were fed *ad libitum* once a day (6 h) one of the five experimental diets (triplicate tanks, 55 fish per tank, 61 days): a commercial-like diet without any growth-promoting additives (control diet, CD); control diet supplemented with 20, 100 and 500 mg of Feed LP20™ kg⁻¹ feed (LP20, LP100 and LP500, respectively); a positive control diet (MG) - control diet supplemented with 2 g of β-glucan kg⁻¹ feed (Macrogard®).

Results and Discussion

*In vitro* results showed that the barrier function of the cell monolayer was strengthened, suggested by the reduced permeability of Lucifer yellow after 6 h exposure (Figure 1A). An improved barrier can improve digestive function and decrease the vulnerability to bacterial infection. At the protein production level (Figure 1B), there was an increased production of IL-1β both after 6 and 24 h after exposure and a decreased production of Anxa1 after 24 h exposure, indicating an activation of pro-inflammatory process. No difference in the expression of E-cadherin was observed.

*In vivo* dietary trial, HK L-137 did not compromise fish growth performance. Intestinal microbiota composition was slightly affected, but without relevant changes in alpha and beta-diversities. This was expected since the *L. plantarum* was inactivated and the inclusion levels were low, preventing colonization. Interestingly, indirect ELISA assay in distal intestine showed that fish fed higher inclusion level of HK L-137 also have a lower production of Anxa1 (Figure 2A), as seen in *in vitro* model, and no difference in production of IL-1β or E-cadherin. Fish fed LP500 also had a higher production of total IgM in plasma, which was not changed specifically by HK L-137 (Figure 2A). The increase of total IgM could be an increase in natural antibodies relevant for defense and homeostasis. Transcriptomic analysis in distal intestine tissue showed that increasing inclusion level of HK L-137 in diets induced an increase in differentially expressed genes. Lowest inclusion level (LP20) induced an up-regulation of 5 terms related with cell structure, adhesion, communication and proliferation and immune regulation (Figure 2B, terms in bold). The up-regulation of the same terms was conserved also in the higher inclusion levels, in addition to other terms related with barrier function, immune response and metabolism (Figure 2B). No differences were found between dietary groups regarding intestinal villi height.

(Continued on next page)
Conclusion
In the current study, we investigated the potential of HK L-137 at both in vitro and in vivo levels. Our results suggest that HK L-137 has immunoproperties by modulating cytokines and effector molecules, suggesting its potential in functional feeds for salmonids. The similarity between the two models indicate that an in vitro model is indeed a useful tool to study the immunomodulatory properties of a novel fed component. This also is a faster, cheaper approach that also promote animal welfare. The current study was performed on healthy fish in fresh water deprived of major stressor factors. This creates a baseline for future work with HK L-137 in Atlantic salmon. A follow-up live pathogen challenge trial with salmon is on-going, where we are evaluating the ability of HK L-137 to reduce mortalities after seawater transfer.
STRAIN-SPECIFIC MATERNAL NON-GENETIC INHERITANCE AND OFFSPRING PERFORMANCE IN RAINBOW TROUT (Oncorhynchus mykiss)

Introduction
Rainbow trout (Oncorhynchus mykiss) is the most important branch of the freshwater aquaculture sector in Europe, responsible for over 75% of the production. Despite of that, the sector suffers from specific problems such as low disease resistance (Tobback et al. 2007) and variability of reproductive performance (Bonnet, Fostier, and Bobe 2007) that are contributing to the stagnation of the production in Europe (FEAP 2020). Lack of genetic information on the strains produced nowadays also put at risk the production and species management (FAO 2020). The sector thus calls for improvement of the productive chain in order to provide food security in a sustainable manner. The selective breeding performed nowadays can be highly enhanced by gathering objective data from various production phases where linkage between the reproductive performance and future performance of the offspring is largely ignored (Janssen et al. 2015). Non-genetic inheritance (NGI) mechanisms are responsible for all heritable features that breeders transmit to offspring that are not directly part of the DNA sequence but still interact or derive from it (Adrian-Kalchhauser et al. 2020). Fish eggs content, in this context, constitutes maternal NGI with major impact in early embryonic development and also later consequences. Investigating these mechanisms can help to shed light on maternal impact on offspring performance and they could also, in a long term run, be considered during selective breeding programs. This project aims to characterize three different molecules responsible for NGI in females and to which extent they are implicated in offspring performance by studying breeders, embryos and juveniles from three farmed strains of rainbow trout.

Materials and methods
Experiments were conducted to evaluate (1) egg quality and thus, maternal investment for reproduction, offspring performance regarding (2) growth and (3) disease resistance and (4) NGI potentially implicated in (1)-(3). More specifically, proteins, mRNA and miRNA profiles in eggs. Additionally, immune response related genes in liver, spleen and gills of fish from (3) will also be assessed.

To assess egg quality, eggs from six females from each strain were fertilized using a pool of sperm of males from the same strain. Fertilization, eyed stage, hatching and mortality rates were recorded for (1). Hatched embryos from all females from one strain were pooled and once larvae reached swimming-up stage, total biomass from each strain was calculated. Larvae were placed into glass tanks for (2) in triplicate. Weekly, larvae were weighted and measured (n=30) for food offer correction and growth evaluation. Mortality during this period was also recorded. When fish reached average 6g individual weight, 162 fish were sampled for (3). They were divided in control and infected group in triplicate (n=27). Both fish groups were subjected to a bath for 1h. Infected group bath contained Yersinia ruckeri at a concentration of 4.5x10⁸ while control group contained only tank water. After, all fish were placed back into their original tanks. Fish tissues that will be used for molecular analysis were sampled and snap frozen before, at three, five and seven days post-infection in both control and infected group (n=6). Mortality and major infection signs were recorded up to 14 days post-infection.

For (4), a portion of unfertilized freshly stripped eggs from same females as the above mentioned experiments were snap frozen for molecular analysis. These samples will be used for RNA and protein extraction and subsequent mRNA, miRNA and proteins profiling that will be compared between and within strains.

(Continued on next page)
Results
High quality eggs were obtained from the two strains already evaluated. Fertilization (93.4±3.8 and 85.8±3.1%), eyed stage (84.7±5.2 and 90.5±3.6%), hatching (97.2±1.0 and 97.5±2.2%), egg mortality (2.8±1.0 and 2.6±2.2%) and larvae mortality rates (1.1±0.5 and 0%) did not present differences between strains A and B. In growth performance, however, difference was observed between both strains from the fourth week. No mortality difference during this period was observed between strains. Concerning bacterial challenge, mortality in strain B started earlier and is already double of the one observed in strain A. Trial is still in progress. Trials for third strain have started and molecular analysis of fish tissues will be performed in May/June. Thus, zootechnical and molecular data will be available for presentation at the conference.

Discussion
Commonly used in farmed mammals, progeny tests are largely applied to select the best breeders and thus improve overall stock quality (Rosa 2013). Selection based on offspring performance is a valid option also for fish selective programs once enough information on progeny is available. Our results will contribute in providing this knowledge in terms of early survival, growth, late mortality and disease resistance. NGI has the potential for changing offspring gene expression and, as a consequence, change offspring phenotype and their interaction with environmental challenges. From this perspective, it is of highest importance to identify mechanisms responsible for expression and/or heritability of particular traits in relation to the genetic background and experience of the population studied. Therefore, the knowledge on maternal NGI implicated in the production of high quality offspring in different fish populations may contribute to improve selective breeders programs and hence aquaculture sustainability.

Acknowledgments
This project is funded by the European Union’s Horizon 2020 research and innovation programme under the Marie Skłodowska-Curie grant agreement No 847639 and by the Polish Ministry of Education and Science. Authors thank Dabie Hatchery (Bytów, Poland) for providing biological material and information on the studied strains.

ARE THE INITIAL STAGES OF FISH INGESTING OR ABSORBING MICROPLASTICS IN THE WILD ENVIRONMENT?

S. M. Rodrigues 1,2, F. Espincho 1,2, D. M. Silva 1,2, R. Pereira 1,2, C. M. R. Almeida 2,3, S. Ramos 2

In recent years, several studies showed that the initial stages of fishes are able to ingest microplastics or absorb them through the gills. These plastic particles with less than 5 mm can cause gut blockage and limit food intake but also can have negative effects on growth, development, reproduction and even lead to death. Although an increasing number of studies focus on the ingestion and effects of microplastics, most studies are laboratory-based, and field studies are still very limited. Therefore, the present work aimed to evaluate if microplastics are being ingested or absorbed by wild larval stages of fishes, collected from the Douro Estuary (northern Portugal), an estuarine nursery ground for marine fish species. Monthly surveys were performed over 1 year (2021-2022) to collect fish larvae and microplastics from water samples. Samples were sorted, fish larvae identified and two fish species relevant for human consumption were chosen to evaluate their ingestion rate, namely the Senegalese sole, Solea senegalensis and the European sardine, Sardina pilchardus. A total of 30 fish larvae of S. senegalensis and 100 fish larvae of S. pilchardus were analyzed to extract microplastics, using a previously optimized protocol where the organic matter is degraded with H2O2 at 65°C. Microplastics present in the water were also quantified, and all microplastics retrieved from water and larval fish samples were characterized in terms of size, color, shape, and the polymer identified through FTIR. So far, results showed that all the microplastics present in fish larvae were fragments or fibers of 0.01 - 2.0 mm in size, and of 8 different colors. In contrast, a higher variety of shapes was observed in water samples, including fibers, fragments, films, foam, and paint, in more than 10 colors and ranging between 0.01 - 5 mm in size. These preliminary results indicate that microplastics present in fish larvae are similar to the ones from the estuarine water, although only the small size plastic fragments or fibers were ingested/absorbed by fish larvae. This study will allow to investigate microplastic occurrence in the initial stages of fishes from an estuarine nursery area, evaluating the incidence of microplastic present in fish larvae and comparing these results with the microplastics collected in the water.

Introduction

The European purple sea urchin *Paracentrotus lividus* is a keystone species of benthic coastal communities and an important marine resource in southern Europe (Bertocci et al., 2018). The growing interest in increasing aquaculture production has been driving the research for diets able to supply species nutritional requirements and produce high quality roe. A well-balanced diet can also contribute to maintaining an efficient immune system. Like other invertebrates, the sea urchins cannot biosynthesize carotenoids *de novo* (Tan et al., 2020), but these are directly involved in the immune and antioxidant defense system. The carotenoids are functional nutrients that stimulate the activity of antioxidant enzymes, increasing the efficiency of detoxification after immune activity (Babin et al., 2015). Simultaneously, by taking over the antioxidant enzyme activity and eliminating free radicals, carotenoids reduce the need for these enzymes and overall burden (Tan et al., 2020). A high dietary carotenoid content enhances immunity by supporting endogenous enzymes (catalase and superoxide dismutase) and detoxifying free radicals produced during immune activity. Despite the important physiologic role, in sea urchins, coelomocytes are the main cellular components responsible for the immune response (Banks, 2014) seconded by the proteases and lysozymes, representing a barrier against bacterial proliferation due to their peptidase activity (Fernández-Boo et al., 2018). The main objective of the present study was to analyze the effect of high and low carotenoid levels on the immune and oxidative response of *P. lividus* sea urchins.

Material and Methods

Adult sea urchins (N = 153) with mean diameter of 38.57 ± 2.99 mm were collected on a rocky beach (Porto Batel, Peniche) and maintained in three recirculatory aquatic systems (RAS) equipped with three 40 L glass tanks each (N = 17 individuals/tank). For 8 weeks, the animals were fed three times a week with three jellified diets: a diet rich in carotenoids (HC); a diet low in carotenoid (LC); seaweed-based control diet (Control). The high content of carotenoids in the diets was accomplished by adding pumpkin and dried *Nannochloropsis* sp to a vegetable-based diet. At the end of the nutritional trial, the sea urchins were exposed to a time-course pathology challenge, where they were inoculated with *Vibrio parahaemolyticus* to stimulate the individual’s immune system. Sea urchins’ weight, condition, immune and oxidative status were measured at the beginning and at the end of the nutritional trial. In detail, the sea urchins were measured and weighed, their gonads were removed and weighed to determine gonadosomatic index and to quantify the activity of oxidative stress related enzymes (Catalase – CAT; Superoxide dismutase - SOD; Lipid peroxidation - LPO). For the analysis of cellular and humoral immune parameters, coelomic fluid (CF) was collected individually to identify and count coelomocytes under 400x magnification microscope. For the analysis of humoral parameters were used the turbidimetric assay to quantify the lysozyme concentration, the azocasein hydrolysis assay for protease activity (Fernández-Boo et al., 2018) and to quantify the nitric oxide content, the Griess reaction procedure (Tafalla et al., 2003).

![Figure 1](image-url) - Values of oxidative stress parameters quantified in *Paracentrotus lividus* gonads at the end of the assay. A - Catalase; B - Superoxide dismutase; C- Lipid peroxidation. a and b indicate significant statistical differences (p < 0.05)

(Continued on next page)
Results
In the end of nutritional trial, there was an increase of coelomocytes in the sea urchins fed with HC and LC diets (respectively) when compared to the initial value ( ), while in the control diet there was a decrease in the total number of coelomocytes ( ). From these coelomocytes, and similarly in the three dietary groups, the most abundant were the phagocytes (HC: 58%; LC: 65%; Control: 69%), followed by the colorless granulocytes (HC: 18%; LC: 17%; Control: 16%). For the humoral parameters, the lysozyme (HC: 0.86 µg/mL; LC: 0.82 µg/mL; Control: 0.42 µg/mL) and protease (HC: 13%; LC: 14%; Control:13%) did not differ between the three diets studied. On the other hand, remarkable differences in the parameters of oxidative stress were observed between dietary treatments. The production of CAT was higher in individuals fed with HC diet (42 U mg/protein) and LC diet (54 U mg/protein) in relation to those fed with control diet. The opposite occurred with the production of SOD. Here, the animals fed with control diet produced a high amount of this enzyme (131 U/mg), compared with animals fed LC diet (50 U/mg). The occurrence of lipid peroxidation was more visible on sea urchins belonging to the treatment with the LC diet (0.043 nmol/g wt).

Discussion
The cellular and humoral immune parameters analyzed in the sea urchins CF were not affected by the dietary carotenoids’ levels selected. Regarding the antioxidant defense system, there was an effect of the carotenoids included in the diets provided to the sea urchins. The high content of carotenoids in an organism, as part of the integrated antioxidant system, enhances immunity by assisting endogenous enzymes (for example, catalase and superoxide dismutase) (Tan et al., 2020). Peroxidation is a common cellular damage caused by oxidative stress, because of the reaction of ROS with lipids. However, the effect of this cellular damage can be minimized by the activation of cytoprotective enzymes, such as superoxide dismutase (SOD) and catalase (CAT) (Amorim et al., 2020). In the present study, the urchins fed with LC diet presented low SOD, higher CAT values and then higher lipid peroxidation values than the HC and Control diet. This could mean that the production of catalase wasn’t enough to prevent the occurrence of lipid peroxidation in this treatment.

Introduction
Approximately 82.1 million tons of aquatic animals are produced per year (FAO, 2020). Sustainable aquaculture, such as Recirculated aquaculture system (RAS), is envisaged as one of the solutions to achieve a further increase in global seafood production. However, even though RAS farms can produce high-quality fish, “musty” and “earthy” off-flavours often taint fish, which is a well-known issue for fish farmers, inflicting significant financial losses as well as a negative perception of the RAS-farmed fish (Moretto et al., 2022). The main volatile compounds that contribute to those flavours in fish are geosmin and 2-methylisoborneol, but other compounds may additionally play a role (Jones et al., 2022). The traditional procedure to deal with off-flavour is the depuration of the fish in cleaner water (Podduturi et al., 2021). In this project sensory analytic instrumental procedures were applied for the characterization of aroma-active compounds in Nile Tilapia (Oreochromis niloticus) fillets to determine the aroma profile and composition of RAS fish and comprehend the impact of the depuration process.

Methods
Samples were collected in March 2022 from a recirculated aquaculture farm (Gårdsfisk, Sweden). Three fish replicates were caught randomly from the production and depuration tank. All samples were directly stunned, hand filleted, skinned and frozen at -20 °C until use for analysis. For efficient extraction of the volatile compounds, the procedure was adapted from Mahmoud 2017 (Mahmoud et al., 2017). Briefly, 50 g portions from the fish fillets were taken and minced into approximately 1 cm³ cubes and extracted once with an aliquot of 100 mL of dichloromethane by stirring at room temperature for 30 min. Subsequently, the extract was collected separately and distilled using solvent-assisted flavour evaporation (SAFE). After SAFE, the sample was dried over anhydrous Na₂SO₄. Prior to further chromatographic analysis, the total volume of each sample was reduced to approx. 100 µL via Vigreux distillation and micro distillation at 50 °C. The aroma analysis was performed using gas chromatography-olfactometry/flame ionization detector (GC-O/FID) equipped with DB-FFAP and DB-5 columns. The comparative aroma extract dilution analysis (cAEDA) was performed using the DB-FFAP column. Moreover, gas chromatography-mass spectrometry (GC-MS) and two-dimensional gas chromatography with mass spectrometry and olfactometry (2D-GC-MS/O) analysis were carried out. The identification of the odour-active compounds was based on the comparison of odour quality, retention indices on two capillaries with different polarities (DB-FFAP and DB-5) and mass spectra with those of authentic reference compounds. Retention indices were calculated for each odour-active compound by means of a reference series of homologous alkanes (C6-C30). Furthermore, the aroma profile analysis was performed according to ISO 13299:2016–09 and complemented by the determination of the overall intensity of the sample’s odours.

Results
The odour attributes fatty, green, mouldy, earthy, fishy and sea water-like/algae-like were selected by the panellists for the description of the fish aromas. Using combined sensory and instrumental techniques, 108 and 79 aroma-active compounds were olfactorily detected in Nile Tilapia from tank and depuration, respectively. Of these compounds, 77 were identified by comparison of the respective retention indices, mass spectra and odour qualities with their corresponding reference compounds, while 31 compounds could not be resolved due to their low concentration.

(Continued on next page)
**Discussion**

In this study, SAFE technique followed by sensory-instrumental analysis was successfully applied to identify odorant compounds in fillets from Nile Tilapia before and after depuration. A higher number of odour-active substances was detected in the fish sampled before depuration. For a detailed comparison of quantitative aspects, further studies involving quantification of the aroma substances would be required. This was, however, not the aim of the present study which focuses on a non-targeted approach for the characterization of odour-active substances that might be related to aquacultural off-odours. Recirculating water in RAS may favour bacterial growth and the accumulation of the substances they produce, often including off-flavours with earthy and musty notes. Little is known about the odorant characterization of fish and the potential impact of the individual odour-active compounds on the overall aroma in the fish matrix (Jones et al., 2022). Therefore, the identification of potent aroma compounds in Nile Tilapia is described to help mitigate the prejudice of the tainting of RAS fish.

Introduction
Climate change presents a risk to aquaculture productivity, particularly through rising temperatures and ocean acidification (OA). In particular, OA can have profound implications for the growth and development of many marine organisms. It has been demonstrated that low pH causes mortality or inhibits the growth, increases plasma cortisol and glucose levels, and decreases plasma chloride ions and osmolality in several species of fish (Reid et al., 2019). While OA has been demonstrated to impair normal calcification in marine invertebrates, its impact on vertebrates bone-cartilage calcification is largely unknown. In one species of elasmobranch an increase on skeletal density in response to acidification has been observed. However, the consequences of marine acidification on teleost fish have not been completely demonstrated (Di Santo, 2019). The aim of this study was to determine how CO$_2$ injection-induced acidification in the water modifies the insulin-like growth factors (IGFs) system members’ gene expression in muscle, liver and bone, as well as the development and mineralization gene markers’ expression in bone of gilthead sea bream (*Sparus aurata*).

Material and methods
Gilthead sea bream juveniles were obtained from the commercial hatchery Piscimar (Burriana, Spain) and were maintained in the animal facilities of the Faculty of Biology at the University of Barcelona (Barcelona, Spain). Fish were randomly distributed into 200 or 400 L tanks in a seawater recirculation system under a 12 h light/12 h dark photoperiod, 38‰ of salinity, and 22 ± 1 ºC. During the trial, one group was maintained at pH 7.9 (control) and the other at pH 7.3 via CO$_2$ injection. Each experimental group was represented by triplicate tanks (two 200 L and one 400L but with equivalent biodensity). After 68 days of exposure, 15 fish per condition were anesthetized and sampled. Body weight (BW) and body length (BL) were measured, and condition factor (CF) was calculated. Somatic indexes including hepatosomatic index (HSI), viscerosomatic index (VSI), and mesenteric fat index (MFI) were estimated, and the specific growth rate (SGR) was determined from a number of tagged fishes. Samples of liver, white muscle and bone were obtained and directly frozen in liquid nitrogen for gene expression analysis. The expression of components of the IGFs system were analyzed in all the tissues, and different bone-related genes were analyzed in bone by qPCR.

Results and discussion
After a 39 days culture period, the fish in the high pH condition exhibited significantly higher values of BW, BL and SGR compared to the fish in the low pH condition. By the end of the experiment, the fish subjected to low pH displayed lower values in BW, BL, SGR, and MFI, but no significant differences were observed in SGR. Regarding the gene expression, no statistically significant differences were observed in the liver for the genes analyzed. However, in both bone and muscle, there was a downregulated expression of the binding protein *igfbp*4 in fish subjected to the lower pH condition. Furthermore, in white muscle, under low pH, there was an increase in *igfbp*3 expression. Changes in the expression of these binding proteins might result from feedback regulatory processes. Thus, although under the low pH condition, a decrease in fish growth was observed in comparison to the control pH-reared fish during the first part of the trial, this condition did not disrupt the expression of key genes from the growth hormone / IGFs axis. The expression of the analyzed osteogenic genes remained unaltered, likely due to a blood buffering mechanism as a response to the low environmental pH. Overall, this study provides information about how OA could impact fish growth, potentially reducing their growth performance.

Introduction
Ocean acidification and warming have been shown to modify the calcification rates of marine invertebrates’ shells. More recently, it has been described that increased CO₂ levels, which cause ocean acidification, can also affect skeletal mineralization of elasmobranch (Di Santo, 2019). In addition, as a physiological response to high CO₂ levels, the plasma pH decreases, leading to acidosis (Drábiková et al., 2023). Primary fish cell cultures derived from bone are a useful model to study the effects of CO₂/pH on skeletal mineralization. The aim of this study was to determine how different CO₂ concentrations modify proliferation and mineralization of gilthead sea bream (*Sparus aurata*) osteoblast cells in culture.

Material and methods
To this end, vertebra bone-derived cells from this species were incubated during 30 days in either growth medium or osteogenic medium at 23°C and, three different CO₂ levels: 0%, 1.5% and 2.5% to generate distinct pH levels. Cell proliferation was assessed every 5 days using the MTT assay and mineralization by means of Alizarin Red staining.

Figure 1. (A-C) Proliferation and (D-F) differentiation of bone-derived cells at days 0 (D0) and 30 (D30) of culture development with 0% (A and D), 1.5% (B and E) and 2.5% (C and F) of CO₂. Data are shown as means ± SEM respect to D0. Statistical differences were determined using a two-way ANOVA (p<0.05) and a Tukey’s post-hoc test when the interaction between the two factors was significant and indicated by different letters (p<0.05). When only the day was significant the differences are indicated by asterisks (p<0.05).

(Continued on next page)
Results and discussion

Data showed that at a CO$_2$ concentration of 1.5% the pH remained close to the gilthead sea bream physiological level (7.54±0.07) and under the 2.5% and 0% CO$_2$ conditions, there was a slight acidification (7.33±0.03) and alkalinization (8.02±0.12) of the medium, respectively. Regarding proliferation and mineralization, significantly higher levels of both processes were detected in cells incubated with osteogenic medium at 0% CO$_2$ only at day 30 (Fig 1A, 1D), compared with the other culture conditions. However, at 2.5% and 1.5% of CO$_2$, significant increases in proliferation from day 5 and in mineralization from day 10 were found, respect to the corresponding day 0, regardless of the incubation media (growth medium or osteogenic medium), that were still evident at day 30 (Fig 1C, 1F for 2.5% and Fig 1B, 1E for 1.5% of CO$_2$, respectively).

Overall, this study provides information about how the CO$_2$/pH levels can affect osteoblasts growth and mineralization and help to elucidate if a reduced pH detrimental to the culture of fish bone cells. Moreover, these results suggest that ocean acidification caused by the increased anthropogenic CO$_2$ emissions could affect the growth and development of gilthead seabream skeleton in vivo.

Introduction
The skeletal muscle of teleost fish is a very plastic tissue that integrates external and internal inputs to adapt to a changing environment. In vertebrates, muscle growth includes the activation of the satellite cells, their proliferation, fusion, differentiation, and maturation in a process known as myogenesis that is regulated mainly by the myogenic regulatory factors (Myf5, Myod1, Myf6 and Myog). Furthermore, muscle growth and development are conditioned by the balance between protein synthesis and degradation, which are controlled by the PI3K/AKT/mTOR pathway that can be activated in response amino acids (AA) or insulinlike growth factor 1 (Igf-1).

In the last decades, research mainly in mammalian models has demonstrated that the noncoding RNAs (ncRNAs) also play a key role in regulating the myogenesis but little is known about their role in fish muscle development. The ncRNAs are a group of RNAs that, generally, do not codify for proteins but perform various regulatory functions in cellular processes, and include the microRNAs (miRNAs) and the long non-coding RNAs (lncRNAs). MiRNAs regulate gene expression by recognition of the complementary sequence present in the target mRNA, either promoting its degeneration, deadenylation or preventing its translation into proteins. LncRNAs can increase or decrease the transcription and function of genes through different strategies, such as direct interaction with the DNA, RNA or even proteins.

To our knowledge, the integrated role of lncRNAs and miRNAs in regulating the response of fish skeletal muscle to pro-growth signals such as AA and Igf-1 has not yet been studied in fish. Hence, this work uses a RNAseq approach to address the present lack of knowledge by generating a transcriptome and microRNAome from gilthead sea bream myoblasts in response to AA or Igf-1, and study the interactions between miRNAs, mRNAs and lncRNAs to better understand the role of ncRNAs in the myoblast’s transcriptional response to pro-growth signals.

(Continued on next page)
**Materials and methods**

The myoblasts were isolated from gilthead sea bream fingerling (≈ 5g) and cultured in complete growth medium until day 8 when they were incubated for 12 h in a free AA and FBS medium to reduce gene expression to basal levels. Then, cells were incubated for additional 24 h in free AA medium (CTR group), medium with AA (AA group), or medium with recombinant Igf-1 (Igf-1 group) [free AA medium supplemented with Igf-1 from gilthead sea bream at 100 ng/mL. After the treatments, total RNA was extracted using Trizol, and transcriptome and microRNAome were obtained through the NovaSeq 6000 platform and the HiSeq 4000 platform, respectively. To determine the effect of the treatments, a principal components analysis (PCA) was performed using all genes identified in the transcriptome of the different conditions. Gene Ontology (GO) analysis was performed using the STRING online tool. Pearson correlations on transcription levels between differentially expressed genes for mRNAs-miRNAs-lncRNAs were determined, and sequences interactions were predicted using RNAhybrid v.2.2.1 and LncTar software. Differences in transcription levels between treatments were considered significant when log2-fold change was > 1.5 and corrected p-values (False Discovery Rate, FDR) was < 0.05. For Gene Ontology analysis, differences between categories were compared against the zebrafish database and considered significant when FDR < 0.05.

**Results and discussion**

The PCA analysis showed that the samples from each of the different conditions clustered together in three distinctive groups (Figure 1), indicating the effect of each treatment. Igf1 cluster was closer to the CT cluster than the AA, suggesting that the global transcriptomic profile of the myoblasts treated with Igf-1 was closer to the CT profile than to that of AA.

The number of mRNAs affected by the pro-growth treatments was significantly greater compared to the ncRNAs. The treatment with AA had a higher impact on transcription (1815 genes significantly changed), compared to the addition of Igf-1 (389 genes significantly changed).

Both treatments stimulated the transcription of genes related to muscle differentiation (GO:0042692) and sarcomere components (GO:0030017), but AA stimulated more the DNA replication and cell division (GO:0007049).

Over 402 different miRNAs were expressed in gilthead sea bream myoblasts but with three (miR-21, miR-146 and miR-22b) clearly dominating the transcription landscape. In addition, over 100 miRNAs had their transcription significantly changed in response to the pro-growth treatments, including several muscle-specific miRNAs (myomiRs), such as miR-133a/b, miR-206, miR-499, miR-1 and miR-27a.

Moreover, 124 lncRNAs with detectable levels of expression were identified in gilthead sea bream myoblasts, with only 29 lncRNAs significantly modified in response to AA, and 11 lncRNAs in response to Igf-1. The majority of lncRNAs detected had relatively low expression, with one (ENSSAUG00010015132) having 10 times more transcription than the second most expressed. Eight lncRNAs appeared to have a strong negative correlation with several mRNAs, suggesting that they might regulate them directly, but with little impact on the global regulation. Also, 30 lncRNAs showed strong correlations and interactions with several miRNAs, suggesting their function as miRNA’s sponges during the response of myoblasts to AA and Igf-1.

**Conclusion**

In summary, AA had a greater impact on the transcriptional profile of gilthead seabream myoblasts compared to Igf-1, and the correlations and prediction of interactions between mRNAs-miRNAs-lncRNAs pointed out the importance and complexity of the network controlling muscle development and growth in response to pro-growth signals.

Introduction
In Mexico the annual shrimp aquaculture rate production is growing, and thus demands more feeding inputs and diseases inhibitors. Among organic fertilizers, Eisenia foetida solid humus is considered as a great promoter for plankton growth, helping to develop these aquatic organisms. In other hand, the excessive use of antibiotics in aquaculture has negatively affected those species who are farmed (Marshall y Levy, 2011), and also has decreased shrimp growth (Bray et al., 2006) because bacteria are more resistant to antibiotics (Karunasagar et al., 1994). That’s why it is important to find environmental alternatives to reduce shrimp diseases. The aim of this study was to evaluate different solid earthworm vermicompost doses as growth promoter and AHPND inhibitor.

Methodology
Five treatments with three replicates each one was seeded with 120 shrimp larvae in 120L tanks with zero water exchange. The tanks were fertilized with initial doses of control, 0.00mg·L−1 solid Vermicompost [VC], 275, 550, 825 and 1100 mg/L. The doses were, thereafter, reduced by half at day fifteen. The experiment lasted 45 days. Growth, Food Conversion Ratio and survival were measured. After the growth experiment, mortality accumulation was evaluated for each treatment when shrimp were challenged against Vibrio parahaemolyticus in three liters bowls with three replicates with 10 shrimp of 1.5g each bowl.

Results
Water quality parameters were not constant during the experiment and had significant difference (P>0.05) between oxygen and pH treatments. We found that shrimp reared with the organic fertilizer had the best growth (Figure 1), and the lowest food conversion average.

On the other hand, we have that treatment over 550mg/l of vermicompost were effective against V. parahaemolyticus. Less than three shrimps died in these treatments in a period of 72h, contrary to treatments less than 550mg/l who had over 50% of the mortality in the first 18h of the challenge. Control had the highest mortality with 80% of the shrimp dead before the 24h trail.

Some studies suggest that vermicompost is an important food resource for juvenile shrimp (Chakrabarty, 2008). This organic fertilizer improves water quality and enhanced phytoplankton production (Bwala and Omoregie, 2009; Chakrabarty et al. 2009). We find that vermicompost is a real option to shrimp growth and can lower productions costs. It also can enhance shrimp survival and increase shrimp production when is used in the first stages of shrimp when it is more susceptible to diseases, but further investigation must be done to find what bacterium conglomerate in the vermicompost acts as inhibitor to AHPND.

**DIGESTIVE BIOCHEMISTRY OF LOBSTER: A JOURNEY FROM FUNDAMENTAL KNOWLEDGE TO THE AQUAFEED INDUSTRY**

L. Rodríguez-Viera*, J.M. Mancera1, J.A. Martos-Sitcha1, E. Perera2*

E-mail: leandro.rodriguez@uca.es erick.perera@csic.es

**Introduction**

Spiny lobster aquaculture has increased during the past decades, attended to their high demand and commercial value. Fast-growing tropical species (e.g., *Panulirus argus*, *P. ornatus*) are the most suitable for this activity. Yet, the absence of cost-effective and nutritionally adequate formulated feeds remains as one of the drawbacks for the sustainable expansion of this activity. The reason is mainly due to the lack of information on digestibility and assimilation of formulated feeds by lobsters. Eighteen years have passed since we first measured the activity of a digestive enzyme in *P. argus*. Then we went into a series of studies covering the digestion of all major nutrients and now we have a clearer view, though still with many gaps, of the digestive capacity of this species. In this work, we integrated the knowledge gained on the digestive biochemistry of *P. argus* and provided important information on the digestion of carbohydrates (CH), protein and lipids, as well as key research directions to improve the performance of formulated feeds for this species and reach suitable commercial feed for this industry.

**Digestion of proteins**

*Panulirus argus* presents a wide battery of digestive proteases, whose activity and variations respond both to the requirements during the life cycle and during moulting. Protein digestion begins in the gastric chamber, where high trypsin and chymotrypsin activities are located. Three main trypsin isozyme phenotypes are present and differ in protein digestion efficiency. More frequent phenotype is the most efficient. Soybean meal is highly digestible due to the high number of protein fractions, though each fraction is poorly digested separately. In contrast, in spite of few soluble protein fractions in fish meals, these are individually more digested. Likewise, squid meal is highly digestible due to high amount of soluble low molecular weight proteins, also stimulating trypsin expression and guaranteeing the synthesis of new enzymes. Conversely, fish meal digestion is limited by the poor solubility of proteins. Secretion and expression of trypsins in *P. argus* are time-regulated processes. Food proteins stimulate trypsin secretion, while protein digestion end products (free amino acids) promote trypsin expression. These processes occur normally when the source of protein in the diet is of animal origin, but they are inhibited when there is an excess of soy protein (Perera and Simon, 2014).

**Digestion of carbohydrates**

The ability of spiny lobsters to use dietary CH as an energy source has been discussed in recent years. In general, crustaceans show a relatively slow incorporation of CH in the citric acid cycle. α-amylases present several isoforms (phenotypes) in *P. argus*, and the isoenzyme composition shapes the efficiency of CH digestion *in vitro*. Conversely to trypsins, the most frequent α-amylase phenotype was the one with the lowest digestion efficiency (Rodriguez-Viera et al 2016). The type A starches are more susceptible to lobster α-amylase, especially those from rice. Wheat has a high-moderate digestibility both *in vitro* and *in vivo*, therefore more appropriate for lobsters. Maize starch is poorly digested, and its inclusion in the diet affected protein digestibility (Rodriguez-Viera et al 2014). Lobsters regularly fed with increasing levels of wheat show a proportional increase in the activity of the glycolytic enzymes hexokinase and pyruvate kinase, corroborating that there is a stimulation of glycolysis. This metabolic modification is not a temporary response after feeding, but a global adjustment of the intermediary metabolism based on the CH in diet. However, this is only possible up to a certain level of CH inclusion (20%). Furthermore, the type of carbohydrate eaten presents a profound effect on the metabolism of other nutrients such as amino acids and fatty acids (Rodriguez-Viera et al 2021).

(Continued on next page)
Digestion of lipid

Despite lipids are important nutrients and energy sources for crustaceans, lipid digestion and the lipolytic enzymes remains poorly understood in this group. Recently, we experimentally demonstrate the presence of “true lipase” in the spiny lobster, and their capacity to hydrolyse different oils (Rodriguez-Viera et al., 2022). Fish oils with long-chain polyunsaturated fatty acids (lcPUFA) (e.g. EPA and DHA) are the most digestible. Yet, algae oils and plant derived oils such as rapeseed oil and olive oil showed high digestion rates and should be also considered in feed formulation for *P. argus*. Considering our results for rapeseed oil, this could be one of the vegetable oils suitable to be included in feeds for *P. argus*. Lipase/esterase activities are higher in the digestive gland with respect to the gastric juice, so there is a need for lipids to be properly emulsified by the gastric juice to reach the digestive gland in the right format for hydrolysis. Thus, we evaluated the effects of various emulsifiers (non-ionic surfactants and phospholipids). The highest final extent of lipid digestion was observed with Arabic gum (AG) and hydrolysed soy lecithin (HSL). However, the initial digestion rate was higher with HSL than with the rest of the emulsifiers tested, thus it presents a greater potential to be used as an emulsifier in lobsters’ feeds.

Final remarks

The protein-sparing effect of lipids and carbohydrates on spiny lobster metabolism is of a particular significance as the spiny lobster metabolism is strongly directed towards the use of protein. Any effort to increase digestive efficiency in lobsters should include the optimization of the gastric digestion. Studies should focus on: i) improve protein solubility to increase digestibility, ii) select adequate sources and levels of CH to favour a gradual release of glucose and promote protein sparing effects, and iii) improve lipid emulsification to be better digested and used in the digestive gland. The knowledge gained on the digestive physiology of this lobster would aid in the design of aquafeeds that make the farming of this crustaceans more sustainable. However, the journey towards the correct dietary formulation for *P. argus* still continues.

Various *Vibrio* species are known to cause severe mortality events in oyster aquaculture, potentially leading to a shortage of bivalve seed for grow-out industries. In France, *Vibrio aestuarianus*, *V. coralliilyticus*, *V. harveyi*, *V. crassostreae*, *V. europeus*, *V. neptunius*, and *V. tubiashii* have been identified as major pathogens causing disease in Pacific oysters (*Crassostrea gigas*). Probiotic bacteria are gaining momentum as a promising strategy for disease management in aquaculture, and previous studies have shown that the pretreatment of larval oysters with probiotics can reduce mortality when challenged with bacterial pathogens. This study aimed to isolate and select novel probiotics to increase the resistance of Pacific oysters to bacterial pathogens threatening aquaculture production. Oyster tissues and microalgae samples were used as sources of probiotics. 16S gene amplicon sequencing was employed to identify the bacterial community composition in the samples, to ameliorate the *in vitro* experiments. The samples were then plated into eight different agar media to allow for the growth of a diverse range of bacterial species. The isolated bacteria were then tested *in vitro* against pathogenic *Vibrio* species using the replica plating technique. Strains that suppressed the pathogens’ growth were screened for safety and physiologic criteria. Safety criteria included hemolysis test, susceptibility to antibiotics, and molecular identification. Physiological criteria included microbial adhesion, autoaggregation and coaggregation, production of siderophore, hydrogen peroxide, organic acid, halogenated furanones, and bacteriocins. The isolated strains identified as *Shewanella* sp. and *Vibrio* sp. met the targeted selection criteria, making them suitable as candidate probiotics. Follow-up research will include *in vivo* experiments to validate the efficacy of the candidate probiotics.
THE EFFECTS OF PRE-SACRIFICE AND CROWDING ON THE HEART ACTIVITY OF COMMERCIAL SEABBASS (*Dicentrarchus labrax*)

The pre-slaughter period is one of the most critical for fish and can affect welfare and influence the quality of the final product during storage. The procedures that are carried out in this period are: fasting, handling and crowding, defishing or pumping, capture and finally death. All of these steps, regardless of how well done, can cause adverse effects on your fish. Stress during the antemortem period can interact with and influence the physiology of the animal, worsening their performance. Additionally, in the postmortem period, biochemical processes generated by the antemortem stress act on the muscle affecting the quality and durability of the final product. There are often unavoidable situations where multiple stress factors interact and affect the final condition. Aquaculture production involves the management of relatively small animals (less than 1 kg) with many thousands of individuals in small spaces (between 37 and 120 million farmed fish were killed for human consumption in 2010). Therefore, from an individual point of view, animal welfare is an important issue in aquaculture. In this sense, it is crucial to obtain information on how the handling of fish during pre-slaughter and slaughter periods can affect their welfare and the quality of the final product. This knowledge will help to propose changes in current handling methods during the final phase of the production process, being one of the critical points that most affect the welfare of the fish.

Crowding is the first stage in harvest and transportation operations. Wall (2001) comments that crowding is one of the main causes of discomfort during harvest, being shortage of oxygen the most common problem associated with crowding. However, even maintaining high oxygen levels, crowding changes many other aspects of fish physiology, the effects of which can be observed up to several days later (Ortuño et al., 2001). Different species respond to this intervention in different ways. Under commercial conditions, the density of fish used for seabass crowding is approximately 250 kg/m$^3$. In sea bass, there are few studies on the effects of crowding and increased physical activity during pre-slaughter operations.

Technology now make possible to monitor the behaviour of small groups of individual fish as bioindicators of wellbeing. Bio-loggers may detect unusual patterns in fish heart rate, which could serve as an early indicator of whether fish health or welfare is becoming compromised. The use of heart rate bio-loggers to monitor fish heart activity, has shown to provide unique insights into the physiological and behavioural state of fish over time (Brijs et al., 2019; Hvas et al., 2020).

The objective of the present study was to assess the effects of confinement in the heart activity of seabass during the period of crowding using individually implanted bio-loggers, which can detect seabass stress levels during crowding events. Commercial size seabass were held in a flow-through system with full strength seawater for a whole year. Dissolved oxygen was maintained close to saturation. Fish were held in a rectangular tank of 10000 L capacity. Stocking density was 11 kg/m$^3$.

Ten days prior to the experiment, nine commercial-size seabass were implanted with DST milli-HRT loggers (StarOddi®, size: 13.0 × 39.5 mm, weight: 11.8 g) which monitor heart rate (fH), electrocardiogram (ECG) and internal temperature (range 5 °C to +45 °C). These loggers are also equipped with real-time clock with accuracy of ±1 min/month.

These loggers recorded heart and acceleration hourly for that particular fish for the 36 h prior to crowding and then every 2 minutes for the 180 minutes which was the crowding period. After this period, fish were sacrificed and the loggers recovered.

During crowding, the level of water was lowered (mimicking bringing the fish to the surface) and fish were cornered at one end of the tank with a net which was place across the tank preventing them from moving. During the crowding exposure period fish were held at an estimated density of 118 kg/m$^3$.

(Continued on next page)
This experiment was performed in the summer with a water temperature of 28°C and in the winter with a water temperature of 9.5°C.

Fish used in this experiment had an average standard length of 32.48 ± 3.25 cm in the summer and 27.66 ± 2.1 cm in the winter and an average wet weight of 555.20 ± 141.97 g in the summer and 389 ± 68.14 g in the winter.

Baseline values of heart rate were 57 ± 2 beats per minute (bpm) in the winter and 69 ± 2 bpm in the summer, showing a strong relationship with water temperature. Averaged heart rates and accelerations showed slightly variations along the 180 minutes that lasted crowding, but no significant effects were observed by crowding procedure during winter. In the summer, however, the heart rate of fish increased significantly at the beginning of the crowding period and slowly decreased over time, with great variation among individuals.

Therefore, the effects of crowding on heart rate seem to depend on the seasonal period when it is performed at the farms.

gregory.rorrer@oregonstate.edu

New approaches are needed for land-based cultivation of macrophytic red algae that reduce costly aeration requirements for biomass suspension and enable process intensification. The goal of this study was to demonstrate the high-density cultivation of the carbohydrate-rich macrophytic red alga Gracilaria vermiculophylla on vertical arrays of panels deployed in an open channel raceway configuration similar to raceway ponds that have been developed for mass cultivation of microalgae.

A clonal culture of G. vermiculophylla, consisting of branched, cylindrical thallus tissues of 8-10 cm length, was mechanically blended into 2-3 cm fragments and then fluidically injected onto a 3 mm polypropylene mesh support. Immobilized G. vermiculophylla mesh panels were aligned parallel to flowing seawater medium at nominal bulk velocities ranging from 5 to 50 cm s⁻¹ in a 100 L raceway pond of 20 cm liquid depth (FIG. 1). This raceway was equipped with real-time measurement of CO₂ concentration in the inlet and outlet gas for determination of CO₂ uptake dynamics. Specific rates for CO₂ uptake became saturated at 8000 ppm CO₂.

To achieve process intensification under nutrient-replete conditions at 22 °C, row spacing was minimized at 6.5 cm, and the inlet gas CO₂ was increased from 1000 to 4000 ppm (day 7-14), and then to 8000 ppm (day 14-23) at 0.010 L gas L⁻¹ liquid min⁻¹ gas flow. Over the 23 day cultivation, biomass on the panel increased by a factor of 48, with final biomass loading exceeding 10 kg FW m⁻² panel area, and cumulative CO₂ capture of 65%. The cumulative average areal productivity within the panel zone of the raceway exceeded 60 g AFDW m⁻² day⁻¹, and final biomass density nearing 7.2 g AFDW L⁻¹ (47 g FW L⁻¹) was achieved after 23 days (FIG. 2). Overall, these outcomes demonstrate the potential for land-based raceway cultivation of clonal red macroalgae of present and future commercial significance.

Introduction
Advanced image processing combined with the development of artificial intelligence algorithms has impacted all industrial sectors, including aquaculture (Zhao et al, 2021). The usual harsh surrounding circumstances, salinity, humidity or ubiquity, among others, make it difficult, but not impossible, to increasingly integrate information and communication technologies (ICT) and AI in this sector. In hatcheries, knowing the biomass of the plant is a key parameter. In many use cases, the initial challenge faced by automation begins with the automatic identification of specimens (Fernandes et al, 2020). This is carried out by a surveillance system and a previously constructed database from which information can be inferred, thus providing an augmented reality-based industrial model. In this work, an autonomous, real-time processing, and low-complexity system for turbot (*scophthalmus maxima*) segmentation and weight estimation is presented. To train the segmentation model and the weight estimation model, a database of more than 6000 turbot images has been created.

Materials and Methods
Specifically, the developed system has been assembled and verified by installing it above a weight classification belt sorting machine used in a turbot breeding plant. The operators transfer the fish one by one from a hopper to a conveyor belt, where they are weighed and distributed into weight-balanced bins. On that belt, the speed is up to one fish per second.

The system is equipped with a camera that records high-resolution video of the fish on the conveyor belt (Fig. 1 left). There is a second camera that records the weight information displayed by belt balance. This recording process is automated by means of OCR identification of the images. This has allowed for the semiautomatic construction of a database that contains for each image of a fish its real weight. Once an image acquisition and processing system was available, a model was developed to detect and segment the fish within the images (Fig. 2). For this purpose, YOLOv5 (Ultralytics) was trained with a database of various species of fish (Roboflow) to self-detect and segment tasks. Then, the hue, saturation and value (HSV) parameters were extracted to perform and umbralisation of the images. The last step consists of applying an opening/closing shift of the pixels. With this post-processing, an accurate binary image of the shape of the fish can be extracted. Later, both the area and the length of the fish are obtained, measured as the total number of white pixels or the number of pixels between the head and the tail, respectively. To do this, the extrinsic parameters of the camera were considered.

Finally, six machine learning models have been compared in order to obtain the best relationship between weight and area or length. For this purpose, a total of 6095 images of fish between 250g and 2kg were used; Fig. 3 presents a graph were each dot corresponds to a fish, its real weight, and calculated length. Finally, each of the six models has been validated using the K-fold technique (Gufosowa).

Results
In fish detection and segmentation tasks, YOLOv5 trained with the aforementioned database was able to detect fish with a measured precision of 0.90 and a recall of 0.92. Table 1 shows the root mean square error (RMSE) obtained inferring the weight from both length and area with 6 different algorithms trained with the collected images. As it can be seen, the 2nd and 3rd grade polynomial regressions and KNV outperforms the rest of algorithms in both cases, length and area. Considering the limitation of processing images at a high rate (less than 0.1s per frame), 2nd degree polynomial regression is chosen as the best option. Thus, the average processing time of the whole system inferring weight from length is 0.065ms using an ORIN NVIDIA platform. Using area-based models this time is up to 5 times higher. Finally, it is work mentioning that although this work focused on turbot as a use case, the technique could be easily transferable to any other flatfish species.

The main driver of the Blue Revolution is the potential of modern aquaculture to provide healthy and sustainable protein for the increasing human population. As in the farming of terrestrial animals, the feed used in aquaculture has great bioeconomic importance. Aquaculture feeds in particular are constantly evolving, driven by economic and environmental factors. A major development is the reduction in reliance on raw materials from marine origin which has led to an increased use of globally sourced plant-based raw ingredients, this in turn inherently increased the risk of mycotoxin exposure.

Fusariotoxins are a group of mycotoxins produced by various fungal species of the genus *Fusarium*. These toxins are among the most prevalent mycotoxins detected globally. The group includes, among others, fumonisins and zearalenone, which are known for their negative effects on sphingolipid metabolism and reproductive-endocrine disturbance, respectively.

European legislation recommends guidance values for certain mycotoxins to ensure food and feed safety and the maintenance of animal welfare. For fumonisins, a 10 mg/kg limit is defined for fish feeds. However, no specific value for zearalenone is defined for this matrix, and a general maximal value of 2 mg/kg (defined for cereal feed materials) is being used de facto as an upper limit.

Unlike other species, few studies describe the effects of sub-regulatory levels of fusariotoxins on salmonids. Two recent studies comprised of three independent *in vivo* trials, were aimed at addressing this knowledge gap. We assessed the impact of oral exposure to the fusariotoxins fumonisins and zearalenone, below EU guidance levels, on rainbow trout at different developmental stages. The study assessed biomarkers such as metabolites in gut content (in all trials), the sphinganine-to-sphingosine (Sa:So) ratio (in the fumonisins studies), and plasma vitellogenin (VTG) and tissue metabolites (in the zearalenone study). These biomarkers were used as endpoints to evaluate the toxic effects of fusariotoxins and the detoxification efficacy of fumonisins by FumD and zearalenone by ZenA, both of which are commercial feed enzymes designed for specific detoxification.

The results of this study indicate that short-term oral exposure to sub-regulatory levels of fusariotoxins has negative effects on rainbow trout. Commercially available fish feeds that comply with the European regulatory levels may still pose a risk to fish health and farmers’ operations. Thus, the guidance levels should be revised, and further studies should investigate these findings. However, the inactivation of the mycotoxins by feed enzymes FumD and ZenA proved to be an effective strategy to significantly reduce the observed effects in the selected endpoints.
ALTERNATIVE DIETS FOR IMTA PRODUCTION OF GILTHEAD SEA BREAM (Sparus aurata): GROWTH PERFORMANCES AND FILLETS QUALITY

Introduction
Worldwide aquaculture production has grown strongly in recent years primarily due to the greater fish demand, which increased from 14.3 kg in the 1990s to 20.2 kg per capita in 2020. Fish is an excellent protein source for human nutrition and aquaculture is gaining importance, especially in developing countries. However, there is a large environmental concern about “aquafeed” and the capture-based production of fish meal and fish oil. For these reasons, several alternatives have been investigated such as processed-animal by-products, insect meals, crop-based ingredients, and algae. Nevertheless, crop-based meals and oils (e.g., soybean, corn, canola, palm, and sunflower) that are currently largely adopted in aquaculture, have been noted to impair growth performances and n-3 fatty acids levels of farmed seafood. Moreover, the environmental impact of feed production should be also considered (e.g., in terms of land use, soil exploitation, and overseas transportation). Based on the production concept of the SIMTAP project, low-trophic organisms potentially producible in integrated multi-trophic aquaculture systems (IMTA) can be exploited as feed for farmed fish. The aim was to investigate the effect of an alternative fresh diet formulated with mussels, clams, and polychaetes on gilthead sea bream (GSB, Sparus aurata) growth performance and fillet nutritional profile, against the commercial feed.

Materials and Methods
All the experimental procedures were approved by the Animal Welfare Board of the University of Pisa and the Italian Ministry of Health (B290E.N.AHZ). The experiments were carried-out in the IMTA system built at the Department of Agriculture Food and Environment of the University of Pisa. A total of 256 GSB individuals (initial body weight, BW 249.17±30.06 g) were pit-tagged and distributed in six 450-L tanks and fed two diets which lasted 64 days. Treatment F100 received a commercial feed containing vegetable ingredients (NaturAlleva® ForeSea 6.5 mm, VRM©, Italy) while treatment M100+ a mixture (on a dry matter basis) consisting of 49% frozen cooked mussels (Mytilus platensis), 30% frozen cooked clams (Paphia textile), 20% frozen marine polychaetes (Nereis virens), and 1% of mineral premix (VRM©, Italy), this latter equal to that used in the commercial feed. Fish BW, length, and feed consumption were measured. Hence, specific growth rate (SGR) was also calculated. Moreover, at the end of the experiment 15 individuals from each tank were slaughtered and dissected for the determination of viscera and liver weight, thus viscera-somatic index (VSI) and hepato-somatic index (HSI). Also, fish fillets from five fish from each tank and feeds were sampled for proximate composition, fatty acid (FA) and amino acid profile, and mineral content. Data were analyzed using ANOVA and the least significance means were compared by the Tukey test, while non-parametric tests was performed for SGR. Mean values of measurements were considered statistically different per P<0.05.

Results and discussion
At the end of the experiment, the individual BW gain was significantly lower in F100 fish (84.2±2.48 g) than M100+ (101.5±2.02 g). Significant differences were also observed for SGR: 0.4±0.12 and 0.6±0.01 % d⁻¹ for F100 and M100+ treatment, respectively. Moreover, VSI and HSI values were significantly higher in F100 group (VSI: 6.4±0.24 vs 5.8±0.15 %; HSI 2.4±0.09 % vs 1.9±0.05 % in F100 and M100+ respectively). These results might be explained by a better digestibility and the high protein to lipid ratio in M100+ diet (9.04 and 2.28 in M100+ and F100, respectively). The latter may have stimulated more the growth rather than fat deposition in viscera. With regards to fish fillet proximate composition, no differences were observed, except for ash content. Unsaturated FA was the main fatty acid class in all fillets, with a significantly higher content in F100 than in M100+ (79.55±0.187 vs 73.52±0.433 % of total FA) due to the significantly higher mono-unsaturated fatty acids (49.97±0.400 vs 44.56±0.541 % of total FA in F100 and M100+ respectively). No differences were observed for poly-unsaturated fatty acids (29.58±0.329and 28.95±0.460 % of total FA in F100 and M100+ respectively). However, some significant differences were observed in individual essential FA such as Arachidonic acid (ARA), eicosapentaenoic acid (EPA), and docosahexaenoic acid (DHA) which were significantly higher in M100+ (ARA: 0.21±0.037 vs 0.557±0.091, EPA 1.19±0.088 vs 3.653±0.192, DHA: 3.22±0.172 vs 6.005±0.255 % of total FA in F100 and M100+ respectively). On the other hand, C18:2-n6 was higher in F100 (18.21±0.224 vs 12.58±0.372

(Continued on next page)
% of total FA in in F100 and M100+ respectively). These differences can be explained by the FA composition in the two diets (data not shown). It is worthy to notice that the composition of M100+ fillets showed relevant similarities to wild GSB. No significant differences were detected in amino acid profile and mineral content of fish, except for potassium content (19.30±0.440 vs 17.82±0.320 g kg⁻¹ DM in F100 and M100+, respectively).

**Conclusion**

In conclusion, the alternative diets based on mussels, clams, and polychaetes potentially obtained from IMTA systems, can be successfully used for sea bream production in substitution of a commercial diet. The alternative diet performed slightly better than commercial feed, in terms of growth performances as well as for the fatty acid profile of fillet, which was more similar to wild GSB in terms of essential fatty acids profile. Further research is needed regarding the exploitation of IMTA-obtained organisms in GSB production in terms of environmental impact.

STATE OF THE ART OF PRIVATELY FUNDED RESEARCH ON ARTIFICIAL REPRODUCTION OF EUROPEAN EEL (A. anguilla), WITH FOCUS ON LARVAL REARING

C. Rosso*, D. Maassen, A. Karyda, R. Leemans and D. Cardoso

Glasaal Volendam B.V.
Nijverheidsstraat 5u
1135 GE Edam, The Netherlands
Email: camillo@volendamglasaal.com

Background

Glasaal Volendam is a private research company founded in 2012 in Volendam, a former eel-fishing city in the north of the Netherlands. The company aims to close the eel life cycle in captivity and set up a large-scale production facility to farm glass eels (juvenile European eel). Glass eels can be sold to eel grow-out companies, which are now solely dependent on wild caught glass eels. Replacing these wild glass eels with farmed ones could relieve the legal and illegal fishing pressure on this already endangered species.

The life cycle of European eel A. anguilla begins with hatching in the Sargasso Sea. From here larvae drift as leptocephali back to the coasts of Europe and then transform into glass-eels as they enter freshwater rivers in Europe. They migrate upstream, maturing into elvers and developing pigmentation in freshwater. Over several years, they become sexually mature adult eels and undergo a final transformation into silver eels before migrating back to the Sargasso Sea to spawn, completing the cycle.

The life cycle of European eel has not yet been closed in captivity, unlike the one of Japanese eel A. japonica, which was completed in 2003 (Tanaka et al. 2003). However, considerable progress has been made in recent years towards closing the life cycle of European eel in captivity. This translates in the production of high-quality gametes, embryos, yolk-sac larvae and pre-leptocephali feeding larvae.

Materials and methods

To conduct our research, we obtain the broodstock from the wild through local fishermen. Eels are housed in 500l tanks with a closed re-circulation system. During the maturation period, they are kept at low density (20 kg/m³), with 36% salinity and 18 °C of temperature. Eels are maintained under dimmed light conditions to mimic daily photoperiod. No feed is provided during maturation. To induce vitellogenesis, females receive weekly injections of Carp Pituitary Extract (CPE) for 15-20 weeks (Kagawa et al., 2005) and weekly biopsies are taken to evaluate oocyte development (Paalstra et al., 2005). To induce ovulation, females are injected 12 hours before spawning with DHP (7α,20ß-dihydroxy4-pregnen-3-one; 2 mg per/kg body weight) according to Ohta et al. (1996). Male broodstock is obtained from commercial eel farms and receives weekly injections of recombinant human chorionic gonadotropin (Perez et al. 2005). Milt is collected after 10 weeks of hormonal treatment, evaluated for quality under the microscope and mixed with eggs at the time of spawning. Fertilized eggs are incubated for 48 hours in 200 l tanks and then hatching larvae are moved to 500 l tanks. On day 14 after hatching, when mouth, primitive digestive system and eyes are formed (Sørensen et al. 2016), larvae are moved to feeding systems where experimental diets of different compositions are being tested. Larvae are fed five times a day a slurry-like diet (Tanaka et al. 2003). Different diet compositions are tested in order to improve survival and growth rates, to reach leptocephalus stage first and glass eel stage ultimately. Through pictures larval growth is measured and developmental changes in larval morphology are monitored. Ingestion is evaluated by direct observation after each feeding session.

Fig. 1: Example of pictures used to measure length and width of 14 days post hatching (left) and 35 days post hatching (right) larvae, during early feeding period.

(Continued on next page)
Results and future steps

At Glasaal Voendam we made significant progress towards closing the life cycle of the European eel. At first, the research was primarily focused on the artificial maturation of the broodstock. Currently we can produce vast numbers of fertilized eggs weekly. From 2018 onwards, the focus shifted to larval feeding. We improved larval survival rates at first feeding (14 days post-hatching) from an average of 0.3% in 2018 to 3.8% in 2021 and 21.7% in 2022. This year, we have observed trials with over 50% of the larval batch surviving until first feeding. These improved survival rates allowed us to focus on the larval feeding. After obtaining the first signs of food ingestion by larvae in 2018, we gradually improved feeding technique and larval diets, to enhance survival and growth rates. Being the average length at first feeding 0.7 cm and the maximal survival 30 days, in 2022 we successfully grew our first batch of larvae up to 1.4 cm. The oldest larvae of the batch survived for 94 days. We then focused on nutritional values of the larval diets, to enhance growth rates and reach the leptocephalus and the glass eel stage.

Alongside, to obtain growing larvae, we conducted experiments on parameters such as temperature, light, salinity, water quality, type of flow and tank design, to identify optimal rearing conditions. We also developed a method to analyze larvae pictures and we weekly process measurement data to extrapolate growth curves, to monitor larval growth rate and to compare it with the ones from past experiments.

In the first quarter of 2023 the larval growth rate was improved by 60%. The primary and most compelling goal for the next years is to reach the glass eel stage. The second phase of our company will then involve upscaling to commercial size.

EVALUATION OF DEFATTED BLACK SOLDIER FLY (*Hermetia illucens*) LARVAE MEAL AS AN ALTERNATIVE PROTEIN SOURCE IN THE DIETS OF EUROPEAN SEA BASS JUVENILES (*Dicentrarchus labrax*): EFFECTS ON GROWTH PERFORMANCE

E. Roussos1*, V. Illia1, G. Karafios1, G. Triantaphyllidis1 and Y. Kotzamanis1

Email: jokotz@hcmr.gr

Introduction
Fish meal (FM) has been considered as the ideal protein source for fish production, due to its overall balanced nutritional composition, high digestibility, and palatability. However, due to shortages in its worldwide availability along with its negative environmental impact, interest has shifted towards the evaluation of sustainable alternatives to reduce the dependence on FM (Nogales-Mérida et al., 2018). The use of insect meals in feed for farmed fish was recently approved by the European Commission. Insects are fast-growing, reproduce easily and efficiently, and have an excellent ability to utilize low-quality organic material and convert it into a high-value protein (Barroso et al., 2014). The aim of this study was to evaluate the potential of Black soldier fly (BSF) larvae to replace fishmeal in terms of growth performance, feed utilization, and the health of European seabass (*Dicentrarchus labrax*).

Materials and Methods
A total of nine different substrates were evaluated as potential feeding mediums for the production of BSF larvae in terms of nutritional profile and growth performance. The HI6 insect meal was chosen as the most promising for use in aquafeeds as it presented the highest protein levels in the shortest possible growth period. However, its inclusion in the aquafeeds proved to be a challenging task as its high lipid content (32%) hampered the homogenous grinding. To resolve this issue, a laboratory defatting method was developed using hexane as an organic solvent to extract the fat. The choice of the solvent was carefully considered and meticulously tested to evaluate its effects on the nutritional profile of the alternative novel feed ingredient. Using the defatted insect meal (12% fat), six isonitrogenous (45% crude protein) and isolipidic (16% crude lipid) diets were formulated: a control diet with a high percentage of fish meal incorporation (30%) was used as well as five experimental diets in which FM was replaced by 20, 30, 40, 50, and 60% with defatted BSF larvae meal, respectively. Differences in the crude protein content between fish meal (67%) and insect meal (53%) were compensated by the simultaneous sequential increase of soy protein concentrate (SPC) and sunflower meal in parallel with the gradual reduction of the wheat flour. All diets (3.5 mm pellets) were produced by cooking extrusion.

European sea bass juveniles were obtained from a commercial fish farm located in Megara, Attiki and transferred to the Hellenic Centre for Marine Research (HCMR) facility located in the campus of Agricultural University of Athens, Greece. The fish were distributed among 18 cylindroconical experimental tanks with a volume of 1m³ in a PLC controlled recirculating aquaculture system (RAS), 32 fish per tank, with 3 replicates for each feed. The average sea bass initial weight among the tanks was 33.85 ± 0.40g (SD). The trial lasted for approximately two and half months, fish were hand-fed to apparent satiation, twice per day, and uneaten dry feed that was collected in each tank’s waste collection system was monitored and taken into account before calculating the daily feed consumption. The average seawater temperature was 22.71 ± 3.3 °C.

Results
The trial was carried out smoothly without any problems or significant mortalities among the treatments. For growth performance parameters, tanks were considered as the experimental units and fish represented the sample units. The data from the individual observations were tested for normality and homogeneity of variance prior to be subjected to one-way ANOVA using Kolmogorov–Smirnov and Levene’s tests, respectively. Significant differences between means were determined by Tukey’s test (Statistica version 13.0). The evaluation of the growth performance indices showed no statistically significant differences among the experimental diets. Although, it is worth noting that the highest individual body weight was observed in both the control and HI6% diets (104.97 g and 105.11 g respectively) and the lowest in the feed HI6 30% (99.02 g). Total feed consumption (TFI), Specific growth rate (SGR) and daily growth index (DGI) followed (Continued on next page)
the same trend. The thermal growth coefficient (TGC) was found similar among the different dietary treatments. In terms of feed utilization, the lowest feed conversion ratio (FCR) was found in the HI6 30% and the Control (1.28 & 1.26) diets along with the highest values of the protein efficiency ratio (PER, 1.73 & 1.75). The somatometric indices did not reveal any statistically significant variations. However, it is of interest that the perivisceral fat index presented its lowest value in the fish fed with the HI6 40% (5.19) diet and the highest in the HI6 60% (7.16). Finally, whole body proximate composition did not present any statistically significant differences among the diets.

Overall, the acquired data were quite promising as the fish growth and health were satisfactory in all experimental diets and zootechnical indices were representative of fish size and species. Furthermore, the results of this study clearly demonstrated the potential of the defatted BSF as a sustainable alternative ingredient to fish meal in the feeds of the European seabass. However, additional analyses are in progress to further evaluate the results of the substitution.

STUDIES ON THE USE OF LOCALLY AVAILABLE (COXS BAZAR AND SAINT MARTIN) ALTERNATIVE RENEWABLE SEAWEED WASTES AS COMPOST ORGANIC FERTILIZER RESOURCES

Durlave Roy

Masters in sustainable agriculture and rural livelihood Student
4th semester, Bangladesh Open University
Bangladesh

Marine red algae from the Bangladesh Bay of Bengal Hypnea Sp have been used as organic materials due to the presence of a number of plant growth-stimulating compounds. The effect of various seaweed species on plant growth and development with an emphasis on the use of this renewable bio-resource in sustainable agriculture of northern fertilizers raw materials system. Organically made fertilizers play an important role in increasing crop yield and the quality of crops promises improvements considering climate adaptation. Seaweed wastes compost was put in evaluation trials at Sreemangal, Bangladesh to evaluate its efficacy and find out the optimum dose for profitable Betel leaf production. This part of the study is directed toward the analysis of the future trend and performances of composting seaweed wastes. The science of seaweeds explores, how analysis of the future trend and performances of composting seaweed wastes. A field study was conducted at three sites at Khasia farmers of Sreemangal Khasia betel leaf cultivation community area of Bangladesh. Seaweed wastes mixed with compost organic fertilizer dose of 50g per support tree. The highest betel leaf yield was obtained from seaweed wastes mixed with compost organic fertilizer applied to plants. Table 1. (2880 leaf). Two people have not used it, but the one who has used it has had good results. This study suggests that seaweed wastes mixed with organic fertilizer are suitable for betel leaf cultivation. Area-based conservation is a key tool for delivering the SDG goal of responsible production and consumption.

INTRODUCTION
Providing a safe alternative to chemical fertilizers is a crying need of the present time. Marine red algae from the Bangladesh Bay of Bengal Hypnea Sp are often regarded as an underutilized bio-resource seaweed and have been used as organic materials due to the presence of a number of plant growth-stimulating compounds. The effect of various seaweed species on plant growth and development with an emphasis on the use of this renewable bio-resource in sustainable agriculture of northern fertilizers raw materials system. Organically made fertilizers play an important role in increasing crop yield and the quality of crops promises improvements considering climate adaptation. (www.northernfertilizer.com). Although chemical crop fertilizers boost crop yield, they are also responsible for environmental pollution all around the world. Northern organic and balanced fertilizers provide a safe alternative to chemical fertilizers while having more agricultural output and reducing chemical fertilizer usage. Technology-based circular economy model. Seaweeds or marine macroalgae are rich in diverse compounds like lipids, proteins, carbohydrates, phytohormones, amino acids, osmoprotectants, antimicrobial compounds and minerals. Their potential for agricultural applications has been used since antiquity, but recent demands of organic farming and organic food stimulated much the application of organic treatments like seaweed extracts in agriculture. Aims of The Study
Seaweed wastes compost was put in evaluation trials at Sreemangal, Bangladesh to evaluate its efficacy and find out the optimum dose for profitable Betel leaf production.

Objectives of the study
The objectives are as follows:

Main Research objectives: This part of the study is directed toward the analysis of the future trend and performances of composting seaweeds wastes and Seaweeds can sequester carbon and reduce atmospheric carbon dioxide levels, thereby mitigating the effects of global warming.

Materials and Methods:
A field study was conducted at three sites at Khasia farmers of Sreemangal Khasia betel leaf cultivation community area of Bangladesh. Seaweed wastes mixed with compost organic fertilizer dose of 50g per support tree.

The present study proceeds to examine the following research questions:
1. Main research question-The science of seaweeds explores how analysis of the future trend and performances of Composting Seaweed wastes?
2. How do the environmental settings of the rich Khasia betel leaf farmers of Sreemangal provide bases for evolving varied seaweed based compost organic fertilizer farming in different parts of the community?
3. In what ways do the traditional values and indigenous knowledge of the farmers contribute towards diversity and sustainability of the community seaweed based compost organic fertilizer farming?
4. How far and in what ways the seaweed based compost organic fertilizer farming in community areas are getting modified overtime and changing socio-economic context?
5. Is seaweed based compost organic fertilizer agriculture currently prevalent in the community sustainable? If not, what are the probable measures to be adopted to make the seaweed based compost organic fertilizer farming economically more viable and ecologically more acceptable?
6. What kinds of difficulties are encountered by the farmers during their cultivation of crops through seaweed based compost organic fertilizer farming?

Sample rich Khasia farmers of Sreemangal khasia betel leaf cultivation community area map selected for meticulous study. Seaweeds wastes mixed compost organic fertilizer dose 50g per support tree for farmer Sonet, farmer Harun, own conventional practice dose and farmer Victor own conventional practice dose per support tree.

1. Harun, Aliachhara, Habiganj, Betel leaf plucking 2780 (own conventional practice dose per support tree application)
2. Sonet, LongliaPunji, Sreemangal, Betel leaf plucking 2880 (50g seaweed wastes mixed organic fertilizer per support tree application)
3. Victor Somer, Dubblechhara Punji, Moulvibazar. Betel leaf plucking 2780 (own conventional practice dose per support tree application)

Two people have not used it, the one who has used it has good results. After the fieldwork primary and secondary data collected from different areas.

Results:
The highest betel leaf yield was obtained from seaweed wastes mixed with compost organic fertilizer applied to plants. Table 1. (2880 leaf). Two people have not used it, but the one who has used it has had good results. This study suggests that seaweed wastes mixed with organic fertilizer are suitable for betel leaf cultivation.

Conclusion:
Khasia community people in Sreemangal Upazila, Bangladesh are used to cultivating betel leaf as their main livelihood. It is their only living means. Their families live on sale of several Kuri (20 kanta or 2880 pieces) of betel leaves daily. Most of the people of this area are involved in agriculture, especially betel leaf. This study suggests that seaweed wastes mixed with organic fertilizer is suitable for betel leaf cultivation. Area-based conservation is a key tool for delivering the SDG goal of responsible production and consumption.

Introduction
Phosphorus (P) is directly linked to eutrophication in shallow-lake systems, either alone (absolutely) or in tandem (relatively) with nitrogen (N). P in aquatic ecosystem can occur bound to sediment (legacy P), seston and nekton (organically bound P), and in free algal-reactive state (orthophosphate-P). The last one is of concern for standing freshwaters, which trigger an overshooting of primary productivity (algal blooms); under equally strong dissolved inorganic nitrogen fluxes (DIN) [1]. Already, the primary excretory product of fish is DIN (ammoniacal-N). In this context, the branchial-urinary losses of digested P by fish as dissolved reactive phosphorus (DRP) is likely the worst situation. Fish can act as pumps in fishponds converting organically (food) bound P to algal-reactive orthophosphate-P [2]. Present study aimed to provide a mechanistic understanding when the fish are source or sink of P, i.e., drive or mitigate dissolved reactive phosphorus (DRP) in fishponds. By doing so, regulating the eutrophication.

Materials and Methods
We hypothesize the more suppressed DRP excretion could be, the more efficient ecosystem P use would be. More P would stay locked in fish biomass (secondary consumers) or zooplankton (primary consumers) and less available to algal biomass (primary consumers). Fish biomass can act as source or sink of P; sometimes related to food’s digestible N: P stoichiometry and many times not. For example, at a constant N or P intake, DRP excretion might depend on supply of one or two indispensable amino acids, and digestible non-protein energy per unit of food intake. Other biological factors, such as presence or absence of scales or switching to basal metabolism might impart control on “phosphorus use efficiency” (PUE) and DRP excretion. Through isogenous but objectively formulated (WinFeed®) semi-purified research diets (fed 4% of body weight; split into 2 doses daily), PUE and DRP losses in a cyprinid model (Cyprinus carpio; age 1+; 22 g to 50.4 g) were investigated.

In a series of five experiments (twelve 120 L tank Guelph-RAS; 4 group x 3 replicate design; ~30 days each; ~250 g biomass tank⁻¹), following objectives were investigated: (a) differences in PUE and DRP losses between scaleless and scaly fish under a P-deficient diet (0.21% P); (b) effect of graded levels of bioavailable P (0.21%, 0.83%, 1.39%, 1.92%) on PUE and DRP losses, at isonitrogenous (38% digestible protein, DP) and isoenergetic diets (185 kcal 100 g⁻¹ digestible non-protein energy, NPE); (c) effect of graded levels of bioavailable lysine (1.43%, 1.71%, 2.05%, 2.39%) and methionine (0.21%, 0.49%, 0.69%, 0.89%) on PUE and DRP losses, at isonitrogenous (26% DP), iso-phosphorus (0.6%) and isoenergetic diets (185 kcal NPE 100 g⁻¹); (d) effect of graded levels of dietary non-protein energy (168 kcal, 181 kcal, 183 kcal NPE 100 g⁻¹) on PUE and DRP losses, at isonitrogenous (37% DP), iso-phosphorus (0.9%); (e) lastly, PUE and DRP losses at basal metabolism conditions (7°C, feed deprivation, 30 days). The entire series of laboratory experiments lasted 40 weeks. The analysis had a mass balance or nutritional bioenergetics approach between fed nutrients (with known and standard digestibility) and carcass/ biomass gain of nutrients (growth trial and carcass analysis) to compute N, P retentions and non-faecal losses [2].

Introduction

In the quest to safeguard nature and its crucial ecosystem services, the monitoring of aquaculture installations demands a regular assessment of the surrounding environment. The traditional approach involves labor-intensive sampling, taxonomic identification of macrofauna, and inference of ecological status. Seeking alternatives, the scientific community is turning to bacteria-based environmental DNA (eDNA) metabarcoding as a promising monitoring tool. By harnessing the power of eDNA monitoring in aquaculture environments, it becomes possible to detect and identify species, as well as monitor environmental impacts. Through the analysis of benthic bacterial communities, eDNA metabarcoding can effectively infer the ecological status of investigated samples in a timely and resource efficient manner. Monitoring based on eDNA links the advantage of bacteria’s rapid response to environmental influences and eliminates the need for laborious enumeration and identification of organisms. Integrating eDNA into the monitoring process not only serves regulatory compliance but also proves to be a valuable farm management tool, as farmers can optimize sustainable production within the limits of the legislature. Real-time eDNA-based monitoring provides farmers with the ability to promptly react to environmental changes and potential challenges, ultimately enhancing their decision-making process. As a result, the eDNA-based monitoring approach is gaining increasing significance in the field of aquaculture.

Current progress in eDNA-based monitoring

Building upon recent scientific studies, significant progress has been made in leveraging eDNA analysis of benthic sediment samples for environmental impact assessments in the aquaculture industry. These studies have demonstrated that eDNA metabarcoding holds tremendous potential in providing valuable insights into the ecological status of salmon aquaculture installations. In line with these advancements, our research endeavors have focused on addressing previously unresolved sub-steps in the eDNA metabarcoding process. This includes crucial areas such as sample preservation during transport, ensuring reproducibility across laboratories, identifying appropriate bioinformatic methods, and determining minimum sequencing depth requirements. We found that the use of common preservation methods during sampling had no discernible effect on the final ecosystem assessment. This insight helps to simplify the sample collection process and enables to adapt

(Continued on next page)
it more easily to individual needs. Moreover, our research highlights the reproducibility of the eDNA metabarcoding-based method. Multiple independent laboratories, when employing standardized protocols, have consistently derived coherent ecological interpretations, further underscoring the reliability and robustness of the approach. In our pursuit of refining the eDNA metabarcoding process, we have explored innovative approaches such as machine learning. This exciting avenue of research has showcased the tremendous potential of machine learning algorithms in reliably predicting the environmental status. In fact, our findings reveal that machine learning algorithms, particularly the employment of the Random Forest algorithm, outperform traditional statistical methods (e.g., Indicator Value-approach) and novel abundance-based models (e.g., Quantile Regression Splines) in terms of accuracy and/or automatability. Furthermore, we have demonstrated that sequencing efforts and associated costs are often overestimated. Surprisingly, even with shallow sequencing depths, our research has shown that machine learning-based prediction of ecological status and accurate biomonitoring can be achieved. This revelation not only underscores the efficiency of eDNA-based monitoring but also positions it as a cost-effective solution that exceeds previous expectations. Additionally, we have successfully identified universal bacterial core taxa that serve as reliable indicators of varying levels of aquaculture impact. These core taxa exhibit distinct patterns that allow for the aquaculture impact, irrespective of factors such as sampling season, sampled country, seafloor substrate type, or local farming and environmental conditions. This remarkable finding highlights the robustness and universality of these bacterial indicators in assessing the ecological status of aquaculture installations, regardless of the specific contextual variables at play.

Conclusion

The use of eDNA-based monitoring in aquaculture can improve efficiency, accuracy, and cost-effectiveness compared to traditional methods. By embracing and integrating eDNA metabarcoding into routine monitoring programs, the aquaculture industry stands to gain substantial benefits. By establishing standard protocols and integrating eDNA metabarcoding into legislative regulations, aquaculture companies can replace or supplement existing monitoring approaches, resulting in cost-effective and efficient compliance monitoring. With the multifaceted application of eDNA technology, aquaculture managers and farmers can now not only comply with regulations but also optimize their practices, ensuring sustainable production and responsible management of aquaculture installations while preserving the surrounding ecosystems.

The provided poster serves as a visual representation of our collective efforts in advancing eDNA metabarcoding for benthic monitoring of aquaculture installations. Moreover, the poster will facilitate engaging discussions about the prospects of eDNA metabarcoding, including the forthcoming challenges that need to be addressed in the future.
BACTERIAL SINGLE CELL PROTEINS: NOVEL ALTERNATIVES TO THE USE OF FISH MEAL IN THE DIETS OF FARmed WHITELEG SHRIMP Penaeus vannamei

Alberto Ruiz*,1, Ignasi Sanahuja1, Julie Lynegaard2, Nana W. Thorringer2, Eleni Ntokou2, Dolors Furones4, Enric Gisbert1

Email: enric.gisbert@irta.cat

Introduction
A potential solution to the increasing demand of fish meal (FM) in aquafeeds would be the replacement of FM in the diets by alternative protein sources, but they do not normally meet with the nutritional requirements of shrimp and can lead to nutritional imbalances (Malcorps et al., 2019). Moreover, shrimp farming is usually affected by bacterial diseases, such as these known as “Bright-red syndrome” and “bacterial white tail disease” in whiteleg shrimp (Penaeus vannamei) caused by Vibrio harveyi, which is one of its most pathogenic agents in terms of mortality rates (Soto-Rodriguez et al., 2012; Zhou et al., 2012). Under this backdrop of threats to shrimp aquaculture, the use of single cell proteins (SCPs) in shrimp diets may be a potential nutritional alternative to FM. In particular, bacterial single cell proteins (BSCP) are composed of up to 80% of protein content and have a high proportion of essential amino acids, vitamins, phospholipids, and other functional molecules (Pereira et al., 2022). Further, some studies testing the replacement of FM by BCSP coming from Methylococcus capsulatus in whiteleg shrimp have reported promising results for improvement of immune status, disease resistance and gut microbiota (Chen et al., 2021; Jintasataporn et al., 2021; Felix et al., 2023). Thus, this work aimed to evaluate the suitability of a BSCP from M. capsulatus as an alternative to FM in Penaeus vannamei.

Materials and Methods
A 140 days-nutritional trial was carried out in whiteleg shrimp fed five isonitrogenous (36% crude protein) and isolipidic (8% crude fat) experimental diets. One was formulated based on a commercial feed for whiteleg shrimp and was used as a control diet (D1), and the others were the same diet but with graded levels of FM replacement by the BSCP (Uniprotein® Aqua, Unibio, Roskilde, Denmark): 75% FM, 25% BSCP (D2); 50% FM, 50% BSCP (D3); 25% FM, 75% BSCP (D4); and 0% FM, 100% BSCP (D5). At the end of the trial, survival, growth in terms of final body weight (BWf) and specific growth rate (SGR), and feed conversion ratio (FCR) were measured. Body proximate composition was also evaluated, as well as the body profile of fatty acids and of amino acids. The overall condition of the intestine was histologically evaluated. In addition, DNA was extracted from the shrimp intestines, and 16S rRNA gene library sequencing (Illumina - MiSeq platform) was conducted using specific primers for the V3-V4 hypervariable regions. After the trial, a bacterial challenge of 10 days was also performed, in which whiteleg shrimp was injected with the pathogen V. harveyi in order to measure the survival rates for each dietary group.

Results and Discussion
Whiteleg shrimp fed the control diet showed a survival rate of 47.7 ± 2.9%, while substituting all the FM by the BSCP it increased to 65.3 ± 2.5%, an improvement of 75% (P < 0.05). On the other hand, the BW, decreased in shrimp fed D4 and D5 (13.1 ± 0.72% and 11.5 ± 0.72%, respectively) with respect to those fed D1 (16.0 ± 0.34%, P < 0.05), while the rest of diets did not compromise the BW (P > 0.05). Similarly, D4 and D5 reduced the SGR from 4.89 ± 0.02% (D1) to 4.74 ± 0.04% and 4.65 ± 0.05% BW/day, respectively (P < 0.05). Considering that there were not differences in apparent FCR values among any dietary group (P > 0.05), probably the decreased BW and SGR with the higher inclusions of BSCP were attributed to the higher stocking density, in line with the observed negative correlation between survival and BW (Pearson Product Correlation; r = -0.90, P < 0.001). In fact, many aquaculture studies in shrimps and fishes have reported a dependency between growth and stocking density, which are usually inversely correlated (Schram et al., 2006; Rodriguez-Olague et al., 2021). Regarding gut microbial communities, shrimp fed D2 displayed a reduction in richness (ACE index = 156.81 ± 26.39) with respect to those fed with the control diet (201.02 ± 68.24; P < 0.05). Similarly, shrimp fed D2 showed a different beta diversity based on Weighted UniFrac distances with respect to the control group (as well as with respect to those fed the D4 and D5) (PERMANOVA; P < 0.05). However, all the dietary groups showed differential phylogenetic features among them (Unweighted UniFrac distances; P < 0.05). These results were reflected in the differential relative abundances of the genera Alibimona, Nautella, Aurantivirga, Tropicibacter, Pseudoalteromonas, Aliiroseovarius and Alkalimarins among others (P < 0.05), as will be discussed. There were no significant differences in survival when whiteleg shrimp was challenged with V. harveyi (P > 0.05). To sum up, the use of Uniprotein® as a protein source in whiteleg shrimp diets is a sustainable and feasible strategy for improving its production.

Introduction
Oxygen is a limiting factor both in the environment and production systems, so reduction may become a stressor. Dielectric cyclic hypoxia may occur with varying frequency and duration in freshwater habitats and in the context of climate change, the frequency of these situations will increase. Under a stressful situation fish activate the hypothalamic-pituitary-interrenal axis (HPI) which triggers the release of cortisol that induces secondary and tertiary responses. The level of activation of this response will depend on the intensity and the duration of the stressor. Also, the recovery of individuals subjected to such stressors depends on their ability to modulate physiological, biochemical, and behavioural responses to maintain metabolic functions and homeostasis. Since episodes of repeated hypoxic stress have been less studied, the aim of this study is to determine the haematological, physiological and molecular response of rainbow trout under repeated hypoxia observe whether there is a habituation response.

Materials and methods
Rainbow trout juveniles were acclimated to AQUAB fish facilities (Universitat Autònoma de Barcelona, UAB). After the acclimation period, fish were randomly divided in 5 different treatment groups, 2 control groups (absolute control (AC) and manipulated control (MC)) and 3 hypoxia groups: H1 that only received 1 hypoxic exposure, group H2 which received 2 hypoxic exposures and group H3 which received 3 hypoxic exposures.

Every exposure to hypoxia consisted in reducing the water oxygen level in the tanks from 8-9 mg/L to 2 mg/L by removing the aeration pumps and bubbling N₂ into the system. Then fish were left in the tanks for 1 hour and sampled subsequently at 1, 6 and 24 post exposure. Water oxygen levels were continuously monitored during the experiment. After the challenge, 9 fish per treatment, and time-point were euthanized with an overdose of MS-222. Samples of blood, skin, gills, and intestine were taken.

(Continued on next page)
**Results**

Haematological parameters as red blood cells number or haemoglobin show that manipulation increase these levels, while hypoxia decreases them. Interestingly, fish are able to recover the control level of haematological parameters after 3 shocks (Table 1).

Respect to the physiological response we observe that cortisol level show and increase at 1 hour post exposure. Also, looking at lactate levels we observe that there is an increase in H1 and H2 at 1 hour, but not in H3 suggesting a metabolic habituation to hypoxic exposures. Finally, regarding glucose levels there is an increase at 1 hour, and a later recovering of control levels at 24 hours.

Finally changes in gene expression were also observed in *crh* and *gr1* stress response genes and in *l1b*, *il10* immune response genes.

**Discussion**

The results of our experiment on induced hypoxia suggest that trout subjected to repeated acute hypoxia could cope with oxygen levels down to 2mg/L of oxygen in water up to 24 hours after the stressor, and that subjecting the fish to the same stressor, trout shows a trend for habituation. Thus, among the hematological variables, red blood cells (RBC) and hemoglobin (HGB) show an increase in the CM group which may be due to the handling of the animals as observed in Acerete et al (2004). On the contrary, as observed in H1, hypoxia produces a decrease in RBCs, probably because the oxygen delivery system is excessively altered and then the overall metabolism and activity decreases (Pichanvart et al 2002). The increase of hematocrit levels after 1 hour would be associated to balancing out the extra need for oxygen (Muszee et al 1998).

Glucose is used as a substrate for glycolytic activity leading to the release of cell energy so that as time progresses these reserves are used. Nevertheless, in most cases an acute stress induces an increase in plasma glucose as a result of the energetic needs derived from the stress situation (Abdel-Twaab et al 2019). Lactate levels increase facing a situation of hypoxia, as to maintain the cellular energy balance. This may be explained by the fact that oxygen-independent mechanisms are needed since oxygen availability is 15 times lower under hypoxic conditions (Richard J.G, 2011).

Introduction
Atlantic salmon is one of the most important aquaculture species worldwide, accounting for 4.5% of global finfish trade, and demand is steadily increasing (FAO 2020). However, production is hindered by skin diseases such as sea lice and winter ulcerating bacterial infections, which cause substantial welfare issues as well as economic losses (Fish Health report 2022). With both diseases on the rise, there has been a growing interest on salmon skin biology. One of the main characteristics of skin is its ability to heal, enabled by the presence of specialized cells that work together to repair damage and restore the integrity of the tissue (Hou et al. 2020). Knowledge of the cellular composition and genetic response to infection, wounding and healing of Atlantic salmon skin is needed in order to gain a better understanding of how these pathogens are bypassing and suppressing the healing capabilities of skin.

Materials and Methods
Samples for single cell sequencing and spatial transcriptomics were collected from two healthy skin samples and four mechanically wounded skin samples at 2 and 14 days post wounding (two samples each time point), representing the early acute inflammatory phase and the tissue repair phase, respectively. Mechanical wounds were introduced by a sterile punch biopsy tool as described by (Sveen et al. 2018). Single-nuclei RNA-seq libraries were generated for all samples using a 10x Chromium and following standard 10x protocols. Spatial transcriptomics libraries where prepared using the 10x visium protocol. Library mapping was performed with STAR (Kaminow et al. 2021) with v3.1 of the genome of Atlantic salmon as reference. Results were analysed using Seurat (Stuart et al. 2019).

Results
We generated single cell atlases across a wound healing time course. We identified pluripotent mesenchymal stem cells that differentiate into diverse cell types including adipose, bone and vascular cells and appear to be crucial in the wound healing process. We then used spatial transcriptomics techniques to locate these cell types in the tissue, and demonstrate their proximity to the wound and importance to the healing process (Figure 1). We further interrogate the role of these cells in the healing process, including their interactions with keratinocytes and immune cells.

Conclusion
This work represents a major enhancement in our understanding of the wound healing process in Atlantic salmon, identifying and characterising the key role of pluripotent mesenchymal stem cells. Importantly, it provides a framework for comparison of healthy wound healing and healing of pathogen-afflicted wounds, such as those caused by sea lice and winter ulcerating bacteria.

(Continued on next page)
Figure 1. Mesenchymal stem cell (MSC) populations in the skin of Atlantic salmon during wound healing. The site of mechanical induced wound is marked with a red circle. (A) Day 2 post injury, during the acute inflammation phase not many MSCs are present. (B) Day 14 post injury, during the remodelling stage MSCs are abundant and likely proliferating in the wound site.

Introduction

Fish is considered a privileged meat product from a nutritional point of view, as it is rich in polyunsaturated fatty acids (especially omega 3), has high quality protein, digestibility, biological value, and is also a source of vitamins and minerals (DIAS and SILVA, 2021).

In the Amazon region, fishing is considered the basis of the economy of some cities and also of traditional communities, which stands out for the richness of fish that are exploited and also for the amount of fish and shrimp captured annually (COSTA et al. 2018).

Thus, thinking about the technologies related to value-added preserves (new cuts, new sauces, new ingredients, etc.), intended for human consumption and nutrition, and also the importance of obtaining information on the centesimal composition of these processed foods, was that efforts were directed towards the characterization of the nutritional components of canned amazonian-shrimp (*Macrobrachium amazonicum*) in two different topping sauces, with a focus on evaluating the dietary patterns of these foods.

Material and methods

Amazonian-shrimp (*Macrobrachium amazonicum*) were acquired in the municipality of Macapá, state of Amapá, Eastern Amazon, through donations made by artisanal fishermen from traditional communities in this municipality.

The shrimp used for the preparation of preserves were processed, where they were first peeled and gutted and then washed in chlorinated water with 20 ppm of free chlorine. The preparation of the artisanal preserves was carried out as follows: first, the shrimp were inspected, after which they were placed in glass jars, and then the topping sauce (tomato sauce (CCMT) and spice sauce was added regional (CCMER)), where then the pots were covered and then submitted to the cooking process. The pots containing the ingredients were subjected to a heat treatment (cooking) in a pressure cooker for 50 minutes. In order to avoid bulging lids, as well as the correct destruction of microorganisms, opening the pan and removing the pots was done after the pan had cooled down.

Results and discussion

Table 1. Proximate composition of artisanal preserved amazonian-shrimp (*Macrobrachium amazonicum*) in tomato sauce and regional spice sauce.

(Continued on next page)
The centesimal analyzes were carried out from the preserves prepared in an artisanal way, in which moisture, mineral residues, total lipids, total proteins, carbohydrates and caloric value were determined, according to the official international methods of food analysis (AOAC, 1990). The centesimal composition analyzes were performed in six replicates, per sample.

**Results and discussion**

After comparison with the literature (DIAS and SILVA, 2021; COLEMBERGUE, GULARTE and ESPÍRITO SANTO, 2011), it was possible to conclude that the CCMT presented low levels of proteins, total lipids and mineral residues, high moisture contents, moderate amounts of carbohydrates, as well as low calorie values. As for the CCMER, they presented moderate levels of moisture, carbohydrates and lipids, high values of total proteins and calories, as well as low levels of mineral residues.

Only the humidity value for CCMER is in accordance with the literature, as it matches a cooked product. Regarding the mineral residue and the amount of lipids, the values found by Colembergue, Gularte and Espírito Santo (2011) for sardines in tomato sauce were higher when compared to this work. As for the protein portion, the values normally found in fresh shrimp (*Macrobrachium amazonicum*) (DIAS and SILVA, 2021) is around 22 g/100g, above that found by the present study for both preserves, 10 g/100g (CCMT) and 17 g/100g (CCMER). In the literature, canned sardines in tomato sauce show higher values for mineral residues, proteins and fats and lower values for moisture and carbohydrates, when compared to this work.

**Conclusion**

Thus, the preserve prepared by this work is easy to prepare and handle, and can be replicated without much cost, since materials and ingredients are used that can be easily found in markets and fairs. Both preserves have shown to have good dietary standards, as they have nutritional components that can be used in diets that require high levels of proteins and lipids, and low levels of minerals, which nutritionally justifies a stimulus to the consumption of artisanal canned fish.

SHOCKING RESEARCH LEAVING EVERYONE STUNNED: USING ELECTRICAL STUNNING AS A METHOD OF EUTHANIZATION OF ZEBRAFISH (*Danio rerio*) IN LABORATORY CONDITIONS

Ulla Saarinen1*, Erika Sundell1, Lynne Sneddon2, Michael Axelsson2 and Albin Gräns1

2Department of Biological & Environmental Sciences, University of Gothenburg

*Email: ulla.saarinen@slu.se

Background

The zebrafish (*Danio rerio*) accounts for approximately 50% of fishes used in research and its adoption has grown rapidly since the 1990’s (Kinth et al. 2013). The high number of individuals used in research warrants for an accessible, effective, and humane manner to stun and kill zebrafish in the laboratory. Common methods adopted in research today include overdose of anaesthetics, rapid cooling followed by brain destruction or exsanguination. However, there is evidence that these methods are aversive (e.g., many anaesthetics) and require capture, handling and transferring to another tank, thus causing stress (Wong et al. 2014). Electrical stunning could be a more effective and less stressful euthanasia method but although it is extensively used in aquaculture, very little is known about the use of electrical stunning for zebrafish (Mocho & von Krogh 2022). One study has demonstrated that euthanizing zebrafish embryos and larvae with electricity is rapid and reliable (Mocho et al. 2022). Here, we have developed a suitable electrical stunning method for euthanizing zebrafish in laboratory settings. Our aim is to investigate i) whether adult zebrafish can be euthanized humanely and effectively using electricity, and ii) what is the minimal, electrical field required to achieve a humane and effective euthanasia without using unnecessarily high voltage. Furthermore, we have developed portable electrode panels that can be placed in a common zebrafish housing tank to reduce the amount of handling and therefore, minimize the unnecessary stress that zebrafish may experience both before and during the procedure of euthanasia.

Material and methods

In all of the trials, water temperature, conductivity, and frequency were kept constant at 28±0.3 °C, 800±5 µS/cm and 50 Hz, respectively, whereas the voltage was manipulated to achieve different electrical field strengths. The first trials focused on finding a field strength that is sufficient to stun the zebrafish immediately without the fish showing any adverse reaction. This was done to verify that the fish experienced an immediate loss of consciousness, and therefore would not endure extreme stress and pain during the stunning. In these trials, the electrical stun duration was 1 s. A behavioural assessment was done by visually inspecting the fish during and after the stun. Video footage was used to revise the reaction and to confirm all the trials. After the appropriate minimal field strength was verified, single zebrafish were stunned for 30 s to demonstrate the efficacy of the field strength to eliminate the subject. The fish were inspected for 30 min after the stun to verify that the stun was irreversible. Zebrafish where then stunned in groups of 5 fish per tank and later in groups of 10 fish per tank for 30 s. After a sufficient field strength was concluded, portable and adjustable electrode panels were constructed. The final design was made to be suitable for an 8 L standardized zebrafish tank (Tecniplast S.p.A, Italy), which is commonly used for zebrafish housing. The electrode panels were designed to have adjustable handles and supporting

| Table 1. The conducted trials separated by tank size, group size, and average field strength (FS) and average current density (CD). The recovery rate was calculated by dividing the recovered fish in the same trial group by the total number of fish in the same trial group. S indicates that the trial group included only successful trials and U that one or more trials were unsuccessful. It is to be noted that more trials are yet to be conducted, and the results may therefore change later.

staffs to be able to adjust the electrode separation to be fitted also into the smaller, 3.5 L standard tank (Tecniplast S.p.A, Italy). The portable electrodes where then tested using both 8- and 3.5 L tanks by stunning groups of 10 fish for 30 s as well as stunning the number of fish equal to the maximum capacity for each tank, i.e., 40 fish in the large tank and 15 fish in the small tank for 30 s. Only trials where all fish were stunned irreversibly were determined successful. If the trial was deemed unsuccessful, the voltage was adjusted so that the electric field strength was 1.0 V/cm higher.

**Results**
Zebrafish that that were stunned irreversibly showed no aversive nor aggravated behaviour during the stun. It was conducted that 5±0.3 V/cm was sufficient to euthanize 1, 5 or 10 fish per trial in a 3.5 L tank, but stunning the maximum capacity of fish in the same tank required a 6.7±0.1 V/cm. For the larger, 8 L tank, 6.0±4 V/cm was sufficient to euthanize 10 fish at once. The trials conducted with the standard housing tanks are presented in Table 1.

**Conclusions**
Electrical stunning was highly effective in causing immediate loss of conscious and death without recovery in zebrafish. Many large facilities are killing hundreds of zebrafish every week thus this technique represents a more refined method without the use of chemicals, cooling stress or handling of the animals. Depending on the number of zebrafish and tank size, the sufficient field strength does need to be adjusted. Our results comply with the previous assumptions regarding electrical stunning of young forms of zebrafish (Mocho et al. 2022), and therefore electrical stunning could contribute to a more humane euthanization and better welfare of adult zebrafish in the future. This approach could be extrapolated to other species of fish used in research including aquaculture species where killing large numbers of fish humanely remains a challenge.

**References**
integrated multitrophic aquaculture (IMTA) allows to diversify production while reducing the footprint of a monoculture and is now widely recognized as a tool to increase the sustainability of aquaculture systems (Chopin et al., 2012). Holothurians, or sea cucumbers, are excellent candidates for integration in IMTA (Zamora et al., 2018), but European demonstrators are still scarce, mostly because of our limited capacity to reproduce European Holothurian species.

This presentation shares the latest results of a 15 months study testing the potential of growing Holothuria forskali underneath flat oysters, Ostrea edulis. Juveniles specimen of H. forskali, fertilized and reared in controlled conditions (Laguerre et al., 2020) up to 5g, have been stocked at different densities: 9, 18, 27 and 36 individuals/m² under 3 rows of flat oysters in mesh bags placed above the intermediate shoreface. Growth and survival have been monitored and showed exceptional results, with a 95% survival and body masses multiplied by more than 20 for the lowest density. Despite slower growth observed for higher densities, total biomass was multiplied by 6 in the highest density, which translated in a 1035 g/m² gain. These results demonstrate the great potential of growing H. forskali in combination with the studied oyster production system, in order to diversify production and income with neglectable extra efforts, time and investment.

Yet, to qualify an aquaculture production system as IMTA, trophic links need to be demonstrated in order to prove that holothurians benefit from the waste of the other species. A supplemental condition was therefore added and consisted in juvenile H. forskali stocked in similar conditions but outside the waste plume of the oysters. Surprisingly, growth was identical as below the oysters indicating that H. forskali can benefit from suitable food independently from oysters’ waste. Isotopic analyses and fatty acid compositions of the different conditions help better understanding trophic relationships in the system.

OPTIMALIZATION OF THE MACRONUTRIENT COMPOSITION IN THE ATLANTIC HALIBUT DIET

Farming of Atlantic halibut had its modest start in the 1980s and has slowly grown into an industry that sold 1900 metric tons in 2020. This has been a challenging endeavor where one bottle neck has replaced the next, and the first decades were largely dedicated to solving difficulties related to larval development. However, the industry has endured, and the current focus has moved from early development to optimalization growth and welfare to market size. We have therefore investigated the effect of varying levels of the macronutrients (protein, lipids and carbohydrates) on the grow out phase. Twelve diets were designed ranging in protein from 45 to 77 %, lipids ranging from 5 to 30 % and carbohydrates from 5 to 25 % of the diet. This represents a three-component mixture design, allowing analysis of the mixed effect of the factors on the fish. Atlantic halibut juveniles (mean weight, 300 g; 120 in each tank) were randomly distributed to 15 tanks for one year.

The effect of macronutrients on growth changed during the growth period. In the start of the trial both high levels of carbohydrate and lipid had a negative effect on SGR, whereas the negative effect of high carbohydrate was less important toward the end of the trial. There was no effect of diet composition on digestibility of lipids and proteins. Muscle composition was not affected by diet composition, but the liver composition reflected dietary variations. Effects on appetite and welfare will be presented and discussed.

Fig. Specific growth rate (SGR) the last two months of the feeding trial. The colour scale indicates SGR between 0.1 and 0.195. This growth period showed a linear negative effect of lipid on SGR.
EFFECT OF DIET COMPOSITION AND STARVATION ON THE EXPRESSION OF AKT/mTOR SIGNALING PATHWAYS IN SKELETAL MUSCLE OF GILTHEAD SEA BREAM (Sparus aurata)

Introduction
White skeletal muscle contributes to 40-60 % of fish body mass and to overall growth in vertebrates. Development of this tissue has a well ordered and adaptative structure. The process of myogenesis shows significant plasticity, which is essential for the proliferation, differentiation, migration, and fusion of new myoblasts. This process is primarily controlled by myogenic regulatory factors (MRFs), a large group of proteins containing a basic DNA-binding motif and a helix-loop-helix dimerization domain (Braun & Gautel, 2011). Moreover, somatotropic components such as insulin-like growth factor 1 (IGF-1) exert an important role in nutritional regulation of metabolism, increasing muscle mass and decreases muscle atrophy (Vélez et al., 2014). IGF-1 and amino acids activate the phosphatidylinositol 3-kinase (Pi3k)-Akt pathway, which leads to phosphorylation of the serine/threonine protein kinase mechanistic target of rapamycin mTOR and activation of a critical pathway involved in cellular processes such as apoptosis, protein synthesis, gene transcription and cell proliferation (Vélez et al., 2014). Indeed, mTOR is an essential sensor of nutrient and amino acid availability through phosphorylation of 40S ribosomal protein S6 (S6). With the aim to increase our current knowledge about the nutritional regulation of skeletal muscle growth and development in fish, we addressed the effect of dietary macronutrient composition on the expression of genes involved in Akt/mTOR pathway, MRFs, and IGF-1 in white skeletal muscle of gilthead sea bream (Sparus aurata) juveniles maintained in different conditions (fed and fasted).

Materials and Methods
S. aurata juveniles were obtained from Piscicultura Marina Mediterranea (Burriana, Castellón, Spain). A total of 330 fish (8.22 g ± 0.26 body weight) were transported to the laboratory and distributed in 12 aquaria of 260 l supplied with running seawater at 21 ◦C in a closed system with active pump filter and UV lamps. Three diets were formulated with gross energy at 20–22 kJ/g and macronutrient composition at levels above and below those in commercially available aquafeeds: HLL (high protein, low lipid, low carbohydrate), MHL (medium protein, high lipid, low carbohydrate) and LLH (low protein, low lipid, high carbohydrate). Fish were fed for 37 days twice daily to satiety. On the other hand, a group of fish was maintained in fasting conditions for the same period of time. Total RNA was extracted from skeletal muscle and gene expression was analyzed by quantitative real-time RT-PCR (qRT-PCR).

Results and Discussion
Among fed fish, the mRNA levels of mTOR and S6 protein showed a significant dependence on the protein/carbohydrate ratio in the diet. For mTOR, diet HLL promoted the highest expression values, which were 1.7-fold and 2.4-fold greater than in fish fed diets MHL and LLH, respectively (Fig. 1a). Likewise, fish fed HLL presented 1.3-fold and 1.6-fold higher S6 mRNA levels than fish supplied with MHL and LLH, respectively. The expression levels of mTOR and S6 in starved fish were similar to those observed in the skeletal muscle of fish fed diet LLH (Fig. 1a-b). On the other hand, the expression of Akt showed a behavior similar to that of mTOR and S6 (Fig. 1c). In agreement with results in S. aurata (Lavajoo et al., 2020), muscle mRNA levels of mTOR and S6 decreased upon starvation. However, no significant differences in Akt expression were found between fed and fasted fish. Starvation for 37 days significantly downregulated 2.9–6.0 fold IGF-I expression depending on the diet supplied. Among fed fish, significant upregulation of IGF-I (1.8–2.0 fold) was found in fish fed diets with improved growth parameters (MHL and HLL) (Fig. 1d). Consistently, the combined action of IGF1 and amino acids stimulated mTOR and Akt activity in S. aurata myocytes (Vélez et al., 2014), and low protein diets diminished growth performance and mTOR signaling pathway in yellow catfish (Pelteobagrus fulvidraco) by downregulating the mRNA levels of key genes such as IGF-I, mTOR and Akt (Qin et al., 2019). Dietary macronutrient composition and food

(Continued on next page)
deprivation significantly affected the expression of MRFs in the white skeletal muscle of *S. aurata*. Starvation for 37 days significantly downregulated the mRNA levels of all MRFs assayed. Concerning fed animals, the supply of HLL and MHL significantly enhanced 1.7–1.9 fold the expression levels of myod2 compared to fish fed with diet LLH (Fig. 1e). In a significant manner but to a lesser extent than myod2, feeding fish with the diet containing the lowest protein/carbohydrate ratio (LLH) decreased myf5 and myogenin mRNA levels when compared to fish fed with MHL and HLL diets, respectively. The only MRF assayed whose mRNA levels did not significantly differ as a result of diet composition was Myf6 (Fig. 1e).

**Conclusion**
The results of the present study show that the expression of genes involved in Akt/mTOR pathway, MRFs, and IGF-1 in white skeletal muscle of gilthead sea bream juveniles maintained in different conditions was markedly affected by nutritional status and dietary macronutrient composition.

Introduction
The prawn *Macrobrachium americanum* is a native crustacean in rivers of northwest part of México. CIIDIR-Sinaloa, is working in establishing conditions for reproducing *M. americanum*. Actually, several variables have been controlled for management of mate, egg and larvae development. During these studies, mortality of berried females was common and deserved our attention. The goal of this study was to analyze the pro-Phenol-Oxidase system, the total hemocytes count and coagulation in reproductive females.

Materials and methods
Four groups of 10 organisms were arranged in four groups: 1. Females with immature gonad, 2. Females after five days of ovulation, 3. females before five days of harvest and 4. Male. Organisms were obtained from Sinaloa River with a mean weight of 74g, they were reared during 2 months feeding tilapia meat and pellets for shrimps at 29±2 °C. At the established times, a sample of 50 µL of haemolymph was withdraw to analyze the coagulation time between the groups and immediately a sample of 0.5 mL of hemolinfa was withdraw from the ventral sinus in an anticoagulant solution. Haemolymph was processed to determine haemocytes account, pro.Phenol-Oxidase content, Phenol-Oxidase activity, and protein concentration.

Results
Results showed uniforms conditions variables in groups 1, 2 and 4. Five days before harvest females group 3, showed a general alteration, pro-Phenol-Oxidase decrease in content, meanwhile the time in coagulation and Phenol-Oxidase activity increased.

Discussion
It was interesting way the increase in Phenol-Oxidase activity without apparent difference in contact with non-self material between groups, since they were reared in the same container. But this is not the cause of mortality. If females do not coagulate, they have to face blooding and the introduction of non-self material. After the addition of Transglutaminase in the 50 µL sample, coagulation time decrease suggesting a malfunctioning of this enzyme during reproduction.

Introduction
The use of terrestrial vegetables as a source of protein and lipid in aquaculture has led to a reduction of n-3 long-chain polyunsaturated fatty acids (LC-PUFA) in salmon fillets. Genetic modification of oilseed crops such as Camelina or rapeseed as well as production of heterotrophic microalgae has allowed the production of land-based sources of LC-PUFA with the potential to take the pressure off fish oil supplies, which mainly come from wild-caught oily fish – a finite resource. Although several studies have investigated the impacts that these new lipid sources have on fish performance and product quality, limited information exists regarding their impact on fish health or adaptation to stress (Napier and Betancor, 2023., Ruyter et al., 2022; Santigosa et al., 2020). The aim of the present study was to assess the impact of different novel lipid sources on Atlantic salmon (*Salmo salar*) parr on their stress response during smoltification by investigating the production of lipid inflammatory mediators (LIM) as well as the head kidney lipid and fatty acid composition and transcriptomic response.

Materials and Methods
A conventional nutritional trial was carried out both in freshwater Atlantic salmon parr from 37.6 ± 6.7 g up to smoltification (109.3 ± 30.3 g). Fish were fed one of eight experimental feeds, in triplicate, containing different commercial and experimental lipid sources. Briefly, oils included two GM-camelina oils (high EPA and high EPA+DHA; ECO and EDCO, respectively), a canola GM oil (high DHA; Aqua), a microalgal oil (high EPA and DHA; Ver), a northern- and southern-hemisphere fish oil (reference feeds, NHFO and SHFO, respectively), krill oil (positive control; KO feed) and sunflower oil (SFO; negative control) (Fig. 1). Feeds were manufactured by BioMar (Brande, Denmark). All feeds used the same base pellet formulation with a fishmeal level reflecting current commercial practice for salmon and were formulated to satisfy all the known nutritional requirements of salmon, including a basal EPA+DHA content of >2.5% of total fatty acids.

Prior to sea water transfer, six fish per tank were humanely euthanized and samples from head kidney either quickly frozen for lipid extractions or stabilized into RNALater for RNAsSeq analysis (Illumina Sequencing). Plasma was also collected from the six sampled fish, quickly frozen in liquid nitrogen until LIM by LC-MS-MS. Additionally, five fish per tank were subjected to a sea water challenge, by transferring the fish for 24h at a salinity of 35 ppt, after which the fish were euthanized and plasma and head kidney collected.

![Diagram of experimental treatments](image_url)

Fig. 1 – Diagrammatic representation of the experimental treatments used in the present trial, including GM-Camelina derived (EDCO and ECO), GM-canola derived (Aqua), microalgal (Ver), krill oil (KO), the positive controls south and north hemisphere fish oil (SHFO and NHFO, respectively) and the negative control, sunflower oil (SFO).

(Continued on next page)
Results and Discussion
Despite experimental feeds being isolipidic, the kidney lipid content varied among the different dietary treatments. In this sense, fish fed NHFO displayed the largest fat content, whereas those fed EDCO displayed the lowest content, with the remaining treatments displaying intermediate values. These different lipid contents also had an impact on the lipid class composition of head kidney, with fish fed NHFO showing the highest levels of neutral lipids, which are mainly used as energy source, specifically triacylglycerols. The opposite trend was observed in EDCO-fed fish, which in contrary displayed higher contents of structural or polar lipids than NHFO-fed fish. The head kidney fatty acid profile mainly reflected dietary input, not indicating any biosynthetic capacity, as expected. In this sense, the lowest n-3 LC-PUFA levels were detected in the group fed SFO and the highest in fish fed the microalgal oil.

The analysis of LIM demonstrated how the levels of those derived from shorter chain fatty acid (e.g. 18:3n-3 and 18:2n-6) were regulated by dietary input, rather than stress (salinity challenge). On the contrary, levels of those derived from n-6 (20:4n-6) and n-3 LC-PUFA (EPA and DHA) tended to increase/decrease mainly along with stress. Further RNASeq results will also be presented and related to LIM production in head kidney.

Introduction

Sea lice parasitism is one of the greatest economic, environmental, and animal welfare issues facing the Atlantic salmon (Salmo salar) aquaculture industry (Torrissen et al. 2013). A potential solution may exist in coho salmon (Oncorhynchus kisutch), a species that mounts a massive inflammatory response to sea lice, resulting in their swift detachment from the skin (Fast et al. 2002). However, it is not known which of the many cell types present in fish skin underlie this remarkable resistance. We therefore employed single-nuclei RNA sequencing, a technique facilitating transcriptomic profiling of thousands of individual cells, to investigate the cell types and gene expression patterns characterizing the response of coho and Atlantic salmon to sea lice.

Materials and Methods

Atlantic and coho salmon were reared in a RAS at the Centre for Aquaculture Technologies (PEI, Canada). Juvenile fish were exposed to copepodid stage sea lice (Lepeophtheirus salmonis) and pelvic fin and skin where lice had attached were sampled at 12h, 24h, 36h, 48h, and 60h after exposure. Fin and skin were also taken from unexposed control fish reared in identical conditions. Nuclei were isolated from one skin and one fin sample from the control and each of the five treatment time points for each species (N = 24 samples total) using a custom protocol (Ruiz Daniels et al. 2023). Samples were processed with Chromium (10X Genomics) and sequenced with Illumina technologies. Library mapping was performed with STAR (Kaminow et al. 2021). Resulting outputs were analysed with Seurat (Stuart et al. 2019). Samples were analysed by species and also integrated into a single dataset using 1:1 orthologs identified with OrthoFinder (Emms & Kelly 2019).

Results

The variety of cell types we detected (Fig.1) were largely consistent in identity and marker genes across species. Integration of both species data using 6494 1:1 orthologous genes detected most of the cell types observed in each of the species-specific analyses. These results suggest the same cell types are present in the skin and fin of both species.

We identified 4567 and 1799 unique genes in Atlantic and coho salmon, respectively, which were differentially expressed between control and any of the treatment time points (Fig.2). Both species upregulated immune genes in response to lice, intriguingly in both immune and non-immune cell types. However, coho salmon uniquely demonstrated a down-regulation of iron-sequestration related genes in red blood cells, potentially to starve lice. Coho salmon keratinocytes also dramatically upregulated genes associated with inflammation and immunity. Our results confirm the importance of previously identified candidate genes associated with lice-resistance but also identify new candidates that may have been missed by previous bulk RNAseq studies due to their expression in multiple cell types.

(Continued on next page)
Discussion

Clearly, multiple cell types, common to both species, are involved in sea lice response in Atlantic and coho salmon. Our results also suggest that coho salmon use multiple strategies (with different cell types and genes) to repel lice. This may explain why a single locus for lice resistance has proven elusive. Yet, the candidate genes we found to underlie coho salmon’s multiple resistance strategies to lice could be targeted in isolation or in combination via gene editing to confer this innate immunity to Atlantic salmon.

Introduction
Aquaculture is an age-old activity that has evolved slowly, often based on traditional knowledge and advances obtained through needs, experience or cooperation. It has expanded and developed over centuries, integrated with social, economic and cultural environment, hand by hand with scientific progress, and today supplies half of the world’s fish and seafood (Yue & Shen, 2021).

The application of genetic and genomic tools has boosted aquaculture production to a higher level, which has enabled improving the main target traits for valuable commercial species. This has been accomplished both through deepening into their genomic architecture and improving genomic predictions in breeding programmes.

In this study, we present a high-density single nucleotide polymorphism (SNP) array for some of the most significant bivalve species in European aquaculture: grooved carpet-shell clam (Ruditapes decussatus), Manila clam (R. philippinarum), Mediterranean mussel (Mytilus galloprovincialis) and common cockle (Cerastoderma edule) taking as reference their highly contiguous published or ongoing genome assemblies. The chip will help for the exploitation of genetic resources associated with traits of commercial interest along with the sustainable management of shellfish beds (Boudry et al. 2021).

One of the experiments that has been designed to validate and apply this chip has to do with a genome-wide association study (GWAS) to understand the genetic architecture of the resilience to Perkinsus olseni in Manila clam.

Material and methods
SNP discovery was carried out through whole-genome re-sequencing of pooled genomic DNA samples from 10 males and 10 females of each species taking as reference the published genomes of C. edule and R. philippinarum, and new ongoing assemblies of the other M. galloprovincialis and R. decussatus. Raw data was filtered and aligned against the reference genome and the millions of SNPs called using SAMtools. The resulting list of SNPs for each species was filtered according to the following criteria: 1) coverage, 2) minor allele frequency (MAF), 3) lack of nearby genetic polymorphisms (± 100 bp).

In addition, previous candidate markers associated with productive traits, such as resilience to species-specific pathologies and sex, were included in the array together with geographical diagnostic variants, when available.

For the GWAS in Manila clam, 1000 individuals challenged with Perkinsus will be genotyped using the SNP chip, and 500 will be used as controls for comparison across the progression of the infection. The parasite load will be estimated in each individual using qPCR as the phenotype for parasite infection. Parasitic load will be estimated by qPCR in each individual and genotypes will be performed on the same individuals with the array to identify quantitative trait loci (QTL) associated with parasite resilience. This will provide key information to identify candidate genes for resilience and to design the best model for genomic or marker assisted selection to control this parasitosis.

(Continued on next page)
Results and Discussion

An Affymetrix Custom array (EUMOLCHIP) has been designed including 15,000 markers from the SNP list selected for each species and will be validated and applied in ongoing GWAS and population genomic screening studies across the natural distribution range of the species.

In particular EUMOLCHIP is being applied to understand the genetic architecture of resistance to perkinsosis in Manila clam through a GWAS experiment, providing key information to face the main issue for Manila clam producers.

This technology will be fundamental to promote the sustainability and competitiveness of our aquaculture in the European and global production framework, contributing to food security in the international framework of population growth.

Introduction
The circadian clock is based on genes that give positive and negative feedbacks to create a self-sustainable molecular clock that is entrained by different environmental stimuli or zeitgebers. The transcriptional factors that are part of the clock system can target many physiological variables like lipid metabolism, which in turn will present a 24-hour periodicity or variations during the day (Pando and Sassone-Corsi 2002, Paredes et al., 2015). This system has also mutual connections with the stress and epigenetic systems. In the first case, several stress parameters display differences during the 24 hours. At the same time, cortisol can affect the clock system by binding the glucocorticoid responsive element present on clock genes like per2 (So et al. 2009). In the second case, it has been recently proved that some epigenetic factors involved in methylation in fish display rhythms in the 24 hours (Paredes et al. 2018), but at the same time dnm3 is considered responsible for the methylation of the promoter of some clock genes and thus it can regulate the clock system activity. Moreover, the epigenetic system is tightly related to stress through the glucocorticoid receptors (gr) (Barlett et al. 2019). Finally, the connection between clock and methylation, suggest that feeding can exert an important role, since methylation relies on the availability of a methyl group given by diet. The aim of this study was to understand how different stressors like density and a low food ratio can affect the circadian clock, the epigenetic system and an output of the clock as the rhythms in lipid metabolism and fatty acid composition. In addition, we also aimed to understand how the time of the day can make a difference in terms of the response. Due to its importance in aquaculture and main concerns related to welfare, we selected the European sea bass (Dicentrarchus labrax) as the experimental model in this study.

Materials and methods
Fish were kept in an open system in a 13:11 Light/Dark cycle and were fed once during the light phase. Four experimental groups were designed based on two feeding ratios (F) and densities (D): high feeding-low density (HF - LD), high feeding-high density (HF – HD), low feeding-low density (LF – LD) and low feeding-high density (LF – HD). All groups were performed in triplicate (3 different tanks). Feeding differed between groups depending on the food ratio provided: 1.5% for the high feeding (HF) and 0.5% for the low feeding (LF). The densities selected were 5 kg/m$^3$ for the low density (LD) and 50 kg/m$^3$ for the high density (HD). Fish were maintained under these conditions for 60 days. Samples were collected at day 0, 5, 10, 25 and 60. Each sampling day, samples were collected both at the middle of the light phase (ML) and at the middle of the dark phase (MD). At each day and time point, 3 fish from each tank (n=9 for each experimental group, 3 fish from 3 tanks per group) were collected and sampled. First, fish were anesthetized, and blood samples were collected by caudal puncture. Then, fish were euthanized, and we collected samples from brain, liver, perivisceral fat and muscle. In the liver samples we analyzed, by qPCR, the relative expression of clock genes (clock, bmal, per and cry), genes from the epigenetic mechanisms (sirt1, dnm3, tet2, gadd45aa, mbd4), and genes from the lipid metabolism (cpt1a, ppars, fas, elvol5, lxr, srebp) as the output signal of the clock. In addition, we evaluated the fatty acid profile of the liver, muscle, adipose tissue (perivisceral fat) and plasma by gas-liquid chromatography.

Results
We expect differences in the response of clock and epigenetic genes due to the stressor with significant differences based on how long these conditions were maintained. Moreover, due to the importance of the time of the day for the response, we expect to describe differences when comparing day and night sampling times. In the end, all these factors will impact the fatty acid composition of the body.

Introduction
Fish have evolved circadian system to synchronize to different environmental cyclic factors like light or food availability. These entraining factors can be referred as *zeitgebers* and they boosted the evolution of a self-sustainable molecular clock formed by positive and negative feedback loops. *Clock* and *bmal* represent the starting point and the positive loop; they work as transcriptional factors activating, among many genes, the negative loop formed primarily by *per* and *cry*, which in turn will work to repress *clock* and *bmal* transcription. This self-sustainable molecular system is the core of the vertebrate molecular clock, and its rhythmicity is transmitted to many physiological processes (Pando & Sassone-Corsi 2002). Even if this system is self-sustainable, several levels of regulation can be present. For instance, epigenetic mechanisms are involved not only as regulators of this system, but also as a target. Mechanisms of deacetylation and methylation seems to be crucial in this bidirectional system. In the deacetylation process, *sirt1* plays an important role (Nakahata et al. 2009) counteracting the intrinsic acetylation activity of *clock*, which is responsible for chromatin remodeling that is associated to circadian control of gene expression. DNA methylation is another process that could be involved in the regulation of the circadian system since it has been proposed that *dnmt3* might be responsible for the methylation of *bmal*’s promoter (Satou et al. 2013). At the same time, the same genes involved in methylation and de-methylation have been described as rhythmic in zebrafish gonads (Paredes et al. 2018), suggesting again the double nature of the interaction between the two molecular patterns. Moreover, sirtuins and DNA methyltransferases are linked to nutrient availability (Su et al. 2016), indicating that feeding time can act on the clock mechanism not only as a *zeitgeber*, but also passing through the epigenetic way. Therefore, the aim of this study was to investigate how feeding time affects the rhythms of the circadian clock and genes of the epigenetic system in the liver of the European sea bass (*Dicentrarchus labrax*). We also focused on the hypothalamus to understand if feeding time has the potential to affect the central pacemaker.

Materials and method
Fish were kept in an open system in a 14:10 LD cycle and fed with 1% of the fish body weight, once a day. Fish activity was monitored by mean of photocells. Two groups were made based on the feeding time: mid-light (ML) and mid-night (MD) feeding. After 30 days under these conditions, fish were sacrificed in a 24-h cycle at seven sampling points after light onset: ZT 0.5, 4, 7.5, 12, 16, 20 and 24.5 h to collect liver and hypothalamus. In the liver, clock genes and genes of the epigenetic system were analyzed, while in the hypothalamus clock genes were considered. Liver was also used to investigate the presence of a rhythm in the SAM/SAH ratio, which is an index of methylation potential.

Results
In the liver, the epigenetic genes analyzed (*sirt1, dnmt1, dnmt3a, gadd45aa, mbdd4 and tet2*), presented rhythm in the ML group, but only *dnmt3a* conserved the rhythm also in the MD group. Additionally, all the acrophases were nocturnal. The analysis of the clock genes revealed that all of them (*clock, bmal1, per1, per2, cry1* and *cry2*) presented rhythms in the ML group, while only for *per2* the rhythm was maintained in the MD group. Finally, rhythms were found in the hypothalamus for the clock genes both for ML and MD groups, except *cry2*, where no rhythm was found. Concerning fish activity, both the groups displayed a diurnal activity.

Discussion and Conclusions
In the liver, the feeding time had a strong impact on the clock genes, since when the fish were fed in MD the rhythm disappeared with only one exception (*per2*). Moreover, when comparing ML with MD mean expression, in most of the cases they displayed a significant difference in most of the ZT points, demonstrating that also transcriptional levels are affected by feeding time. *Sirt1* was rhythmic in ML group, but not in MD group and the differences between the two groups were significant in most time points. The explanation could be related to the availability of its cofactor, NAD+, that could

(Continued on next page)
have been affected by feeding time as well. Dnmt1 seems to be more affected by the feeding time than dnmt3a, since it presents rhythm only in ML group. This can suggest that the maintenance of the pattern of methylation in the cells could be affected as well by feeding. Also, the genes involved in de-methylation process present the same pattern observed for dnmt1, since the rhythm was only present in ML group. Moreover, comparing ML with MD group, is clear that feeding time has affected the transcriptional levels as well. In the hypothalamus, most of the clock genes analyzed displayed rhythm both in the ML and MD groups, and this is consistent with other data in fish that confirm that light is the main synchronizer in central tissues like the brain. However, when the two groups are compared, significant differences are present between the same ZT points. For this reason, it’s not possible to exclude an important effect of feeding time in the central pacemaker. Since both groups were diurnal, and most of the genes displayed a nocturnal acrophase, we can speculate that during the resting phase fish prepare the factors that are involved in the connection between clock system and epigenetic machinery. To better understand the connection between clock system and epigenetic mechanism, our research is currently focusing on the analysis of the methylation potential, to understand if methionine metabolism (1-C cycle) can be connected as well with the clock system.

NATURAL SPAWNING AND LARVICULTURE OF *Holothuria grisea*: A NEW CANDIDATE FOR MARICULTURE IN THE WESTERN ATLANTIC COAST

Universidade Federal do Rio Grande – FURG, Instituto de Oceanografia
Laboratório de Piscicultura Estuarina e Marinha (LAPEM). Rio Grande (Brazil)
E-mail: luisandresampaio@gmail.com

Introduction

The control of hatchery protocols for seed production of Holothurian species is key for successful aquaculture, ocean ranching, and stock enhancement of these endangered species. Therefore, in this study we present the results of broodstock collection in the wild, transport to the hatchery, conditioning for natural spawning, and embryonic and larval development of *Holothuria grisea*.

Materials and Methods

Adult *H. grisea* (n=72) were collected from the wild, off the Brazilian Atlantic coast (27.8° S – 48.6° W) during the Spring (2022). They were placed in a container equipped with pure oxygen supply and transported in a pickup truck for 800 Km. On arrival at the hatchery in Rio Grande (Brazil), they were separated into three tanks in a RAS. During five months the sea cucumbers were kept along with juvenile *Pogonias courbina* (Sciaenidae) and allowed to feed on fish biodeposits and waste feed.

After five months, the sea cucumbers and fish were transferred from these tanks to another RAS, with the same water quality. Two days after transfer, we observed broodstock releasing gametes and less than 1h after that, fertilized eggs were collected from the tank through a sieve (80 µm). Eggs were incubated in cylindric-conical tanks using a semi-static system, larviculture was performed in the same tanks. Larvae were fed on microalgae (*Chaetoceros calcitrans*). Glass plates colonized with the same diatom were placed in the larviculture tanks once the late auricularia stages were observed. The juveniles were later transferred to flat bottom tanks. Embryonic, larval, and early juvenile development were followed using photography taken under a microscope.

Results

Adult individuals kept in a RAS with juvenile *P. courbina* (Sciaenidae) spawned within a couple of days after they were stimulated by disturbance and movement to new tanks.

The first cleavage was observed approximately 1h after the gametes were released in the broodstock tanks (Figure 1 B). Gastrula were first observed around 30h after fertilization (Figure 1 E). Two days after hatching the early Auricularia stage was first observed (Figure 1 F). The first hyaline spheres were observed 28 days after fertilization (Figure 1 I)

Abundance of larvae decreased with development towards the late auricularia stage. After reaching the doliolaria and pentactula stage, larvae assumed demersal behavior and were no longer available in the water column. Early juveniles were observed in the glass plates placed in the larviculture tanks (Figure L).

Five months after fertilization, juvenile length achieved between 1-2 cm. Their color is yellow, and they are successfully fed on organic debris siphoned out of juvenile *P. courbina* rearing tanks.

Discussion and conclusion

The results presented here show *H grisea* can spawn in captivity and the fertilized eggs can develop into juveniles using techniques common to other Holothuriidae species. Adult sea cucumbers kept in a RAS with juvenile *P. courbina* successfully spawned. Fertilized eggs were successfully collected and transferred to an incubator in a semi-static system. Auricularia larvae fed on microalgae (*C. calcitrans*) and developed to the juvenile stage.

The description of these breeding techniques is the first step to the introduction of a new species of sea cucumber to aquaculture, allowing diversification of mariculture operations in the Atlantic Ocean, with focus on low trophic species.

Virus infection and disease outbreaks are a massive problem in aquaculture. Salmonid alphavirus (SAV) and infectious salmon anemia virus (ISAV) causes economic losses as well as welfare and sustainability issues in farmed fish. To enter their hosts, fish viruses must cross mucosal barriers. This includes skin, intestines, and gills, and the latter is identified as the primary entry site [1]. Mucus is known to provide protection against pathogens, both physically and chemically [2].

...Enter: Substance X! We hypothesise that Substance X has the potential to increase mucus production, and thus decrease viral infection levels in salmonid cells.

Methodology: In vitro experiments
We will perform basic research on substance X through in vitro experiments with two salmonid cell lines: RT-gillW1 (gill) and ASK (kidney). Cells will be infected with SAV (subtype 3) and ISAV. Effects on cellular responses and virus dynamics will be evaluated with and without the presence of Substance X.

Workflow: Our research design in three steps
1. Expose salmonid cells to four different treatments
   • Control
   • Virus
   • Substance X
   • Substance X and virus
2. Harvest cells at different timepoints
3. Analysis:
   Microscopy: Dye cells for mucins. Do the cells produce more mucus?
   RT-qPCR: Virus dynamics. How much virus is taken up in the cells?
   RT-qPCR: Cellular responses. RT-qPCR Do we see a higher expression of mucus-related genes, or other interesting changes?

In the future...
We hope that we are able to elucidate the mechanisms and potential usefulness of Substance X. Work package 2 in the project will perform in vivo trials with farmed fish.

(Disclaimer: Unfortunately, at this stage of the project, we cannot reveal the chemical name of Substance X. Stay tuned for results.)

Introduction

The development of a sustainable business model with social and consumer acceptance makes it necessary to develop new strategies and tools to guarantee the growth, health, and well-being of farmed animals. In this context, the introduction of new ingredients and feed additives has managed to improve not only the productive performance but also improve the sustainability in the production of feed. In the recent years, the use of yeasts has shown to be a good health modulator and growth enhancer. However, these probiotic effects depend on several factors like the type of species, sources, and feed level inclusion. Among the most used species, *Debaryomyces hansenii* (CBS 8339) is an efficient probiotic in marine fish aquaculture. Among its reported properties are: i) immunostimulatory effects, ii) gut microbiota modulation, iii) enhanced cell proliferation and differentiation, and iv) enhancement of the digestive function. However, less is known about its effects on mucosal health, and specifically on the gut and skin mucosa, the main defensive tissues of fish.

Materials and methods

- Diet composition

To evaluate the effects of *D. hansenii* as a probiotic in aquafeeds, two diets were formulated with similar levels of protein content (48.4% crude protein), lipid content (17.2% crude fat), and energy levels (21.7 MJ/Kg gross energy). The diets were formulated with low levels of fishmeal (7%), which only differed in the inclusion of *D. hansenii* (CBS 8339) at an inclusion rate of 1.1% (17.2 x 10⁵ cfu). *D. hansenii* was provided by CIBNOR (La Paz, Mexico) and grown as described in Tovar et al. 2021.

- Experimental Model and Design

A total of 500 *S. aurata* juveniles (body weight, BW= 14.5 ± 1.2 g; mean ± SD) were obtained from a commercial farm (PISCIMAR S.L.; AVRAMAR, Burriana, Spain), and acclimated in in two tanks of 2,000 L connected to a IRTAmar® recirculating system under natural conditions. The trial lasted 70 days, 200 fish (25 fish per tank; 4 tank replicates per diet), during which fish were fed at 3.5% of the stocked biomass by means of automatic feeders, monitoring the temperature, salinity, and uneaten pellets daily, and the nitrogen-derived compounds weekly.

- Transcriptional Analysis

Total RNA from the anterior-mid intestine and skin of nine randomly selected fish per dietary treatment (n = 3 fish per tank) was extracted and analysed as described in Reyes-Lopez et al., 2021. Microarray Hybridization and Analysis from both experimental groups was carried out using the Aquagenomics Sparus aurata Oligonucleotide Microarray v2.0 (4 x 44 K) (SAQ) platform, and detailed information and transcriptomic raw data are available at the Gene Expression Omnibus (GEO) public repository at the US National Center for Biotechnology Information (NCBI), accession numbers GPL13442, and GSE162504, respectively.

- Statistical analysis

Data on growth and feed performance indicators are expressed as mean ± standard deviation. Following confirmation of normality and homogeneity of variance, an ANOVA was performed followed by the Tukey’s multiple range test when statistically significant differences were detected among experimental groups (p < 0.05).

(Continued on next page)
Results and Discussion
After 70 days of a nutritional trial in which a diet with low levels of fishmeal (7%) was supplemented with 1.1% of D. hansenii (17.2 × 10⁵ CFU), an increase of ca. 12% in somatic growth was observed together with an improvement in feed conversion in fish fed a yeast-supplemented diet. Considering that feeding costs represent up to 50%–70% of total production costs in intensive fish farms (Rana et al., 2009), and fishmeal being amongst the most expensive raw materials in aquafeeds (Tacon et al., 2008), the nutritional strategy tested in our study with the supplementation of a live probiotic seemed very promising when KPIs related to growth and feed utilization were considered. In addition to those findings, the microarrays-based transcriptomic analysis found 232 differential expressed genes (DEGs) in the anterior-mid intestine of S. aurata (mostly related to metabolic, antioxidant, immune, and symbiotic processes), and 712 DEGs in the skin (mostly related to metabolism and immunity, mainly with a specific barrier function). Angulo et al. 2020 reported that D. hansenii supplementation promote gut protection in several aquatic and terrestrial species at immunological and gene expression levels, which agree with our results in terms of gut and skin gene expression. In that sense, it has been postulated that D. hansenii might modulate host’s immunity through its wall-related β-glucan, mannan and polyamine content, increasing functional and decreasing deleterious immune responses in fish (Reyes-Becerril et al., 2011; Fernández-Montero et al., 2019).
Thus, these results support the dietary administration of D. hansenii as an excellent tool to promote the gut and skin mucosa defensive capacity, the first line of fish defense against environmental and biotic challenges, when included in low fish meal based diets for S. aurata.

Introduction
Nowadays aquaculture provides animal protein of quality for human consumption, necessary to maintain the high world population, thus supporting fisheries production constrained by overexploitation of fishing grounds (FAO, 2022). However, it is important to produce it in a cost-effective and sustainable way. Since 2012, biochar (i.e., activated carbon) is starting to be included in animal feed (Gerlach & Schmidt, 2012). Biochar is obtained by pyrolysis from organic waste in a low-to-no oxygen thermal process, reusing by-products from other industries (European Biochar Foundation - EBC, 2012). This product has been shown to improve nutrient intake efficiency, absorb toxins and generally improve animal health besides improving the quality of the effluent water (O’Toole et al., 2016; Toth and Du, 2016; Schmidt et al., 2019), making it a good candidate for its inclusion in aquafeeds. This study aims to test the putative improvement produced by the dietary inclusion of biochar in Senegalese sole, a species of great interest in Spain.

Material and Methods
A total of 135 Senegalese sole juveniles (initial body mass, ~41.13 g) were distributed in an open system circuit with 9 tanks of 500 L, which constituted the 3 experimental groups (in triplicate): i) Control group (CT) fed with a control diet mimicking the commercial formulation for this species; ii) group fed 0.5% Biochar (B0.5), introducing 5 g biochar/kg control feed and iii) group fed 2% Biochar (B2), introducing 20 g biochar/kg control feed. After 180 days of the feeding trial, a biometric sampling was done, and samples from plasma, liver and muscle were taken. Somatic and zootechnical indices were calculated, and samples from each tissue were analysed.

Results and Discussion
No significant differences were observed in the final body mass among experimental groups, although B2 group showed a clear a positive trend towards related to the significantly higher feed efficiency obtained. Therefore, it can be suggested that in a longer feeding trial, greater growth could be obtained in the group with the highest inclusion of biochar (B2), as obtained in previous studies in other species, indicating a growth performance improvement due to increased feed efficiency (Lan et al., 2018). In terms of organosomatic indices, only the intestine length index (ILI) showed different, with a dose-dependent decrease, being significant in the B2 group respect to the control fish. These results are in controversy with other studies with low inclusion of nutraceuticals derived from microalgae, which obtained an increase in the intestine length by increasing the dose, possibly due to lower digestibility of the compounds (Perera et al., 2020; Molina-Roque et al., 2022). However, biochar seems to facilitate the digestive processes, producing an intestine shortening, and agreeing with other authors who suggested that biochar could facilitate the formation of biofilms as habitat for gut microbiota which could be the reason for the improved growth rates (Lan et al., 2018; Schmidt et al., 2019). Regarding intermediary metabolism, the results showed a reduction of all plasmatic metabolites with the biochar inclusion (even at the lowest inclusion), suggesting a decrease in plasma metabolite mobilization or even an increased metabolite consumption. Respect to energy reserves, fish fed biochar-supplemented diets maintained homeostatic levels in the liver, but not in the muscle, which may be associated with the higher (but physiological) levels of cortisol detected, also in a dose-dependent manner, causing energy mobilization from this tissue and not allowing its accumulation in the muscle. This hypothesis also explains the dose-dependent increase in muscle lactate by glycolysis, which could be transported to the liver for acting as a lactate sink (Milligan and Girard, 1993).

DIFFERENT WATER SALINITIES IMPACT MICROBIOTA DYNAMICS OF RAS SYSTEM AND BARRAMUNDI (Lates calcarifer) DIGESTA UNDER TEST DIETS SUPPLEMENTED WITH THE MARINE MICROALGAE Microchloropsis gaditana

P. Sánchez-Cueto¹*, M. Bosch¹, G.M. Cusimano², T. Bardócz², S. Lladó¹

Introduction
Barramundi (Lates calcarifer) is a euryhaline fish species considered as an ideal model for optimizing aquaculture production based on resource availability [1]. Its adaptability to a wide range of water salinity is attributed to various evolutionary and physiological adaptations [2], that are expected to be accompanied also by changes in the host-environment microbiota [3]. In this study, our objective was to assess the extent to which different water salinities can influence both environmental and fish microbial communities, focusing on potential changes induced by the supplementation of Microchloropsis gaditana in the test diets.

Materials and Methods
The trial was carried out in two independent recirculating aquaculture systems (RAS) of 6X500L tanks each at AquaBioTech Group. Asian seabass, Lates calcarifer (50 fish/tank; initial weight of 64.9 ± 0.1g) were reared at two different salinities, 38+/-2ppm (S1) and 14 +/- 2ppm (S2). Fish in both systems were fed four times daily to satiation with either a control diet (CTRL) or the CTRL diet supplemented with M. gaditana liquid extract top coated at 3% (W/V) (ALG). Samples of fish digesta, sludge, surrounding and inlet water, and the biofilter were collected at the beginning of the trial, after 5 weeks and at the end of the growth phase (10 weeks) and characterised for bacterial populations. Bacterial diversity was assessed through 16S rRNA sequencing. Raw data were processed with QIIME2 and taxonomy analyses performed with R software.

Results
The characterisation of the samples showed that water salinity significantly impacted the environmental and fish microbiota composition, independently of the diet applied (Fig. 1). Environmental bacterial communities were observed to exhibit an increase of different potential probiotics genera depend on the salinity, being the genus Ruegeria increased under the S2 and the genus Pseudoalteromonas under the S1. Member of these genera were characterized by their antagonistic effect against Vibrio pathogenic strains and their involvement in protein utilization. Albeit the bacterial communities within the digesta exhibited differences from those in the environment throughout the experiment, an increase in the Ruegeria genus was also observed in fish subjected to S2 conditions. Nevertheless, the Mycobacterium or Legionella genera were found to be significantly increased in the same fish stock under S2 conditions. Both of these genera contain high pathogenic strains for fish and humans (e.g. Mycobacterium marinum, Mycobacterium tuberculosis, Legionella pneumophila). In terms of growth, the variation in salinity, diets and microbiota composition did not show a significant impact.

Fig 1. Beta diversity Principal Coordinate Analysis (PCoA) computed upon the Bray-Curtis index. Samples have been colored and grouped by the salinity condition; different shapes were used in terms of the diet utilization. Significant correlated phyla (p < 0.001) with bacterial communities changes were represented by arrows.

(Continued on next page)
Conclusion
This aquaculture microecology research provided has offered comprehensive insights into the independent dynamics of the barramundi digestive tract and the microbiota associated within the RAS system. Despite being strongly affected by the water salinity level, the microbiota, which did not experience significant changes under the *M. gaditana* supplemented diet, has no measurable effects on barramundi growth. Further studies on the dynamics between probiotics and potential pathogenic strains in waters with widely varying salinities should be conducted in order to ensure the safety of culturing euryhaline species.

Introduction
In aquaculture, as in others economic activities, the main objective is to obtain the maximum possible economic benefit. For this reason, several studies have focussed on the influence of an increase in density, considered as a stressful situation, on the growth and physiology of farming specimens (e.g. Montero et al., 1999 in Sparus aurata; Laiz-Carrion et al., 2012 in Pagrus pagrus). It is known that stress situations cause the activation of the HPI axis with the release of cortisol as the end product (Schreck and Tort, 2016). If this situation is maintained, it will lead to chronic stress that will decrease welfare, and for instance also appetite, feed efficiency and feed conversion ratios (Arends et al., 1999; Montero et al., 1999; de las Heras et al., 2015; Skrzynska et al., 2018). In this sense, it is known that crowding situations cause these responses in terms of performance, but it is unknown how much stress is related to this decrease in feed intake and how much to crowding per se. Our study proposes to determine the effect of stocking density in terms of growth, metabolism and welfare, discriminating the metabolic orchestration derived from the reduction in feed intake.

Material and Methods
A total of 371 gilthead sea bream juveniles (initial body mass, ~ 31.3 g) were distributed in an open system circuit with 9 tanks of 400 L, constituting 3 experimental groups (in triplicate): i) Low Stocking Density (LSD) fed ad libitum with an initial density of 3.6 Kg/m3; ii) High Stocking Density (HSD) fed ad libitum with an initial density of 38 Kg/m3 and iii) Low Stocking Density Pair Feed (LSD-PF) with the feed intake of HSD fish set at LSD. After 90 days of the feeding trial, a biometric sampling was done, and samples from plasma, liver and muscle were taken. Somatic and zootechnical indices were calculated, and samples from each tissue were analysed in terms of metabolism and welfare.

Results and Discussion
Significant differences were observed in the final body mass of fish between treatments, being statistically lower in the HSD group from the third week of the experiment. The condition factor (K), feed efficiency (FE), weight gain (WG) and specific growth rate (SGR) were also lower in this group. However, LSD-PF group maintained the same growth potential as LSD with less feed conversion rate (FCR) and feed intake, thanks to an improvement in feed efficiency, as observed in previous studies, indicating a growth performance improvement by optimizing digestive processes (de las Heras et al., 2015). In terms of somatic indices, only the hepatosomatic index (HSI) presented significant differences, with a decrease in HSD group respect to LSD, related to the lower hepatic glycogen reserve (see below). A metabolic orchestration, due to the lower feed intake situation, were observed in the LSD and HSD-PF groups, which could be related with i) a decrease in plasmatic mobilization of metabolites, ii) the major consumption of them, or even iii) after reaching a homeostatic load during the medium/long-term feeding trial (TAG, cholesterol and proteins). Regarding to energy reserves, fish under HSD condition maintain homeostatic levels of hepatic and muscle TAG, but not in hepatic glycogen, which may be associated with the increased levels of cortisol detected (although not significant) that could cause energy mobilization and stimulating mainly carbohydrate metabolism to cope with stress. This trend also explains hepatic lactate decrease in HSD group, as it has been demonstrated to be used to produce energy by gluconeogenesis in the liver through the Cori cycle (Perera et al., 2020). Therefore, with the present experimental approach we can suggest that the metabolic modifications (and growth performance) that occur under high stocking densities previously demonstrated (e.g. Skrzynska et al., 2018), are mainly produced by crowding chronic stress, but with a certain contribution of decreased feed intake.

**Introduction**

Finding novel sustainable feed ingredients for the aquaculture industry is crucial to reduce the climate footprint and increase the production volumes in this industry. Marine by-products such as viscera, head, skin, backbone and cut-offs from fish are local and sustainable raw materials for feed production. Enzymatic hydrolysis of by-products facilitates use of hydrolyzed proteins as feed ingredients for the same species as it came from (Council Regulation (EC) No 142/2011, 2011). The aim of this study was to partially replace fish meal with salmon hydrolysate in feed for post smolt Atlantic salmon, and evaluate the effects on growth, digestibility and gut health. Salmon hydrolysate was also characterized and analyzed for prion content by proteomics.

**Materials and methods**

Salmon protein hydrolysate was produced by Nutrimar AS by enzymatical hydrolysis of salmon by-products followed by separation, concentration and spray drying of the liquid hydrolysate. The high molecular weight peptides in the hydrolysate was concentrated by dialysis (10 kDa cut-off) and analyzed for salmon prion protein content by targeted and shotgun proteomics analysis with LC-MS/MS. A feeding trial with Atlantic salmon (Salmo salar, Rauma strain, mean weight 141.5 g) post smolts was conducted to test isonitrogenous diets with different levels of salmon hydrolysate (FPH) replacing fish meal (FM) protein. The control diet with 30 % FM was compared with test diets containing 20 % FM with 9 % FPH (FPH-09), and 10 % FM with 18 % FPH (FPH-18). Atlantic salmon were fed until doubling of weight before collecting intestinal samples for histological evaluation of gut health as described in (Nordvi et al., 2023). Digestibility was examined by stripping feces and analyzing for protein, fat and ash content compared to inert yttrium oxide added to the diets.

**Results and discussion**

Proteomics analysis of the salmon hydrolysate used in this feeding trial did not detect any salmon prions. Salmon protein hydrolysate (FPH) increased the initial specific growth rate (SGR) significantly compared to the FM control diet (Figure 1). This is probably due to attractant effect of free amino acids and peptides that stimulate feed intake (Kousoulaki et al., 2018). The FM fed salmon showed compensatory growth by having the highest SGR in the second growth period (day 25-58). The weight difference was not significant after 58 feeding days but the stimulatory effect on feed intake is still industrially relevant for the sea-transfer phase and other changes in feed during fish farming.

The salmon hydrolysate amino acid profile is excellent for salmon in addition to being highly digestible as peptides. The apparent digestibility of protein was significantly higher in the FPH-18 diet compared to the other diets (Table 1), likely due to the free amino acids and peptides in the salmon hydrolysate (Hevrøy et al., 2005). Interestingly, the apparent ash digestibility increased linearly (p < 0.001) with increasing FPH content (Table 1). Histological analysis of midgut and hindgut from salmon fed the FM and FPH-18 diets did not reveal any significant differences between the diets, and the intestines looked normal and healthy.

**Conclusion**

Salmon hydrolysate is a promising novel feed ingredient for Atlantic salmon, due to its high protein digestibility and attractant effect that stimulates feed intake and growth. Atlantic salmon fed 9 % and 18 % salmon hydrolysate showed higher initial growth rate compared to a 30 % fish meal control diet in this feeding trial. Including 18 % hydrolysate in the diet significantly increased the protein digestibility, and the ash digestibility increased linearly with the hydrolysate inclusion level. Morphological analysis of gut samples revealed no significant differences among the diets. No salmon prions were found in the hydrolysate used in this feeding trial.

(Continued on next page)
Figure 1: Mean (n = 3) specific growth rate (SGR) in the first 25 feeding days (left) and last feeding days (middle). Mean weight (g) as a function of feeding days (right) for the different feeds: Fishmeal (FM) control diets, 9 and 18 % salmon protein hydrolysate (FPH-09 and FPH-18, respectively). The SGR calculations are based on individual fish (that were PIT tagged). The error bars represent standard error (SEM) and the significance is presented as different letters based on p-value 0.05 from a nested One-way ANOVA analysis.

Background
Some fishes including salmonids have a coronary circulation that supplies the outer compact myocardium of the heart with fully oxygenated blood. This arterial blood supply complements the luminal venous O\textsubscript{2} supply that delivers relatively poorly oxygenated blood to the inner spongy myocardium. The role of the coronary circulation may be of particular relevance in farmed salmonid fishes, as our group (and others) have shown that they more frequently develop lesions and arteriosclerosis in the main coronary artery; a condition that narrows the vessel lumen and may decrease blood flow to the myocardium (Brijs et al, 2020; Farrell, 2002). This condition can, in turn, reduce overall cardiac and metabolic performance, and possibly the tolerance to environmental stressors that incur an elevated metabolic challenge. There is also a growing body of evidence demonstrating that coronary lesion development is positively correlated with factors promoting rapid growth in the smolt production phase (e.g., supra-optimal rearing temperatures; Brijs et al, 2020), and may be a key factor underlying adult fish mortality in aquaculture (Poppe et al, 2021). Yet, it is still not fully understood how coronary blood flow affects overall cardiorespiratory performance. Moreover, its functional role in setting tolerance limits to environmental extremes such as heat waves and hypoxia, and how it affects resilience to stressful metabolic challenges in aquaculture, has not been extensively studied. Thus, to analyze the functional significance of coronary oxygen delivery in salmonids, we measured \textit{in vivo} coronary blood flow under various thermal regimes in male and female rainbow trout (Ekström et al, 2017). In an additional series of experiments, we surgically ligated the coronary artery to mimic extreme coronary arteriosclerosis and explored its impact on cardiovascular performance and metabolic scope (Ekström et al, 2017; Morgenroth et al, 2021), as well as hypoxia and warming tolerance limits (Ekström et al, 2019; Morgenroth et al, 2021).

Material and methods
Fish were anesthetized in aerated freshwater (10°C) containing buffered MS-222. In one experiment, the coronary artery was dissected free and a Transonic transit time blood flow probe was placed around the vessel. In other experiments, the vessel was exposed and either ligated with a silk suture or left intact resulting in surgically ligated and sham operated experimental groups, respectively. In some experiments, sham and ligated fish were additionally instrumented with a flow probe around the ventral aorta to measure cardiac output or custom-made subcutaneous electrodes to record the electrocardiogram (ECG) and heart rate. Fish were typically left to recover from surgery for 24-48 h in respirometers to record oxygen consumption rate and then exposed to various metabolic and environmental challenges including exhaustive exercise, acute warming and aquatic hypoxia.

Results and Discussion
Routine coronary blood flow at 10°C was markedly higher in females than males (0.56±0.08 vs. 0.30±0.08 ml min\textsuperscript{-1} g\textsuperscript{-1} ventricle). Warming increased coronary blood flow in both sexes until 14°C, at which it peaked and plateaued. This meant that the scope for increasing coronary blood flow during warming was 101% in males, but only 39% in females. While coronary ligation reduced routine stroke volume relative to sham operated trout with intact coronaries, cardiac output and standard metabolic rate was maintained via an increase in heart rate. However, coronary ligated trout had reduced maximum oxygen consumption rate and aerobic scope when subjected to a 5 min exhaustive exercise protocol, and they had a markedly reduced ability to increase stroke volume to maintain cardiac output when bradycardia developed during acute hypoxia exposure. This was associated with a slightly reduced hypoxia tolerance in coronary ligated trout. During acute warming, coronary ligation caused cardiac function to collapse at lower temperatures and significantly reduced the overall acute warming tolerance relative to sham operated trout with intact coronaries.
Conclusion
Collectively, our findings show that coronary perfusion improves cardiac $O_2$ supply and overall cardiorespiratory function at environmental extremes, which benefits tolerance to environmental and anthropogenic metabolic challenges. The aquaculture industry should, therefore, consider the potentially detrimental effects of rapid smolt growth rate on coronary health and functionality, as this may result in raising fish that are more susceptible to environmental and metabolic stressors in challenging farm environments. In light of these findings, we are currently conducting several new experiments to shed light on how juvenile rearing conditions subsequently impact cardiac and coronary health of the adult fish.

Introduction

Fish sedation may help to secure fish health, welfare, preventing damages and negative side effects, when carrying out some farming procedures such as fish selection, transportation, vaccination and fish handling. To supply a slight sedation, or synthetic and natural (plant-based) sedative can be used. For aquaculture industry, the use of plant-based sedative has become a suitable alternative to the synthetic product, being more appreciated by the consumers and potentially claiming a reduced environmental impact (Aydın & Barbas, 2020). Lemon balm (Melissa officinalis) is well-known for its pharmacological effects. It contains different classes of phytochemicals, such as polyphenolic compounds which have many biological properties, including antioxidants, anti-anxiety, antidepressant and neuroprotective properties. Moreover, this plant affects the nervous system decreasing the symptoms of neurological disorders such as sleeping disorders, stress, anxiety, and irritability (Petrisor et al., 2022). Among mineral feed additives, MgCl₂ is use as relaxant for research and commercial applications because it acts as a calcium channel blocker, preventing calcium ions (Ca²⁺) from entering the cells and blocking the release of acetylcholine (Azizan et al., 2021). Also, zebrafish (Danio rerio) has emerged as a model in neurobehavioral research; there are several studies that examined zebrafish behavior and their response to different drugs and sedatives products. The aim of the present study was investigating the potential toxicity and sedative effects of a commercial blend of Melissa Officinalis and soluble magnesium (AFI calm prototype®, Artic Feed Ingredient AS, Norway), on zebrafish larvae and adults.

Material and methods

The experimental procedures were approved by the Animal Welfare Board of the University of Pisa and the Italian Ministry of Health (B290E.N.0F7.). The study consisted of two trials, the first carried out on zebrafish larvae and using 5 different water concentration of AFI calm prototype® (0-, 0.5-, 1.0-, 2.0-, and 4.0- ml L⁻¹). Since the 2nd day post-fertilization (dpf) onwards, the larvae were exposed to the solution and on 5th dpf tested for locomotor behavior (distance moved, velocity, movement cumulative time) using DanioVision® (Noldus®, The Netherlands). Based on the observed results, the second trial was carried out on 260 adult zebrafish. Four treatments (CTRL, CTRL-R, T1 and T2) and three different AFI calm prototype® water concentration (0-, 1.0- and 2.0- ml L⁻¹) were used. On the 3rd, 6th, 9th day of treatment, fish behavior was tested using the Novel Tank Test (NTT). Two video cameras were used for recording fish behavior from the side and the upper view. This latter camera was connected to a pc and video elaborated by Ethovision XT 16® software (Noldus®, The Netherlands). Moreover, after 3 days of suspension of the treatment, all the fish were tested once again for evaluating the recovery time. Finally, for groups CTRL, T1 and T2 the same individuals were tested at each time point, while in order to highlight possible inurement test effect, for CTRL-R group naïve fish were used. Each NTT lasted 4 minutes and each minute was analyzed both individually and as a whole period.

Figure 1a, 1b and 1c: Zebrafish larvae behavior performances of the different treatments

Figure 2a, 2b, 2c: Zebrafish adult behavior performances of the different treatments

(Continued on next page)
Results
The test carried out on zebrafish larvae showed toxicity effect and reduced larvae survival rate only when 4.0 mL L\(^{-1}\) water concentration was used (44±32 %). Locomotor performances showed sedative effect already at 1.0 mL L\(^{-1}\), with a dose-dependent effect (Fig. 1a, 1b, 1c). Based on locomotor performances, no sedative effects were observed on adults on 3\(^{rd}\) and 6\(^{th}\) days of treatment. Effects were detected on 9\(^{th}\) day of treatment at 2.0 mL L\(^{-1}\) concentration and on 4\(^{th}\) bin (4\(^{th}\) minute of test) fish of the treatment T2 showed higher exploration attitude than T1 in terms of distance moved (645.80±303.48 and 332.40±359.59 cm, respectively), movement cumulative duration (45.61±18.66 and 30.37±25.16 s, respectively) and velocity (11.29±5.27 and 5.79±6.25 cm s\(^{-1}\) respectively). Moreover, at 9\(^{th}\) day of treatment, T2 showed shorter latency time to reach the top section of the water column and spent more time exploring this section of the tank than T1 (Fig. 2a, 2b). Also, T2 entered more time the upper section of the water column than T1 and CTRL (Fig. 2c). Furthermore, at 9\(^{th}\) day of treatment, CTRL-R showed shorter latency time to enter, and spent more time exploring the upper section of the water column than CTRL and T1 (Fig. 2a, 2b); CTRL-R, also showed more entries to the upper section of the water column than T1 (Fig. 2c). Finally, at recovery CTRL-R showed a shorter latency time to enter the upper section of the water column than CTRL and T1 (37.74±64.90, 16.86±35.10 and 14.50±18.21 s, respectively).

Conclusion
The water exposure of zebrafish larvae to 1.0 mL L\(^{-1}\) and 2.0 mL L\(^{-1}\) of the tested herbal and Mg blend, showed no negative effects on larvae survival rate and induced lower locomotor performances. Similarly, adult zebrafish exposed for 9 days to 2.0 mL L\(^{-1}\) of the tested herbal and Mg blend, showed more capacity to cope with the stress supplied through the NTT test, demonstrated also by an increased environment exploration attitude. Repeatedly supplying the NTT stressor, induced in fish a certain grade of habituation. Hence, the observed results (CTRL-R group) support the hypothesis that the exposure to the herbal and Mg blend may reduce the stressor sensitiveness of fish through the sedation effect. These results open to interesting applications in the aquaculture sector. Despite that, it might be of great interest investigating about the possible administration of the sedative compounds through the inclusion in aquafeeds.

Introduction
β-glucans are polysaccharides extracted from bacteria, fungi, yeast, algae, and plants. They have several biological activities and function, including immunomodulation, antioxidation and metabolic regulation (Ma et al., 2021; Liu et al., 2022). To promote fish health and reduce the use of antibiotics and/or other drugs, immunostimulant dietary supplementation has been proved a powerful tool (Liu et al., 2022). In mammals, β-glucans immunomodulatory effects are largely studied, and more recently particular attention has been given to the use of β-glucan in fish diet (Hadiuzzaman et al., 2022). Zebrafish has been widely used as a model organism for aquaculture nutrition research (Ulloa et al., 2014), such as fishmeal replacement (Barca et al., 2023), dietary nutraceutical effects, interactions between gut microbiota and dietary additives (Imperatore et al., 2023). The zebrafish model is a valuable model to directly observe the immune cell function (Sanderson et al., 2015; Kaveh et al., 2020). Zebrafish larvae are optically transparent, this allowing in vivo observation of specific cell populations (López Nadal et al., 2020). The fish gut is a physical barrier to pathogen entry and host the gut-associated lymphoid tissue (GALT) (Salinas & Parra, 2015). The gut has the largest aggregation of immune cells of the vertebrate body and zebrafish GALT include macrophages and neutrophils (Hadiuzzaman et al., 2022). These immune cells play a role in the inflammatory immune response of most fish species against different gut parasites (Salinas & Parra, 2015). Macrophages are essential effector cells in the immune response to injury, infection, and disease. They take on a different phenotype based on their activation state, which can be proinflammatory (M1) and anti-inflammatory (prohealing, M2) (McWhorter et al., 2013). M1 and M2 phenotypes can be distinguished by a different cell elongated shape, indeed M2 phenotype is characterized by a more elongated cell shape than M1 phenotype (McWhorter et al., 2013). Tg(coro1a:eGFP;lyz:DsRed) is a double transgenic zebrafish line, in which macrophages and neutrophils can be distinguished by green and red fluorescence, respectively. Microglia/macrophages express eGFP only and neutrophils express both eGFP and DsRed (Li et al., 2012). For this reason, Tg(coro1a:eGFP;lyz:DsRed) are a powerful tools for studying the effects of dietary interventions on macrophage activation status with the aim of improving fish health in aquaculture (Sanderson et al., 2015).

Material and methods
Five treatments were carried out on 24 hpf (hours post-fertilization) zebrafish larvae until they reached 120 hpf. The Tg(coro1a:eGFP;lyz:DsRed) double transgenic zebrafish line was used. Forty-five embryos per treatment (3 replicates each) were exposed to 5 different water concentrations (0-, 200-, 20-, 2-, and 0.2- ml L−1; CTRL, T1, T2, T3, T4, respectively, of 1,3-1,6 β-glucans (Glucan+, Arctic Feed Ingredients, Norway). On 48 hpf, egg hatching rate was determined and larva survival rate on 120 hpf. Moreover, at 120 hpf imaging of live anaesthetized larvae was performed using confocal microscopy (Axio observer, Zeiss©) of the mid- and hind- gut portion. Microphages number and activation status was then assessed on confocal images using Zeiss Zen Lite 3.7© software. Moreover, M2 phenotype percentage on the total number of macrophages was calculated and statistically analyzed (Chi2 for hatching rate; One-way ANOVA and HSD Tukey Test for % survival rate, total number of macrophages and % of M2 on total macrophages).

Results
No differences were observed for larvae hatching and survival rate (Figure 1 and Figure 2), this meaning that at the tested β-glucans concentrations no toxicity effects were detected. Also, no differences were observed for total number of macrophages (Figure 5). The images analysis showed that the two different macrophage phenotypes (M1 and M2) were present (Figure 3 and Figure 4) in all the treatments. Significant difference (* p<0.05) between CTRL an T2 was observed for M2 activated macrophages (7.96±10.43 and 44.15±25.43 %, respectively) (Figure 6). Moreover, all treatments exposed to β-glucans showed higher incidence of macrophages in the M2 state of activation in comparison to the CTRL group (Figure 6).

(Continued on next page)
Conclusion
The 1,3-1,6 β-glucans water exposure of zebrafish larvae showed no negative effects on larval hatching and survival rate at the tested concentrations. Already at the lowest β-glucans concentration used, the total number of macrophages was higher than in the control group. Moreover, the number of macrophages at the M2 activation state were mostly present in larvae exposed to β-glucans being significantly higher when larvae were exposed to 20.0 ml L\(^{-1}\). Thanks to the use of Tg(corol1a:eGFP,lyz:DsRed) zebrafish line, it was possible to assess the macrophages activation status induced by dietary β-glucans in fish. These findings suggest that the exposure to 1,3-1,6 β-glucans enhance the intestinal immunity already at early developmental stage of fish (120 hpf larvae) with that promoting fish immunity, welfare, disease resistance and, ultimately, aquaculture production efficiency. Hence, it is of great interest to carry out further investigation on the mechanism of macrophage phenotype (M1 and M2) polarization induced by 1,3-1,6 β-glucans, in addition immune performances of the treated fish.

Because aquafeed accounts for up to 70% production costs and up to 80% of a producer’s environmental footprint, the opportunity for more sustainable aquaculture is closely linked to availability of sustainable raw materials. Recent aquafeed price increases of up to 30% reflect in part the limited raw material basket, and the fact that our drive to extend this basket with novel, more sustainable proteins is only partly successful.

Microbial or single cell proteins (SCP) are the frontrunner when it comes to emerging proteins. Fermentation technology have a massive potential for scalability and other advantages include factors such as shorter generation times, the use of different feedstocks or substrates, and minimum requirements for land. In addition, single cell proteins generally have a high protein content and contain all or most essential amino acids required by fish for growth and development.

Early prototypes of a single cell protein produced by researchers at the DSM Bioscience Centre in Delft, The Netherlands showed excellent performance comparable to feeds containing fish meal and soy protein concentrate. Rainbow trout were grown for 12 weeks on different inclusions of SCP ranging from 0%, 5%, 10% to 20% on extruded feeds, with single cell protein replacing a combination of fish meal and soy protein concentrate. The results showed that single cell protein inclusion leads to equal fish performance measured by final body weight.

Availability of novel raw materials rich in protein would bring with it stability of supply and economics as the aquaculture industry grows. Collaborating across the value chain is key to drive the continued sustainable production of aquaculture, every member of the value chain has a role to make this happen and enable production at scale of single cell protein.
EFFECTS OF WATER TEMPERATURE ON GROWTH AND DIGESTIVE PROCESSES OF THE THICKLIP GREY MULLET Chelon labrosus

Introduction

Water temperature is one of the most significant abiotic factors influencing fish energy partitioning and digestive capacity, which determines the amount of energy available for processes such as growth (Papoutsoglou & Lyndon, 1995; Nytrø et al., 2014). Knowing the optimal water temperature for the rearing of a given fish species is highly important from the productivity, nutrition and animal welfare points of view. The present work aimed to identify the optimal water temperature for the culture of the thicklip grey mullet Chelon labrosus, as well as to assess the effects of said temperatures on the activity and gene expression of its digestive enzymes.

Materials and methods

The fish (C. labrosus, N = 168, initial length 13.93 ± 0.96 cm, initial weight 32.09 ± 7.11 g) were distributed into 12 recirculating tanks (100 L), separated in four water temperature treatments (18, 22, 26 and 30 °C) with three replicates each. Fish were fed twice a day on a commercial feed (Gemma Diamond 1 mm, Skretting) containing 57 % protein and 15 % lipids for 90 days. Biometrical measurements (fork length and total weight) were recorded at days 0 (T0), 30 (T1), 60 (T2) and 90 (T3). At T1, 4 fish of each group were sacrificed and liver, muscle and gastrointestinal tract samples collected for biochemical composition, digestive enzyme activity and gene expression analyses. The same was done with the rest of the fish at T3.

Table 1: biometrical parameters and plasma, liver and muscle biochemical parameters of C. labrosus reared at different water temperatures at day 30 (T1) and 90 (T3). SGR = Specific Growth Rate; Gl = glycogen; Tg = triglyceride. Data are presented as mean ± standard deviation. Values highlighted in bold show significant differences (p < 0.05) between sampling times inside a given temperature treatment. Different superscripts represent significant differences (p < 0.05) between temperature treatments inside a given sampling time. Low letter superscripts: comparisons inside T1 sampling; capital letter superscripts: comparisons inside T3 sampling.

(Continued on next page)
Results and discussion

The best growth results were achieved at 22 °C, with a downwards trend at either side of the temperature spectrum (Table 1), although the only significant weight differences were observed at T3, between the 22 and 30 °C groups. This accurately reflects the dome-shaped growth curves typically caused by water temperature (Nytrø et al., 2014), due to the interaction between the acceleration of biochemical reactions, increases in feed intake (Davis & Hardy, 2022) and digestibility (Papoutsoglou & Lyndon, 1995), and the raise of basal metabolic demands (Kaushik & Schrama, 2022). In general, exposure to different temperatures did not produce changes in performance at the different samplings except the 30 °C group, as its SGR significantly improved at T3 when compared to T1. Even though this shows the ability of the fish to somewhat acclimate to this extreme temperature, it is still outperformed by the other groups. Our results suggest that the temperatures selected for the trial are at the upper part of the theoretical curve (except 30 °C), with the peak being close to 22 °C.

The group with the most energy reserves at both samplings, in term of carbohydrate and lipid contents (Table 1), was the 18 °C group. The fact that these fish did not grow as much as others despite their high energy availability indicates that at this temperature the metabolism of the fish is slower than at the other temperatures used, which causes a low energy expenditure and, concomitantly, growth. As already mentioned, the 22 °C group performed the best in terms of growth, which is reflected in containing lower energy reserves than the 18 °C group, suggesting that this group is expending much more energy, and directing it towards growth. This shows that this expenditure is not a sign of stress (Wendelaar Bonga, 1997). Energy reserves in the 26 °C group are similar or lower than in the 22 °C group, but with a slightly lower growth performance. It has to be taken into account that, in general, feed intake and digestibility increase alongside water temperature until a certain point (Papoutsoglou & Lyndon, 1995; Davis & Hardy, 2022), so groups 26 and 30 °C could have a higher energy and nutrient intake than the others. The fact that the 26 °C group did not reach the growth values of the 22 °C group, coupled with the theoretical higher availability of energy and nutrients, could indicate that 26 °C are stressful for the fish (Wendelaar Bonga, 1997), although not critically. In the 30 °C group, the lowest energy reserves and growth values were found, especially at T1, and even though they slightly improved at T3, it can be said that this temperature is out of the optimal range, and it is stressful for the fish (Wendelaar Bonga, 1997). Anyway, it is clear that raising the temperature above 26 °C could be dangerous for the well-being of the fish. The measurement of digestive enzyme gene expression and activity will help to clarify our observations. Nevertheless, those analyses have not been fully performed, and they will be key to shed some more light to the results obtained and draw conclusions that are more robust.

The welfare of cultured fish is of increasing concern for all stakeholders in the aquaculture sector. This rising interest is responsible for growing regulation at international level, as well as for the appearance of welfare standards in certification schemes. Concern for the welfare of cultured fish arises in part from ethical considerations based, for example, on the moral importance of caring for captive animals. Over and above this, good welfare potentially benefits all parties in fish culture. From an economic perspective, up to a point and in many cases, good production and good welfare go hand in hand, with poor welfare often impacting production-related traits. In addition, in some markets, there are premiums to be charged for fish cultured under welfare assurance schemes. Additionally, ensuring good welfare in farmed fish is an important aspect of job satisfaction for fish-farm workers. Finally, poor welfare often increases the adverse impacts of aquaculture on the environment, such as when appetite is suppressed in stressed fish which increases feed wastage into and pollution of the water surrounding farm cages.

Climate change is underway and is already having an impact in aquaculture, being set to alter profoundly the activity of fish farming, especially in open systems exposed to weather and climate such as pond and cage farming. Increasing our knowledge on cultured finfish biology and their diversity, as well as on welfare science will help us cope with the inevitable consequences of climate change.

The term ‘finfish’ (‘fish’ in what follows) refers to a great variety of animals that have little in common, except they are vertebrates that live in water, have fins and mostly respire using gills. More than 34,000 species of fish are recognized; less than 1000 are cartilaginous fish (elasmobranchs), the remainder being bony fish. The great diversity among teleosts in physiology, behaviour and ecology influences how they cope with environmental challenges. Additionally, there are also striking differences within a given species, associated with life history stage and among populations adapted to different habitats. In terms of coping style (or personality traits), for example, proactive and reactive animals flourish in different environments in the wild, proactive individuals being favoured when resources are abundant and predictable, population densities are high and predation is low, while reactive animals do best in the opposite conditions. This variability in personality traits is well documented to occur in farming systems and has clear implications for how well farmed fish adapt to aquaculture conditions, present and future.

To protect the well-being of farmed fish, much effort has gone into developing systems for improving fish health, directed at pathogen-induced diseases and other threats to health, such as malnutrition and injury. This is entirely appropriate because ill health is usually a powerful cause and indicator of poor welfare. This is not just because disease generates poor health and mortality, but also because survivors may experience welfare problems after the disease has passed. However, there are some interesting layers of complexity because 1) poor general welfare often makes fish more susceptible to disease, 2) disease treatments may also compromise welfare, 3) good health does not necessarily equate to good welfare and 4) poor health does not always equate to poor welfare.

Protection of fish welfare makes it imperative that climate changes are anticipated, and that coordinated action is taken before it becomes impossible to ensure that pond or cage-farmed fish have the environmental conditions they need for good welfare. It is more than likely that technological advances will allow not only a better understanding of farmed fish biology and their responses to farming contexts, but also the development of more adequate and effective welfare measures and their monitoring. This should include disease prevention (involving new diseases, emerging from climate change), precision fish farming, analysis of big data and more knowledge on positive welfare, for example.

Climate change is also likely to influence the range of species and strains of fish farmed in cages, in favour of those that are more tolerant of high temperatures and of environmental fluctuations. The welfare imperative here is to ensure that enough is known about the biology of the species and strains concerned to allow their welfare needs to be met, before intensive farming of such fish gets under way and lessons have to be learned by trial and error.

(Continued on next page)
Besides the expected steady increases of temperature, fish in exposed farming systems will also experience an increasing number of acute events such as storms, algal blooms and heatwaves, which can only have adverse effects on their welfare (Table I). Little can be done to protect fish against such events, except making good use of available computational tools to predict these accurately and to have systems ready and in place to protect them.

In conclusion, measures to mitigate the effects of climate change could include, for example, upgrades in cage design, making the stronger and submersible; preference for resistant fish strains and species; relocation of fish farms; and improvement of fish monitoring systems and weather forecasting. All these responses will be challenging, but the fact that production and economic goals will be pulling in the same direction as the demands of protecting welfare is one reason for optimism.

**Table I.** Some interrelated effects of increased temperature on key physiological systems in fish.

<thead>
<tr>
<th><strong>Neuroendocrinology</strong></th>
<th>Exposure to higher temperatures initiates neuroendocrine responses in the central nervous system, triggering release of corticosteroids and catecholamines. Chronically elevated plasma cortisol levels are costly, diverting energy from growth and reproduction and may result in morbidity and mortality.</th>
</tr>
</thead>
<tbody>
<tr>
<td><strong>Circulation</strong></td>
<td>Both acute and chronic high temperature reduce cardiac function due to altered ionic balance and decrease blood flow to brain, liver, kidney and intestine, compromising biological functioning generally.</td>
</tr>
<tr>
<td><strong>Respiratory metabolism</strong></td>
<td>Standard metabolic rate (SMR), the minimum oxygen uptake needed to sustain life, increases rapidly with temperature, while maximum metabolic rate (MMR), the maximum rate of oxygen uptake (e.g. during intense exercise), increases to a plateau and then falls. Therefore, aerobic scope (MMR – SMR), the energetic potential of an organism to accomplish all of its tasks, eventually falls, constraining various functions in fish even at non-lethal temperatures.</td>
</tr>
<tr>
<td><strong>Digestion</strong></td>
<td>Increased metabolic demands may increase food requirements. High temperature may also influence feed conversion efficiency and the digestibility of specific nutritional categories, potentially leading to malnutrition.</td>
</tr>
<tr>
<td><strong>Iono-regulation</strong></td>
<td>Temperature change results in net ion loss in freshwater fish; the opposite occurs in seawater fish. The resulting ionic imbalances impair synaptic transmission in the central nervous system, with negative effects for general physiological functioning, amplified by rising salinities during droughts. Thus, maintaining the hydromineral balance becomes an increasing metabolic drain.</td>
</tr>
<tr>
<td><strong>Immunology</strong></td>
<td>Temperatures above the species’ optimum have numerous adverse effects on immune function due to stress and increased maintenance costs are limited as energy is diverted to homeostasis. Impaired immune function at higher temperatures reduces the ability of fish to fight pathogens.</td>
</tr>
<tr>
<td><strong>Reproduction</strong></td>
<td>Deviations from optimal temperatures have numerous effects on sex ratios and the timing of and investment in reproduction in fishes, with implications for reproductive success in breeding fish. Early maturation in fish farmed for food has negative effects on welfare.</td>

Fish are now widely recognised to be sentient animals. Good welfare practices are therefore not only ethical, but they also are demonstrated to improve fish quality and may even drive consumer choice. A critical point in the life of a captive fish is the final stages of their production. Not only this moment has the risk of dramatically affecting the welfare of the individuals, but it can also cause serious economic impacts to the farm, since the slaughter process can affect meat quality and carcass appearance. The most common method to slaughter fish (including trout) is by asphyxia either in ice-water or in the open air. However, this method induces prolonged and intense suffering, which is a poor practice in ethical, commercial, and legal terms. To achieve a humane slaughter practice, a stunning method needs to be implemented before slaughter, and it must render the fish immediately unconscious until death. In this regard, electrical stunning prior to slaughter has been proposed as a humane stunning method for trout, although there are anecdotal reports of trout carcass and fillet damage, with consequent decrease in value. In this experiment we tested a newly devised temperature stunner, in which the fish were immersed in water that achieves water temperatures of -8°C still in liquid state. The objective was to evaluate and compare the effectiveness and welfare effects of four types of stunning methods in rainbow trout *O. mykiss*: cold shock by fast-chilling (FC) as a novel method, asphyxia (ASP) as the current method, electrical stunning (ES) as a humane method, and anaesthesia with MS-222 (AN) as a positive control. We used a multi-level approach to address the welfare of 176 juvenile trout, combining behaviour (individual swimming activity, equilibrium, opercular movement and eye-roll), physiology (heart rate and amplitude of electrocardiogram signal) and stress biomarkers (plasma cortisol and osmolality), and proteomics. We then proceeded to analyse the effects on shelf-life fillet and quality of fish subjected to each of these methods, using a wide range of indicators (namely rigor mortis, water content, fillet colour, pH and ATP degradation). This is, to our knowledge, the most detailed assessment of rainbow trout welfare at slaughter.

Behavioural indicators showed that ES presented quick and effective induction of unconsciousness (i.e., absence of all consciousness indicators in 20s), while AN was slower yet 100% effective. Fish subjected to FC showed signs of extremely poor welfare (e.g., gill haemorrhage, brain damage, eye freezing and thawing, heavy mucus release) and this method was not only ineffective (only 13% lost consciousness) but also inconsistent (they recovered consciousness quickly). ASP also induced extremely poor welfare, with fish dying slowly (up to 20 min or more) and maintaining consciousness until death in 44% of cases.

Physiology indicators showed that ES had higher osmolality than AN, while ASP higher osmolality than AN and FC. Fish subjected to ASP had higher cortisol levels than AN, while ES and FC showed large variation in this hormone level. Regarding electrocardiogram signal, ES presented stronger heartbeat than ASP, while AN showed stronger heartbeat than ASP and FC. No differences were found in heart rate.

Regarding proteomics, FC and ASP had the highest impact on the brain proteome with bimodal effects. On one hand, FC registered a significant number of reactions, biological and metabolic processes. On the other hand, ASP results suggest suppression of the coping mechanisms and therefore an allostatic cost that may infer higher suffering. Interestingly, AN also induced a significant impact on the brain proteome as indicated by significant involvement of programmed cell death processes, which is probably linked to the opioid nature of MS-222.

(Continued on next page)
Regarding quality indicators, ASP and FC showed faster rigor onset than AN and ES until 6 h post-mortem. Energy depletion was lower in AN and ES than in ASP and FC, while AN showed higher pH than all the other treatments, and ASP presented the lowest pH. Fish subjected to ASP showed the highest fillet weight loss after rigor, ES and AN the lowest.

Our results demonstrate that, other than anaesthesia (which is generally not permitted in fish farmed for food), electrical stunning consistently showed good results as a humane stunning method. This was presented at all levels of welfare analysis, as well as in fillet quality terms. The fast-chilling method, on the other hand, presented very poor results both in welfare and in quality and did not seem to be a viable humane alternative to asphyxia.

Additionally, the proteome analysis opens new windows into the selection of fine-scale biomarkers of welfare and, more specifically, provides very interesting insights into the brain mechanisms of rainbow trout at slaughter.
ANTIMICROBIAL ACTIVITIES OF Nannochloropsis oceanica FRACTIONS AGAINST BACTERIAL PATHOGENS

1CIIMAR, Interdisciplinary Centre of Marine and Environmental Research of the University of Porto Matosinhos, Portugal
2GreenCoLab - Associação Oceano Verde, University of Algarve, Faro, Portugal
3Allmicroalgae Natural Products S.A., R&D Department, Pataias, Portugal 4SPAROS Lda., Olhão, Portugal
e-mail: msaraiva@ciimar.up.pt

Introduction
Algae inhabit a diverse range of ecosystems, contributing to their ability to synthesise diverse classes of highly active metabolites. These metabolites exhibit considerable antibacterial activity against a broad range of bacteria, thus making them promising sources of antibacterial compounds. Fish, due to their ecological environment, are in constant contact with pathogens, thus fish bacterial diseases are an important and recurrent problem in aquaculture. Natural antibacterial and/or immunostimulant compounds are greatly needed for a more sustainable industry. This study aimed to assess the antimicrobial properties of several Nannochloropsis oceanica fractions obtained through marine biorefinery concepts.

Material and Methods
Four different concentrations (0.5-, 0.25-, 0.1-, and 0.01 mg.mL−1) of three Nannochloropsis oceanica fractions (lysed microalgae, crude polysaccharides, and sulphated polysaccharides-rich fractions) were tested in vitro for their antibacterial activity against Vibrio anguillarum, Vibrio harveyi, Vibrio parahaemolyticus, Aeromonas salmonicida, Photobacterium damselae piscicida, Edwardsiella piscicida, and Tenacibaculum maritimum species. Different fraction exposure times (1-, 2.5-, and 4-h) were also tested.

Results
The lysed microalgae fraction presented a higher bacteria inhibition spectrum. The adjusted means from Tukey’s post hoc test indicated that aqueous lysed microalgae of Nannochloropsis oceanica inhibited all bacteria tested, with Aeromonas salmonicida being significantly affected (p<0.05; survival:12–55%). However, a range of bacteria growth inhibition was obtained (10–90%), with Vibrio sp. being less affected. Except for V. parahaemolyticus and independently of the fraction and concentration used, all bacterial growth was mostly inhibited at 1h post-fraction exposure, whereas a higher cell viability tendency was observed in longer fraction-exposure times. This phenomenon can be explained by the bacteria adaptation to growth conditions.

Discussion and Conclusion
Besides their appreciable levels of primary metabolites, such as polysaccharides, protein, carbohydrates, and vitamins, microalgae produce high-value secondary metabolites. Collectively these metabolites present antioxidant, antimicrobial, antitumor, anti-inflammatory, and anticancer capacities. The polysaccharides’ antibacterial activity underlying mechanism has been hypothesised to be based on glycoprotein receptors in the polysaccharides, which bind to molecules on the bacterial cell wall, membrane, and nucleic acids.

The obtained results clarified that the crude lysed fraction maintains a potent antimicrobial activity, making it a promising source of new antimicrobial drugs.

However, antimicrobial susceptibility testing for aquaculture-relevant strains is highly recommended, as resistance to antibacterial agents may be strain dependent.

Introduction
Disease outbreaks are one of the major challenges to the sustainable development of marine aquaculture. Many species from the Vibrionaceae family are serious opportunistic pathogens responsible for relevant monetary losses to aquaculture producers (Ina-Salwany et al., 2019). However, to date, little attention has been paid to the susceptibility of fish to pathogen infections when they undergo an inflammatory process as a consequence of the intensive production conditions typically applied in the aquaculture sector. For this purpose, we used carrageenin, a sulphated mucopolysaccharide derived from the cell walls of red algae (Rhodophyceae family), as a model of acute inflammation in the skin of gilthead seabream (*Sparus aurata*), due to its local effects and high reproducibility (Campos-Sánchez et al., 2021). On the other hand, *Photobacterium damselae* subsp. *piscicida* (*Phdp*) is known to cause pasteurellosis, a septicemic disease with high mortality rate in farmed fish, and whose infectious process depends on the fish species, temperature, salinity, and other unknown factors (Santos et al., 2022). In this regard, the present study aims to evaluate the susceptibility of the immune status of gilthead seabream during the course of a bacterial infection by *Phdp* after an inflammation provoked by carrageenin.

Material and methods
In this study, 24 specimens (75.25 ± 3.77 g, 15.98 ± 0.22 cm) of gilthead seabream (*S. aurata*) from broodstock at the aquaculture Research Station of Olhão (Portuguese Institute for the Ocean and Atmosphere) and maintained in the same facilities, were injected intramuscularly with 50 µL of phosphate buffered saline (PBS, as control), or carrageenin solution (1%, Sigma) in PBS. At 3 h post-injection, half of the fish in each predefined group were injected intraperitoneally with 100 µL of PBS (control group), while the other half of the fish were injected with *Phdp* (106 UFC/mL, *Phdp* group). At 24 h after carrageenin injection, blood samples and skin mucus were collected by following the methods described by Guardiola et al. (2014). Esterase activity, peroxidase activity, lysozyme activity, bactericidal activity against *V. anguillarum*, as well as total immunoglobulin levels were analysed in both serum and skin mucus (Guardiola et al., 2016). The results were expressed as mean ± standard error of the mean (SEM) and data were analysed by one-way ANOVA (followed by Tukey tests) to determine differences between experimental groups. The level of significance used was p < 0.05 for all statistical tests.

Results and discussion
The results obtained in serum showed an increase in esterase activity in the *Phdp* group compared to the control group. However, bactericidal activity against *Phdp* decreased in the carrageenin-injected and *Phdp*-infected fish group compared to the control and *Phdp* groups. Peroxidase, lysozyme and bactericidal activity against *V. anguillarum*, as well as total immunoglobulin levels remained equal among groups. Similar to serum, bactericidal activity against *Phdp* studied in the skin mucus decreased in the carrageenin + *Phdp* injected fish group compared to the control group and the carrageenin group. In contrast, bactericidal activity against *V. anguillarum* increased in the *Phdp* group compared to the other groups, while the total immunoglobulin level increased in both the *Phdp* group and the carrageenin + *Phdp* group compared to the control. According to the literature, *Phdp* is able to enhanced immune activity of gilthead seabream by activation and differentiation of phagocytes (Pellizzari et al., 2013). In addition, *Phdp* has a capsule of polysaccharide composition that confers protection against bactericidal activity (Magariños et al., 1996), which could explain why in our study there were

(Continued on next page)
no significant differences when studying the bactericidal activity against \textit{Phdp} between the group of fish infected with the bacterium and the control group. However, since this activity decreased in the skin mucus of fish injected with carrageenin + \textit{Phdp}, they might be more susceptible to infection than the control fish. In addition, due to the possible enhancing of the immunity caused by the bacteria, this group of fish could be on alert against other pathogens, explaining the increased bactericidal activity against \textit{V. anguillarum} in the skin mucus of \textit{Phdp}-infected specimens. Otherwise, no differences were found in esterase, peroxidase and lysozyme activities in the skin mucus between groups.

\textbf{Conclusion}

Our results provide an overview of the effect of \textit{Phdp} on the immune status of gilthead seabream. Furthermore, our data suggest that fish subjected to an inflammatory process, such as the one tested in this trial (carrageenin), might be more susceptible to a bacterial infection. These results could be used in other future studies and contribute to a better understanding of bacterial infections in aquaculture and, therefore, to their resolution.

IDENTIFICATION AND ENZYMATIC CHARACTERIZATION OF MARINE MICROBES ASSOCIATED WITH SEAWEEDS AND THEIR POTENTIAL FOR CAUSING ICE-ICE DISEASE AND PRODUCING BIOETHANOL

Prakash Saravanan*, Antara Chatterjee, Gourav Dhar Bhowmick

Introduction:
Before initiating seaweed cultivation in integrated multi-trophic aquaculture (IMTA) or large-scale production in open ocean environments, it is imperative to address potential issues that could impede biomass production and result in significant economic losses for producers. While limited research has been conducted on the role of microorganisms and their interactions in the seaweed life cycle, their impact on seaweed cultivation is well recognized. To address this knowledge gap, the present study aimed to isolate marine bacteria and fungi associated with seaweeds and their role in causing Ice-Ice disease and to characterize their agar and carrageenan degrading abilities to assess their potential application in bioethanol production. While previous studies have reported on degrading agar and carrageenan microorganisms (Chi et al., 2012; Kang & Kim, 2015), identifying microorganisms with the ability to degrade both agar and carrageenan remains limited.

Materials and methods:
Our study focused on three species of red seaweed (Kappahucus alvarezii, Gracilaria edulis, and Eucheuma cottonii) collected from a seaweed cultivation site in Ramanathapuram, India. The seaweeds were transported to the lab in sterile plastic bags. The epiphytic and endophytic microbes were isolated for microbiological and biochemical analysis. Subsequently, the seaweed species were placed in glass tanks for growth assessment to evaluate whether the microbes could cause ice-ice disease in stressful environments. After five days, all seaweed species started losing pigments and turned pale white indicating symptoms of ice-ice disease, leading to complete degradation, as confirmed by visual observations Fig.1 and Fig.2. This confirmed that associated epiphytes and endophytes could degrade agar and carrageenan.

We isolated 18 marine microbes from the three seaweed species using spread plate techniques and pure culture methods. Qualitative assays were conducted to assess the ability of isolated microbes to degrade agar and carrageenan using lugol’s iodine. DNA sequencing was performed for all the positive microbes in the agar and carrageenan qualitative assay, and their enzymatic activity was characterized using the 3,5-dinitro salicylic acid (DNSA) assay.

Results:
Out of the 18 isolated marine microbes’ species, our investigation identified six with positive agar and carrageenan enzymatic activity, three with only agar, and three with only carrageenan. DNA sequencing revealed that ten species were bacteria, while the other two were yeast. Further, the results showed that Bacillus kokeshiiformis strain SM24, Nitratreducer kimnyeongensis strain E14, Brevibacillus agri strain 13, Caldibacillus kokeshiiformis strain FJAT-47861, Lentibacillus salarius strain BH139, Bacillus thermolactis strain SM10, Micrococcus endophyticus strain HCDB6, Caldibacillus thermolactis strain NWFY-11-4, Oceanobacillus caeni strain LNPC16, and Bacillus thuringiensis strain SH26 are the isolated bacterial species. The isolated yeast species are Pichia fermentans strain PM79 and Geotrichum candidum. The 3,5-Dinitrosalicylic acid (DNSA) assay results showed that Caldibacillus kokeshiiformis strain FJAT-47861 had the maximum carrageenase enzymatic activity of about 0.76 units/ml and Pichia fermentans strain PM79 had the maximum agarase enzymatic activity of about 0.52 units/ml. The highest agarase and carrageenase enzymatic activity was found in the Pichia fermentans strain PM79, with an average of 0.63 units/ml of agarase and carrageenase activity, the highest among all six species that tested positive for agar and carrageenan. Moreover, the average carrageenase enzymatic activity of all six microbes was found to be 1.5 times higher than their agarase enzymatic activity.

(Continued on next page)
Conclusion:
This investigation represents the first report of isolating four microbial strains: *Caldibacillus kokeshiiformis* strain FJAT-47861, *Lentibacillus salarius* strain BH139, *Micrococcus endophyticus* strain HCDB6, and *Caldibacillus thermolactis* strain NW FY-11-4, from red seaweeds. In addition, identifying species with bioremediation potential, such as *Pichia*, *Geotrichum*, *Caldibacillus*, *Lentibacillus*, *Micrococcus*, and *Bacillus*, is also significant as these species have been reported to remove organic pollutants, hydrocarbons, and polycyclic aromatic hydrocarbons (PAHs) from the environment. Using halophytic and thermophilic bacterial species, such as *Bacillus thermolactis* strain SM10, *Caldibacillus thermolactis* strain NW FY-11-4, and *Oceanobacillus caeni* strain LNPC16, for bioethanol production from macroalgae, offers a promising alternative to traditional biofuel production methods. Overall, our findings indicate that all 12 microbes can be used in bioethanol production from macroalgae. Their agarase and carrageenase activity indicates their ability to break down the complex carbohydrates in seaweed cell walls. The fact that the average carrageenase enzymatic activity was found to be 1.5 times higher than their agarase enzymatic activity is particularly noteworthy. Additionally, the higher carrageenase enzymatic activity of the *Caldibacillus kokeshiiformis* strain FJAT-47861 suggests that this microbe may be highly beneficial for producing bioethanol from seaweed. In conclusion, this study has contributed to the scientific understanding of the microbial diversity associated with seaweeds. It highlights the potential applications of the isolated strains in various industries, especially bioethanol production. Further research, such as the enzyme’s ability to efficiently extract and hydrolyze the polysaccharides from red seaweed, the yield of fermentable sugars, the efficiency of the fermentation process, and the overall ethanol yield are needed to fully explore the potential of these strains and develop new biotechnological applications.

References:
To address the shortage of cheap and sustainable feed-protein ingredient for aquaculture, this study developed *Gracilariopsis heteroclada* protein concentrate (GHPC) and evaluated its nutritional value as a replacement to soybean meal protein in the diet of black tiger shrimp, *Penaeus monodon*. Five isonitrogenous and isolipidic diets were formulated replacing soybean meal protein at 0% (control), 12.5%, 25%, 50%, and 75%.

Results showed that the developed GHPC has a protein, lipid, fiber and carbohydrate content of 31.11±0.12%, 1.57±0.61%, 1.87±0.31% and 24.99±0.33%, respectively. The nutritional value of GHPC was found high, exhibiting an ingredient digestibility index of 91.84±0.06% and Essential Amino Acid Index (EAAI) of 0.996. Feeding trial results revealed that the overall growth performance, feed assimilation efficiency and biochemical composition of the shrimp fed with the 50% GHPC diet were similar to the control group fed with full soybean meal based-diet (Table 1). The high acceptability of this feed ingredient to *P. monodon* is attributed to its high digestibility and adequate content of essential amino acids. However, shrimps fed with replacement levels beyond 50% exhibited significant growth depression that might be due to the presence of antinutritional compounds as observed with the reduction of digestive enzyme activities (Figure 1) and histomorphological changes (B-cell enlargement) (Figure 2).

Collectively, the findings suggest that GHPC has high nutritional value and could be used as a plant protein ingredient in the diet of *P. monodon*. Utilization of GHPC is a sustainable approach to meet the growing requirements of feed-proteins in the expansion of *P. monodon* aquaculture.

USE OF STEREOVISION TO ASSESS VERTICAL SIZE-STRATIFICATION OF ATLANTIC SALMON (Salmo salar) IN A COMMERCIAL SEA-CAGE: A CASE STUDY

Introduction
Norway is the largest exporter of Atlantic salmon (Salmo salar) in the world, with a production of 1.5 million tons in 2020 (FAO., 2022). Most of the grow out period happens in sea-cages which can host up to 200,000 individuals in a volume comprised between 18,500 and 80,000 m$^3$. Sampling fish for size and biomass estimation at such scale is challenging and time-consuming for farmers. They usually sample around 20 fish per week for lice counting and use this sampling periodically to measure and weight fish, which may be not representative for the whole cage. This can have a strong impact on feeding strategies and slaughtering prevision, followed by effects on production cost and yields. New technologies, like automated measurements from images of stereo-paired cameras to estimate salmon size and biomass in sea-cages, are developing fast for more representative and non-invasive samplings. Nevertheless, previous studies suggested that salmon distribution might not be as homogeneously thought. Folkedal et al. (2012) showed that the vertical distribution of salmon in 2000 m$^3$ sea-cages is size-dependent, suggesting repercussions on biomass estimation depending on the sampling method. This needed to be confirmed at commercial scale. Similarly, Johannesen et al. (2022) suggested that horizontal distribution of fish in relation to depth might be very different in a commercial sea-cage. Both findings are important to consider for the deployment of automatic cameras to get representative results.

Materials and methods
Low-cost action cameras (GoPro Hero 8) were time-synchronized and deployed to cover 16 positions in a commercial sea-cage (18,850 m$^3$) of the salmon sea-farm in Gudmunset-Norway (62.45366, 6.60326). Four depths (1 m, 5 m, 9 m, 14 m) were covered at four horizontal positions (North, East, South, West) in the sea-cage. Cameras were set to record for at least 1 h, four times in one day (4 deployments, during: 1$^{st}$ feeding and 2$^{nd}$ feeding periods, between feedings, and after 2$^{nd}$ feeding). On the east side of the cage, homemade stereovision rigs with paired GoPros were deployed. 3776 fish through the different depths and deployments were manually fork-length measured with Eventmeasure software (SeaGis 2006-2023). Fish abundance was scored from 0 to 3 (absence of fish, low, medium, high) and growth-stunt fish counted at every position in the sea-cage on screenshots taken every minute for 60 minutes per deployment. Fish swimming speed was also estimated on a portion of the fish length measured using a vertical reference line and counting the time the fish took to pass the reference line from snout to fork-length (BL/sec). Average fish length was compared per depth and per deployment and the same procedure was applied for swimming speed. Cumulative means for fish size were created per depth to estimate when a sample was representative for its depth and for the whole cage.

Results
Salmon fork-length averages were significantly (p < 0.05) different between depths with longer salmon found deeper in the sea-cage (9 m and 14 m) compared to the shallowest depth (1 m) and intermediate one (5 m). This was the case for every deployment that day. A strong variation in size, from 24 cm up to 70 cm, was present and mostly showcased at 1 m than at deeper depths. Distribution of fish appeared quite homogenous on the horizontal plan, with higher fish abundance at 9 m and 14 m, intermediate at 5 m and low at 1 m depth. No difference was found between feeding or none feeding periods and fish were more abundant at the deeper depths during the day. Fish mean swimming speed was around 1 BL/sec. Most growth-stunt fish were located at 1 m and some individuals could clearly be identified and observed several times at the same position. The cumulative means per depth indicated that average size for a particular depth could be reached with 50 individuals measured in some cases, but most of the time after 150 individuals measured.

(Continued on next page)
Discussion and conclusion

These results are in accordance with the findings from Folkedal et al. (2012) and Nilsson et al. (2013) which found a vertical size-stratification with depth in smaller sea-cages. The use of stereovision to measure salmon in this study allowed to reduce potential bias in the selection of the fish to be measured as fish were not afraid of the stereo rig and were randomly selected to be measured. It appeared that this display did not disturb salmon in their “regular” sea-cage behavior. Results on fish abundance registered at the different positions in the cage suggest that in the absence of strong current or weather, salmon seem to use the whole cage quite homogeneously on the horizontal plan. The fact that high fish abundances were found at 9 m and 14 m, even during feeding times, suggest that the whole school of fish does not gather close to the feeding area at the same time. A different pattern would probably be observed in the center of the cage, not covered by our cameras, where feeding is occurring. From the different findings on vertical size stratification, horizontal and vertical distributions, and average size representativity per depths, several potential implications for an optimal deployment of automatic biomass estimating cameras can be mentioned. On one hand, if the primary objective of the farmers is to get the overall size/biomass variation in the cage, positioning the camera higher up appears more strategic as smaller fish tend to stay higher in the water column and might not be caught at deeper depths. This might be relevant for sea cages in which a large size stratification is present. On the other hand, if the objective is to get a close estimation of the mean size or biomass, it would be more interesting to stand were the larger part of the school is, in our case study: between 9 m and 14m. Anyhow, it seems difficult to obtain the exact average size if the camera is deployed at a single depth. Depending on the weather conditions, fish might use preferentially a part of the cage (Johannesen et al. 2022), and this should be accounted for when deploying equipment. Such studies should be conducted in different localities, during different seasons and production stages to be able to generalize, and automatization of measurements is necessary to conduct more experiments at that scale. This case study aimed to enrich what was previously known on salmon distribution at commercial scale and showed potential considerations for the use of innovative methods to measure salmon size.

Introduction
Live preys are most important feed in larval fish nutrition. Rotifer and Artemia are first live feeds in fish larval feeding. Those live preys need intensive labour and energy. However, water flea (*Daphnia magna*) is become alternative zooplankton due to containing high protein and lipid levels (Turcihan et al., 2022). In addition, *Daphnia* culture can be performed in outdoor wastewater systems that lead to higher biomass production. Microalgae are commonly used for live prey, alternative microdiet ingredients, green energy production and wastewater treatments (Soto-Sánchez et al. 2023). In our study, fresh *Euglena gracilis* and *Pavlova lutheri* were used for *Daphnia* feeding. In addition, several commercial diets were evaluated such as Algome® (dried *Schizochytrium* sp.), Naturiga® (dried *Spirulina platensis*), AlgomeGrow® (dried *Chlorella* sp.) and ProteinPlus®. The aim of this study, was to evaluate amino acid compositions of *Daphnia magna* fed two fresh and four commercial microalgae products.

Materials and Methods
*Daphnia magna* cultured under controlled laboratory conditions. *Daphnia* stock cultures were maintained continuously aerated tap water at 21°C. Broodstock of *Daphnia* were fed baker’s yeast. *Daphnids* were counted by pasteur pipette daily and settled at the same number (n=20) with triplicate in polyethylene culture vessels. Freshwater microalgae *Euglena gracilis* was cultured in 3N-BBMV medium whereas marine microalgae *Pavlova lutheri* was incubated f/2 medium. Culture medium and vessels of microalgae previously sterilized at 121 °C for 15 min. (Guillard, 1975). The microalgae species was scaled up in erlenmeyer flasks from 50 mL test tubes to 250 mL erlenmeyer flasks, followed by 1-L, and 5-L. Microalgae were counted in each experimental flask. Commercial microalgae feeds were ProteinPlus® (Aquafauna Bio-Marine, USA), Naturiga® (Naturiga Natural Foods, Turkey), Algome® (MarineBio, Turkey) and AlgomeGrow® (MarineBio, Turkey). All feeds were prepared at 2 g/L ratio. Total amino acids analyses were conducted at the Scientific and Technological Research Council of Turkey (MAM, Turkey). From each sample, 5 mg was added to a glass ampoule together with 5-mL lithium citrate loading buffer. Ampoules were sealed and placed in an oven (115 °C) for 2 h to facilitate hydrolysis. The samples were then removed, allowed to cool, and filtered with a 0.45 PTFE syringe filter. Samples were diluted as necessary to fall within the detectable range for the assay. Amino acids were measured with a Biochrom 30-amino acid analyzer (Biochrom, Holliston, MA, USA) (Hawkyard et al. 2016).

Results and Discussion
Protein contents of live prey are important for larval and juvenile fish in aquaculture for their optimum growth and survival. *Daphnia* studies are mostly related to their growth, fatty acids and proximate composition. It is reported that *Daphnia* can be alternative live prey for sustainable aquaculture production with partly used instead of Artemia (Chakraborty and Mallick, 2023). Microalgae species can affect *Daphnia* culture performance. For instance, *Cryptomonas* sp. had positive affect on reproduction whereas feeding with *C. reinhardtii* had resulted resting eggs in *Daphnia*. Moreover, addition some of amino acids such as Arginine and Histidine in microalgal diets could result less resting egg occurance in *D.pulex* (Fink et al., 2011). Each microalgae has different amino acid composition (Brown, 1991). From this respect, amino acid composition of microalgae and alternative diets have crucial importance in *Daphnia* reproduction. Karakaş et al. (2023) isolated cyanobacteria *Phormidium lucidum* and evaluated for culture performance. In order to develop and commercialize *Daphnia* culture, alternative instant use diets should be introduced in aquaculture sector. However, commercial diets have not been evaluated for *Daphnia* culture. In this study, we used two fresh microalgae and four commercial diets and investigated effects on *Daphnia* amino acids. The AlgomeGrow diet (dried *Chlorella vulgaris*) showed best results in amino acids of *Daphnia*. The present study showed that the Naturiga diet contained higher amount of amino acids, *Daphnia* individuals fed Naturiga did not contain higher levels of amino acids (Table 1). In fact, AlgomeGrow group showed higher levels of essential amino acids even though this diet had second levels of total amino acids. This result could be related to Nitrogen limitation in *Daphnia* diet (Wagner et al., 2017). Future studies are needed for large scale commercial experiments in daphnia culture with those commercial diets.

AQUAKULTURINFO – OVER 10 YEARS OF COMMUNICATING ABOUT AQUACULTURE IN GERMANY

Fabian J. Schaefer*, Werner Kloas
Leibniz-Institute of Freshwater Ecology and Inland Fisheries (IGB)
Dpt. Fish Biology, Fisheries and Aquaculture
Müggelseedamm 310
12587 Berlin, Germany
E-mail: Fabian.Schaefer@igb-berlin.de

Introduction

While the demand for fish and other aquatic food as well as the market share of aquaculture are on the rise globally, consumption of these products and the aquaculture sector in Germany is relatively stable on a comparably low level. Average per capita consumption ranged from 14.1 to 14.8 kg in the years 2016 to 2020 amounting to 1.231 million tons of total consumption in 2020 (FIZ 2022). In parallel, aquaculture production in Germany provides only a share of less than 3% of this consumption. Besides species mainly originating from capture fisheries, predominantly farmed species, such as salmon, trout or various crustaceans, are favorites among the market in Germany (FIZ 2022).

While fish farming has a long tradition in many regions across Germany, where mainly trout and carp production in flow-through and pond systems as well as mussel production on the shores dominate the sector, German consumers do not necessarily know much about aquaculture (Feucht und Zander 2017; Risius et al. 2017). Given the moderate consumption and small domestic aquaculture sector, contact between consumers and the primary production is fairly limited. Consumers are mainly confronted with aquaculture through products in supermarkets or restaurants. The dynamic development of the sector and the global trade result in ecological and social challenges. These and other topics, e. g., related to product quality, often put aquaculture into the public and medial interest. While fish is generally perceived as healthy food, impressions from neighboring sectors, agriculture and capture fisheries, are being transferred and the public perception of aquaculture and its practices remains ambiguous. This current state of comparably low knowledge, perception and awareness was also considered within the German Strategy Plan for Aquaculture highlighting the need for trustworthy information transfer and communication (NASTAQ 2020).

The project AQUAKULTURINFO

To allow for responsible, fact-based decision making by consumers as well as representatives of trade, processing industry, associations, NGOs, administration or politics, the IGB has launched the third-party funded project AQUAKULTURINFO in 2012. Mainstay and visible core of the project is the website www.aquakulturinfo.de (Fig. 1). The website offers in-depth, science-based articles on aquaculture related topics separated into thematic fields, such as husbandry, animal health and welfare, product quality, environmental interactions or economy and marketing. A section of the website offers species articles on fish, mollusks, crustaceans and algae. The articles are authored by aquaculture scientists and undergo a review process prior to publication on the website to ensure the independent character of the information and objectivity. The website also features a news section and embedded videos. Overall, the original content of the website results in very good rankings among search engines and is highly visible.

In addition to the website, AQUAKULTURINFO provides a variety of services at the interface of science and society and actively engages in public outreach. The project serves as a sought-after information hub for media, politics and administration, trade, industry and associations as well as NGOs and other organizations with interest in the field. Within the framework of the project, consumer and professional events related to aquaculture, fisheries, food, agriculture or general natural science are supported. Furthermore, AQUAKULTURINFO participates in research within the field of consumer perception and communication and supports other projects by dissemination of results. To further strengthen an active role in knowledge transfer, AQUAKULTURINFO seeks innovative approaches in science communication, e. g., through scientific gaming (Fig. 2). Through these means of PR in combination with the website, active and passive information transfer into the society is realized. In conclusion, AQUAKULTURINFO provides a unique link between science and society and offers comprehensive experience in aquaculture related science communication.

Introduction

Seaweed cultivation is rapidly developing in Europe (García-Poza et al., 2020). The cultivated brown sugar kelp (Saccharina latissima, Phaeophyta) has a diplo-haploplontic life cycle (Visch et al., 2019). For cultivation, early life-stages are glued directly onto ropes and, while developing, attach firmly using own holdfasts until harvesting. A major cultivation challenge is the > 90 % loss of seeded seaweed. This study is part of the SEASeEDS project that aims to improve the sugar kelp attachment and as such limit such loss. One approach is to better understand the role of the associated microbiota (e.g., Proteobacteria, Bacteroidia or Bacillariophyta; Burgunter-Delamare et al., 2023; Liu et al., 2022), potentially involved in improving development and attachment. We focused on developing and improving a first method to specify bacteria associated with cultivated sugar kelp. As baseline, DNA extraction and HiSeq2000 sequencing methods were tested, also to get insight in the ratio between sugar kelp chloroplasts and bacteria. To do so, seeding material samples were provided by the Hortimare B. V. (NL) and harvest samples were provided by The Seaweed Company (NL).

Materials and methods

Sample collection

For method testing, the seeding material samples (i.e., gametophytes and early-stage sporophytes of the Dutch HNL strain) originally provided by Hortimare B. V were aliquoted in quadruplicates per three fresh weights tested (i.e., 12 samples) and stored at -20 °C. In addition, early-stage seeding sugar kelp samples (i.e., Dutch ZWG1 strain; cultivated in Autumn 2022) were aliquoted (i.e., at least 175 mg; 8 samples) and stored at -20 °C. In April 2023, late-stage sugar kelp samples from the seaweed cultivation site in Oosterschelde (NL), owned by The Seaweed Company, were harvested. For each of the four collected sugar kelp blades, 2 cm² discs in triplicates were cut out (i.e., 12 samples) and stored at -20 °C.

Method testing & application

Using the testing seeding material samples, the standardized DNeasy PowerSoil ProKit (ID: 47014) by QIAGEN followed by the established HiSeq2000 sequencing protocol (Indraningrat et al., 2022) were used to test the impact of 1) the sample fresh weights (i.e., 100 mg, 175 mg or 250 mg), 2) the sample dilution prior to DNA extraction (i.e., no dilution vs. diluted to 20 ng DNA/ µL nuclease-free water) and 3) the number of PCR cycles (i.e., 25, 27 or 30). Preliminary quantity and quality evaluation of this method testing (i.e., Qubit and gel electrophoresis) indicated that 175-250 mg initial sample fresh weight, no initial sample dilution and 27 or 30 PCR cycles are most promising for this study. To apply these findings, the early-stage seeding and late-stage harvest sugar kelp samples were investigated for their prokaryotic communities.

Data analyses

The Illumina 16S HiSeq 150bp amplicon sequencing data resulting of all samples was analyzed using the FastQC v0.12.0 (Andrews, 2010), the Galaxy NG-Tax2 Pipeline (Poncheewin et al., 2020), the SILVA 1.32 database (Quast et al., 2013) and R (RStudio Team, 2020).

Results

First, the higher the initial sample fresh weight (250 mg > 175 mg > 100 mg), the higher was the mean extracted DNA concentration (p(0.05; 250 x 175 mg = 0.020; p(0.05; 250 x 100 mg = 0.004; p(0.05; 175 x 100 mg = 0.560). Second, undiluted samples showed statistically significantly higher mean amplified DNA concentrations compared to diluted samples after running the 25-cyclic PCR (p(0.05; sample dilution x amplified DNA x sample fresh weight = 3.16e-6), independent on the initial sample fresh weight (p(0.05; sample dilution x amplified DNA x sample fresh weight = 0.189). And third, on average only 2-3 % of the total DNA reads of the undiluted testing seeding material samples were bacterial, independent on the initial sample fresh weight and the number of PCR cycles.

(Continued on next page)
Considering the number of PCR cycles, 27 cycles yielded the highest relative bacterial abundance (as compared to chloroplasts) for both, early- and late-stage sugar kelp. On average, 25% of the total DNA reads of the early-stage seeding sugar kelp samples were bacterial and included Proteobacteria, Planctomycetota, Verrucomicrobiota and Bacteroidota. Only <1% of the total DNA reads of the late-stage harvest sugar kelp samples were bacterial (i.e., Proteobacteria only), while 99% of the reads were sugar kelp chloroplasts. Proteobacteria only appeared throughout sugar kelp life-stages in cultivation.

Discussion

Method testing indicated that 1) using 175 mg wet weight for DNA extraction 2) no dilution of DNA before PCR, and 3) 27 PCR cycles are the most promising adaptations of the established laboratory procedures. It was successful for studying bacteria associated with early-stage sugar kelp, but highlighted limitations for late-stage-specific assessments. Specifically, for early-stage sugar kelp, the diverse taxa found are consistent with previous findings (e.g., Burgunter-Delamare et al., 2023; Liu et al., 2022; Tourneroche et al., 2020) confirming the method applicability and reliability. However, the low bacterial diversity and low relative abundance of bacteria found in the late-stage sugar kelp highlight the need of further method development. Also, to examine the interaction between cultivated sugar kelp and its associated bacteria (such as the found predominant Proteobacteria). Potentially, epiphytic microbial assessment by using sterile swabs instead of disc cutting may be more applicable (Liu et al., 2022). The high number of chloroplasts sequences could be reduced using primers amplifying the V5-V7 region (Tourneroche et al., 2020) as it prevents the amplification of microbiota-like 16S rRNA genes chloroplastic sequences (Beckers et al., 2016). Overall, fundamental understanding of proper bacteria assessment associated with cultivated sugar kelp could be fostered. This is valid for investigating their impact on sugar kelp to improve cultivation.

References

Background

Lusatia, which extends partly over the German federal states of Saxony and Brandenburg, is the largest connected pond area of Middle Europe. The region has a history in carp production in man-made ponds of more than 750 years with management principles for the low-impact production having changed very little over time. Carp ponds are valuable habitats providing a variety of ecosystem services. However, changing framework conditions have caused severe economic pressure in the last three decades, and many businesses have been given up. Governance structures and policy instruments have been applied over the last decade in Saxony and Brandenburg trying to preserve carp pond farms including promotion of sustainable management practices. At the same time, only few in-depth economic analyses of production systems in carp pond farming exist. In the present study, the effects of existing regulations and policy measures on the economic efficiency of carp pond enterprises were evaluated by applying a microeconomic benchmark approach.

Methods

Typical carp production systems for the Lusatian region of Saxony and Brandenburg were defined according to the agri benchmark methodology (Lasner et al., 2020). Such typical farm datasets are based on real costs and prices and represent the production sector within the target region without including specific characteristics of individual enterprises. They can be used as tool to analyse short-, medium- and long-term profitability of the related sector in order to illustrate impacts of e.g. changing climatic, technical and political framework conditions. Within the present study, the datasets were used for microeconomic analyses of existing policy measures. Based on the results, economic improvement and adaptation potential of current support programs are explored in order to compensate for ecosystem services of ponds and to support long-term viability of the sector.

Results

Three typical carp farm systems were defined for the current study. In all models, fish are reared in traditional earthen ponds, producing table fish of around 2 kg/piece after a three-year production cycle.

DE-FCP-20 represents a small farm in Brandenburg, integrating nursery, grow-out and processing for a production of 20 mt carp, selling directly or to wholesalers. DE-FCP-80 and DE-FCP-200 represent two typical farm models for the region of Saxony producing 80 mt and 200 mt carp, respectively. Both DE-FCP-80 and DE-FCP-200 hatch their own fingerlings for on-growing. The carp is processed and sold directly, to the gastronomy market, to wholesalers and fish farms.

Short-, medium- and long-term profitability results with and without measures for all farm models on grow-out, grow-out with subsequent processing as well as on whole farm level revealed differences depending on farm size and specifics related to the federal states. DE-FCP-20 in Brandenburg showed the highest financial loss on long-term scale. For grow-out and grow-out including processing DE-FCP-20 was only profitable on short-term scale with subsidies, while on whole farm level no profitability could be reached independent of measures applied.

On whole farm level DE-FCP-80 and DE-FCP-200 were only profitable short-term but not on long-term scale. In the short- and medium-term DE-FCP-80 was profitable for grow-out and grow-out including processing. However, on long-term scale, grow-out without processing was only profitable with subsidies.

Grow-out including processing was profitable in DE-FCP-200, while grow-out without processing was only profitable on long-term when measures were included.

(Continued on next page)
Conclusion

The results revealed the high relevance of governance structures and policy instruments on the rentability of carp farms in eastern Germany. Measures are necessary, however still not sufficient, to secure long-term profitability on whole farm level in all three farm models. Moreover, farm size, location and fish processing seem to be of significance. As carp farming provides ecosystem services and cultural value, further development of governance and policy options could balance the mismatch between costs and returns to maintain this unique man-made landscape.

Introduction

The aquaponic system, a combination of soilless hydroponic crop production with recirculating aquaculture, relies on diverse consortia of microorganisms (Schmautz et al. 2017; Bartelme et al. 2019), to convert nutrients from fish excreta and non-consumed fish feed into nutrients for plants (Goddek et al. 2016). In these systems, each of the components such as fish tank, biofilter, sump, hydroponic table, mechanical filters, and sludge reactors, feature unique environmental pressures, which may trigger the formation of different microbial communities (Bartelme et al. 2018). Most attempts to characterize the microbial communities of aquaponics have been focused on the sampling of the water column and biofilter material (Blancheton et al. 2013; Hu et al. 2015; Schmautz et al. 2017; Eck et al. 2019). However, little consideration has been given to the microbial populations that may be developing in other compartments of such systems.

Methods

Three identical aquaponic systems, run in parallel over a 12-week period, were used to investigate the microbial community composition during three cycles of lettuce production in the greenhouse facilities of the Zurich University of Applied Sciences (Wädenswil, Switzerland). A community pattern based on amplicon sequencing of bacterial and archaeal 16S rRNA genes was generated through localized sampling of individual compartments at the beginning and the end of every lettuce growth cycle. Samples were taken directly from the fish tank (FTW), sump (HPS), and hydroponic table (HTS) surface using a cotton swab, as well as the moving-bed biofilter material (BFO) by collecting around 20 biocarriers. The roots (ROT) were sampled by cutting a few fine roots from three randomly selected lettuce plants from each replicate system. Fish feces (FEC) were obtained by stripping one anesthetized fish per system. To obtain samples of the microbial community present in fresh sludge (FRS), digested sludge (DIS), and the supernatant of digested sludge returned to the system (RSS), 1.5 mL of each was collected.

Figure 1. Network clustering using Bray-Curtis distance between different compartments of the aquaponic system, where bacterial primer set (A) could predict the origin of the sample with less than 5% error rate and archaeal primer set (B) with a more prominent 38% error rate.

(Continued on next page)
Results and discussion

Results indicated higher overall population diversity for bacteria than archaea, particularly in aerobic compartments, with lower diversity observed in fresh fish feces, disclosing a highly discrete gut flora composition (Figure 1). Furthermore, nitrifying bacteria were identified on the hydroponic tables, indicating that this compartment may play a more significant role than previously thought in the systems nitrogen cycle, transforming undesirable ammonium and nitrite to nitrate and improving water quality for the fish. Alongside the observed temporal changes to community compositions within the anaerobic compartments, higher archaeal taxa could be established in the anaerobic sludge samples. This was likely the result of the more extreme environmental pressures prevailing there. Finally, the most pronounced differences in microbial community compositions were observed between the aerobic and anaerobic loops of the system, with unique bacterial compositions established for each compartment.

BROODSTOCK FISH SIZE AFFECTING SPAWNING SUCCESS OF BALTIÇ COD *Gadus morhua IN CAPTIVITY

N. Schmidt1*, M. Garate-Olaizola1 and M. Hauber2

1 Department of Ecology & Genetics, Evolutionary Biology Centre, Uppsala University

Introduction
The cod (*Gadus morhua*) population in the Baltic Sea is drastically depleted due to decades of overfishing, unsustainable management and habitat degradation. Severe oxygen deficiency and decreased salinity in their spawning grounds further limited successful spawning to the Bornholm basin, which caused a decline in recruitment. To facilitate the populations’ recovery, a range of measures are necessary, including the implementation of restocking programs. Baltic cod, which are genetically distinct from other cod populations, are however not successfully cultivated yet, creating the need for the development of breeding efforts. We therefore investigated the quality and quantity of the reproductive output from Baltic cod in relation to broodstock size. The results of this study will give insight into reproduction of Baltic cod, which is valuable for broodstock management to achieve high breeding success.

Material and methods
Broodstock fish of the eastern Baltic cod stock were caught between February 2021 and March 2023. At the research station Ar, Gotland, Sweden, they were separated into three different tanks according to capture time, in which they were kept in recirculating seawater (17 psu, 7 °C) and followed a natural light cycle. The study is carried out in 2023, from April to August, when the fish naturally spawn. Quantity of produced eggs is measured daily in each tank. Quality of produced eggs in each tank is assessed weekly, focusing on deformities, developmental stage, size and thiamin content. For each tank, 100 eggs are then transferred into a 400 mL beaker and incubated for a total of 14 days. Water change occurs daily, along with counting of dead eggs/larvae and hatched larvae. At the end of the incubation period, total survival, hatching success and quality of produced larva is assessed, including presence of deformities, length, and yolk-sac size.

Expected results
With this study, we expect to be able to describe the reproductive output of Baltic cod, a threatened population of small fish in bad condition (Ero et al., 2020), possible under controlled conditions in captivity. We will further compare the relation between Baltic cod female size and quality of reproductive output to known ratios of other cod populations (e.g., Chambers & Waìwood, 1996; Kjesbu et al., 1996). Additionally, we aim to find out whether even small sized broodstock can produce good quality reproductive output in a controlled environment with sufficient nutrient-rich feed supply.

Introduction

Oysters are abundantly harvested shellfish and are highly perishable due to their high water activity, neutral pH and chemical composition. Deterioration can be caused by enzymatic autolysis, oxidation and microbial growth of the natural spoilage microbiota. Refrigeration is used to limit the risk associated with potentially pathogenic microorganisms and to delay changes in freshness, undesirable odour, off-flavour and texture. However, maintaining low temperature throughout the supply chain can be difficult, making additional preservation measures desirable.

Post-harvest treatments based on coatings, electrolyzed or ozonated water, rapid chilling, irradiation, hydrostatic high-pressure processing, and vacuum or modified atmosphere packaging (MAP) have been investigated as additional measures to reduce the levels of pathogens and spoilage in oysters. Among the non-thermal intervention strategies, not extensively studied for fish products but considered promising for maintaining food quality and safety, cold atmospheric pressure plasma (CAP) has received increasing attention in recent years. Plasma, the “fourth state of matter,” is a neutral gas containing various species such as electrons, ions, reactive atoms, free radicals, neutral molecules, and photons in a metastable state with a roughly zero net electrical charge. If enough energy is added to a gas or gas mixture, it generates a plasma that produces a wide range of unique species, including reactive oxygen and nitrogen species (ROS and RNS) and UV radiation. These reactive species play a crucial role in microbial inactivation by damaging microbial DNA and causing oxidative damage to cell envelopes and membranes. The CAP configuration and processing conditions must be optimized to maintain nutritional and quality characteristics, depending on the food matrix composition and chemical-physical properties. Plasma technology is a smart, green, non-thermal technology with relative advantages in extending the shelf-life of various foods, with limited side effects on quality parameters thanks to the low treatment temperature.

The aim of the present research was to develop a prototype of fresh oysters treated post-harvest with CAP. The setup of protocols and identification of the best performing conditions were based on a preliminary screening by modulating different processing variables such as the feeding gas (argon or atmospheric air), the main reactive species generated during the treatments (ozone or NOx), and the processing time. The effects of the different conditions were checked by evaluating the reduction of the natural spoilage microbiota and retention of nutritional and quality features of the treated products. The selected conditions were then assessed through shelf-life tests by combining CAP treatments with two different MAP conditions.

![Figure 1. Main phases of the experimental design: fresh shucked oyster (a), CAP prototype used for atmospheric air or argon gas treatments (b), CAP prototype used for treatments generating ozone or NOx reactive species (c), oysters packed in two MAPs (d).](image-url)

(Continued on next page)
Materials and methods

Pacific oysters (Crassostrea gigas) (shell length 11±1 cm) were harvested from France and transported to the laboratory under refrigeration within 24 hours. The live oysters, after cleaning and draining excessive drip solution, were shucked and the meat left on one side of the valve used for experiments. Two CAP prototype were used (Figure 1):
- with argon gas or atmospheric air and treatment times of 20 and 45 minutes,
- with ozone or NO\textsubscript{x} reactive species with treatment times of 20 and 45 minutes.

Untreated (control) and treated oyster samples were analysed for quality parameters (pH, dry matter, oxidation, texture, colour and sensory properties) and natural microbiota (e.g., Pseudomonas spp., aerobic mesophilic and psychrotrophic bacteria). After plasma treatment, oysters were packed in high-density polyethylene (HDPE) boxes and high barrier film under two MAP conditions (20% CO\textsubscript{2} + 80% N\textsubscript{2} or 80% CO\textsubscript{2} + 20% O\textsubscript{2}) and stored at 4 °C as an additional intervention to prolong the product shelf-life. Microbial load and pH were analysed at storage times of 0, 3, 7, 10, 15, 21, and 28 days, while the other quality controls were carried out up to 7 days of storage.

Results

During the application of cold plasma at atmospheric pressure to fresh oysters, different processing parameters were selected to control the generation of reactive species that can significantly affect the quality of the final product. The pH, dry matter and texture of the innovative oysters showed no significant changes in most cases immediately after the CAP treatments. However, after 45 minutes of treatment, the oysters showed a darker colour, regardless of the feed gas, which affected their visual quality. Despite this effect, the CAP treated oysters scored very well overall in terms of sensory freshness. Nutritional quality, assessed by lipid oxidation, showed that the 20-minute treatment with argon did not affect this parameter, while the 45-minute treatment with argon, ozone and NO\textsubscript{x} increased lipid oxidation, also if below the expected limit for seafood.

From a microbiological perspective, CAP treatment with argon gas resulted in an immediate reduction (1-2 Log CFU/g) of Enterobacteriaceae, aerobic mesophilic and psychrotrophic bacteria. Similar results were obtained after treatments with ozone as reactive species, while those generating NO\textsubscript{x} mainly delayed and limited the extent of cell proliferation over storage of the microbiota that survived the treatments. Overall, the chosen CAP processing conditions in combination with MAPs helped to maintain the microbiological quality of the product within acceptable limits.

Conclusions

In summary, the results of the study showed promising effects of cold gas plasma treatment on some of the microbiological and physicochemical parameters investigated, with synergistic effects derived from the use of MAPs. However, given the inherent variability of the raw material and the multitude of parameters that need to be adjusted to optimize the quality and stability of the oysters during transport or storage, further studies are needed before considering actual industrial application of CAP. In addition, it is important to consider eventual potential toxicological concerns in future studies.

Acknowledgements

This research was conducted under the NewTechAqua project supported by the European Union’s Horizon 2020 Programme (grant agreement No 862658). The project aims to expand and diversify European aquaculture production by developing and validating technologically advanced, resilient, and sustainable applications for finfish, molluscs, and microalgae.
WATER PURIFICATION THROUGH MICROALGAE AQUACULTURE - ANALYTICAL AND TOXICOLOGICAL EVIDENCE OF THE REDUCTION OF TOXIC POLLUTANTS IN WATER FROM SEALED SURFACES

Introduction
On biogas plants, large areas are sealed (silo and driving surface) on which water accumulates primarily due to precipitation. This water from sealed surfaces (WSS) often contains pollutants as heavy metals or organic pollutants, as well as increased nutrient concentrations. Hence, it cannot be discharged directly into receiving waters. The collection, storage and ultimately regeneration of the polluted water is quite cost intense. However, the use of the nutrients and trace elements in WSS in cultivating algae biomass - sustainable value creation through production of economically usable microalgae biomass - could remedy the situation. Microalgae aquaculture can serve as bioremediation method to improve the water quality of WSS.

Materials and Methods
A microalgae-cyanobacteria mixture, resistant to germ pressure from WSS, was established and adapted to the WSS of the reference biogas plant. WSS was used as cultivation medium in laboratory trials to evaluate the cleaning performance of the microalgae mix in regards to several environmental pollutants. Further the mix was cultivated on WSS in a semi-continuous production with an algae reactor directly at the biogas plant. The water cleaning effect of the microalgae cultivation was analytically quantified looking at contaminants such as Pb, Cd, As, Hg, polychlorinated biphenyls (PCB) and mineral-oil-derived hydrocarbons (MOSH/POSH and MOAH). Which are the pollutants identified in preliminary tests to mainly occur in WSS from biogas plants.

Single water polluting substances can be analytically quantified and toxicologically evaluated regarding their effects on diverse organisms. However, the real toxicological effects of the exposure to the simultaneous presence of many different substances can still only be inferred to a very limited extent. So in addition to analytics, the water cleaning effect was assessed toxicologically. Therefore, the possible reduction of the mutagenic activity of the WSS after the algae cultivation was quantified with Salmonella typhimurium TA 100 in Ames Test.

Results
The results show that primarily heavy metals and PCB are cleaned from the WSS through the microalgae cultivation. While lead was cleaned from the water by up to 50% (fig.1), cadmium and individual polychlorinated biphenyls were cleaned by up to 60% after the algae cultivation.

Conclusion
Microalgae aquaculture in WSS can not only produce economically usable biomass but also significantly reduce individual pollutants in the water. Further, scientific assessment of mixed exposure effects on organisms is still very difficult and complex, but the use of contaminated natural matrices as WSS in toxicological tests might give an initial insight.

(Continued on next page)
Fig. 1: Reduced concentration of Pb and Cd in the WSS from before to after the cultivation of the algae mixture for 14d in laboratory conditions. As for the assessment of the mutagenic properties of the WSS the results show significant reduced revertants for the WSS in which the microalgae mixture was cultivated previously (fig. 2).

Fig. 2: Number of TA 100 revertants/plate (corrected by negative control group (WSS 0 µL/mL)) when incubated in WSS concentrations of 400, 300, 200, 20 and 2 µL/mL with the addition of S9 cell lysate. Each comparison includes the same concentration of water from the WSS before and the after the microalgae cultivation for 14 d in the algae reactor (****=p<0.0001, n=3).
NEAR INFRARED SPECTROSCOPY AS A NOVEL NON-INVASIVE TOOL IN AQUACULTURE

Istituto Zooprofilattico Sperimentale del Piemonte
Liguria e Valle d’Aosta
via Bologna 148, Turin
simona.sciuto@izsto.it

Introduction

In the last decades aquaculture production has expanded rapidly, due to the increasing demand for human nutritional purpose. Infectious diseases strongly impact on aquaculture sector. Lactococcosis, sustained by the warm-water pathogen *Lactococcus garvieae*, is a disease associated with high mortality and economic losses (1). Main symptoms are mono or bilateral exophthalmia, haemorrhages around the eye area, opercula, and mouth region, swollen abdomen, and anal prolapse. Since traditional laboratory investigation techniques are time consuming, expensive, and have limited sample flow, an effective system of surveillance activities on fish diseases is needed, that makes use of rapid, in situ and low-cost diagnostic tools. Near Infrared Spectroscopy (NIR) technique is an example of phenotypic approach for early diagnosis. Through this practice, it is possible to obtain information, directly by in-situ analysis, on the structural properties of matter, studying the interaction with electromagnetic energy, reducing considerably time and costs. This sector has found application in many fields (2), but not yet used for diagnostic purposes in aquaculture. Aim of this work was the evaluation of the potential of portable NIR, in particular SCiO miniaturized technology (3), in the aquaculture sector, to discriminate the health status of fish.

Materials and methods

Analyses were carried out in a natural outbreak of lactococcosis in rainbow trout, located in Northern Italy. Two categories of samples were used: 20 symptomatic and 20 asymptomatic trout. SCiO acquisitions were performed directly on site. Prior to acquisition, excess of water and mucus were removed from each individual. Trout were submitted to measurement three times, scanning them on a flat bench top, with the device placed over the fish. Scans were initially acquired in one specific point on the dorsal and the abdominal area (caudal to the perianal area) to account for possible variations. Each sample, after morphometrical parameters evaluation, was subjected to necropsy to highlight the presence of pathological alterations and/or lesions of internal organs. Bacterial isolation was carried out from kidney and spleen, in parallel with specific PCR amplification and sequencing to determine presence of *Lactococcus garvieae*.

Figure 1. SCiO spectrum of the trend of healthy trout (yellow) and sick trout (blue).

(Continued on next page)
Results and Discussion

SCiO acquisitions provided more reliable results in the proximity of the abdominal area. SCiO obtained very good results, with sensitivity of 0.95, specificity of 0.87 and accuracy of 0.90. There are various hypotheses for the mechanism by which the device proposes differential spectra between sick and healthy individuals, but the most plausible one is the fatty acids profile of analysed tissues. Moreover, it is known that lactococcosis induces severe inflammatory and haemorrhagic lesions in the intestine and in the surrounding abdominal fat (4), which could be detected by the SCiO device as alterations of biochemical properties in affected tissues.

Conclusions

Results demonstrate high performance of SCiO to discriminate between healthy and sick animals. The rapidity of acquisition, low cost, and the possibility to use the device directly on site, preserving animal welfare, make the SCiO a prognostic tool useful to implement control on animals, in order to avoid economic losses.

Introduction
Today, most of the shellfish products on the market comes from aquaculture, but this offer is often limited to a small number of species, so there is a need to introduce new species. The Mediterranean scallop Pecten jacobaeus (Linnaeus, 1758) is the largest bivalve of the Pectinidae family that lives in the Mediterranean and Adriatic Sea. Due to its size, fast growth, and high market demand, P. jacobaeus seems like a potential aquaculture candidate. Aim of this study was to provide information on some of the biological characteristics of P. jacobaeus from the Krka River estuary, through analysis of seasonal variations of some physiological indices, that can be of use for the potential introduction of this species into the commercial aquaculture in the Adriatic Sea.

Materials and methods
In the period from December 2021 to May 2023, approximately 20 specimens of P. jacobaeus were collected monthly from the Krka River estuary. Shell dimensions (length, height, and width (cm)), and shell and soft tissue mass (g) were measured, in wet and dry state. Based on the obtained measurements, water content (WC) and gonadosomatic index (GSI) and muscle index (MI) were calculated according to Lucas and Beninger, 1985:

\[
GSI = \frac{\text{gonad dry weight (g)}}{\text{total tissue dry weight (g)}} \times 100,
\]

\[
MI = \frac{\text{muscle dry weight (g)}}{\text{total tissue dry weight (g)}} \times 100.
\]

Results
Soft tissue WC was high (~82%) but varied seasonally and by soft tissue parts. Gonads’ WC was lowest in early winter, and highest in summer period, while muscle’s WC was highest in spring, and lowest in summer period.

Results of GSI suggest that there were three spawning periods in a year, the main one in early winter/spring season that lasted until summer, during which gonads seemed to be dormant. Second, shorter spawning period was in early autumn, and the possible third one was in early winter.

GSI showed significant inverse correlation to MI, which was highest during summer period, while lowest in early spring, when gonads were fully developed. GSI also showed significant inverse correlation to gonads’ WC, while MI showed significant inverse correlation to muscle’s WC.

Discussion
Gonadosomatic index is used for assessment of the reproductive cycle which can provide valuable information for collection of spat from nature or for conditioning of broodstock. Muscle index can indicate the state of nutrient reserves in the muscle, the most sought-after part of scallop meat, and can thus be used to estimate its quality for the market. Inverse correlation of GSI to MI, suggests that partitioning of energy is divided between storage of nutrient reserves in the muscle and gonads development. Water content in the gonads and muscle, can provide additional insights into gonads and muscle state, as an indicator of gonads ripeness or of muscle nutrient reserves.

Conclusions
For the possible aquaculture development, the most favourable period for setting up collectors for wild spat collection, as well as for collecting and conditioning of broodstock under laboratory conditions, would be during spring season.

For the market and consumer consideration, we suggest that harvest of natural populations would be best during summer season when the muscle is at its highest size and nutritional value.

Introduction
Tuna farming and fattening play an important role in Mediterranean aquaculture production and the tuna sushi sashimi industry. To preserve the tuna stock, the International Commission for the Conservation of Atlantic Tunas (ICCAT) establishes mandatory management measures to regulate fishing effort, catch, and farming capacity, and allocates annual state quotas (Fromentin, 2006). To better control Bluefin tuna farming/fattening practices, the Commission requested in 2018 an update on farmed fish growth rates, i.e., determining the growth of individual fish under farmed conditions. Therefore, the objective of this study is to present the novel tagging method, used for the first time in tuna farming, with the derived results of individual fish growth during the 18-month farming cycle.

Materials and methods
The tagging experiment targeted 2-3-year-old fish (> 8 kg) caught for commercial farming purposes and then kept under standard farming conditions for 18 months. In July 2019, a total of 206 tuna juveniles between 7.5 and 25 kg were PIT tagged in the head muscle. The fish were individually weighed, measured, and distributed in equal numbers in the two experimental cages for farming. During the farming cycle, fish growth was monitored seasonally for each cage using a stereo camera and image analysis system. All fish were harvested at the end of the season and subsequently measured individually.

Results and discussion
A total of 206 fish distributed between two cages were tagged with PIT tags, most of which were successfully captured at harvest, allowing 157 individual growth rates to be determined. PIT tagged fish were mostly evenly distributed across all size classes in the experimental cages. During the farming cycle, juvenile Bluefin tuna reached the overall harvested weight between 58 and 64 kg. The average 500% increase in body weight during the experimental period did not differ between two experimental cages or between tagged and untagged fish. Recorded mortality of tagged fish throughout the farming period was negligible (1%). The unrecorded proportion of tagged fish (22%) could be due to a combination of factors, such as detector and reader failure due to routine harvest procedures. The PIT tag appears to be biologically inert, as there is no evidence of tissue inflammation in the wound area. In summary, an experienced and trained team is capable of performing mass tagging of juvenile tuna for scientific research purposes with acceptable losses.

Acknowledgments
Financial support for this study has been provided by Atlantic-Wide Research Programme For Bluefin Tuna (ICCAT GBYP) (Phase 10).

Introduction
The concept of pathogen presence resulting in reduced production performance of livestock and aquatic species has been embodied in text books for decades. Despite this, many shrimp producers often don’t understand and/or have not been able to quantify the true impact of multifactorial pathogen presence, load and prevalence on production. This is understandable when you consider that only until recently were the tools available for accurate multiple pathogen detection at an affordable cost and that shrimp can have any number of 13 commercially relevant (impactful) pathogens, often harbouring 3-4 of these at any one time. Establishing data points that give farmers a quantitative pathogen profile of their crop over time empowers them with data to quantify the true impact of pathogens on culture and on which to make management decisions that can change the outcome and profitability of a crop.

This study will present case studies from around the world on how the application of the multiple pathogen detection platform Shrimp MultiPath has re-defined how farmers think about pathogens, assess pathogen loading and manage pathogens throughout the production cycle.

Materials and methods
Statistically significant sample plans are designed with farmers to allow sampling of appropriate tissue types in a timely manner for testing on the Shrimp MultiPath system. Tissue types that provide accurate detection of virus, bacteria and microsporidians are pooled together for testing. A typical grow out farm samples at postlarvae stage 10, 25 days of culture 50 days of culture and 70 days of culture for early pathogen detection to characterise pathogen presence and prevalence before having clinically sick animals. This provides up to four weeks early warning of pathogen presence and prevenance during which time a farmer can change management protocols to maximise crop outputs and minimise pathogen impact. Management decisions include actions such as increased biosecurity, reduced shrimp stress and feeding of alternative diets depending on the pathogen.

Results
Latin America, for example are using this knowledge and technology as part of their broodstock selection program resulting in a 10-15% improvement in production and a 10% improvement in fertility. Asia-Pacific farmers utilise the technology to monitor pathogen presence and prevalence during grow-out to provide an early warning that allows simple but smarter management practices to be applied on a case-by-case basis.
EVALUATION OF 20 YEARS OF MONITORING DATA TO CORRELATE ENVIRONMENTAL AND BIOLOGICAL FACTORS RELATIVE TO SHELLFISH PRODUCTION – A NORTHERN IRELAND CASE STUDY

1Institute for Global Food Security, School of Biological Sciences, Queen’s University Belfast
19 Chlorine Gardens, BT9 5DL, Belfast, UK.
2Agri-Food and Biosciences Institute, 18a Newforge Lane, BT9 5PX, Belfast, Northern Ireland, UK.

Email: dsenovillaherrer01@qub.ac.uk

Introduction

Shellfish are potentially hazardous foods, particularly when consumed raw, as in the case of oysters, and as a result can be the origin of foodborne illnesses due to the proliferation of pathogenic microorganisms or the build-up of natural toxins. Live bivalve molluscs, as filter-feeders, can bioaccumulate various harmful substances or marine contaminants prevalent in coastal estuarine regions that have been significantly impacted by human activities (Ferreira et al., 2018; Zuykov et al., 2013). Consequently, the biomonitoring of shellfish is crucial not only for ensuring food safety but also as a bio-indicator to keep track of waterborne pollutants. Currently in Northern Ireland, environmental factors affecting shellfish production are monitored and tested for separately using a diverse range of methodologies. On top of that, data obtained from these analytical approaches is often reviewed in isolation, whereby any related synergistic or antagonistic effects in the natural environment may go unnoticed.

Methodology

A historical compilation analysis was carried out to examine past surveillance data collated by the Food Standards Agency related to the coastal and estuarine waters of Northern Ireland across two decades, from 2001 to 2022. A total of 26,182 samples over seven water bodies in Northern Ireland were evaluated. The factors studied were phytoplankton species *Alexandrium* spp., *Dinophysis* spp., *Pseudo-nitzschia* spp.; *Escherichia coli* counts in shellfish flesh as a sentinel species for seawater quality; heavy metals (cadmium, mercury, lead); polycyclic aromatic hydrocarbons (PAHs); and marine biotoxins causing Diarrhetic Shellfish Poisoning (DSP), Azaspiracid Shellfish Poisoning (AZP), Paralytic Shellfish Poisoning (PSP) and Amnesic Shellfish Poisoning (ASP). Figure 1 shows the percentage of samples evaluated per environmental contaminant category. Additionally, chemical contaminants in water, biota and sediment samples monitored under the Water Framework Directive (European Parliament and Council of the European Union, 2000, 2020) and the Clean Seas Environmental Monitoring Programme (CSEMP) by the Department of Agriculture, Environment and Rural Affairs (DAERA) were also evaluated.

![Image](chart.png)

Fig. 1: Percentage of sample entries evaluated across datasets provided by the Food Standards Agency in Northern Ireland between 2001 and 2022 per environmental monitoring category.

(Continued on next page)
Results

Northern Irish Sea waters have historically presented and still hold good biological and chemical status for shellfish production. Phytoplankton and *E. coli* counts were generally below trigger levels. Positive incidents for marine biotoxins and chemical contaminants above regulatory limits in the region were extremely low, suggesting NI aquaculture production sites are an ideal safe location to sustainably develop the sector further.

Conclusion

This review provided a baseline reflecting the current status of information from a public health perspective. Our examination of historical data revealed gaps and inconsistencies, limiting its utility for tracking public and environmental health trends. Nonetheless, the data collected by environmental monitoring agencies still holds high value as it did allow for points in time analysis which may or may not be subject to change.

In order to create a coherent picture of marine contaminant trends for NI marine aquaculture moving forward, we need a structured, long-term monitoring strategy that incorporates more frequent and diverse data. Such an approach would bolster our Blue Growth Strategy by ensuring sustainable growth in the marine sector. As technology evolves, we must correlate analysis methods from different periods, helping future researchers and facilitating the development of predictive models, possibly through artificial intelligence. We suggest increased investment in rapid screening tests and citizen science programmes to facilitate frequent sampling. Simultaneously, sharing and centralising environmental data will empower us to address climate change and public health concerns more effectively, thereby contributing to a robust aquaculture strategy for Northern Ireland with potential for global application. By adopting a more holistic approach to monitoring, we can resolve current challenges and shape the future of sustainable aquaculture and food safety standards.

E-mail: s21dre02@s.kochi-u.ac.jp

Introduction

Yellowtail (Seriola quinqueradiata) is a large oceanodromous fish and an important Japanese aquaculture fish species with strong carnivorous characteristics (Masumoto, 2002). Recent global developments in aquaculture have led to the depletion of resources such as sardines, the main feed source for aquaculture fish. Fish meal substitution with plant proteins has been recommended for sustainable aquaculture; however, feed intake has decreased because of the low preference for plant proteins in yellowtail. Mixtures of alanine (Ala), proline (Pro), and inosine 5'-monophosphate disodium salt hydrate (IMP) have been reported as feeding stimulants for yellowtail in non-fish meal diets (Senzui et al., 2020). Behavioral and physiological approaches are required to elucidate the mechanisms underlying this increase in feed intake. However, few studies have investigated yellowtail feeding behavior and appetite hormones. Therefore, the mechanism of increased feed intake is relatively unknown. The purpose of this study was to investigate feeding behavior, orexigenic hormone expression, and feed intake in response to feeding stimulants (Ala, Pro, and IMP) in yellowtail.

Materials and methods

Yellowtail was reared in fiber-reinforced 200 L tanks supplied with seawater maintained in a continuous flow-through system with a natural photoperiod. The stimulus solutions used consisted of 10 mmol each of Ala, Pro, and IMP. [Appetite] Hypothalamus was collected before the addition (0 min) and at 10 min and 30 min after the addition of the stimulus solutions (n = 8 at each point). Gene expression of the orexigenic hormone (neuropeptide Y [NPY]) was measured using RT-qPCR. [Feeding behavior] Two weeks before the feeding behavior test, fish were acclimatized to a commercial floating extruded pellet (EP) diet. The control was a water-soluble fraction of soy protein concentrate (SPC) that yellowtail showed a low preference. Cotton puffs soaked in the stimulus solutions were placed in baskets in the tanks, and feeding behavior was recorded for 10 min. Instances of “search” (moving to the upper zone of the tank) and “bite” (pecking at the water surface) were recorded using an action camera, and the frequency was counted. [Feed intake] After the feeding behavior test (15 min after adding the stimulus solution), a commercial floating EP diet was fed until satiation and feed intake was measured.

Results

[Appetite (Fig. 1)] Hypothalamic npy mRNA expression significantly decreased after Ala addition compared to that at 0 min (before addition). However, npy expression was significantly increased by IMP addition compared to that at 0 min. No change was observed in the npy mRNA expression for Pro addition. [Feeding behavior (Fig. 2)] The mean frequencies of “search” for control, Ala, Pro, and IMP were 169.0 ± 29.7, 458.01 ± 39.3, 420.7 ± 30.3, and 397.0 ± 5.3, respectively. The frequencies of “search” for Ala, Pro, and IMP were significantly higher than that for control (P < 0.05). The mean frequencies of “bite” for control, Ala, Pro, and IMP were 3.7 ± 2.7, 8.0 ± 1.2, 33.7 ± 5.7, and 6.0 ± 2.3, respectively. The frequency of “bite” for Pro was significantly higher than that for the other groups (P < 0.05). [Feed intake (Fig. 3)] The amounts of feed intake after addition for the pure water (vehicle), Ala, Pro, and IMP were 6.2 ± 0.38 g, 4.1 ± 0.41 g, 6.1 ± 0.48 g, and 7.6 ± 0.48 g, respectively. The feed intake of Ala was significantly lower than that of the other, and the feed intake of IMP was higher than that of the vehicle.

Fig. 1. Hypothalamic npy mRNA expression levels after Ala, Pro, and IMP addition to the rearing water (n = 7–8 at each point). The npy expression levels are shown as 0 min before stimuli solution and 10 min and 30 min after addition. All measurements were standardized using efla mRNA expression levels. Different letters indicate significant differences (P < 0.05).
Discussion
The results of the feeding behavior and appetite tests suggested that Ala decreased feed intake by decreasing npy expression in the hypothalamus, the center of appetite. Pro increased “bite” but did not affect hypothalamic npy expression and feed intake. These results suggest that IMP increases feed intake by increasing hypothalamic npy expression. Ala, Pro, and IMP increased feeding behavior “search,” and Pro increased “bite,” but only IMP increased feed intake. This suggests that there may be a weak relationship between feeding behavior and feed intake. In contrast, Ala decreased feed intake along with hypothalamic npy, whereas IMP increased feed intake along with hypothalamic npy. These findings suggest that hypothalamic npy levels and feed intake are related.

Introduction

Design and planning of pond aquaculture require a unified, quantitative pond model that can be linked also with the simplified quantitative models of neighboring areas of different land use. Considering the labor-consuming and expensive experimentation of individual production ponds, in this study we present the reusability check-based improvement of a formerly validated production pond model (Varga et al., 2020), applying the modeling framework of Programmable Process Structures (Varga and Csukas, 2022).

Materials and methods

The testing and improvements include both the reduced and the extended use of the reference model (i.e., appropriate reduction and extension of a selected reference model to describe the various pond managerial cases e.g., natural fishpond with no feeding and manuring, manured pond, manured and foraged pond with optional artificial fertilizer, etc.), and its application for the model-based scaling-up.

To check and improve the reference model, data generated during the vegetative seasons of 2021 and 2022, from carp-rearing experiments conducted in frequently monitored pilot ponds of MATE AKI HAKI, Szarvas, Hungary were used. This included data on stocking and harvesting of fish (mainly carp); on manuring, fertilizing, and feeding strategy; on manually measured and sensor-based water quality; on the concentration of food web elements (zooplankton, Chl-A represented phytoplankton); as well as about meteorology (Sharma et al., 2023). In order to pre-process this data, Matlab® Data Cleaner was utilized, and the moving median smoothing approach with a smoothing factor of 0.25 was also applied. The normalized root mean square error (NRMSE, %) was used to calculate the average deviation of simulated and calculated data in the absence of knowledge of the obvious sampling errors.

Results & Discussion

In the first phase of the suggested stepwise reusability check, each step ended with the necessary refinement and testing of the refined parameters or prototype models, while the already made improvements were fixed for the further steps. A simplified structure of the investigated model was created showing the contribution of the various nutrients (e.g., from feed, manure, and, inorganic fertilizer) to the food web of the produced carp. Finally, a hypothesis-based extension was suggested to distinguish phytoplankton’s eukaryotes and cyanobacteria groups. After iterative testing and verifying computations in multiple steps, a unified model was created for a wider range of ponds, from natural lakes to heavily stocked and manured ones. The input files, describing the structure, the input data, and parameters, as well as the prototyped local programs of the applied Programmable Process Structures, can be found in the contributing Mendeley database (Sharma et al., 2023). The obtained large NRMSE values contain both sampling & measurement and model errors. The reusability checking procedure brought attention to the even more conscious planning of experiments. In order to develop the strategy for sampling and measurements, which must comprise a small but essential number of spatially distributed and simultaneous measurements, the experimental design must involve the model specialists and some preparatory modeling. The inclusion of the pond history and the comprehensive set of initial concentrations are quite crucial since food web models in particular are very sensitive to the initial conditions.

The resulting model was also tested for model-based scaling-up of production ponds in the knowledge of the very limited amount of case-specific input data. In addition to the estimated approximate fish production, the up-scaled simulation can give estimations also about the other characteristics and environmental impacts of the production pond (e.g., for the necessary water supply, nutrient emission, O2 production and consumption, CO2 sequestration, and emission, etc.).

COMPONENTS OF BLUE WHITING (*Micromesistius poutassou*) FISH WASTE AS GROWTH FACTORS FOR GUT-FRIENDLY BACTERIA

D. Sharma¹*, S. Gite², M. Tuohy¹

¹Molecular Glycobiotechnology Group, Biochemistry, School of Natural Sciences, University of Galway
Galway, Ireland
²Bio-marine Ingredients Ireland
Email: d.deepanshi1@nuigalway.ie

Introduction
Protein hydrolysates enzymatically derived from under-utilised fish waste can potentially serve as valuable sources of dietary protein. Although oligosaccharides are the most commonly utilized prebiotics, the prebiotic properties of enzymatically produced peptides in the digestive system are receiving attention for the development of functional foods [1]. Lactic acid bacteria (LABs) may use the free amino acids and peptides found in fish waste as nitrogen sources, allowing them to grow and multiply [2]. Additionally, the use of fish peptones as a suitable and economical substitute to currently available meat-derived peptones of pig or cow origin is being investigated. This chapter explores the development, advantages, and possible uses of prebiotics derived from fish waste as functional foods.

Materials and methods
Bio-marine Ingredients Ireland Ltd. (Lough Egish Food Park, Castleblaney, Co., Monaghan, Ireland) developed two products from frozen blue whiting (BWFPH-A & BWFPH-B). Following homogenization, the substrate was subjected to proteolysis by a microbial enzyme at a temperature of 50°C. Following hydrolysis, the soluble fraction (BWFPH-B) was separated from the insoluble fraction (BWFPH-A), and then spray dried and milled respectively to obtain powders. A microplate assay for seven lactic acid bacterial cultures was employed where their growth was measured after incubation at 37°C overnight at 595 nm. The growth media deMan, Rogosa and Sharpe (MRS) was modified by substituting the nitrogen content with peptones derived from the hydrolysates. These results were compared to their growth in presence of commercial nitrogen sources like tryptone and peptones from soy and potato.

Figure 1: Growth of *Lactobacillus reuteri* in the presence of different peptone sources

(Continued on next page)
Results and discussion
Stimulated growth was observed in most bacteria in presence of the hydrolysates, but superiorly in BWFPB-B, when compared to the commercial nitrogen sources. An example is shown in Figure 1 where the growth of *Lactobacillus reuterii* is stimulated in the presence of peptones derived from BWFPB-B as compared to commercial MRS media or peptones from soy or potato sources. Our findings indicated that the hydrolysates produced from fish waste, which served as nitrogen sources, effectively promoted the growth of lactic acid bacteria. The hydrolysates thus have the potential to offer nutrients linked to prebiotics in addition to contributing to the economic and environmental sustainability.

Introduction

Specialized aquaponic diets could help to reduce the need for artificial fertilizer use in on-demand coupled aquaponic systems. Following the logic of reducing the dependence on marine ingredients from capture fisheries and respectively using pertinent alternative ingredients, the present study aimed to compare the potential of a fixed combination of animal protein sources – poultry by-product meal (PM), catfish by-product meal (CM) and poultry blood meal (PBM) - with a fixed combination of plant protein sources – soybean meal, rapeseed meal, guar korma, corn gluten meal, wheat gluten and soy protein concentrate - for use in aquaponic diets that aim to provide an improved dissolved plant nutrient profile. While by-products of animal origin, particularly when high in bone content, could represent an ample source of phosphorus (P) in aquaponic diets [1], plant protein sources may provide higher levels of potassium (K) as one of the most abundant cations in plants [2]. In this sense, African catfish (Clarias gariepinus) were fed four different experimental diets ranging from entirely animal protein based to primarily plant protein based in a systematic RAS feeding trial in which growth performance was tracked and dissolved inorganic nutrient excretion of major plant macro- and micronutrients were compared, particularly N, P and K.

Material & methods

Four isolipidic and isonitrogenous (42% crude protein - CP, 12% crude fat) were designed to have a blend of animal by-products contribute 100% (A100), 75% (A75), 50% (A50) and 25% (A25) of the CP delivered through the protein ingredients in the diet with a concomitant increase of the CP contribution through a blend of plant protein ingredients. The ratio of the animal protein sources as well as the plant protein sources among each other was kept constant in all diets. All diets featured the same amount of monoammonium phosphate (0.5%) and phytase (1000 FTY/kg). Diets were fed at a daily ration of 3.8% to African catfish (initial weight 11 g) reared in recirculating aquaculture systems (RAS - 400 L system volume) in a 7-week trial (n=4). Feed rations were increased daily and individually per RAS according to determined

Figure 1. Excretion of major dissolved plant nutrients per unit of feed by African catfish reared in RAS.

Table 1. Modelled RAS water exchange rate required to achieve the nitrogen concentration of a standard hyporonic nutrient solution, i.e. 210 mg/L, and the consequently establishing concentrations of P and K; assumptions include a constant rearing density of 70 kg/m³, a 2% daily feeding rate and the rearing volume making up 50% of the total RAS volume.

(Continued on next page)
feed conversion ratios (FCR). A daily water exchange of 10% was maintained and pH was kept above 6.5 by the help of daily NaOH dosing over 12-18 h. Fish growth performance was recorded and dissolved nutrients in the process water were analyzed weekly (continuous flow analysis (CFA), ICP-OES). Under certain assumption, the water exchange rate necessary to reach the N concentration of a hydroponic standard nutrient solution [3] was calculated on the basis of the determined nutrient excretion per unit of feed.

Results
Uniform growth performance between most diets was recorded with a biomass increase of 839-959% over the course of the trial and only at the maximum plant protein inclusion (A25) performance was slightly impacted; i.e. FCR and protein efficiency ratio was significantly lower for the A25 diet compared to the A75 and the A50 diet. Regarding the excretion of total dissolved nitrogen (TIN) per unit of feed, no significant differences were detected between the experimental diets, with diets occupying a range of 24.8-25.7 mg TIN excreted per g of feed (Figure 1). However, higher plant protein inclusion led to significantly elevated dissolved potassium excretion and higher animal protein inclusion to significantly elevated soluble reactive phosphorus excretion. Hence, the animal protein-based diets produced RAS process water with a better dissolved N:P ratio for aquaponics, whereas the plant protein-based diets resulted in RAS water with a better N:K ratio. At a similar RAS water exchange rate, it was modelled that the A100 diet could potentially reach 86% of the P concentration suggested by a standard nutrient solution and the A25 diet 15% of the respective K concentration (Table 1).

Discussion
The results support the notion that for the most part animal by-products as well as plant protein sources can support good growth performance in African catfish. However, they appear to have different advantages in terms of the plant macronutrients they supply to the hydroponic unit of aquaponic systems. While P-rich animal by-products seem superior over the used plant protein mix in terms providing plant available P, the plant protein mix provides higher K levels. Considering the illustrated potential to eliminate the need for P fertilization in aquaponic systems, P provisioning through strategic protein ingredient choice could be a focus point in aquaponic diet development in the future.

Introduction
The shift from a marine-based to plant-based diet in farmed Atlantic salmon has revealed new challenges concerning the dietary requirements necessary to ensure fish health. Among the nutrients discovered to be lacking in plant feeds, choline has been identified as essential to guarantee efficient lipid transport and metabolism¹. The distinctive sign of choline deficiency is an excessive presence of fat within the enterocytes, a condition known as steatosis. A recent study estimated a choline requirement of 3.4 g/kg in Atlantic salmon weighing 200-400g raised in freshwater². However, it is not unlikely that choline requirement is influenced by production conditions such as dietary lipid level, environmental temperature, life stage, growth rate, etc. In a previous experiment we investigated to which extent dietary lipid level and water temperature influence steatosis symptoms. The findings confirmed the influence of lipid level and water temperature. The results to be presented are part of a following screening study investigating the possible effects of dietary lipid quality and fish size on choline requirement in Atlantic salmon. To perform the statistical analysis, a Bayesian approach was used. This approach provides careful and robust reasoning as well as accurate uncertainty handling for resource demanding studies aiming to describe dose-response relationships.

Materials and methods
Six experimental diets were formulated to contain 32 % fat, varying in ratios of rapeseed oil to fish oil, from 0/32 to 24/8. The diets were fed to two groups of Atlantic salmon raised in sea water: the smaller fish had an average initial weight of 1500g, while the larger fish weighted 4500g. At the end of the 8-weeks feeding trial, twelve fish from each tank were sacrificed and their body measures taken. The fish were then opened ventrally, and the intestinal package removed. The intestine was sectioned into pyloric, mid, and distal portion and weighed. The pyloric section was cleaned of mesenteric fat and weighed again. The liver was removed and weighed. Tissue samples from all the organs and sections were taken and processed for analyses of fat content and fatty acid profile, gene expression and histological characteristics. Enterocyte vacuolization was scored according to their morphological appearance and graded as normal, mild, moderate, marked and severe. Feed and feces were analyzed for dry matter, ash, crude protein, fatty acids and starch content. The digestibility of the macronutrients was assessed by using yttrium oxide as internal marker. Plasma was collected and stored for evaluation of biomarkers of nutritional status: glucose, free fatty acids, cholesterol and total triacylglycerides.

(Continued on next page)
Results
Growth performance, identified as Thermal Growth Coefficient (TGC), was higher in the large fish, whereas the increasing rapeseed oil level had no effect. A similar picture was observed for the organosomatic index of the pyloric intestine (OSI PI), which was higher in the large fish and not clearly influenced by lipid quality (Figure 1). Likewise, the histological assessment showed a higher vacuolization degree in the pyloric caeca of the larger fish. The vacuolization increased with the increasing rapeseed oil level, suggesting a dose-response effect (Figure 2), which was confirmed by analyses on fatty acids content. Neither fish size nor lipid quality affected the expression of the targeted biomarker genes.

Other data are under evaluation and further results will be presented at the conference.

Conclusions
The results obtained so far showed that steatosis symptoms and therefore choline requirement is mainly affected by fish size, whereas lipid quality showed less clear effects.

Introduction

Aim of the INAQUA-2-O project is to improve the quantity and quality of the farmed freshwater fish through the definition of specific feeding plans and the control of their physiology. This to expand the offer of aquatic products of the Apulian aquaculture enterprises, support their productions, and increase their competitiveness. Studying the effects of regular and special feed with enhanced product characteristics falls into the objectives of the project. Emphasis is given to the research, development and use of probiotics, due to their now recognized beneficial properties on the health of the farmed fish, in terms of optimization of the processes of digestion and absorption of the food, immuno-modulation and enhancement of certain anti-inflammatory and protective effects, and control over pathogens and/or infectious agents (Zabidi et al., 2021). The analysis of essential physiological functions such as gastro-intestinal, endocrine and cardio-circulatory function, as well as the behavior of the animals in the tank, are also considered in the project in order to obtain high quality fish.

Materials and Methods

**Fish.** Apulian naturalized (Scordella et al., 2003) Nile tilapia (*Oreochromis niloticus*) were purchased from Azienda Ittica Agricola Residence San Nazario srls (Lesina, Foggia, Italy) and reared indoor in tanks in a recirculating aquaculture system set at the Laboratory of Urban Farming, Department of Innovation Engineering, University of Salento (Lecce, Italy).

**Rearing system.** The system consisted of tanks (360 L each; 300 L water) with UV-treated (Velda Clear Pond UV-C 7 W) urban tap water. Dissolved oxygen was maintained above 4 mg/L using an impeller aerator (aquael oxyboost 200 plus) per tank to provide continuous aeration. The aquaria room was at controlled temperature (air conditioning system: 21-25 °C). Fish were kept under natural photoperiod. Water temperature and dissolved oxygen were continuously monitored by probes (Hanna Instruments HI98193). Other water quality parameters, such as ammonia, nitrite and nitrate, were monitored three times a week. During the experimental period, water temperature was 22.9 °C, pH 8.2, oxygen dissolved 6.8 mg/L and total ammonia-nitrogen < 1 mg/L.

**Probiotics.** Among probiotics, *Bacillus* appears to be the second most studied/used genus (Arsène et al., 2021). Notably, *B. velezensis* is one of the most studied/used species for fish feeds (Yi et al., 2018; Khalid et al., 2021). *B. velezensis* MT9, as isolated in the Laboratory of Microbiology (DiSTeBA-University of Salento), was chosen to integrate the diet. Growth and tolerance tests were conducted in a range of temperatures (bacteria grown in liquid GYM medium for 6 hours) from 30 to 70 °C. Bacteria showed viability and good growth up to 40 °C, making it suitable for the purpose of this study (Figure 1A).

![Figure 1. (A) Growth of *Bacillus velezensis* MT9 at various temperatures. (B) Preparation of the new feed. (Continued on next page)](image-url)
The serial dilution method was used to measure the bacterial load and standardize bacteria growth. When the culture reached $\text{OD} = 0.7$ (absorbance at 600 nm), 7 serial dilutions (1:10) were made in saline solution (NaCl 0.9%). 10 µL of each dilution were plated onto Petri dishes containing solid GYM. The plates were incubated at 28 °C for 24 hours and then the colonies were counted.

**Diet.** A diet was formulated, including the probiotic *Bacillus velezensis* (Khalid et al., 2021) as isolated in the Laboratory of Microbiology (DiStEBA-University of Salento). This diet was tested vs. a control diet without probiotic. Fish feeds were prepared starting from a complete commercial feed (Veronesi CFW 4; extruded pellets, 4 mm diameter). The two diets were isoproteic (35% crude protein), isolipidic (10% crude fat) and isoenergetic (crude fiber 4.80%, ash 5.95%, calcium 0.60%, phosphorus 0.80%, sodium 0.12%). The commercial feed was first fine powdered and then mixed with water (50 ml dH$_2$O for 100 g feed powder) alone (control diet) or containing the probiotic *B. velezensis* MT9 (Calcagnile et al., 2022) (7 × 10$^6$ bacteria, OD = 0.7 resuspended in 50 ml dH$_2$O for 100 g feed powder). The ability of the probiotic to resist was routinely assayed at 40 °C for 6 hours. The mass obtained was roughly extruded with a potato smasher to get a new 1-2 mm diameter pellet. After desiccation overnight in a dryer (40 °C), the new feed was considered ready for use (Figure 1B).

**Feeding trial.** To start the experiment, 48 hours fasting fish were distributed into 2 tanks. In particular, out of 75 selected uniform-sized fish (average body weight: 41.5 ± 8.3 g) (means ± SD; n = 75), 2 groups of 25 fish each were randomly composed and distributed into the 2 tanks. After 1-week adaptation, an initial sampling (T0) was carried out followed by a second sampling (T1) after 21 days of feeding control or experimental diet (2% fish weight).

**GI function.** To monitor the health state of the fish GI tract, selected intestine and liver enzymatic activities were checked. Briefly, fish were euthanized by phenoxethanol/chilled water. Intestines and livers were isolated and homogenized, and leucine aminopeptidase (LAP), lipase (LIP) and alkaline phosphatase (ALKP) activities measured by spectrophotometry using a suitable substrate (i.e., L-leucine p-nitroanilide for LAP, p-nitrophenyl myristate for LIP, p-nitrophenyl phosphate for ALKP; absorbance at 405 nm). The values of the initial sampling (T0) (means ± SD; n = 6) were as follows: (liver) ALKP: 142.1 ± 14.3 mU/mg protein; (intestine) ALKP: 680.6 ± 12.1 mU/mg protein; intestinal LIP: 31.6 ± 11.7 mU/mg protein; LAP: 91.4 ± 33.1. In addition, viscerosomatic (VSI) and hepatosomatic (HSI) indexes were calculated.

**Results**

We planned to calculate growth performance parameters and somatic indexes at the beginning of the experimental trial (0 day) (T0) and after 21 (T1), 42 (T2) and 63 days (T3). Here, we report the results referring to the T0 and T1 time points, while the experiment is still underway. The initial (T0) average weight (means ± SD; n = 6) was 47.3 ± 10.0 g, while after 21 days (T1) it was 60.4 ± 9.9 g for the group of fish fed the control diet and 69.6 ± 7.3 g for the group of fish fed the experimental diet containing the probiotic. The initial (T0) length (means ± SD; n = 6) was 129.7 ± 10.4 mm, while after 21 days (T1) it was 144 ± 12.4 mm for the group of fish fed the control diet and 157 ± 7.6 mm for the group of fish fed the experimental diet containing the probiotic. During the feeding trial, both VSI and HSI (means ± SD; n = 6) increased passing from T0 (VSI = 8.0 ± 0.3 and HSI = 1.2 ± 0.3) to T1 (VSI = 13.2 ± 2.5 and HSI = 1.8 ± 0.5 in the group of fish fed the control diet, and VSI = 11.5 ± 0.8 and HSI = 1.9 ± 0.4 in the group of fish fed the experimental diet containing the probiotic). Both diets were well accepted and the survival rate was 100% for both fish groups. During the experiment, current regulations on the protection of animals used for scientific purposes were respected, with particular emphasis on the health and welfare of the fish during the growth, testing and sacrifice phases.

Introduction

Fish nutritional requirements are generally estimated through analysis of dose-response studies involving essential nutrients, which condition the nutritional targets of fish feeds during formulation. Due to the high cost of undertaking such studies, they are often performed under simplifying assumptions (e.g., the effects of nutrients on growth are marginally independent) and the implicit notion that nutritional requirements are essentially static: once the requirements of a specific nutrient have been estimated for a specific species, at a specific size and under specific environmental conditions, its value is simply accepted as being universally valid and seldom re-evaluated.

On the other hand, genetic improvement programs of commercial fish species through selective breeding are known to have potential effects on fish traits which directly condition nutritional requirements (e.g., feeding and growth potential, retention efficiencies, body composition). Thus, and given the importance of the genetic-nutrition interaction in the process of fish growth, it seems relevant to be able to quantitatively predict the impact of such changes in fish traits on optimal feed formulation targets.

In this work, we develop analytical formulas that directly relate “relevant fish traits” to “optimal feed formulation” as a way of tackling this question without resorting to (possibly biased) observational data.

Materials and methods

In order to establish general formulas, we start by assuming energy and mass conservation to define a budget for energy, protein and phosphorus (i.e., gain = intake – losses). Then we consider a series of assumption sets with increasing levels of complexity (and realism).

Expanding the budgets under each of these sets of assumptions leads to different closed-form formulas that directly relate relevant fish traits to the optimal feed inclusion levels of energy, protein and phosphorus. The specific effect of each trait on optimal inclusion levels were then obtained and analysed both through an analytical sensitivity analysis and plots of the marginal effects of each trait (under varying conditions).

Results

The formulas obtained under a simplistic assumption of a linear relationship between intake and retention (of energy and nutrients) provide a useful first-order approximation to the effect of changes in fish traits due to genetic improvement on optimal feed formulation targets: the digestible amount of a certain nutrient (or energy) required in the diet is proportional to the relative amount of that nutrient (or energy) in the body of fish, and inversely proportional to FCR and to the retention efficiency of that nutrient (or energy). This implies that the effect of relevant fish traits on optimal feed formulation targets is, in this case, straightforward, since each trait multiplicatively and independently affects the optimal target in the same way.

On the other hand, the more realistic formulas, obtained under an assumption of a saturating (rational) relationship between intake and retention, display a slightly more complicated structure, where (unlike in the previous formulas) both the feeding rate and the growth/anabolic rate play a relevant role (see Figure 1 for an example), and where the effects of the different traits on the optimal inclusion rates is not necessarily multiplicatively separable. Despite these challenges, these formulas end up being more useful than the previous ones, not just due to the increased realism (e.g., effective retention efficiency should go down at high intake levels), but due to the fact that the nutritional and genetic effects are more clearly separated and identifiable, which is not the case for the first set of formulas (since FCR is not a feed-independent trait).

(Continued on next page)
Discussion and Conclusion

The formulas developed within the traits-to-feed framework seek to help aquaculture stakeholders make more informed decisions: for fish farmers, these formulas can be used to adjust feeding rates to achieve specific growth rates (as a function of fish size, diet composition and environmental conditions); for fish breeders, these formulas can inform them on the relative importance of different fish traits (and the relevance of estimating them within breeding programs); for fish nutritionists and aquafeed formulators, these formulas can guide the formulation of diets that are adapted to specific fish strains and under specific conditions and growth targets.

Introduction

Between 1950 and 2021, the annual production of plastics has continually increased from 1.5 to 390 million metric tonnes. Regarding microplastics (MPs), plastic particles smaller than 5 mm, there is a worldwide growing interest and awareness on its impacts in the marine environments and organisms. Seafood has a crucial role for human consumers because it is an important source of high-quality proteins, unsaturated fatty-acids, fat-soluble vitamins and minerals, with numerous nutritional and health benefits. Thus, understanding the potential contamination of seafood with MPs is critical for food security and human health. Seafood is also highly perishable, and several preservation methods (like salting, freezing, or canning) are traditionally used to ensure the quality of the products. Canned seafood corresponds to approximately 10% of the total 178 million tons of the world fishery production, with the existence of a wide variety of canned organisms (e.g., fish, molluscs, crustaceans), immersed in different edible liquids (e.g., sunflower oil, olive oil, tomato sauce). Since consumers eat these products without any additional cleaning process, from a health perspective it is crucial to have a better understanding on possible MPs contamination both in the food tissues, as well as in the respective immersive liquids. The occurrence of MPs has been widely studied for several seafood species but, regarding canned seafood, there is still limited information. The main objective is to better understand possible MPs contamination during the canning processing of the seafood. From our knowledge, this is the first study comparing the occurrence of MPs in fresh and canned samples from the same seafood species.

Materials and methods

Four seafood species with relevance for human diet were selected and studied, both in fresh and canned samples: sardine (Sardina pilchardus), chub mackerel (Scomber colias), octopus (Octopus vulgaris) and mussels (Mytilus galloprovencialis). Fresh seafood was obtained directly from fisheries harbor, and canned seafood were obtained from local markets. MPs were extracted using 30% H2O2 to digest organic content, followed by vacuum-filtration and subsequent observation under a stereomicroscope, according to a previously optimized protocol. For canned samples, the edible tissues and immersion liquids were separately analyzed; for the fresh samples, MPs contamination was investigated in subsamples from the dorsal muscle of the organisms.

Results

For all the fresh samples (n= 107), an average (± SD) of 0.086 ± 0.088 MPs/g of was obtained, while for the canned samples (n= 50), an average (± SD) of 0.040 ± 0.070 MPs/g of seafood tissue was observed. In general, some variability among MPs concentrations were observed in the two types of samples: sardine presented an average of 0.211 ± 0.074 MPs/g for fresh samples, and 0.020 ± 0.052 MPs/g for canned samples (in tomato sauce and sunflower oil); for octopus, an average of 0.006 ± 0.009 MPs/g in fresh samples, and 0.070 ± 0.106 MPs/g in canned samples (in tomato sauce) were obtained; concerning mussels, fresh samples presented an average of 0.066 ± 0.095 MPs/g, while canned samples (in escabeche sauce) presented 0.050 ± 0.071 MPs/g; for chub mackerel, an average of 0.060 ± 0.115 MPs/g for fresh samples, and

(Continued on next page)
0.040 ± 0.052 MPs/g for canned samples (in sunflower oil) were reported. Also, an average of 0.004 ± 0.012 MPs/mL was obtained for the immersion liquids from the cans, an important finding since some of the liquids are ingested by human consumers. Microplastics were observed in all the studied seafood species including fragments, films and fibers from eleven different colors, and with a size range from 250 to 3000 µm. Plastic polymers such as polypropylene, polyester, polyethylene, rayon, polyvinyl and nylon were identified through FTIR analysis.

Conclusion

The present study shows MPs contamination in four relevant and commercialized seafood species, in both fresh and canned samples. This is an important finding, indicating that MPs contamination in seafood may result from two paths: i) direct and continuous contact between marine organisms and the surrounding contaminated environment, or ii) human handling and industrial process as canning. Quantifying and regulating MPs in canned seafood is crucial to increase food safety and human health, and a better knowledge on the possible MPs contamination from the capture of seafood organisms until the final products sold to consumers (considering all the human handling and industrial canning steps) is of major importance for a better understanding of MPs occurrence in canned seafood.

NORTE-01-0145-FEDER-000040) projects, supported by the Norte Portugal Regional Operational Programme (NORTE 2020) under the PORTUGAL 2020 Partnership Agreement and through the European Regional Development Fund (ERDF). Also, FCT is awarded by the Strategic Funding UIDB/04423/2020 and UID/04423/2020 through national funds provided by FCT and ERDF, and a PhD fellowship to DMS (2020.06088.BD) and a research contract to S. Ramos (DL57/2016/CP1344/CT0020).
In face of global biodiversity losses, due to habitat degradation and pollution, the creation of biodiversity biobanks has been explored as a promising approach for the conservation of endangered species. In Portugal, the creation of a national biobank for marine resources is deemed a strategic priority, not only to promote the country’s role in increasing the current knowledge of the planet’s biodiversity, but also to contribute to the international visibility of national bioresources and its economic valorisation in international chains. In view of the above, the Portuguese Blue Biobank project was established in late 2022, focused on the implementation of a national network of marine resources Biobanks, with a dedicated infrastructure and increasingly digitalized tools to enable mapping the national resources, monitorization of their end-uses and distribution (both for commercial exploitation and scientific research), as well as the application of the international Nagoya Protocol on Access and Benefit-sharing.

In order to facilitate industrial research, the Portuguese Blue Biobank main goals are to 1) establish a demand-centered distribution system, by creating a single, regulated system for distribution of isolates and samples (with special focus on microorganisms, macrophytes, invertebrates and marine vertebrates), and expanding the available samples typologies (strains, DNA, extracts, and tissues), 2) develop a repositorium for the national marine biodiversity (mainly microorganisms that present high biotechnological value), and 3) develop a quality management system for the Biobank, by operating a standardized management protocol and introducing a certification process (ISO 20387-2018, for the competence, impartiality and consistent operation of biobanks).

Two partners of this Portuguese Blue Biobank are S2AQUAcoLAB, a collaborative laboratory for a Sustainable and Smart Aquaculture, and IPMA/EPPO, a state laboratory that has a pilot station to improve aquaculture research, product development and experimental procedures. As part of the Portuguese Blue Biobank Consortium S2AQUAcoLAB’ collection will be focused on pathogenic bacteria isolated from different marine fish species and confirmed by biochemical and molecular tools, fish-derived cell lines with high potential for cellular in vitro research, and macroalgae collected from the Portuguese coast. IPMA’s collection will consist in marine fish broodstock from different species with the main goal to increase the aquaculture biodiversity, external parasites isolated from fish cultured in IPMA’s facilities, and microalgae. The project’s idea is to collect and cryopreserve these marine bioresources to push forward advancements in aquaculture research.

Introduction
Aquaculture industry progress depends on fish health and welfare. Nowadays, with the production intensification to meet the needs of a continuous growing human population, fish are exposed to challenges (e.g., diseases, stress) that limit their performance with consequences on the overall productivity. It is essential to implement sustainable strategies to prevent, mitigate and overcome these deleterious events. Hence, functional nutrition is key for creating precise solutions to improve fish performance and robustness. Algae, both micro- and macro-algae, are high value ingredients due to the diverse bioactive compounds present in their composition (Ampofo and Abbey, 2022). The inclusion of these bioactive biomasses and/or extracts in fish diets for commercial species will be a differentiating element, as it may improve overall fish resistance to stressful events (Reis et al., 2021). This trial aimed at evaluating the biological efficacy of different functional microdiets with different amount of micro- and macro-algae inclusion for gilthead seabream (Sparus aurata) post-larvae on survival, growth, robustness, and resistance against pathogenic stresses.

Materials and Methods
The trial was performed at EPPO/IPMA (Olhão, Portugal) and was divided in two phases: 1) 33DAH post-larvae started an experimental feeding that consisted in four different feeds: Winfast (control diet, SPAROS Lda.), BLEND1, BLEND2, and BLEND3 (three different diets with different amounts of micro- and macro-algae). Fish were fed respective diets until 42DAH, where they changed to a control feed for 1 week until 50DAH, and then back to the functional feeds for another week, until 58DAH. Fish were sampled at that point (S1) for growth assessment and effects of blends in gene expression and oxidative stress related enzymes activity. 2) The second stage of the trial initiated at 58DAH where all fish groups were fed a boost diet for 1 week (BLEND6). BLEND2 was eliminated to give place to a CTRL group that did not receive a boost diet. Fish were sampled previously to stress exposure (S2) to evaluate boost effects. After this period, larvae were subjected to a stress event (air exposure) and samples were collected 6h hours after exposure (S3) for gene expression analysis, oxidative stress enzymes’ activity, and survival.

Results
At the end of trial 1 (S1), the seabream post-larvae fed with diets containing micro- and macro-algae showed no differences in growth. Although not significant, a higher fish survival was observed in the fish fed with the BLEND diets. Regarding gene expression, an increase in stress-related genes, such as GPX1 and GPX4, was observed in all BLENDS when compared to CTRL. In S2, the addition of a boost diet (BLEND 6) decreased the expression of antioxidant enzymes to control levels (S2 vs S1). After the stress event (S3), the addition of a boost diet (BLEND 6) increased the expression of antioxidant enzymes such as GPX1 and GPX4, in a dose dependent manner.

Figure 1 – Experimental scheme of the trial. CTRL, BLEND1 BLEND2 and BLEND3 diets were used in a first trial. BLEND6 was used as a boost diet before the stress in the second trial. S1, S2 and S3 represent sampling times. S1 was performed for 3 weeks (3w), boost period was 1 week (1w) and sampling after the stress was performed after 6h.

(Continued on next page)
Figure 2 – Summary of the results from the trial. Results are expressed as mean ± SD. Weight is expressed in mg, and gene expression data is expressed as relative expression to EF1a/β-Actin housekeeping genes, using the Pfaffl method. S1, S2 (pre-stress) and S3 (post-stress) are related to the sampling times in the trial. Gpx1 and gpx4 gene expression was accessed.

Conclusions
These results suggest that in the early stages, the performance of seabream larvae might benefit by the incorporation of micro- and macro-algae in the diets. The results observed show that the inclusion of these algae in the fish diets increase the expression of antioxidant enzymes after a stressful event. Nevertheless, in order to validate these results further studies are needed and the identification of the mechanisms involved in this response, as well as the long-term effects of these substitutions, are of paramount importance.

This study assessed the two unprocessed microalgae (*Nannochloropsis oceanica* and *Tetraselmis* sp.) and macroalgae (*Gracilaria gracilis* and *Ulva rigida*) meal in sea bass diets to enhance the utilization of micro- and macro-algae on immune response of European seabass. As a reference (control, CNTR) commercial-based diet was used and experimental diets were prepared by replacing 30% of the control diet with each algal meal used. Triplicate groups of fish (initial 23.9 g) were fed five experimental diets containing 30% *Nannochloropsis oceanica* (Nano-D), *Tetraselmis* sp. (Tetra-D), *Gracilaria gracilis* (Gra-D), *Ulva rigida* (Ulva-D) and CNTR for 60 days. IL-1β expressions in Gra-D were significantly higher than those in Ulv-D and were significantly lower than those in Tet-D, Nan-D and CNTR diet. The strongest response to diets containing macroalgae was seen in juvenile sea bass, induced the secretion of anti-inflammatory IL-1β and IL-18 genes in pathways for pro-inflammatory response, modulating both innate and adaptive immune response. HSP70 expression levels in Tet-D were significantly higher than those in Nan-D, Ulv-D and Gra-D. However, there are still crucial knowledge needs to assess of these algae sources in the aquafeeds, enabling to prove comprehensively effects on immune response/mechanisms in fish having high trophic levels or commercially cultured marine species.

**Introduction**

Disease outbreaks in fish farming are expected to intensify in the next years, which could compromise global food production and security [1, 2]. Some nutritional strategies can be applied to ameliorate the detrimental effects of disease outbreaks, including dietary functional feed supplementation [3]. Owing to several bioactive compounds in its composition, microalgae have been suggested for this purpose. Particularly, *Nannochloropsis oceanica*, a microalgae cultured industrially by Allmicroalgae Natural Products and other companies, has received great attention as it is rich in bioactive compounds with antioxidant [4], anti-viral, and anti-bacterial properties [5]. Recently, a group of aqua-soluble sulphated polysaccharides (SPS) obtained from *N. oceanica* showed immune stimulant properties [6], revealing its great potential in innovative animal health therapeutic products. Although *N. oceanica* has diverse valuable bioactive compounds, there are no reports on applying different concentrations of fractions from *N. oceanica* for immune stimulation. This study aimed to assess the immune-boosting effect of several *N. oceanica* fractions obtained through marine biorefinery concepts.

**Materials and Methods**

Four different concentrations (0.5, 0.25, 0.1, and 0.01 mg mL\(^{-1}\)) of crude lysate (CL), crude polysaccharides (CP), and sulphated polysaccharides-rich (SPF) fractions obtained from *Nannochloropsis oceanica* were tested in European seabass *Dicentrarchus labrax* head-kidney primary cells (1 x 10\(^{7}\) cell mL\(^{-1}\)) to assess cell viability and myeloperoxidase activity. Afterwards, CL, CP, and BGF were used at 0.5 and 0.01 mg mL\(^{-1}\) concentrations for 24h to assess their effects on cell viability, myeloperoxidase activity and respiratory burst (RB) of head-kidney primary cells of European seabass after stimulation with inactivated *Photobacterium damsela piscicida* for 4h.

**Results**

Results showed that the cell viability of European seabass head-kidney primary cells ranged from 70% to >100%, depending on the fraction and concentrations. Higher cell viability was exhibited when cells were exposed to CL and SPF, regardless of the concentrations. In addition, cell viability was higher at 0.5 mg mL\(^{-1}\) compared with other concentrations. Regarding myeloperoxidase activity, results revealed that cells at 0.5 mg mL\(^{-1}\) and 0.01 mg mL\(^{-1}\) tended to present higher myeloperoxidase activity, depending on the fraction (*P*>0.05).

RB was measured in European seabass head-kidney primary cells after 4h of exposure to inactivated bacteria. The results indicated that RB was not affected by the fractions, as no significant differences were detected, regardless of the concentration (ranging between 0.44 ± 0.20 and 0.73 ± 0.29 nmol O2\(•\)-, *P*>0.05).

**Conclusions**

The results support the idea that *Nannochloropsis oceanica* presents bioactive compounds with the ability to induce immune responses in European seabass head-kidney primary cells. Further analysis focusing on ATP and nitric oxide production, total antioxidant capacity, and gene expression will be assessed in European seabass head-kidney primary cells stimulated with inactivated bacteria to determine whether *N. oceanica* fractions exert a consistent immune modulatory effect.

Introduction
In response to the increasing demand for food worldwide, the aquaculture sector should explore the biological and socioeconomic potential of new species in order to expand the industry. In this sense, the greater amberjack (Seriola dumerili) is a good candidate due to its high growth rates and consumer acceptance. However, as a carnivorous species, it has high protein requirements, mostly provided by fishmeal. Thus, it is necessary to develop new formulations based on plant sources and nutraceutical compounds that allow good growth rates as well as the sustainable development of the sector. However, these ingredients can cause negative effects on the digestibility and bioavailability of nutrients, as well as on intestinal functionality and health. Therefore, the aim of this study was to improve the absorption and digestibility of diets with a high content of plant ingredients and its supplementation with nutraceuticals derived from micro- and macroalgae, pre-treating them biotechnologically by enzymatic hydrolysis. For this purpose, growth parameters, and intestinal function and health were examined by electrophysiological techniques, gene expression of immune-related genes, and microbiota characterization.

Material and methods
Juveniles of S. dumerili with 6.34 ± 0.01 initial mean body mass were randomly distributed in 9 tanks of 400L (25 fish/tank) at the experimental facilities of Servicios Centrales de Investigación en Cultivos Marinos (SCI-CM, University of Cádiz). After a two-weeks acclimatation period, fish were fed ad libitum for 69-days with 3 experimental diets, in triplicate: i) CTRL, similar to commercial feeds with 60% total protein (>92 % from animal origin); ii) PP, with the replacement of 50% of animal products with plant ingredients; and iii) PP-LB, as PP but supplemented with 3% of macro- and microalgae extracts. All vegetable ingredients were pre-treated biotechnologically by enzymatic hydrolysis. Temperature (22°C) and salinity (37‰) were constant during all feeding trials. Biometric samplings were performed every 3 weeks to assess growth parameters. At the end of the trial, 12 fish per experimental diet (4 fish/tank) were anaesthetized with a lethal dose of 2-phenoxyethanol and then biometric measurements and intestine samples were taken for further growth, electrophysiology, microbiota, and gene expression analyses.

(Continued on next page)
Results and discussion

After 69 days of the feeding trial, fish fed PP and PP-LB diets showed a significant increase in feed intake and specific growth rates without differences in feed efficiency. Accordingly, fish fed with the PP and PP-LB grew faster achieving a final body mass of 67.7±0.95 g and 70.8±1.7 g, respectively, compared to control fish (57.3±0.28 g) (Fig.1A). Also, fish fed with the PP diet showed the highest condition factor, reaching values of 1.70 ± 0.01, similarly to other studies in wild and cultured specimens of *S. dumerili* (Fernández-Montero et al., 2018). On the other hand, we also observed the typical increment of intestinal length index in fish fed with plant-based diets. Nevertheless, electrophysiological analyses of the intestine only showed changes (a decrease) in the epithelial resistance (Rt) in fish fed the supplemented diet (PP-LB), which may indicate alterations in intestinal barrier integrity and functionality (Fig.1B).

However, the paracellular permeability, using standard methods with 4kD FITC-dextran and 70 kD RITC-dextran, was unchanged although a non-significant decrease was observed in the permeability of the epithelium to larger molecules (70kD) in PP-LB. Regarding the epithelial intestinal integrity, there was a slightly (non-significant) decrease of *cldn19* in anterior intestine in PP-LB diet but a significant increase of *cldn11* and *cldn12* in medium and posterior intestine, respectively. We also analysed the gene expression levels of six amino acid and peptide transporters of which only *slc15a1* and *slc7a5* changed in anterior intestine increasing in PP and PP-LB diets respectively, while *slc3a1/a2* and *slc15a2/a4* showed, in general, an increase in plant-based diets in medium and posterior regions. Hence, the increase of transporters studied could indicate a major of nutrient bioavailability as a result of the biotechnology treatment. Besides, diet also had an effect on inflammatory and innate immune response as judged by the increase expression of several immune genes in medium (*il12p35a*) and posterior (*il34*, *il12p35a*, *infg*) intestine of fish fed with PP-LB. Likewise, changes in bacterial communities were showed by diet, with the reduction of Proteobacteria, the dominant phylum in this species (Sánchez-Cueto et al., 2023) in both plant-based diets (Fig.1C). Moreover, the class Gammaproteobacteria was reduced in fish fed vegetable diets and accompanied by the emergence of Cyanophyceae and Alphaproteobacteria classes, especially in PP-LB group. In conclusion, the enzymatic pre-treatment of vegetable ingredients improves growth performance in *S. dumerili* without affecting intestinal integrity or immune response, although some changes in these parameters were observed after nutraceutical inclusion (PP-LB diet). Nevertheless, both plant-based diets generate changes in transport processes and microbiota.

Introduction
Common aquaculture practises constitute a major threat to fish health and welfare, which can affect farming performance and productivity. Fish response to a stressor involves the activation of the hypothalamic-pituitary-interrenal axis (HPI), generating several physiological and metabolic changes. Cortisol, considered the major stress-marker hormone, has been extensively studied in aquaculture to assess the effects of different rearing conditions in fish. This hormone is a reliable acute stress indicator in plasma; however, the blood collection procedure can be a source of stress, becoming necessary to find alternative lower invasive matrices to measure cortisol (Sadoul & Geffory, 2019). Therefore, this study aims to evaluate the physiologic and metabolic effects of an acute stress, as fish transport, in European seabass (Dicentrarchus labrax), with a special focus on the correlation of cortisol levels in different matrices (plasma, skin mucus, and water) trying to develop less invasive stress biomarkers.

Material and methods
Fish were distributed in nine 400L tanks and acclimated for one week to an initial stocking density of 4 kg/m\(^3\). Overnight fasted fish were introduced in 10L plastic bags saturated with oxygen (density: 30 kg/m\(^3\)) and transported for 4 hours by a transport van. Then, just after finishing transport, half of the transported fish were sampled while the rest were returned to their initial tanks, constituting the recovery group, which was sampled 24 hours later. At each sampling point, non-previously disturbed fish were sampled as controls of transported (Control 1) and recovery groups (Control 2). In all cases, water temperature, oxygen, and pH were measured from the bags or tanks, and extra samples were collected for further analyses. Besides, 12 fish/group were anaesthetized with a lethal dose of 2-phenoxyethanol and then biometric and tissue samples were taken (blood, skin mucus, liver, and white skeletal muscle) for metabolic and cortisol analyses.

Results and discussion
Water quality parameters (O\(_2\), ammonium, nitrite, and nitrate levels) remained within optimal ranges after 4 hours of transport. However, as a typical response in short transport, water acidification was observed (pH=6.9) in transported fish compared with the control (1 and 2) and recovery groups (pH=7.5) which could be the consequence of CO\(_2\) increase. This causes a reduction of haemoglobin-O\(_2\) affinity (Sampaio y Freire, 2016) confirmed by the increase of this haematologic parameter in transported fish. Also, a reduction of haematocrit was observed after transport, which may be related to electrolyte-water balance of the fish blood (Seibel et al., 2021), as observed by changes in plasma osmolality, in part, orchestrated by cortisol. As a primary response to stress, transported fish showed an increase in cortisol levels in plasma, skin mucus and water which corroborates the fact that cortisol is a good marker of acute stress produced by transport in all matrices analysed. In addition, cortisol levels in the plasma correlated positively to skin mucus (Fig. 1A) and water (Fig. 1B) levels which supports the previous studies in fish (Fanouraki et al., 2008; Franco-Martinez et al., 2022) and allows the use of less or non-invasive matrices to evaluate a situation of acute stress in fish, such as transport.

On the other hand, cortisol induces secondary responses related mainly to energy requirements. Accordingly, in plasma, several metabolites such as glucose, triglycerides and lactate increased in transported fish, which could indicate an increased energy mobilisation in order to maintain homeostasis, highlighting the almost total or total re-establishment of these values 24 hours later. Fewer differences were observed in liver and muscle tissues, although lactate and triglyceride levels decreased in transported fish in white skeletal muscle, with the recovery of these levels 24 hours later. To sum up, changes observed in different tissues after fish transportation are the result of the increasing energy demand to cope with the stress situation. Likewise, cortisol has demonstrated to have an important role in the stress response in different matrices, which opens the possibility to use non-invasive methods to measure stress without compromising the animal’s welfare.

Introduction
Microalgae have already been evaluated in several studies for their application as feed ingredient in aquaculture and due to their high contents of polyunsaturated fatty acids (PUFA) they are considered as valuable lipid source in fish feed (Haas et al., 2016; Sarker et al., 2016). However, a factor limiting their application in aquaculture feeds is their species-specific cell wall which could hinder nutrient accessibility. Processing methods for disruption can improve digestibility and optimize microalgae application (Teuling et al., 2019; Tibbetts et al., 2017). The purpose of this study was to obtain digestibility data for the microalgae species Isochrysis galbana and Tetraselmis chui treated with different processing methods and to evaluate their potential as a lipid source in feeds for rainbow trout.

Material and Methods
The two microalgae species Isochrysis galbana (25.6 % lipid) and Tetraselmis chui (13.3 % lipid) were tested in five test diets which consisted of 70 % reference diet and 30 % algae meal as pelleted feed. For each algae species two meals were produced via freeze-drying after harvesting and via freeze-drying and additional homogenization via a centrifugal mill (300 µm). For T. chui a third test meal was produced through supplementation of enzymes (mannanase, xylanase and glucanase) before freeze-drying. Titanium dioxide was used as inert marker in the diets for the determination of the apparent digestibility coefficients (ADC). Rainbow trout with ~ 500 g were held in a recirculating aquaculture system in triplicates of trial diets. Faeces were collected via manual stripping 28 h after each feeding event for two weeks during which the fish were fed with 1.5 % of their body weight per day.

Results and Discussion
The ADCs of dry matter and protein were not significantly different between the diets. The crude lipid ADC was lower for the I. galbana diets (77.2 %) compared to the T. chui diets (87.3 %) and the control diet (91 %). Regarding the digestible lipid content of the diets the control diet showed the highest value (15.3 %) followed by I. galbana diets (14.8 %) and T. chui diets with the lowest values (12 %). The lipid digestibility of Isochrysis was found to be negatively influenced by higher dietary saturated fatty acid (SFA) contents (Caballero et al., 2002) but showed no impairment of feed intake and growth performance in European sea bass (Tibaldi et al., 2015). T. chui showed a higher digestibility for nutrients and fatty acids compared to I. galbana. Examining total fatty acid groups within algae species, a higher digestibility for monounsaturated fatty acids (MUFA) was observed for T. chui followed by PUFA and SFA whereas in I. galbana PUFA showed the highest digestibility verifying an efficient accessibility and the potential as applicable lipid source. The homogenization after freeze-drying had no beneficial effect on the digestibility of any nutrient or fatty acid of the microalgae.

Conclusion
Both algae species showed a promising applicability as a multiple nutrient source in aquafeeds for rainbow trout providing important fatty acids and high protein availability. Mechanical or enzyme-treating processing however did not increase the nutrient digestibility of the here used microalgae and sole freeze-drying sufficiently provided nutrient accessibility in this trial. Further research in applying other processing methods to improve digestibility of microalgae is necessary to fully exploit the microalgae potential as well as research in nutrient usability as growth performance in fish.

FLOATING RAS, THE SOLUTION FOR CLIMATE CHANGE RESILIENT MARINE AQUACULTURE

Paul-Daniel Sindilariu*

* Next Tuna GmbH, Londoner Strasse 3, 60327 Frankfurt am Main, Germany
paul@nexttuna.com

Introduction

Climate change is one of the biggest threads to marine aquaculture. Mass mortalities caused by adverse weather conditions, high water temperatures at sea, algae blooms and jellyfish mass invasion have been an ever more frequent news in the relevant seafood and aquaculture newspapers.

To address this issue a floating recirculating aquaculture system: RASxFloater, has been developed by Next Tuna in cooperation with Seafarming Systems AS for the fully closed production of marine species. The specific design of the system has been filed for IP protection with the Norwegian patent authorities and is going to be presented more in detail here.

System requirements

The following design requirements were set:

- Stable floating with wave resistance of min. 1m; suitable for protected areas
- Movable within protected areas to facilitate fish logistics
- Thermal independence from surrounding water temperature
- Possibility for fish transfer through the tank wall
- Size; comparable to standard net pen, feeding into existing value chains
- State of the art RAS system, scalable through replication
- Suitable for precision farming applications

Solution

The developed RASxFloater design is comparable to a 30m diameter, 10m depth net-pen (7’000 m³). However, instead of a net that keeps the fish, the RASxFloater has a fish tank made of insulated steel and the RAS treatment infrastructure is allocated on the same floating structure (Fig. 1).

The closed characteristic of the system makes it fully independent of environmental influences and as such climate change resilient. In addition, the system has a minimal effect on the environment since all effluent can be treated on land or supply barge and no construction for the implementation is needed.

The novel system with its unique feature of symmetrical allocation of the treatment area and floating support infrastructure around the centre production tank, is constructed and fully mounted in a shipyard and delivered as a plug and play set-up to the fish farmer.

The floating RAS systems has two operational modes:

1. Production mode: the system is connected to a harbour dock, or moored in a sheltered area and receives all essential supplies from land; or barge.
2. Delivery mode: the system is disconnected from land supplies, pulled out of the sheltered/harbour area into the open sea and joint with the delivery net-pen, for safe and stress-free fish transfer and customer delivery (Fig. 1).

During production mode, the floating RAS receives all supplies from land or, if operated in open water, from a supply vessel, including, electricity, oxygen, new (sea) water and delivers all residuals back to land for final effluent water treatment (Fig. 2). For transport, the system is detached from harbour or supply vessel and tugged to destination.

(Continued on next page)
Discussion

Next Tuna wants to present this novel solution for marine aquaculture to the audience and discuss the chosen solutions and their implications with the experts present at the conference.

In addition, new approaches to precision farming and centralized O&M service developed for this new scalable approach to marine aquaculture are presented and submitted to discussion.

The target of Next Tuna is to replace up to 10% of global net-pen aquaculture production by production in floating RAS systems.

Introduction

The plant-based protein (PP) can negatively impact growth as well as fillet quality of fish due to the presence of anti-nutritional factors, imbalanced nutrient content, and low digestibility. Consequently, the incorporation of feed additives into PP feed holds promise in enhancing its utilization in fish and improving fillet quality. Thus, the objective of this study was to assess the effects of supplementing PP diets with two different types of additive mixtures on the growth, myogenic gene expression and fillet quality of rainbow trout (*Oncorhynchus mykiss*).

Materials and methods

Two thousand rainbow trout (2.22 g) were distributed in four groups with 5 replicates (100 fish/tank) and fed four isonitrogenous (42% CP) and isolipidic (20% lipid) diets namely fishmeal based diet as control (30% fish meal, FM), plant based diet (PP), PP+A1 (PP supplemented with mixture of krill meal, taurine and organic selenium) and PP+A2 (PP supplemented with mixture of proline, hydroxyproline and vitamin C). Fish were fed twice daily and six days a week at apparent satiation for 30 weeks. After end of the feeding trial, growth (weight gain, WG) and feed conversion ratio (FCR) were calculated. The relative expression of myogenic genes (myoblast determination protein 2, *MyoD2*; myogenic factor 5, *Myf5*; and myocyte-specific enhancer-binding factor 2a, *MEF2A*) were measured. The fillet quality parameters like texture profile analysis (TPA: hardness, cohesiveness, springiness, chewiness, and resilience) and fillet color properties (lightness, *L*; chroma, *C*; and hue, *h*) were measured. All the data were subjected to one-way analysis of variance (ANOVA) using General Linear Model in R-programming (RStudio version 2023.06.0).

![Figure 1](image)

Figure 1: (a) Weight gain and (b) myogenic gene expression of different groups after 30 weeks

(Continued on next page)
Results

Results showed that dietary supplementation of additive mixtures in PP diets significantly ($p < 0.05$) improved the growth performance as compared to PP group without additive mixture and comparable to FM group (Figure 1a). Although there was no significant difference in FCR (0.83-0.87), the overall feed intake on PP group was lower than other groups. Hyperplasia related myogenic genes ($MyoD2$ and $Myf5$) were significantly ($p < 0.05$) up-regulated in the additive mixture supplemented groups (Figure 1b). Whereas no difference in hypertrophy related gene, MEF2A was observed between additive mixture supplemented groups and other groups. Fish fillet quality was also affected by additive mixture supplementation (Table 1), hardness of both additive mixture supplemented groups was higher than other groups, whereas cohesiveness of these groups were comparable to FM group. Fillet color properties showed that PP+A1 had higher value of $C^*$ and lower value of $L^*$ and $h^*$ as compared to other groups.

Discussions

The supplementation of additive mixtures has been shown to ameliorate the negative impact of PP-based diets and improve the growth of rainbow trout. Furthermore, the up-regulation of myogenic genes ($MyoD2$ and $Myf5$) in the groups supplemented with the additive mixture supports its positive impact on growth and nutrient utilization, leading to enhanced muscle mass. The supplementation of additive mixtures has been found to improve fillet quality, particularly in terms of fillet hardness in both supplemented groups. Additionally, the fillet color properties were improved in the PP+A1 group compared to other groups. While previous studies have shown that the complete substitution of fish meal from various species does not have a negative impact on fillet quality during short-term culture periods (Kaushik et al., 1995), long-term feeding of a fish meal-free diet has been found to significantly reduce growth, as well as color properties and sensory quality in rainbow trout (De Francesco et al., 2004). In summary, the supplementation of additive mixtures in PP-based diets positively impacts the growth, muscle development, and fillet quality of rainbow trout.

Introduction
The presence of off-flavour compounds, produced by various microorganisms, in Recirculating aquaculture systems (RASs) represents a major risk for reducing the quality of farmed fish. Despite being nontoxic in the concentrations detected in RAS systems and fish tissue, they pose a serious threat to the profitability of RAS operator as tainted fish causes customers dissatisfaction. Even at very low levels (< 20 ng/L), the accumulation in fish tissue can reach hundreds of ng/kg of fish (Houle et al., 2011). It has been shown, that humans can detect off-flavors in concentrations close to 250 ng/kg of fish (Lindholm-Lehto et al., 2020). In this study, we investigated the occurrence of two off-flavors, geosmin and 2-methylisoborneal (2-MIB), responsible for earthy and musty taste. The study was performed in a full-scale land-based RAS (located in Germany) during cultivation of greater amberjack (Seriola dumerili). The fate of the off-flavors in the system was examined on two occasions before and after feeding at various locations in the system.

Materials and methods
The study was carried out in a RAS working with artificial seawater and less than 1% of the water renewal rate per day. Seawater was prepared by mixing tap water with a commercial salt mixture (Sequasaal). The RAS comprised of two drum filters with a 100 and 60 mm screen panels and a protein skimmer to remove large and fine particulate waste, respectively. The protein skimmer was operated with ozone (dosing interval between 170-280 mV) to enhance the removal of fine solids, reduce bacteria load, and oxidize part of the total ammonia and nitrite. The system held a total biomass of 4 Metric Tons (MT), and fish were fed with 7 mm Seriola Protec (Skretting, France) at a feeding rate of 0.9% of the body weight (BW). Water parameters were the following: Temperature 21°C, pH 7.6 - 7.8, Oxygen 95-100%, Salinity 20 PSU, Total ammonia <0.5 g-N/l, Nitrite <0.1 mg-N/l, Nitrate 30-70 mg_N/l and Residual Ozone <0.001 mg Cl-/l. Sampling of RAS water was performed before and after feeding, at 6 locations of an industrial RAS (2500 m³), i.e. Tank 1 (T1), Tank 2 (T2), after drum filter 1 (ADF1), inside protein skimmer (ISK), after biofilter (ABF) and after drum filter 2 (ADF2). First set of samples was collected 1 hour before feeding in the morning, whereas the second set of samples was collected after feeding in the middle of the day. The samples were taken twice from inside the protein skimmer with ozonation being on and off. All samples were collected in triplicates. A GC-MS/MS method was developed to measure geosmin and 2-methylisoborneol in RAS water. Water samples (0.7 L each) were concentrated by dichloromethane extraction alongside a stable isotope labelled geosmin internal standard (geosmin-d3). Extracts were analyzed by an Agilent 7890A gas chromatograph coupled with an Agilent 7000 triple quadrupole mass spectrometer fitted with an EI source and collision cell was used (Agilent Technologies, Santa Clara, CA, USA). An Agilent DB-5MS UI GC-column (30 m x 0.25 mm x 0.25 µm) was used in analysis. The carrier gas was high purity helium at constant flow (1.2 mL/min). The detection limit was determined through calibration curve slope method and was 1.8 and 2.9 ng/L for Geosmin and MIB, respectively with a linear range of 1-100 ng/L (Correlation coefficient of 0.9997 and 0.9994 for GSM and MIB).

Results
RAS water tested at various locations in the system showed to contain low amounts of geosmin, with an average of 4.8 ng/L before feeding and 4.9 ng/L after feeding. No “hot spots” for geosmin and 2-MIB were identified in the system. The sensory threshold is believed to be influenced by differences in sensory evaluation person to person, sensory characteristic of the fish species and presence of other off-flavors that could mask the earthy flavor (Lindholm-Lehto and Vielma, 2019). Nevertheless, Petersen et al. (2011) attested that tainting of the fish by geosmin occurs when its concentration in water exceeds 10 ng/L (study performed on rainbow trout). Sensory analysis of the harvested fish confirmed that the geosmin levels were low enough to not cause off-flower issues. Concentrations of off-flavour compounds in the RAS allowed for a spatial mapping and are provided in Table 1.

DISAPPEARING SPAT ON NEW ZEALAND’S GREENSHELL™ MUSSEL (Perna canaliculus) FARMS, MAGNITUDE, CAUSES, AND POSSIBLE SOLUTIONS

Brad Skelton* and Andrew Jeffs
Institute of Marine Science
University of Auckland, New Zealand
Brad.Skelton@auckland.ac.nz

The Greenshell™ mussel (Perna canaliculus) industry is New Zealand’s largest and most valuable aquaculture industry, and yet despite its success, the industry remains extremely inefficient at converting seed mussels (“spat”) into market-ready adults. The cause of this inefficiency is largely due to high spat losses that often take place early in the production cycle, shortly after seeding out (i.e., within the first 3 months of production). However, until recently, little was known about the magnitude of spat losses across the industry, and the potential causes of these losses. In turn, this lack of knowledge made it difficult to begin to develop any practical solutions aimed at addressing the problem and reducing spat losses. This presentation will summarize the findings of several studies which were undertaken to 1) begin to quantify the magnitude of spat losses both on individual farms and on an industry-wide basis, and 2) to start to identify some likely causes of the problem. The presentation will demonstrate that, despite considerable research effort, the exact causes of spat losses remain poorly understood. However, this presentation will also outline the results from initial studies that show that land and/or sea-based nursery culture (i.e., growing spat to larger sizes prior to seeding) may be a promising approach to finally solving the problem for production.
UNVEILING THE FOOD PREFERENCES OF COMMON CARP IN FISHPONDS: EXPLORATION OF DIET COMPOSITION OVER GROWING SEASON

kajgrova@frov.jcu.cz

Introduction
European fishponds have a centuries-old history that has played a pivotal role in shaping both local economies and the environment. The central figure in European pond aquaculture is the common carp. Pond aquaculture primarily employs the semi-intensive method, wherein carp rely on both natural prey and supplemental feed (usually cereals). Common carp are known to be omnivorous, consuming a diverse array of food items. This study undertakes a comprehensive exploration of the diet consumed by common carp in Czech fishponds under semi-intensive management.

Material and methods
We did a survey in 3 experimental ponds (surface area: 0.16 ha; average depth 80 cm) in South Bohemia (Czechia). All ponds were similarly stocked with the same size-class common carps (2 years-old age cohort; mean total length: 267.9 ± 15.2 mm; mean weight: 337.2 ± 56.6 g) corresponding to 938 ind. ha⁻¹ and 316 kg ha⁻¹. Following established practices, fish were fed with cereals since May (Füllner, 2015). Fish were sampled monthly to monitor growth and to collect samples of the digestive tract content (the non-lethal method was used; see Faina, 1983). Furthermore, the fish stock index and food conversion ratio were calculated. Physical-chemical environmental parameters and food items (zooplankton, zoobenthos) were monitored and sampled monthly.

Results and discussion
The total biomass gain yielded 1,420 kg ha⁻¹ per pond, with the food conversion ratio reaching 2.83. Common carp consumed a wide range of food items, yet their diet changed throughout the growing season. The common carp consumed primarily zoobenthos at the beginning of the growing season (April–June), and cereals did not contribute significantly to carp nutrition. Nevertheless, the contribution of both cereals and zooplankton to carp diet increased from the mid-summer (June/July). Crustaceans (cladocerans and copepods), therefore, played a more substantial role in the carp’s diet during the latter half of the growing season as well as cereals.

THE EFFECT OF INSECT-BASED EXTRUDED DIETS ON GROWTH PERFORMANCE, SHELL DEVELOPMENT AND CAPTIVE HUSBANDRY OF SIDE NECK TURTLE (*Emydura subglobosa*)

P. Skrzypczak, M. Rawski, B. Kierończyk, J. Mazurkiewicz

Poznań University of Life Sciences
Laboratory of Inland Fisheries and Aquaculture
Email: paula.skrzypczak@student.up.poznan.pl

Introduction
This study provides empirical data on the balancing, production and quality of freshwater turtle diets containing partially defatted *H. illucens* meal (BSFL) as a fish meal replacement. The BSFL was applied as 7.5 and 15% of the diet substituting 25 and 50% of fish meal, respectively.

Materials and methods
Three diets were calculated: control (CON), consisting of 30% FM and 0% BSFL; H75, consisting of 22.5% FM and 7.5% BSFL; and H150, consisting of 15% FM and 15% BSFL. Feeds were prepared by extrusion processing with a single-screw warm extruder. Experimental feeds were analysed in terms of pellet length, width, expansion, water binding capacity and volume increase. The growth trial was carried out using 27 six-month-old *E. subglobosa* juveniles with an average body weight of 45.7 g (weight range from 42.6 to 49.4 g). The animals were same-age full siblings hatched in the Laboratory of Inland Fisheries and Aquaculture of Poznan University of Life Sciences. They were randomly distributed into 9 rectangular tanks (3 tanks per treatment). A total of 9 turtles were used per treatment. The experiment was 70-days-long.

Results
Post-extrusion tests showed that feed technological parameters are dependent on the BSFL meal share in terms of pellet length, expansion rate, volume increase and water binding capacity. The obtained experimental feeds were well accepted by the animals. In the 70-day-long experiment, no turtle mortality or diet-related issues, as well as differences were recorded in turtle shell development and growth performance among the treatments. However, BSFL meal application increased feed intake when 7.5% BSFL meal was used and decreased the feed conversion ratio for the 15% BSFL-containing treatment. For the first time, it was empirically proven that red-bellied short-necked turtle (*Emydura subglobosa*) efficiently utilizes BSFL meal in up to 15% of the diet. Moreover, the possibility of decreasing total marine resource use by 55.8% in turtle husbandry was recorded, mainly due to 57.4% lower fish meal use per kg of turtle weight gain.

Conclusions
This study proves that partially defatted *H. illucens* meal is a suitable novel feed component for extruded aquafeed production. The obtained results of turtle growth performance and feed conversion indicate that it is well accepted by *E. subglobosa* and its components well utilized. It was empirically proven that the dietary application of *H. illucens* increases the environmental sustainability of *E. subglobosa* husbandry.
INDICATORS FOR SUSTAINABLE PRODUCTION METHODS IN ATLANTIC SALMON FARMING

H. T. Slette*, A. Misund, A. V. Strand

SINTEF Ocean, Postboks 4762 Torgarden, NO-7465 Trondheim, Norway
E-mail: hans.slette@sintef.no

Introduction
During the last ten years a wide range of concepts have been developed for facilitating the grow-out phase of Atlantic salmon (Salmo salar) farming. In addition to traditional sea-based, open, flexible net pens, current available production methods cover land-based, submerged, semi-closed, closed, and offshore. There are large variations in solutions within each category, with some concepts crossing categories, and there is not complete agreement on where to draw the lines between categories.

Drivers for the development of novel concepts include challenges related sea lice, escapes, effects on wild salmon, fish welfare, climate, and environment. In Norway, production capacity is regulated through the traffic light system which is based on number of sea lice. The various concepts have different solutions for dealing with the challenges of the industry, however they often introduce new concerns such as material use, energy consumption, operational and structural challenges. The development licenses scheme in Norway from 2015 was a significant driver for development of new concepts (Moe Føre et al., 2022). A requirement for being awarded licenses was that the solution was novel and required significant investments (Osmundsen et al., 2022).

Ongoing processes for possible new license schemes are likely to have strict requirements for technology and area use to solve important environmental challenges. Knowledge about the effects of technology and operation on sustainability can become very important in future license schemes. However, uncertainty is still related to effects of novel concepts on environment, economic, and social sustainability.

An ambition of significant increase in Norwegian production in the next decades calls for more knowledge about what effects this growth can have on sustainability. This includes consideration of effects on local environments, climate, social and economic impacts on local, regional, and national levels. For example, land-based production is expected to have higher energy and material consumption than traditional pens, but is also expected to solve challenges related to sea lice, pollution and effects on wild salmon. Therefore, if most of the growth is realized by land-based facilities the total footprint of the industry would be different than if most of the growth was made in traditional pens.

The project “Increased knowledge about effects on climate, nature, and environment from different production methods for salmon”, funded by FHF (Norwegian Seafood Research Fund, grant #901833), seeks to enlighten this topic. This presentation focuses on the topic of work package 1 in the project, which is to document and analyse indicators for sustainability for all three dimensions of sustainability – environmental, economic, and social.

Methods
This study investigates indicators for evaluating the sustainability of different production methods for salmon farming. Considering each of the six production methods; traditional/open, land-based, submerged, semi-closed, closed, and offshore, the goal is to map and define relevant indicators for all three sustainability dimensions. The research question is what indicators are the most relevant for evaluating sustainability of production methods, what is the knowledge status, and what are the research gaps?

Initially, document analysis is performed to describe the status from existing literature on effects of salmon farming. This covers research literature, standards, regulations and sustainability reports from companies. Workshops with industry partners are then held to discuss their perception of the practicalities and usefulness of indicators, and what are the most important in their opinion with respect to the challenges of the industry and achieving sustainable farming of salmon. This step is supplemented with assessments in the project group to arrive at a selection of indicators that are more effective and comprehensive, hence having a higher utility than other indicators. Finally, interviews and discussions with key resource individuals both in industry and research will enable clarification and quality assurance of the work. In addition, a questionnaire is sent to a selection of industry partners ahead of the workshops.

(Continued on next page)
Results & Discussion
There is need for a common set of indicators to assess the sustainability of aquaculture and production in new systems. Our work presents an overview of all current indicators for environmental, social, and economic sustainability and a recommendation of the indicators that are most relevant to provide a just assessment of overall sustainability. The indicators will also be weighted to reflect current regulations and national and global sustainability targets.

A wide range of indicators are used in different relations to describe aspects related to sustainability in salmon farming. Several indicators have large impacts on the companies, for example, by being used by authorities in regulating production or in reporting to investors affecting the attractiveness of the company. Uncertainty, precision, and comparability of indicators are important topics determining the trust to and legitimacy in addition to the usefulness – either in terms of directing operation in the desired direction or for gathering information on development. An example of uncertainty is when counting sea lice in a pen. Counting all 200 000 fish frequently is currently not an option, therefore there is statistical uncertainty related to the sample. Precision can be considered in terms of how well the indicator represents the more complex reality it is meant to describe, for example, how well does mortality describes fish welfare? The concern of comparability is related to the degree to which an indicator can be used to make useful comparisons between systems and productions. For example, if indicators are formulated in ways that open for “creative accounting” this can result in data making comparisons futile.

The Horizon 2020 All Atlantic Ocean Sustainable, Profitable and Resilient Aquaculture (ASTRAL) project focuses on supporting and promoting integrated multi-trophic aquaculture (IMTA) farming and sustainable aquaculture production across the Atlantic. The development of new and improved technological innovations, as well as knowledge sharing and capacity building, are priority areas within the project. A combined output from the ASTRAL human capital development plan and technology work packages, is the ASTRAL Technology User Guide for Training Courses and Apprenticeships (Smith et al, 2022), which provides a broad overview of the state of the technology landscape available for aquaculture.

The ASTRAL technology user guide provides information on a range of technologies suited to all levels of IMTA farming and aquaculture, from cost-effective solutions for small scale farms to more advanced and data-intensive systems appropriate for larger commercial and research operations wanting to increase efficiency in farm management and optimise production. While there are technology applications in many aspects of aquaculture, this guide focuses on the use of technology for water quality, biomass measurements and monitoring, and touches briefly on the relevant parameters, sensors, associated analytics, and considerations associated with their use and application. The guide is split into several sections including: the sensors and technology used for four different monitoring topics, namely physico-chemical water quality parameters and sensing methods, aquaculture stock and biomass estimation sensors, threat detection, and environmental variables; and the considerations in terms of instrument choice, operational environment, and system design.

Bearing in mind the unique requirements of each site, farming system, and business model, this guide provides an overview of principal water quality parameters, biomass estimation methods, and sensor technologies commonly used to measure and monitor these variables. Examples are provided of relevant commercial solutions, in addition to pertinent ASTRAL-specific technological developments and research topics. It is our hope that this guide will provide an approachable and informative reference source for aquaculture-related training courses.

*E-mail: filipesoares@sparos.pt

Introduction
Estimating the body composition of fish is an important step in fish nutrition, as it is the basis to calculate nutrient retention efficiencies and utilization rates. In fish nutrition studies, nutrient retention can be used to assess the nutritional quality of diets, but also to support the definition of nutrient requirements and the estimation of nutrient waste outputs. From the point of view of fish farmers, knowing the body composition of fish more regularly throughout the production cycle can help in the search for more effective feeding strategies and also to have a better quality-control of their products.

Usually, body composition of fish is estimated through analytical methods, such as the ones described by the Association of Official Analytical Chemists (AOAC). Despite being reliable and robust methods to estimate the body composition of fish, these analytical methods are not always a viable option to estimate the body composition of fish, since they are time-consuming and expensive. This translates into a limitation of the number of samples collected for body composition analysis, which can hinder a detailed analysis of nutrient flux in fish.

Here we present ficoEst, a public web-tool for researchers and fish farmers to estimate the body composition of farmed fish (https://webtools.sparos.pt/ficoest/). ficoEst uses calibrated and validated mathematical models to provide estimates on the body composition of different fish species (i.e., gilthead seabream, European seabass, meagre, rainbow trout, Atlantic salmon and Nile tilapia). ficoEst can be seen as a complementary tool to support studies on fish nutrition or to increase information collected at the farm level, whenever analytical methods are not a viable option.

Data collection and model development
Data on the whole-body composition of fish were collected for the abovementioned fish species. All data was processed into a standard format and analyzed. The outcomes of the data analysis process were crucial in providing a solid foundation for the model development phase, e.g., for identifying the key explanatory variables.

Different types of models and calibration methods were developed and tested, aiming to select the best methods in estimating the body composition of fish. All developed models fall into one of the following three families:
• BC1: models that consider only the body weight of fish as input;
• BC2: models that consider the body weight and water percentage of fish as inputs;
• BC3: models that consider the body weight, water and ash percentage of fish as inputs.

To select the best combination of model and calibration method (e.g., least squares, Huber loss minimization, mixed-effects, seemingly unrelated regressions), per family, we used cross-validation, where different error metrics were evaluated (e.g., MAPE, RMSE, AE). After selecting the model and calibration method to use per family, the models were calibrated and validated for each species. Figure 1 shows the model validation results for the BC3 model (similar analysis was conducted or BC1 and BC2 models, but not presented here).

Figure 1. BC3 model validation results. The “error - PREDICTIONS” is associated with the model performance and is calculated as the mean absolute percentage error (MAPE):

$$\text{MAPE} (%) = \frac{100}{n} \sum_{i=1}^{n} \left| \frac{P_i - O_i}{O_i} \right|$$

with the average coefficient of variation in the data.

$$PE_{\text{observations}} (%) = \frac{100}{n} \sum_{i=1}^{n} \left( \frac{sd_{value_i}}{mean_{value_i}} \right) P_{E_{\text{observations}}} (%) = \frac{100}{n} \sum_{i=1}^{n} \left( \frac{sd_{value_i}}{mean_{value_i}} \right)$$

(Continued on next page)
Tool implementation
All modules that compose the ficoEst tool were implemented in R. The back-end engine consists of different functions used to: compile, process, and plot data; evaluate, calibrate, validate and run models; and generate reports. The front-end (i.e., user-interface) consists of functions used to create input controls, and informational and navigational elements. Figure 2 shows the user-interface. To get estimates on the crude protein, crude lipids, water, ash, phosphorus and energy content of fish, users need to enter data on the body weight, and/or water and ash content of fish (depending on the model selected).

Introduction
Sustainable aquaculture involves monitoring water quality, food safety, and microbiological indicators. However, with the intensification of the production, as a result of the pressure to provide food to a growing world population, with increasing farming densities and with the use of live preys in the early larval stages, the occurrence of disease outbreaks increases (Sanches-Fernandes et al, 2022). These outbreaks are normally provoked by bacteria and there’s the need to recourse to antibiotics, which may pose some problems of bacterial resistance (Radhakrishnan et al, 2023). Probiotics are microorganisms that are administered as a dietary supplement to protect the host against pathogens and improve the immune system (Rohani et al, 2022). The aim of this study is to understand how the addition of probiotics in life preys impacts the gut microbiota when antibiotic treatments are performed.

Methods
To test the effect of two algae-based formulations for live feed enrichment (rotifers and artemia) Sparus aurata larvae were distributed through nine tanks of 300 L, at an initial density of 76 larvae L⁻¹, in triplicates. Treatments were as follows: RP - RedPepper (Bernaqua™), ALL - a mix of Nannochlororpsis sp., Tisochrysis sp., Aurantiochytrium sp., Tetraselmis sp. microalgae with the addition of probiotic and vitamins and POC - a mix of Nannochlororpsis sp, Tisochrysis sp., Porphyridium sp., Aurantiochytrium sp., Tetraselmis sp. with the addition of probiotic and vitamins (Necton, Portugal). The culture was maintained at 18.0 ± 0.6 ºC, with 6.9 ± 0.4 mg L⁻¹ of oxygen and a photoperiod of 14:10 (day/night). Suddenly, at 17 DAH (days after hatching) all tanks had high mortality, and microbiological analysis was carried out on plates with twenty-five larvae collected from each tank, which were homogenized in sterile saline solution and plated on tryptic soy agar medium (TSA) (Lyophilchem, Italy) with 1% (w/v) NaCl for total marine bacteria and on thiosulphate citrate bile salts medium (TCBS) (ITW Reagents, Spain) exclusive for Vibrionaceae, with 0.5% (w/v) NaCl. The plates were incubated at 24°C for 48h and the bacterial colonies (Colony Forming Units (CFU)) were counted. To choose the most effective treatment, antibiograms were performed with four different antibiotics, enrofloxacin (ENR), florfenicol (FFC30), flumequine (UB) and oxytetracycline (OTC), placing the plate to incubate at 24°C for 24h, verifying that the bacteria were sensitive to OTC. The treatment with 30 ppm of oxytetracycline (OTC) for 2 h was administered during 10 days. Microbiological analysis of the larvae’s digestive tract was performed at different sampling points throughout the trial (at 3, 15, 24, and 33 DAH) in the three treatments. Larval survival was calculated at the end of the trial (38DAH).

Figure 1 - Mean colony forming units (CFU) of a) Total Marine Bacteria and b) Vibrionaceae bacteria from Sparus aurata larvae at 0, 15, 24 and 33 days after hatching (DAH) in different treatments (ALL, POC and RP). Asterisk marks significance between treatments (*** - ANOVA, p<0.001)

(Continued on next page)
Results and Discussion
At initial analysis (3 DAH) no bacterial growth was observed in TSA and TCBS, as sampling was performed prior to the introduction of live preys. At 15 DAH there was higher growth of total marine bacteria than Vibrionacea, except for the ALL group which had a value similar in both mediums. The ALL group, although it had a lower growth of total bacteria, compared to the POC, was the group that had a higher prevalence of Vibrionacea. At 24 DAH there was no growth of total marine bacteria or Vibrionacea, which is probably related with the OTC treatment performed. Seven days after the treatment (33 DAH) there was a significant increase in total marine bacteria in the POC group compared to the other groups. Besides, there was also a tendency for the POC to present a higher prevalence of Vibrionacea compared to the other groups. In conclusion, the inclusion of probiotics does not appear to have any benefit on the recovery of the gut microbiota after treatment with the OTC antibiotic, however, this did not affect larval survival at 38DAH in the three treatments (ALL - 18.7%; POC - 16.1%; RP - 15.5%), corresponding to weaning time.

E-mail: fsoares@ipma.pt

Introduction
Integrated Recirculating Aquaculture Systems (iRAS) is a closed system that reuse the water of production based on the use of mechanical and biological filters to remove the toxic compounds produced by the animal, such as ammonia. This system, besides being more costly-effective, allow a better control of parameters such as temperature, salinity, water supply, among others (Sujita, 2021). Although RAS generally reduces disease outbreaks, but rearing conditions can sometimes provide a favorable environment for the reproduction of opportunistic pathogens (Balami, 2019). This study aims to evaluate the impact of macroalgae production on the parasite load in Sparus aurata, on an iRAS system.

Methods
The trial was carried out in two independent iRAS systems at the Aquaculture Research Station of Olhão (EPPO): 1) with algae (SA) and 2) without algae (SB). Each system consisted of four fish tanks, nine algae or water tanks, and one filtration zone composed of a mechanical filter and a biological filter (Fig.1). The initial density on the fish tanks was 12 kg/m³ and the water temperature was around 24±1°C. During the experimental period, fish from each system tanks A (FA3, FA4) and B (FB1, FB2) were periodically sampled for the observation of parasites. For that, the first two branchial arches on the left side were visualized under an optical microscope (Leica ICC50W) at 0 (T0), at 26 (T26) and 55 (T55) days after the beginning of the experiment. Monogenea eggs occurrence was monitored weekly (T4, T11, T18, T25, T32, T39, T46, T53) by placing quadruplicates of cotton with 11.2 cm each, during five days, in the fish tanks from system A (FA) and B (FB), in the tanks with (SA) and without algae (SB), and filters of both systems (A and B) and the total number of eggs was counted under a magnifying glass, Nikon SMZ1000.

Results and Discussion
Throughout the trial, the occurrence of monogenea eggs was analyzed in the different tanks. No eggs were ever found in the SA and SB tanks (Fig.2a). In the fish tanks (Fig.2b), five days after the beginning of the trial there was a significantly higher number of eggs in the FA4 than FB2, but at the following sampling point, there was an increase in the FB2 tank and a significant decrease of eggs in the FA4 tank remaining stable throughout the trial. The occurrence of eggs in the tank filters (Fig.2c) was lower than the presence of eggs in the fish tanks. From the first observation, there was a decrease in the presence of eggs, and on the remaining days, the quantity of eggs visualized was low.

Figure 1 - Schematic representation of the RAS system (by Ivo Monteiro)

(Continued on next page)
Concerning the total number of parasites (Fig. 3) observed in the fish, the initial point had a higher parasitic intensity per fish corresponding to the mean monogenea quantity of fish before distribution to the system tanks, decreasing in the following two points. At T24 the mean occurrence of monogenea was similar in both systems (A and B), with a tendency to increase at T53. In conclusion, the presence of algae in the iRAS system does not affect the appearance of monogenean eggs.

References

Introduction
With the intensification of aquaculture, and consequently the increase on the farming densities, there’s also an increase on the appearance of epizootics, resulting from the imbalance of the conditions of the surrounding environment which greatly impact the profitability of the production (Jerônimo et al, 2022). Thus, for a successful aquaculture production, one of the most important parameters to consider is the water quality of the systems as it can have effects on survival and growth, as well as on the overall fish immunity and resistance capacity (Waruiru et al, 2020). Another important factor for an efficient production is the concentration of dissolved oxygen in the water column. The optimal levels for this parameter are species-specific, dependent on the temperature and any changes may have an impact on the produced fish welfare (Akhter et al, 2021). The aim of this work is to evaluate the impact of different oxygen levels on external parasite prevalence in meagre farming.

Methods
The experiment was conducted at the Aquaculture Research Station at Olhão (EPPO) with 250-350g meagre, *Argyrosomus regius*, distributed in triplicate, with a density of 9 Kg/m³ per tank under natural temperature conditions, over three different dissolved oxygen levels: DO1 - low oxygen (2.5 - 3.0 mg/L); DO2 - medium oxygen levels (4.0 - 5.0 mg/L); DO3 - high oxygen levels (6.0 - 7.5 mg/L). The trial had a duration of 26 days and at the end, 6 fish per tank were sacrificed for observation of external parasites. The first two gill arches on the left side were removed and observed under an optical microscope (Leica ICC50W) and the number of parasites observed was recorded and identified.

Figure 1 - a) Mean number of monogenea per fish and b) number of monogenea per gill arch present in meagre (*Argyrosomus regius*) exposed to three different dissolved oxygen levels: DO1 - low level (2.5 - 3.0 mg/L); DO2 - medium oxygen levels (4.0 - 5.0 mg/L); and DO3 - high oxygen levels (6.0 - 7.5 mg/L). Asterisks and a and b mark significant between treatments (** - 2-way ANOVA, P≤ 0.002 and *** - 2-way ANOVA, p<0.001)
Results and Discussion
Observation of the gills revealed the presence of monogenea parasites. In general, the mean number of parasites (Fig. 1a) was significantly lower in the DO3 treatment compared to the other treatments, with a tendency for DO1 to be higher than DO2. Analyzing the parasitic occurrence in two gill arches separately (Fig. 1b) we found that DO1 had a greater effect on the occurrence of monogenea presenting statistically significant differences with DO3. DO3 was significantly lower in the intensity of monogenea per arch than DO1 and DO2. In the DO1 treatment, we observed significant differences in the occurrence of monogenea between brachial arches. Despite the presence of parasites in the gills, growth, feed intake and survival were not affected as described by Barata et al. (2023). In conclusion, higher levels of dissolved oxygen in the water contribute to reduce the occurrence of external parasites, contributing to better welfare conditions.

Introduction
Earthly and moldy off-flavors in aquaculture products reduce consumer preferences for farmed fish and consequently, the off-flavors also cause economic loss for RAS farmers (Abd El-Hack et al., 2022). Finding solutions to this reduce the presence of these compounds is essential, both for economic reasons as well as for the reputation of the entire aquaculture industry. Such off-flavors have historically been affiliated with the compounds geosmin and 2-MIB. These microbiologically produced compounds have mainly been attributed to Cyanobacteria and Streptomyces, but as gene sequence databases recently have expanded, molecular studies now indicate that the more obscure Myxobacteria may be the leading bacterial group responsible for earthy off-flavors in aquaculture (Lukassen et al., 2022, Lukassen et al., 2019). For the first time, we succeeded in isolating these bacteria from RAS, enabling their production of geosmin, 2-MIB and other off-flavors to be studied in details by GC-MS. After cultivation in growth media with a variable nutrient composition, production of geosmin and 2-MIB by selected Myxobacteria was characterized to estimate which compounds might control off-flavor production in RAS. These findings provide valuable information to the aquaculture sector to optimize their practice to combat off-flavor issues produced by these bacteria.

Material and Methods
Samples from different compartments of two different Recirculating Aquaculture Systems (RAS) in Denmark were used for the isolation of the bacteria. Isolated strains were identified through 16S rRNA gene amplicon sequencing and subsequently whole genome sequenced using Nanopore. The isolates were cultivated in growth media composed of varying levels of relevant nutrients (nitrogenous compounds, phosphorus, carbon), and volatile organic compounds (VOCs) were extracted using stir bar sorptive extraction (SBSE). VOCs were analyzed through Gas Chromatography-Mass Spectrometry (GC-MS). Production of VOCs in the different media were normalized to cellular production by enumeration of cells through fluorescence microscopy.

Results and Discussion
For the first time, isolation of Myxobacteria from RAS was successful. This bacterial group has the largest genomes among prokaryotes, ranging from 9-16 Mb, which might explain their notoriously slow growth. The slow growth, in combination with their slime-production and swarming colonies, makes isolation and purification of isolates especially hard. Utilizing baiting techniques for both predatory and saprophytic Myxobacteria, three different strains were isolated and purified. Results from 16S rRNA gene amplicon sequencing identified two of the isolates as belonging to the genera Myxococcus and Corallococcus, with high sequence identity similarity to species Myxococcus virescens and Corallococcus exigus. The closest relative to the third isolate was found to be the genus Pseudenygromyxa. Growth of the isolates in rich media, e.g., containing high levels of all considered nutrients, produced insignificant levels of 2-MIB. However, under the same conditions, geosmin was produced in levels >1200 ng/L. For reference, the human odor threshold for geosmin in water is about 5 ng/L (Srinivasan and Sorial, 2011). The high geosmin production supports that these bacteria may have a significant contribution to off-flavours in RAS-reared products. Results from other cultivation conditions are currently undergoing data analysis but will be presented at the conference.

Conclusion
Myxobacteria are prolific producers of the prominent off-flavor compound geosmin in RAS. Strategies to combat the production of off-flavor in these systems can only be developed through knowledge regarding the production of the specific bacterial producer in question. The present study provides further knowledge of how the nutritional characteristics of the rearing water will influence geosmin production in these bacteria.

GENOMIC ANALYSIS OF A DOWNGRADING TRAIT IN ATLANTIC SALMON USING FIELD DATA

*Nofima, Osolevien 1, 1430 Ås, Norway
*MOWI Genetics AS, Sandviksbodene 77A, NO-5035 Bergen, Norway
Email: anna.sonesson@nofima.no

Introduction
Downgrading traits are economically important for the Atlantic salmon industry because they are directly related to the price of the products. Their prevalence is typically low, and it is therefore difficult to obtain data in a normal sib trait testing regime for genetic studies and thus obtain breeding values for selection as part of a breeding programme. In this study, we focus on melanin spots in the fillets, which is the most common fillet quality problem (Nordberg, 2018). Melanin spots is estimated to be the cause of 9–67% price losses, depending on the intensity and size of the discoloration (Färber, 2017). There are only a few reported estimates of heritability of melanin spots in salmon fillets; they typically indicate only low genetic variation for melanin, and the heritability estimates were coupled with high standard errors ($h^2 = 0.025 \pm 0.019$ in a study where 32% of fish had melanin on at least one of their fillets; Kettunen et al., 2020) and $h^2 = 0.01–0.02$ in a study where ca 15% of fish had melanin spots (Mørkøre et al., 2015). We hypothesise that these low heritability estimates were a result of the poor data quality, in particular the low overall frequency and unbalanced data with regard to family origin. In this task we set up a system where we sampled production fish at a processing site of MOWI and used this fish for a genetic study, once we had obtained enough data. These fish are related to the nucleus fish and each batch has a limited number of families. The analysis included estimation of heritability, and a genome-wide association study. We compared the parameters obtained from a quantitative analysis assuming a normal distribution of the trait to a probit analysis, to take account of the binary nature of the trait.

Materials and Methods
Data were collected at the processing site of Mowi at Egggesbønes, Norway. At the slaughter line, filleted Atlantic salmon were sorted into Superior (no melanin spots) or Melanin (presence of melanin spot in the front part of the fillet under the spine). Four random batches of fish were sampled from cages with known geographical origin, but with unknown sires and dams. There were 1643 fish in total with 45% Superior and 55% Melanin fish. All fish were genotyped with the in-house custom made SNP-chip of MOWI. 63,826 SNPs passed filters and quality control and were used to set up a genomic relationship matrix using the GCTA software of Yang et al. (2011). Genomic estimates of variance components were estimated from a univariate threshold (with, \texttt{!BIN} and \texttt{!PROBIT} functions) and linear models implemented in ASREML 4.2 (Gilmour et al., 2015), using sex (2 levels) and batch (4 levels) as fixed effects. A genome wide association analysis was performed using the following linear mixed animal model implemented in GCTA program with the “--mlma-loco” function (Yang et al. 2011) using sex, batch and five principal components showing stratification in the genetic structures.

(Continued on next page)
Results and Discussion
The use of data from non-family nucleus fish from a processing site proved successful for variance component estimation of Melanin spots in Atlantic salmon fillets. The genetic variation for melanin accumulation in fillet obtained using genomic information were low to moderate with estimates of $0.202\pm0.040$ and $0.326\pm0.035$ with linear and threshold models, respectively. It should be noted that heritability of case/control traits often are overestimated.

In the genome-wide association study, chromosome ssa03 had 7 SNPs located in the region between bp 88.3Mbp - 92.4Mbp that surpassed the chromosome-wide significance threshold. On ssa07, 9 SNPs located in the region between 37.1Mbp - 45.7Mbp surpassed the chromosome-wide significance threshold. This is the same genomic region where QTL linked to resistance to Pancreas Disease (PD) have also been detected (Hillestad et al., 2020; Aslam et al., 2020). A random sample of 10 fish were analyzed for the detection of PD virus which showed that 7 out of 10 had PD virus. These results indicate a possible genetic link between melanin spots and susceptibility to PD. They also agree with previous suppositions that the prevalence of melanin spots is linked to inflammatory diseases such as PD (Mørkøre et al., 2015).

Introduction
Norwegian aquaculture has undergone significant growth and development in less than 50 years. This success, however, has come at a cost, such as pollution, sea lice, and escapes, as well as industry costs related to the combat of these problems. For instance, the cost of combating sea lice increased from about NOK1/kg (€0.085/kg) in 2011 to NOK4.25/kg (€0.36/kg) in 2016. For the industry as a whole, this amounted to an increase from NOK4 billion (€338 million) in 2011 and NOK5 billion (€422 million) in 2016 (Abolofia, Asche et al. 2017, Iversen, Hermansen et al. 2017). To tackle these issues, the government facilitated industry innovation through a temporary licensing regime in 2015, known as the development license regime (or development projects). This has led to a range of new production systems based on a mixture of heterogenous and complex technologies. This paper shows:

1. How these new technologies and production systems challenge the existing governance system, and
2. How increased this in turn demands an adaptive governance approach.

Materials and methods
The paper is an empirical paper, based on an inductive multimethod approach. We examine six new and significantly different production systems. Through almost fifty semi-structured interviews with various actors involved in the processes of developing these systems, we gain a deep understanding of how new technologies change the system-to-be-governed and how this, in turn, affects the governing system (Johnsen 2017). Through Thematic Content Analysis (TCA), we identify common themes, while also presenting the voices across all participants (Anderson 2007).

Results
The paper will show empirically how new technology increases the “wickedness” of aquaculture governance by increasing the complexity, diversity, uncertainty, and controversies in the aquaculture governance system (Marchant 2011, Marchant, Allenby et al. 2011, Marchant 2020). Due to the increased wickedness, there are no optimal solutions to how to manage these emerging technologies. Moreover, as the development projects always are “work in progress”, objectives are not permanent, but dynamic and subject to adjustments based on experience and learning. Consequently, the messiness created by these new technologies slows down regulatory processes, but also challenges the bureaucratic processes related to the development projects (Gaudet and Marchant 2011). To handle the rising complexity, diversity, uncertainty, and controversies; the governing system “muddles through”, creating working, but imperfect solutions.

Conclusion
Based on a case study of six technological aquaculture innovations, this article shows how government-initiated technological innovations challenge the aquaculture governance system, and how the governing system must adapt to these changing conditions.

AQUACULTURE DEVELOPMENTS IN EAST AFRICA THROUGH THE LENS OF TWO EUROPEAN FUNDED HORIZON PROJECTS FOODLAND AND PRACTICE

F. Robinson, A. Chantzaropoulos, D. Sorella,* T. Bardocz, T. Atiye, M Setti, J Hoinkis

FOODLAND and PrÆctiCe are European funded Horizon projects focusing on food production and farming in Africa. FOODLAND began in September 2020 and will run until August 2024 aiming to enhance the diversity of food production and consumption in six African countries displaying different stages of the nutrition transition. To this end, FOODLAND will create a network of 14 local Food Hubs that will aggregate relevant actors and serve as injection points for the introduction of innovations. FOODLAND has identified specific objectives addressing the organizational, technological, and nutritional needs of the local African food systems: 1. To detect behaviour and preferences of consumers and producers, in order to customize innovations to local sensitivities; 2. To develop and implement organizational innovations, aimed at boosting coordination among food operators; 3. To develop, test, and validate (open) technological innovations in the laboratory and in the field; 4. To disseminate knowledge of solutions towards malnutrition reduction and innovations.

PrÆctiCe began in November 2022 and is a 42-month project that will provide a novel agroecology indicator set for East Africa, aimed at helping smallholder farmers in their agroecological transition. The project goes beyond the existing indicator frameworks by putting the “concept into action” with a decision support tool for agroecology advisors supporting the selection of the best suited combination of agroecological farming practices in a local context.

These projects give strong attention to activities pertaining to aquaculture. FOODLAND is developing aquaculture technologies for urban and peri-urban areas to ensure the production is brought closer to the markets resulting in a shorter distribution chain that can be more competitive with imported products. The Aquaculture Working Group, based in Kenya, Uganda, Tanzania, and Tunisia, are innovating in several different areas to develop technologies and techniques that will support and develop local aquaculture practices. New feeds are being investigated to reduce the reliance on fishmeal heavy, imported feeds, new and updated protocols for the production of local species are being created, recirculating technologies that can be reproduced by small-scale farmers for fingerling production are being assessed and research on integrated agri-aquaculture production systems, using wastewater from aquaculture to grow crops, is currently ongoing.

The PrÆctiCe project will establish three living labs focusing on circular water-energy-nutrient systems of integrated aqua-agriculture. Living lab one builds on a previous Horizon 2020 project “VicInAqua” and is a recirculating aquaculture system run on municipal wastewater filtered using a membrane bioreactor, the system will be upgraded to include grow-out ponds and wastewater from the fish production systems will be used to irrigate crop production. Living lab two is an aquaponics system, integrating fish production with a range of crops. The third living lab will utilize a pond culture system integrated with poultry and vegetables, the poultry waste will be used to fertlize the ponds and the wastewater from the ponds will support in the irrigation of the crops. Each of these systems will be adapted to an East African environment and showcase available technologies and opportunities that will be replicable by local farmers.

Each project highlights the different directions into which aquaculture is developing in the different East African countries, emphasizing the technologies, techniques, and systems that are of the highest interest and benefits to the different regions. These differences allow for many exciting areas of research and development across and between the partners involved while also bringing into focus the primary commonality between both projects which is the necessity for all systems developed to be replicable by local farmers at different scales, small-scale, subsistence farming as well as larger, commercial scale endeavours.

Introduction
To overcome the challenges posed by unstable water conditions in traditional marine hatcheries due to climate change and human activities, this project aims to revolutionize the concept by implementing recirculating principles to minimize reliance on natural water resources. A crucial element of recirculating systems is effective water disinfection and treatment, ensuring a suitable environment for farmed species and reflecting on their health, welfare, and product quality. This study evaluates the impact of a prototype hydro cavitation device on water quality parameters, growth, and feed utilization performance in European seabass (*Dictentrarchus labrax*).

Material and methods
The experimental trial consisted of two phases. Phase 1 focused on testing the hydro cavitation device’s impact on biofilter maturation and related water quality parameters. Phase 2 involved a growth trial with European seabass at the hatchery stage to assess the extent to which growth and feed utilization performance were potentially affected by using the aforementioned equipment.

The experiment was conducted in a recirculating aquaculture system (RAS) comprising 12 culture tanks of 130 liters each. The system included a protein skimmer, UV sterilization, ozone sterilization, and a biological filter.

Phase 1 lasted for six weeks, during which the system was prepared and managed by monitoring water quality and providing carbon and nitrogen sources to stimulate bacteria development.

In Phase 2, the growth trial spanned four weeks. Four different disinfection setups were tested: WK1 (hydro cavitation + UV), WK2 (UV disinfection), WK3 (hydro cavitation), and WK4 (no disinfection). Multiple samplings were also performed during each week to monitor the water quality, estimate the total numbers of bacteria (TVC) as well as health checks of fish. The aim was to evaluate the potential impact of hydro cavitation technology on water quality and fish growth performance. European seabass of approximately 5g were randomly allocated, with a starting number of 30 fish per tank in seven experimental tanks.

| Table 1. Growth performance of European seabass after four weeks of trial. |

(Continued on next page)
Results
The results of the biofilter maturation experiments showed the conversion of NH$_4$ to NO$_2$ starting on day 15. The total ammonia concentration initially increased to 1mg/l, but then sharply declined to 0.25mg/l. NO$_2$ levels exhibited a spike between days 3-4, reaching 100mg/l, which decreased to 0mg/l from day 5 until day 14. A peak of 10mg/l was observed on day 14, followed by wide fluctuations ranging between 10 and 100mg/l from day 17 onwards until day 40.

In phase 2, the overall growth performance followed a similar trend across all tanks. Tank 2 had the lowest feed conversion ratio (FCR), while tank 3 and 10 had the highest. Specific growth rate (SGR) was lowest in tanks 3 and 4, and specific feed rate (SFR) was highest in tank 10 and lowest in tank 2. The survival rate showed no mortalities in tanks 2, 3, 4, and 5, with only one mortality each in tanks 8 and 10.

The water quality profile (temperature, pH, dissolved oxygen, and CO$_2$) remained stable throughout the four-week experiment, unaffected by the different disinfection setups. The CO$_2$ levels increased by 0.7mg/l compared to phase 1 (average value 0.2mg/l) due to the fish respiration. There were no significant differences in NH$_4$ and NO$_2$ levels among the disinfection setups, but significantly higher NO$_3$ levels were observed during UV disinfection compared to HC+UV.

Overall, the results indicate that the hydro cavitation device, in combination with UV disinfection, did not significantly impact water stability, growth, or water quality parameters (except for NO$_3$) during the four-week experiment.

The bacterial counting was performed 24h after the incubation and the results showed a significantly higher value of CFU/ml before the disinfection in WK1 compared to the other weeks. However, a sharp decline and a consequent raise were recorded in the following weeks. The samples collected after the disinfection system showed an exponential increase of CFU/ml over the weeks without a significant difference of WK4 compared to WK3. WK1 and WK2 were not considered due to the absence of CFU/ml recorded.

The overall survival rate of 98.9% recorded during phase two of the trial showed the absence of severe negative effect on fish health. However, the most severe clinical sign were found in the animals sampled in absence of disinfection were the congestion and hyperplasia of the gills was indicative of a water quality impairment.

Introduction

The current project, part of Switchmed phase two, is built upon the results of the project’s first phase, which was dedicated to characterizing the Tunisian aquaculture value chain. This second phase aims to support further the sustainable development of the aquaculture sector, in line with the Tunisian aquaculture development strategy for the sustainable expansion of this sector. In the last decade, Tunisian aquaculture demonstrated a significant production increase, mainly from intensified offshore marine finfish culture. However, one of the key aquaculture performance indicators, the Feed Conversion Rate (FCR), remains high. High FCR can negatively effect the economic and environmental sustainability of the aquaculture sector. Farmers can improve FCR by regularly adjusting feed quantities to avoid excessive or under-feeding, considering the actual biomass and daily conditions. Over recent years, the aquaculture sector has developed innovative technologies and processes to improve farming efficiency. Adopting appropriate SMART technologies can reduce fish feed losses, reducing the amount of feed being dispersed into the water and, thus, the environmental impact of aquaculture. Many of these systems have high investment costs and are unaffordable to many farmers. More affordable options do exist but they lack demonstration in a production system. This pilot project aims to demonstrate affordable and innovative technologies’ advantages in optimizing feed conversion ratio by conducting an experimental campaign in actual production conditions. The Integration of these innovative technologies is accompanied by a training and awareness campaign. The campaign is open to all aquaculture and institutional players who wish to participate and benefit from the expertise of the project partners.

Materials and methods

A combination of SWOT analysis and a cost-benefit approach was used to select the most suitable technologies for improving feed conversion efficiency. The technologies selected for this study include: 1) offshore individual automatic fish feeder, 2) AI software, 3) 4G antenna, 4) underwater camera, and 5) power station based on solar energy. The two parameters that the AI software is based on are feed loss and fish swimming behaviour. Also, a pilot site (Aquafarm) selection process for the trial of selected technologies was carried out based on a decision matrix on key parameters and site suitability. Then, at the selected offshore site, 14 km offshore the coast of Monastir, four different farming scenarios were designed for the experimental campaign: 1) One cage including all the technologies selected, 2) One cage with only the automated feeder and the power station, 3) One cage with an underwater camera, AI and the power station, 4) A control cage with none of the selected technologies. The online training covering the aquaculture value chain’s main aspects was created using video presentations on PowerPoint, and the infield training was designed to share practical experience to use these SMART technologies at the offshore site.

(Continued on next page)
Discussion

The logic of integrating five technologies at the selected farm site in four scenarios aims to assess how using three different combinations of technologies during the experimental campaign influences the FCR and fish feed losses. In particular, the combination of automatic feeder, AI, and camera (scenario 1), compared to scenario 2, in which only the automatic feeder is employed, aims to establish if AI improves the feeder’s performance in delivering feed more efficiently. Similarly, scenario 3, where only camera and AI are employed, plus the canon traditional feed administration method, compared to scenario 1 (full fl  edge), to determine which of the two administration techniques (i.e., canon or automatic feeding) is more efficient. Finally, the control cage, where no smart technologies are employed, to determine how efficient is the current canon feeding strategy compared to scenarios 1, 2 and 3. According to recent statistical data, the average FCR in Tunisia is currently about 2.3. for seabass, meaning that to obtain the commercial size of 400gr, about 920g of feed is needed at the cost of 4 Tunisian dinars (TD) or 1.2 euros per fish. Assuming that the use of Smart technologies improves feeding efficiency, reducing the amount of feed loss and, at the same time, the FCR to 1.3, this would have two main benefits for farms: 1) a decrease in the cost of production per fish of 44% 2) an reducing its environmental impact. Potentially, on an economy of scale for offshore aquaculture, this could be an incentive to adopt technologies, at affordable cost, to monitor feed and fish management, and this shift can potentially disrupt the whole offshore aquaculture industry towards a more profitable and environmentally sustainable finfish farming practice at local and international level. To this extent, online and in-field training aims to increase social awareness about the potential of the introduction of these novel technologies into the offshore aquaculture industry.
THE POTENTIAL OF HIGH INCLUSIONS OF INSECT PROTEINS FOR SUSTAINABLE AQUACULTURE: A STUDY ON GROWTH PERFORMANCE, FEED UTILIZATION AND HEALTH OF JUVENILE RAINBOW TROUT (Oncorhynchus mykiss)

Introduction
The sustainability of aquaculture has been a key topic since the beginning of the millennium. Over the years, efforts have been made, especially for carnivorous species, to achieve nutritional efficiency in the sector by lowering the fish-in-fish-out ratio of feeds. And by finding sustainable and cost-effective terrestrial ingredients that can meet the necessities of carnivorous species, while still maintaining the quality of the final product. In recent years, many plant-based ingredients have been proven as viable alternative ingredients for aquaculture feeds, with soybean meal (SBM) becoming one of the most used alternatives for the partial replacement of fishmeal (FM) in commercial aquafeeds. However, SBM use comes with challenges. Significant inclusions of SBM in fish diets may negatively impact fish health due to intrinsic anti-nutritional factors, which might induce inflammatory responses in fish’s distal intestine. This issue can be mitigated by using sophisticated processing techniques, that come at considerable cost. Additionally, replacing FM with SBM may not produce feeds that provide reliable all-round nutrition for carnivorous fish species, as earlier studies had indicated. Furthermore, practices associated with soy production, such as deforestation and pesticide use are environmentally problematic. One promising alternative to SBM are insect meals (IM). As a component of their natural diet, insects provide a sound balance of amino acids, lipids, vitamins and minerals for salmonids, such as rainbow trout (Oncorhynchus mykiss). Moreover, insect production can utilise food waste: forming part of the circular economy. Plus, the utilisation of normally wasted products makes insect production economically competitive.

This study evaluated the effect of substituting up to 100% of SBM protein with Black soldier fly (Hermetia illucens) meal (BSFM) with and without addition of 0.3% guar gum, with respect to growth performance, feed utilization and health of rainbow trout.

Materials and Methods
A dose-response study was conducted with a homogeneous group of juvenile rainbow trout (initial body weight: 135.8 ± 15.3g), randomly distributed in twenty 0.33m³ circular tanks. Ten balanced experimental diets were formulated to be isonitrogenous (45%) and isolipidic (28%) by replacing SBM with increasing levels [0% (control), 25%, 50%, 75%, and 100%] of BSFM, with and without addition of guar gum (0.3%). The fish were fed ad libitum by hand for a period of 69 days (6 days a week) and growth performance, feed utilization efficiency, and nutrient digestibility were evaluated.

Results
At the end of the experiment, all groups showed a linear positive correlation between the increasing replacement of SBM with BSFM with all measured fish performance parameters [final body weight (FBW), specific growth rate (SGR), total feed intake (TFI) and feed conversion ratio (FCR)]. The addiction of 0.3% guar gum had no effects on fish performance.

Conclusion
The results suggest that the inclusion of high amounts of BSFM in rainbow trout diets can be a viable option to replace plant-based ingredients in aquafeeds, with respect to important performance parameters. However, although there is growing evidence of the benefits of insect components in aquafeeds, further research is needed to fully understand the potential advantages and limitations of including insect protein in aquafeeds.

VIRUS-INDUCED INTERFERENCE AS A MEANS FOR ACCELERATING FITNESS-BASED SELECTION OF CYPRINID HERPESVIRUS 3 SINGLE NUCLEOTIDE VARIANTS in vitro AND in vivo

Introduction
Cyprinid herpesvirus 3 (CyHV-3) is the archetype of fish alloherpesviruses. It causes severe economic loss within the carp culture industry worldwide. Genomic and biological comparisons of CyHV-3 strains have revealed a negative correlation among strains, suggesting the existence of genovariants conferring advantages in vitro but reduced fitness in vivo, and vice versa. We identified such genovariants of the CyHV-3 ORF131 gene. This gene is essential for viral growth in cell culture and encodes a 429 amino acid type 1 membrane protein. We demonstrated by mutagenesis that the genetic determinant of the phenotypic trait related to ORF131 depends on a single nucleotide polymorphism (SNP) (C225791T mutation) that results in codon 183 encoding either an alanine (183A) or a threonine (183T) residue. Understanding the key factors that determine how purifying (negative) selection operates on herpesvirus genomes would provide useful insights into the evolution of these viruses. In the present study, pairs of viruses differing only by the C225791T SNP were generated and compared for fitness in vitro and in vivo by infection with single viruses or co-infection with both viruses. This study illustrates how the host-virus interactions and the fundamental biological properties of some viruses and their hosts may have a profound impact on the degree of diversity that arises within viral populations.

Materials and methods
Common carp brain (CCB) cells were cultured. A total of seven CyHV-3 strains from various geographic origins were used and indirect immunofluorescence staining was done. Multiple DNA sequence alignments were made using MAFFT online version 7 and then processed using MEGA X software. CyHV-3 strain FL was isolated in Belgium from a fish that died from CyHV-3 infection and used to produce the FL BAC plasmid. FL EGFP rec ORF131-A (or) -T and FL mCherry rec ORF131-A (or) -T were produced by transfecting the FL BAC plasmid into CCB cells. The recombinant strain was cloned by three successive steps of plaque picking. All recombinant strains were confirmed by monitoring SacI restriction fragment length polymorphism (RFLP) and full-length genome sequencing. Growth curves, plaque size assay and syncytial plaque assay were investigated. Live cell images were collected using Incucyte to ensure that cells detected as double positive represented cells co-infected by EGFP and mCherry recombinants. In vivo infection was carried out either by immersion of uninfected fish in water containing virus or by cohabitation of uninfected fish with infected fish. The experiments, maintenance and care of fish complied with the guidelines of the European Convention CETS 123. Viral genome copies were quantified by real-time TaqMan qPCR. Fish were analyzed using an IVIS Spectrum in vivo imaging system.

Results
The results demonstrate that among the strains studied, FL, Cavoy and T strains were the most fit in cell culture but the least virulent in vivo. The opposite was the case for the M3, I, E and GZ11-SC strains. The strains with the 183A genovariant formed syncytia, whereas the strains with the 183T genovariant did not. This suggests that the ORF131 183A genovariant is responsible for syncytial plaque formation. The experiment involving simultaneous or delayed infection (one genovariant, then infection with another after) of monolayer revealed that the primary infection of monolayer reduces its ability to be superinfected by a second virus and that this phenomenon increases with the length of delay between the first and second infection. The ORF131 183T genovariant confers higher fitness in vivo than the 183A genovariant but in the case of in vitro it is vice-versa.

(Continued on next page)
**Conclusion**

The present study indicates that CyHV-3 may have an intrinsic ability to actively contribute to the purifying selection of less fit variants by stimulation of superinfection inhibition at both the cellular and the host levels. However, more widely, our observations demonstrate how the fundamental biology of some (perhaps many) viruses and their hosts may have a profound impact on the degree of diversity that arises within viral populations.
DISEASE MITIGATION: A POSITIVE AND NEGATIVE APPROACH

Benedict Standen*, Bo-Groth Bendsen

*Corresponding author: Benedict.Standen@dsm.com

Disease remains a major bottleneck for the expansion of aquaculture. This is particularly true as aquaculture intensifies and production stressors negatively impact the animal, increasing disease susceptibility and denting the profits of producers. This has created the need for prophylactic disease management, through the use of functional feed. There is often a misconception that additives can solve all problems, and these unrealistic expectations have resulted in skepticism about feed additives.

This is particularly true when combatting bacterial disease. There are two types of bacteria, which differ in membrane structure. Gram-negative bacteria have an outermost layer of lipopolysaccharides (LPS) whilst the external layer in Gram-positives is comprised of peptidoglycans. Both types contain pathogens and not surprisingly, different management approaches are needed to combat them. In tilapia this is particularly relevant, as the fish are exposed to many bacterial pathogens, including *Aeromonas hydrophila*, *Edwardsiella tarda*, *Francisella noatunensis* etc. (G-ve) and *Streptococcus* spp. (G+ve).

Organic acids and their salts have been used extensively in aquaculture and are a ‘go-to’ additive to combat fish disease. It is often thought organic acids act to reduce the pH in the gut, but this is not always true unless a very high dosage is used. More important is to explore antimicrobial properties where lower doses might work but are highly formulation specific. For example, an enhanced acidifier (Biotronic® PX Top3) was found to be more effective than similar products, despite having a 4x lower inclusion rate (0.5 kg/t vs 2.0 kg/t). After an eight-week feeding period, tilapia (initial weight = 10.96 ± 0.02g) were exposed to an *Aeromonas hydrophila* challenge via IP injection (7.5 x 10^5 CFU/ fish). After monitoring for 20 days, highest survival was seen in the Biotronic® treatment (85.7%), followed by the competitor products (50-64.58%) and lowest in the control (43.75%). These data demonstrate the value that organic acids can bring in the fight against G-ve pathogens, but also highlights the importance of product formulation.

On the other hand, phytogenics have not been used so widely, but their benefits are particularly interesting against Gram-positive pathogens. To demonstrate this, tilapia fingerlings (initial weight = 10.63 ± 0.01g) were randomly split into two treatments and stocked into 12 tanks (n = 6). Fish were fed either a control diet, or one supplemented with a phytonic feed additive (PFA, Digestarom® P.E.P. MGE) at 0.2 kg/ t. After a 57-day growth trial, where the PFA significantly improved biomass, weight gain and FCR (p < 0.05) fish were exposed to an *S. agalactiae* challenge via immersion (5 x 10^6 CFU ml^-1 for 1 hr). Following a 15-day monitoring period, a survival of 52.5% was seen in the control treatment. This compared to 70.0% survival in the PFA treatment, a real term increase of 33.3%. This demonstrates that phytogenics can be a useful tool in the continual fight against *Streptococcus* spp.

These studies demonstrate that in order to see the value of feed additives, the additive type and active components should be carefully selected for the specific field challenge. In addition, they are not ‘silver bullets’, and their use should be complemented with other management considerations, including biosecurity, vaccinations, water quality etc.
Introduction

Triploidization is a common technique of chromosome set manipulation that promises benefits associated with reduced fertility or sterility in aquaculture by the incompatibility in homologous chromosome pairing during meiosis I (Lee 2018.). Production of sterile fish finds its use when sexual maturation affects growth and development as in salmon, loach, or catfish production (Janhunen 2016., Park 2006.). Triploidization can reduce aggressive behavior through altered hormonal and metabolic homeostasis, which can also be applied to fishes of the Percidae family (Garner et al. 2008). Also, sterile triploid fish are used as surrogate hosts in primordial germ cell transplantation. The production of pikeperch with diminished fecundity but with acceptable vigor is particularly specific and complicated because pikeperch is considered a highly stress-sensitive fish, and the triploid fish in general appear to be more susceptible to stress (Fraser 2012.). Interspecific hybridization is a commercially used genetic tool in aquaculture to improve disease resistance and environmental tolerance in many species (Jiang 2022.) Nevertheless, thus far the issue of how triploidization would affect the gamete development of originally fertile hybrids was not evaluated.

Material and Methods

Hybrid triploid pikeperch was produced by hybridization of pikeperch (Sander lucioperca) females with Volga pikeperch males (Sander volgensis) and triploidized by inhibiting the first polar body using hydrostatic pressure, 8000 PSI, for 10 min. Larval ploidy level was determined by flow cytometry and chromosome analysis (Káldy 2021). The trial included a hybrid triploid group and three controls, hybrid diploid, pikeperch diploid, and its triploid form. Fish were kept in a recirculation system under natural light at a temperature of 16-22 °C for 330 DPH. Gonads of juvenile fish were fixed in a modified Davidson solution and analyzed using conventional histological techniques, staining with hematoxylin and eosin (Latendresse 2002.).

Results and discussion

Chromosome analysis showed that the triploidization procedure was successful with a 100% rate, in both pressure-treated groups. There were no detected individuals with diploid or mosaic chromosomal structures. In females of both diploid groups, successive development was recorded from the oogonia stage until the cortical alveoli stage, while in males, development from spermatogonia to spermatids was recorded. Among hybrid triploids, there were also two types of gonads. Besides the primordial germ cells - spermatogonia, males showed spermatocytes and spermatids in one of the 5 samples. Hybrid triploids with phenotypically female gonads developed both oocytes (to the same stage as diploids) and spermatids. These fish did not develop normal female gonads but formed an intersex structure. Males, on the other hand, at this stage of development still did not show structural disorders. Triploid pikeperch had uniformed gonads with predominant PPGC and occasional primary oocyte.

From the results of this research, it can be concluded that the gonads of the pikeperch and its hybrid with the Volga pikeperch, in both sexes, develop without a difference, and it seems that they could sexually mature. In the case of triploid pikeperch, a large number of germ cells that did not enter meiosis, with sporadic primary oocytes, and spermatocytes in 100% of the analyzed samples, can justify the conclusion that triploids are infertile due to phenotypically bisexual gonads. While triploid hybrids developed two types of gonads a) pro-male - which did not deviate much morphologically from diploid juvenile testes, neither in shape nor in size, so at this stage of development it cannot be claimed that they are infertile; b) pro-female - due to the large number of spermatocytes and oocytes in the gonad at this stage of development, it can be concluded that they are intersex, and most likely functionally infertile. Further investigation in older age groups of fish is required to confirm these indications.

INFLUENCE OF A TEMPERATURE DROP FROM 15 TO 8 °C BEFORE OR AFTER WINTER SIGNAL ON EARLY SEXUAL MATURATION IN ATLANTIC SALMON (*Salmo salar* L.) POSTSMOLT

K. F. Staveland*, E. Pino Martinez, M. Fleming, P. Balseiro, S.O. Handeland

Introduction
The drive to produce larger Atlantic salmon smolts and postsmolts on land, has intensified the production protocols resulting in increased number of postsmolts maturing early. Early maturation represents both an economic and welfare challenge for producers. Causes for early maturation are multiple, including growth rate, energy surplus, photoperiod and temperature among others. The switch in daylength from winter to spring is the cue that entrains onset of sexual maturation (Fjelldal et al., 2018). However, high temperatures are regarded as the most important factor for early maturation (Melo et al., 2014; Pino Martinez et al., 2023) and has shown to stimulate the process under different photoperiods (Imsland et al., 2014; Martinez et al., 2023). In these studies, high temperature has induced maturation both when kept stable high during the trial (12,15 and 18 °C), and when it has been increased up to 16 °C together with daylength after winter signal. The present study, in contrast, aimed to assess if dropping water temperature from 15 to 8 °C during or after a winter signal can arrest the development of early sexual maturation in Atlantic Salmon postsmolts.

Materials and methods
900 parr were transferred to eight freshwater tanks at the flow-through facilities of the Department of Biological Sciences (University of Bergen, Norway). Four temperature regimes were established in duplicates (Fig 1A). The first group were held at 15 °C throughout the trial (15), as this temperature is shown to promote early sexual maturation in male salmon (Martinez et al., 2023) The second group started at 15 °C and lowered to 8°C after a 5-week LD12:12 winter signal (15-8L). The third group were started at 15°C and lowered to 8 °C at the start of the winter signal (15-8E). The fourth group were held at 8 °C through the experiment (8), as this temperature is shown to inhibit maturation. We performed nine samplings, collecting n= 6 males per tank per sampling. Body and gonad weight were measured and gonadosomatic index was calculated as GSI (%) = \(\frac{\text{Gonad W (g)}}{\text{Body W (g)}}\times 100\) and used to assess maturation status (Pino Martinez et al., 2023). A Fisher’s Exact Test for Count Data used to find differences in proportion of maturing males between treatments. Statistical analyses were performed in RStudio.

![Experimental design](image1.png)

**Figure 1** A) Experimental design with four experimental groups (15, 15-8L, 15-8E, 8), light regime, temperatures, and sampling points. B) Maturation (%) per experimental group and sampling. The period of winter signal is marked in gray.

(Continued on next page)
Results
Maturing males were observed in the three 15°C groups from sampling 2, prior and during the winter signal. After the winter signal, a highly synchronized onset of maturation occurred in all males in group 15, and also commenced in an increasing number of individuals in 15-8L and 15-8E (Fig 1B). Hardly any sign of maturation was observed in the group held at 8 °C throughout the experiment. Some individuals maturing in 15-8L and 15-8E displayed very high GSI and running milt, in contrast to those in 15. Interestingly, other males in 15-8L and 15-8E had a relatively low GSI (i.e. 0.29%), but a white foamy testis appearance typical of spermiogenesis (differentiated spermatozoa).

Discussion and conclusions
Temperature determined the life history strategy of the experimental groups, with all males at 15°C maturing at the end, and none at 8 °C. All groups treated at 15°C had some parr maturing, and the maturation seen prior to sampling 6 was all driven only by the high temperature experienced before the LD 12:12 winter signal. The drop in temperature to 8 °C before or after LD 12:12 caused a significant reduction of maturation. However, the increasing number of males found maturing in 15-8L and 15-8E suggests that the decision to mature had been made before the winter signal, and that the drop in temperature did not reverse but only delayed the process in many individuals. Furthermore, the presence of testes in spermiogenic phase but with low GSI suggests that those fish may have irreversibly committed to maturation early, and the switch to cold water only interrupted the proliferative stage and induced meiotic and spermiogenic phases.

Introduction
Harnessing energy from the wind is becoming an increasingly important research field, particularly in offshore environments. In addition, combining energy production with fish farming under common infrastructures has been highlighted as a priority at a European level. A challenge in that regard is that the effects of electromagnetic fields (EMF) generated by the wind turbines on the farmed species are largely unknown. Yet, studies on several species indicate that the presence of strong EMF may affect, among others, the embryonic development, circadian rhythm, metabolism, orientation, and migration (Formicki et al., 2019; Newton and Kajiura, 2020) of fish. In this study we investigate effects of EMF of industrial intensity on the growth performance, metabolism, and behavior of an important Mediterranean aquaculture fish, the European seabass (Dicentrarchus labrax).

Materials and methods
A trial was performed in the Recirculating Aquaculture System of HCMR (Greece) where juvenile European seabass of approximately 200 g were subjected to an EMF of 20 mT for three months. Growth performance was monitored monthly (weight measurements) while towards the end of the trial an intermittent flow respirometer was used (N = 15 per group) to determine the Standard Metabolic Rate. Additional were performed on E. seabass fingerlings (approximately 2 g) using a T-maze setup in order to investigate behavioral effects relating to swimming and directional orientation. These tests were performed with the aid of a Helmholtz coil (Fig 1.) which generates a uniform EMF at a strength of 10mT.

Results
There were no significant differences between the control and the EMF groups in growth performance of the fish. Both groups exhibited normal growth and increased in weight by 150 g over the trial period. Similarly, results from respirometry suggest that the EMF did not significantly affect their basal metabolic requirements; SMR showed minimal differences between groups exhibiting values between 85.1 – 88.4 mg kg\textsuperscript{-1} h\textsuperscript{-1}. However, the initial results using the T-maze (Fig 1.) indicate that the EMF may significantly affect some behavioral traits in E. seabass. In particular, application of EMF appeared to increase the prevalence of “freezing behavior” (assigned to fish that remain immobile) from 15% to 25% in the tested fish. Moreover, preliminary analysis indicates that while the control group showed uniform distribution towards the south-north axis, the EMF may exhibit a preference for the magnetic South.

\begin{figure}[h]
\centering
\includegraphics[width=\textwidth]{helmholtzcoil.png}
\caption{Left: The Helmholtz coil and T-maze setup used for the behavioral analysis, Right: Heatmap showing the movements of an individual fish in the T-maze, red indicates higher frequency.}
\end{figure}

(Continued on next page)
Conclusion
In this study we investigated the effects of EMF on several biological aspects of an important aquaculture species. Our results indicate that under industrial EMF intensity, the growth performance and basal metabolism of E. seabass are not significantly affected. In turn, this is a promising outcome for promotion of multi-use platforms combining fish farming with wind energy production. However, preliminary analysis indicates possible effects on the behavior of young fish which requires further investigation before management and policy recommendations can be made.

Introduction
Oyster beds and reefs provide essential ecosystem functions within coastal and offshore ecosystems around the world, providing structural complexity leading to numerous ecosystem services, as well as contributing to coastal economies for centuries (Beck et al., 2011). As such, they are the focus of several flat oyster nature-based solution projects, restorative flat oyster aquaculture projects (Carranza & Zu Ermgassen, 2020) and a multitude of habitat creation or restoration projects in almost all countries border the North Sea or the English Channel (https://noraeurope.eu).

Methods
A DEB-IBM (Dynamic Energy Budget - Individual Based Model) population model was coupled with the LARVAE&CO larvae dispersal model. The DEB-IBM is a bioenergetics-based population model (Stechele et al., 2023). The LARVAE&CO model is an IBM that simulates egg and larval dispersal. This work establishes a population model for flat oyster population dynamics and dispersal and applies the model to the English Channel and the North Sea to indicate suitability for offshore flat oyster habitat restoration and restorative aquaculture.

Suitable locations for restorative aquaculture are indicated by quantifying suitability indicators including population increase, fitness, reproductive potential, self-recruitment and sediment suitability.

Figure: Suitability for flat oyster restorative aquaculture and habitat restoration

(Continued on next page)
Results
Restoration hotspots (total suitability indicator score = 4) are located in the Wash (UK), all along the coast of East England and the outer Thames estuary (UK), in the offshore mid Channel south of the Island of Wight, around the Isle of Wight (UK), all along the coast of Dorset and Devon (UK), all along the coast from Saint-Brieuc (FR) to Le Mont-Saint-Michel (FR), Côte Fleurie (FR) all along the coast of Haute Normandy from Fécamp to Le Tréport (FR), around Dunkerque (FR), in the Northern parts of the Scheldt Estuary (NL), off the coast of Noord-Holland (NL), in and around both the Western and Eastern Frisian Islands (DE) and around Helgoland (DE).

Suitability indicators scores can be linked to the occurrence of historical beds.

Conclusion
The English Channel is highly suitable for flat oyster restorative aquaculture (both nearshore and offshore). In offshore locations of the North Sea, we do not expect to see high population increases due to colocation of flat oyster aquaculture and restoration, and restorative aquaculture efforts should be scaled up, to boost larval production and recruitment. To increase success of flat oyster habitat restoration in the offshore environment, we suggest the implementation of a basin-wide coordinated restoration effort that promotes the connectivity between natural oyster beds, restoration sites, oyster NID developments and aquaculture sites.

SIMULATING NUTRIENT FLUXES AND CARBON BUDGETS FOR AQUACULTURE: MUSSEL AND RAINBOW TROUT FARMING IN THE BALTIC SEA

Brecht Stechele*, Jonne Kotta2, Romain Lavaud3, Nancy Nevejan1

Introduction
The links between human footprint and ecosystem is becoming clearer, leading to the development of management tools that incorporate both scientific and socioeconomic information into decision making processes. The valuation of ecosystem services provided by human activities such as aquaculture becomes more prominently present in legislative context and may have the power to change public’s, often negative perception of aquaculture. Nevertheless, there is still a significant knowledge gap in systematically quantifying these ecosystem services. Dynamic Energy Budget (DEB) models offer the possibility to quantify nutrient emissions or eutrophication mitigation (N and P) of aquaculture production in dynamic environments, and coupled to spatial biogeochemical datasets, DEB models can provide information regarding spatial variability of these ecosystem services.

Bivalves removing suspended solids from the water that are excreted by finfish, is a classical example of IMTA (reference !) where nutrients are recycled to the benefit of the water quality. Quantification of the nutrient fluxes in IMTA setups remains a challenge. Thanks to a DEB extension that allows for quantification of product formation, such as shells, it is now also possible to quantify carbon cycles through farms.

Methods
Dynamic Energy Budget models provide a generic framework to estimate mass and energy balances. They can be applied to all living organisms and all ecological scales from cells to ecosystems. Applying DEB models to aquaculture relevant species enables quantification of several relevant variables including growth, reproduction, and physiological processes such as feeding, ingestion, assimilation, respiration and (pseudo-)faeces production.

Nutrient fluxes through finfish and mussel farms in the whole Baltic Sea region were quantified using a DEB modelling framework (Kotta et al. 2023). DEB models for the rainbow trout and the Baltic mussel were parameterised and validated using in situ observation of the metabolic performance (e.g., respiration, growth, and reproduction) over a salinity gradient. Standardised fish and mussel farms where introduced and spatial distribution of nutrient uptake and nutrient emissions of these farms were evaluated.

Results
Finfish farms (standardized to 265 tons of wet weight production) on average emit 6500 kg N and 520 kg P to the water column during a production cycle. Mussel farms (standardized to 24 tons of wet weight production) remove on average 210 kg N and 25 kg P from the water column. Spatial variability of nutrient emission and incorporation of both finfish and mussel farms (Figure 1) is large in the Baltic. Nevertheless, simulations demonstrated that despite suboptimal mussel growth conditions, mussel farming has the potential to fully compensate for the discharge of nutrients from finfish farms and may thus represent a solution to sustainable finfish farming in the Baltic Sea region. Besides eutrophication mitigation, simulating filtration, incorporation and biocalcification enabled complete estimation of carbon budgets of shellfish farms.

Conclusion
DEB is a generic framework that enables quantification of ecosystem services related to nutrient and carbon fluxes in dynamic environment such as the Baltic Sea. It has the power to become an important tool in nutrient or carbon budgeting for single activities and can be used to quantify nutrient fluxes through IMTA setups.

Introduction

Atlantic salmon (Salmo salar) is one of the most globally economically important marine aquaculture species1. Improving our understanding of the teleost immune response to pathogens could help combat the high disease burden in the aquaculture sector. Ubiquitination is an essential post-translational modification, known to play critical roles in the initiation, regulation, and termination of the innate immune system in mammalian species2. Ubiquitin is present in all eukaryotic cells and is highly evolutionary conserved suggesting that its role in immunity may be conserved in other vertebrates3. Despite evidence of many virus-inducible ubiquitination-related genes in fish4 and the observed up-regulation of the ubiquitination pathway in infected fish5, the role of ubiquitination in response to infection is still poorly understood. To identify the network of ubiquitin-related responses to viral infection this study combines analysis of the ubiquitinated proteome and gene expression of an Atlantic salmon cell line post-viral infection, using mass spectroscopy and RNA sequencing.

Materials and Methods

Salmon Head Kidney cells (SHK-1) were inoculated with Infectious salmon anaemia virus (ISA V) or Infectious pancreatic necrosis virus (IPNV). Samples were collected at 24 and 48 hours post-infection (hpi), along with time-matched controls (4 biological replicates per condition). For proteomics, cells were lysed by freeze-thaw and ubiquitinated proteins were enriched using HaloTagged Ubiquilin. Ubiquitinated protein content was measured via western blot, then submitted for Mass spectroscopy analysis. Mass spectroscopy was performed with data-dependent scanning, selection based on the host and viral proteome. RNA was extracted using TRIzol, and polyA RNA-seq libraries prepared using standard Illumina protocols and sequenced on a Novaseq 6000 as 150PE reads. Low-quality reads were removed, and gene expression was estimated using Kallisto6 and the Atlantic salmon reference transcriptome (Ssal_v3.1, GCA_905237065.2)7.

Fig.1 Analysis of Ubiquitome of ISA V and IPNV challenged SHK1 cells at 24 and 48 hours post infection. (A) Western blot gel image and quantification of bands using LICOR imaging software. (B) Heat map of ubiquitinated proteins from mass spectroscopy data (p value <0.05).

(Continued on next page)
Results

Infection of SHK-1 cells with ISA V induced a global up-regulation of ubiquitin, whilst IPNV infection induced an overall decrease in cellular ubiquitin (Figure 1A). This is consistent with the mass spectroscopy data, where the total ubiquitination profile of ISA V samples incurred a net positive fold change, whilst IPNV induced an overall negative fold change in ubiquitinated proteins, especially at 24 hpi (Figure 1B). A small number of proteins (4-50 depending on the condition) showed significant differences in ubiquitination in response to infection, including several relevant immune genes. For example, a TRIM ubiquitin ligase, TRIM25-like protein, showed significantly increased ubiquitination in response to ISA V at 24 hpi. Interestingly, all viral proteins were identified in the mass spectrometry data, and both the viral polymerase basic protein 2 and Matrix Protein 1 of ISA V contained di-glycine remnants consistent with ubiquitination.

RNA sequencing of the same samples revealed a massive up-regulation of gene expression in response to IPNV, both at 24 hpi and 48 hpi, while the response to ISA V was considerably more restricted (1033 vs 157 differentially expressed genes at 24 hpi).

Conclusion

Our results demonstrate a differential regulation of ubiquitination upon viral infection of different viruses in Atlantic salmon cells. We have found a TRIM25-like protein amongst the proteins with increased ubiquitination in response to ISA V. However, IPNV infection mainly led to decreased levels of ubiquitination in a small number of proteins. This lack of ubiquitination response contrasts with the large dysregulation of gene expression, and may suggest IPNV has the ability to regulate ubiquitination to enable infection. Additionally, multiple viral proteins contained ubiquitination sites upon digestion, namely ISA V viral polymerase basic protein 2 and matrix protein 1.

References

Capacitive deionization (CDI) is an environmentally sustainable technology that utilizes low electric voltage to adsorb ions onto electrical double layer region around high surface area electrodes through electric double layer capacitor mechanism at the electrodes-solution interface that is known to be energy-efficient and environmentally sustainable. Capacitive deionization (CDI) is an upcoming technology, positioned to transform the field of cost-effective, low carbon footprint water desalination. The technology has also been examined with municipal wastewater for removing and recovery of nitrogenous and even off flavor compounds. This also gives the option for fish purging and aquaponics applications. It is possible to engineer capacitive electrodes to target specific charged molecules in the input water stream. Our test in RAS water was the first attempt with salmon to examine its usability as a potential bypass biofilter and possible purging applications.

The capacitive deionization system used was from Stockholm Water Technology AB (Sweden) model STROM. Six individual 1000 L MicroRASs (Landing Aquaculture, the Netherlands) at Nofima Sunndalsøra were used for the experiment with Atlantic salmon. It was designed to have a long-term exposure (60 days) of Atlantic salmon to two different organic loads in a RAS experiment defined by using 2 drum filter mesh sizes. The water treatment used 100 µm drum filter for dirty water and the clean water was cleaned using 20 µm drum filters. Technically this should create an environment with 2 different water bodies that do not harm the fish but should facilitate off flavor compound production in the dirty treatment. The portable CDI unit was used 8 hours in each tank every 20 days. Water was pumped out of the fish tank, and treated for 19 cycles in 8 hours using the STROM system. Clean treated deionized water was sent back to the RAS system and effluent (waste, loaded with ions) water was discarded. During the experiment, 494 L of water was flown through the CDI systems resulting in 342 L being recirculated back to the tank generating only 152 L of reject water. Main components analyzed were nitrogen compounds (total ammonia, nitrite, and nitrate). Off-flavor compounds analysis is still ongoing. Water samples were collected in the beginning of the 8 hours treatment period from the fish tank, deionized water- and effluent water outflow. The same was done at the last cycle after 8 hours. Morning and evening fish tank values of the same molecules were compared to test the effect of continuous CDI usage over 8 hours in the RAS systems.

The results concerning the different nitrogen compounds showed that using CDI technology in aquaculture system needs more tuning of the CDI unit treatment variables, like used Voltage on the electrodes. The unit was adjusted for salinification and could do more to reduce the low concentrations of nitrogenous products of the fish and bacterial metabolism. Performance of the CDI system changes over the day so that the TAN removal tends to be better after running for longer hours. Something unexpected was that in all measurements of nitrite concentration after the CDI unit increased, in the treated and effluent water. Nitrate showed the most promising removal efficiency. Mass balancing of the system was not possible since there was always mixing of inflowing and outflowing water during deionization cycles. We will present the development of the testing procedures and learning experiences by doing different experiments. The latest experiments done at the University of Aarhus with Rainbow trout demonstrate finally that the CDI can remove higher N compound concentration much better than lower. Also, it could be shown that at least under low stocking densities the CDI unit can be used as a biofilter substitute.

Since this was after our knowledge the first try to use the system in salmon RAS application, the CDI unit still has a high potential as an ion removal tool. It could be off flavor purging or especially accumulating of nutrients for aquaponic systems. This used voltage could have led to some reactions for oxidizing Ammonia into Nitrite or reduction of Nitrates into Nitrites at the electrode surface. It could also lead to hydrolysis of bacteria and release of off-flavor compounds which we still try to investigate. In summary we will present results for using a CDI system as something like a “electrical biofiltration” unit and present attempts for further applications based on our findings. As the first experiment of its kind for salmon RAS applications, CDI holds significant potential as an ion removal tool for tasks like off-flavor purging and nutrient accumulation in aquaponic systems.

THE CLEAR-CUT FUZZY BASIS OF BIOSECURITY. KNOWLEDGE AND RISK MANAGEMENT IN PRACTICE IN NORWEGIAN SALMON FARMING

Kristine Størkersen*, Andreas Misund, Cecilie Salomonsen, and Trine Thorvaldsen

SINTEF Ocean
7465 Trondheim, Norway
Email: kristine.storkersen@sintef.no

Introduction and research question
As we speak, more or less well-founded biosecurity plans are being created in aquaculture companies across Europe. New regulations require companies to control biosecurity in their production and area. Thus, company managements, biologists, and operational personnel are making plans on how to achieve and maintain biosecurity in their production and activities. In the operational end, the plans must be interpreted and played out by the personnel. Since plans are not always easy to comply with, the operational personnel have a major responsibility to make the good intentions embedded in the plans come into action.

That is why we in this study ask: What are the personnel's considerations about routines and knowledge when biosecurity management is developed and played out?

Method
This presentation will discuss results from an interview study of how biosecurity is handled in practice by biological, managerial, and technical personnel at Norwegian salmon RAS hatcheries and smolt transport. 18 persons involved in hatcheries and 11 persons in the well boat segment were interviewed in 2022.

The study is a part of the “Smittekontroll”/”Infection control” research project, funded by the Norwegian Seafood Research Fund (901734) and aimed at suggesting measures for predictable water treatment and disinfection in recirculating aquaculture systems (RAS) salmon hatcheries and smolt transport. The project studies microflora and technology, in addition to this study of operational routines.

Definition and earlier research
Biosecurity involves a set of management measures to reduce the risk of transmission, development and spread of infectious diseases, between populations, production zones, vessels, sites, and enterprises (Lillehaug et al. 2015). Diseases have been on the agenda for the aquaculture industry since its commercialization in the 1960s. Disease spread has been reduced through technological, organizational, and biological advances such as vaccines, disinfection systems, hygiene routines, and combat zones for diseases.

For increased biosecurity, one must identify risk factors, and use the risk assessments to make biosecurity plans (Lillehaug et al. 2015). Yet, further improvement has been hampered by limited knowledge, cost considerations, technology design, and increased professional and operational complexity (Larsen et al. 2020).

Transport of live animals is one of the most prominent risk factors for the spread of infectious diseases, and in aquaculture, wellboats are a significant route of infection (e.g. Murray et al., 2002). Nevertheless, there is still limited knowledge about infection in and from wellboats. Biosecurity on wellboats is supported by e.g. technical standards, cleaning practices, and hygienic treatment of intake and discharge water from the vessels, but the practices are not compliant (Larsen et al 2020). It has previously been described that wellboats operate with small margins which can lead to shortcuts (Fenstad et al. 2008).

There has been a significant development with the use of RAS, which require new practices and knowledge about biosecurity and disinfection routines at hatcheries. Different facilities have different practices for production and disinfection, resulting in different microbiota composition at plants (Dahle et al., 2021; Lazado & Good, 2021). In addition, there are major differences in mortality between hatchery facilities, giving opportunities for improvement, e.g. through routines and technology (Tørud et al., 2019). Interview studies at RAS facilities, among others, have shown that employees consider some operational routines to be unwavering due to the plant’s design, but that many hatcheries still can improve their biosecurity routines (Tørud and Størkersen 2021).

Larsen et al. (2020) urge for more knowledge so it can be possible to establish a best practice and biosecurity analysis for RAS facilities and wellboats. As we see, both biological and organizational research is needed.

(Continued on next page)
Discussion and conclusion

Our study has gone into the transport and RAS segment, where the research gaps are deep, which influence the biosecurity management.

The interviewed personnel in this study describe how they work to manage biosecurity. They have an array of descriptions of how measures are made, used, and collaborated around, and how biosecurity relates to the job they are there to perform. Some consider routines and procedures to be clear, and they perform their work without doubts. Still, the majority express concerns around their biosecurity measures, and find the knowledge base to be uncertain and the intention behind biosecurity plans difficult to meet.

Altogether, the interview findings illustrate how biosecurity management is based on biological knowledge, but dependent on knowledge-strength, technology, investments, production routines, regulatory demands, habits, and other organizational conditions. In that sense, biosecurity is similar to other values that organizations need to control – like safety, quality, and ethics. Biosecurity also includes several sciences, like biology and natural sciences, that interact with a line of organizational conditions. This requires scrutiny and attention moving forward.

The increased use of the term biosecurity illustrates an awareness of this dependency in the aquaculture industry. Currently, many think of biosecurity as health studies, but it is also an organizational study object. Some of the biological foundations of biosecurity are well-researched and agreed upon, while others are either unknown, uncertain, or debated, causing trouble for risk assessments and the trustworthiness of biosecurity plans. To manage problems of diseases, one needs more biological knowledge, but also to utilize it in management and regulations, in a practical and enforceable way.

E-mail: andrea.v.strand@sintef.no

Introduction
Atlantic salmon (Salmo salar) is one of the most important export commodities in Norway. Future growth in the industry is expected, and global demand for Norwegian produced salmon is rising. Salmon is generally accepted as a sustainable source of protein, and several studies state that the carbon footprint of salmon is lower than for example beef, pork and poultry (Hilborn et al., 2018; Nijdam et al., 2012)aquaculture, and capture fisheries that measured four metrics of environmental impact (energy use, greenhouse-gas emissions, release of nutrients, and acidifying compounds. A majority of the carbon footprint of the salmon from farm to harvest is accounted for by the feed (Ziegler et al., 2021). Feed for salmon produced in Norway has global and complex supply chains, with 92% of all ingredients imported in 2020 (Aas et al., 2022). An average for the last 10 years show that around 45% of ingredients in compound feed for livestock production in Norway were imported (Landbruksdirektoratet, 2023). These global value chains can be vulnerable for political shifts, conflicts, epidemics as well as climate change. There is a national goal to increase the Norwegian self-sufficiency degree, and producing sustainable feed resources in Norway is a key component to succeed here. The SusFeed project, financed by the Norwegian Research Council (grant #326825) aims to increase raw material for feed produced in Norway and investigates the potential and sustainability of novel feed ingredients such as insects, microalgae, and grass fibres.

To investigate and assess the sustainability and robustness of the feed system, a holistic perspective on the feed system is needed. We aim to quantify the current supply chains of feed in Norway using Material Flow Analysis (MFA) (Brunner and Rechberger, 2016). MFA is useful methodology to assess the resource efficiency of a system. A quantification and visualisation of the feed system with a MFA gives a deeper understanding of the current feed system, on the amounts of mass, protein and energy currently used and how new ingredients can increase the sustainability of the feed system.

Methods
The quantification of the current feed system is done based on the MFA methodology. The system boundaries are from feed ingredient to edible product of animal in Norway in 2020. Separate systems were made for salmon, cattle, pork, and poultry. The system was quantified for total mass of feed, protein, and energy in the feed. The MFA is based on numbers on total feed consumption and animal production from official statistics data sources (Fiskeridirektoratet, 2023; Landbruksdirektoratet, 2023; SSB, 2023). Feed composition is based on average diets from the major feed producers for salmon (Aas et al., 2022) and livestock (Animalia, 2023). Rest raw materials are calculated using conversion factors. Other inputs than feed and waste streams have not been quantified for this work. The systems are visualized using Sankey diagram in Python with the use of the plotly package (Plotly Graphing Libraries, n.d.).

Results & Discussion
In a world with increasingly higher demand of food and animal-based proteins, sustainable supply chains are important to reduce negative environmental, social, and economic impacts. It is important that new ingredients fulfil the animal’s nutritional requirement, is produced in a sustainable manner and that resources are used efficiently. Therefore, knowledge on the current feed system can help to identify where improvements can be done. Using MFA to quantify and visualize the feed system gives a great overview of the current resource utilization and efficiency. Our model also considers a protein and energy layer as well as the mass layer, giving an even more profound understanding of the system. This methodology is also useful to assess the suitability of new resources in terms of required amounts of mass, protein, and energy.

(Continued on next page)
The visualisations show both how much ingredients are imported, and the degree of resource utilization based on feed ingredients into the system, compared to the amount of the edible product as output of the system. However, our work is based on the national feed system, which means our findings is not valid for individual producers, but our results do give indications of the current resource use and efficiency in the Norwegian feed system. New ingredients will change both the mass of ingredients, and the feed system as whole. We also identify that the degree of utilization of rest raw materials have great impacts on the efficiency of the system.

Further work in the Susfeed project will analyse the resilience of new feed value chains and the environmental impact of novel feed ingredients using a life cycle assessment and the socio-economic impacts using input-output modelling.

START-UP AND PERFORMANCE TEST OF TWO NITRIFICATION BIOREACTORS IN A COMMERCIAL SMOLT RECIRCULATING AQUACULTURE FACILITY IN FINNMARK, NORWAY

S. M. Strauch*, Jacob Bregnballe, Raymond Sæther Limstrand, Mariel Ingelin Skogstad, Siri Tømmerås

AKV A group ASA
Plogfabrikkvegen 11
4353 Kleppe, Norway
E-mail: sstrauch@akvagroup.com

Aim
The performance and welfare of Atlantic salmon (Salmo salar) in land-based recirculating aquaculture systems (RAS) depends on a well matured microbiota of the nitrification biofilter (Dahle et al., 2023). To achieve cash flow in land-based operations as early as possible after start-up, the time needed for nitrification biofilter maturation should be short. The “Core-RAS” (AKV A group, Norway) includes the nitrification bioreactor(s) for ammonia removal by autotrophic microbial nitrification. While performance of mature biofilters and maturation of lab-scale nitrification bioreactors is well documented, data on the maturation of a juvenile filter of commercial scale is lacking. To assist project managers and RAS operators with these challenges, we tested a protocol that allows achieving complete nitrification within 6 weeks of biofilter maturation. We will share our recommendations to minimize maturation time.

Materials and Methods
The 2 RAS tested are identical and part of a smolt production facility in Finnmark, Norway. The removal of solids is achieved by 2 mechanical drum filters, the nitrification by a combination of 1 moving bed bioreactor (30 m³ bio-media × 800²/m³ ~25,000 m²), 6 fixed bed bioreactors (FBBR) (~16 m³ bio-media × 800²/m³ × 6 ~157,000 m²). Ozone is used to control turbidity and degassing of CO₂ is achieved in a degassing tank, located above the FBBR. The system is illustrated in Figure 1. To allow for inoculation of biofilters with high numbers of nitrifying microorganisms adapted to target salinity once commissioning was completed, 2 pre-cultivation systems were set-up. Each pre-cultivation system consisted of 1 Intermediate Bulk Containers (IBC), 1 submersible heater + regulator (500W, Aqua Medic), and 1 shared aeration system (Aqua Forte V60). To supply nutrients, a premix was added (adapted from Navada et al., 2020): to supply ammonia oxidizing bacteria (AOB) in with ammonia, ammonium chloride (40 g/IBC) was added initially. To kick start nitrite-oxidizing bacteria (NOB), sodium nitrite (30 g/IBC) was added initially. To provide for phosphate, trisodium phosphate (10 g/IBC) was added initially. To control pH (target 8.5), alkalinity was added in form of sodium bicarbonate (250 g/IBC). Salinity was set to 3 ppt using sodium chloride. To accelerate microbial growth, the water temperature was set to 27°C. To inoculate nitrifying microorganisms, organic substrate (100g/IBC) was added.

Maturation of the biofilters: the bio-media (PP, 800 m²/m³) were first soaked in water for 4 weeks and then introduced in the FBBRs. Both RASs where then filled with fresh water and saltwater was added to set salinity to 11ppt. Circulation over the biofilters was started using the main RAS-pumps. To feed AOB and NOB, ammonium chloride (14 kg/RAS) and sodium nitrite (10kg/RAS) were added to set levels of 5 mg/l NH₄⁺-N and 3 mg/l NO₂⁻-N. To supply phosphate, 5 kg Na₃PO₄ were added to set a ratio of 0.2 g P per g NH₄⁺-N. The operating temperature was set to 24°C. Per day, 50% (500L) of the starter cultivate from each IBC was added to each RAS into moving bed. The IBC was then refilled with water, ammonium chloride, sodium nitrite, trisodium phosphate and sodium bicarbonate to create conditions as during pre-cultivation. Levels of NH₄⁺-N, NO₂⁻-N, ortho-phosphate were measured daily using spectrophotometry (Hach Lange DR3900), and alkalinity using drop count test kits (Hach Lange dct). pH, temperature, salinity, and oxygen levels were measured daily (Hach Lange HQ2200).

Results
Pre-maturation in IBC: on day 1, NH₄⁺-N was set to 10 mg/l. On day 5, NH₄⁺-N levels were 0.1 mg/l in both tanks, and it was decided to reset NH₄⁺-N to 30mg/l daily. The daily removal rate averaged ~2 g/m²/d. Maturation of the biofilters: the removal of NH₄⁺-N was observed in RAS 1 on day 11 and in RAS 2 on day 16. Removal of NO₂⁻-N observed in RAS 1 on day 31 and in RAS 2 on day 37. Levels of NH₄⁺-N were reset to 3 mg/l daily. A nitrification rate of 0.09 g/m²/d was documented on day 42 (Figure 2).

(Continued on next page)
Discussion and Conclusions
This study demonstrates that the maturation protocol applied, allows to achieve full nitrification within 6 weeks. Levels of NH$_4^+$-N (Kolarevic et al., 2013) and NO$_2^-$-N (Gutiérrez et al., 2019) were well below the tolerance levels for Atlantic salmon, allowing for stocking of juveniles 6 weeks after starting the maturation of the biofilters. The results enable project managers and farm operators to integrate the maturation period within a clear timeframe of a project. Because adequate housing conditions for the fish are established within 6 weeks, fish welfare is accounted for prior to stocking. This sets the ground for better growth performance and fewer losses, so economic returns can be achieved earlier.

OVERVIEW: HOW CAN FISH RESEARCH BE IMPROVED ACCORDING TO THE 3R – GUIDELINES

B. Grunow¹*, S.M. Strauch²

¹Fish Growth Physiology, Research Institute for Farm Animal Biology (FBN), Dummerstorf, Germany
²AKVA Group ASA, Klepp stasjon, Norway*
E-Mail: grunow@fbn-dummerstorf.de

Introduction

The implementation of the 3R principle (Reduce, Refine and Replace of animal experiments) established by Russel and Burch, is of growing importance in fish research. Nevertheless, the number of experiments on fish has increased tremendously. In 2019, more than 2.5 million fish were used in experimental projects in the European Union and Norway of which 20% were zebrafish and 80% were „other fish species“ (Eur-Lex 2022). Overall, fish are the second most used animal group after mice (52.5%), accounting for 24.6% (2,559,532 animals). Within the “other fishes” group, animals were mainly used for the following categories: animal diseases and disorders (709,198 fish), preservation of the species (207,051 fish), protection of the natural environment in the interests of the health or welfare of human beings or animals (205,317 fish), regulatory use (102,802 fish), as well as 126,053 fish for animal welfare experiments (Eur-Lex 2022). Due to these numbers, efforts are present to reduce them and to achieve more animal welfare, especially in the aquaculture sector. For several years, researchers have therefore been developing alternative experimental methods, which were highlighted in the review article by Grunow et al. (2023).

Materials and methods

To illustrate the necessity of implementing the 3R concept in fish research, on the one hand, the statistics of the European Commission were evaluated to gain insight into the amount of animals, especially fish, used for research. On the other hand, we provide an overview of established alternative methods that have been published and are thus accessible to everyone, showing good solutions to promote fish welfare and implement the 3Rs concept in fish research (Grunow et al., 2023).

Results

In order to reduce the number of animals, several studies have proposed the use of DNA extracted from the mucus layers of the skin and mouth and from faeces, but also the use of eDNA (environmental DNA) from water. This method can be used not only for genetic analysis but also for determination of enzyme and hormone concentrations. This technique does not require direct in vivo intervention and is therefore more animal-friendly. The use of eDNA is also completely non-invasive and can even be used to analyse populations in larger waterbodies without the need to remove individual animals.

Under the aspect of „refinement“, the focus is on species-appropriate husbandry and the improvement of animal experiments. Thus, biotic and abiotic parameters must be determined in the keeping, breeding as well as rearing of fish, which combine the wellbeing of the animals with the best possible growth. An example of an abiotic parameter is the light regime, which must be used in a very species-specific manner. Furthermore, the fish species must also be considered when euthanizing them. Various studies show how different species respond to anaesthetics and the concentration used. In addition, the depth of anesthesia needs be studied so that the fish is not simply paralysed by the use of, for example, a muscle relaxant such as MS222 as an anaesthetic and end up fully conscious.

Another non-lethal method is gastric lavage, which can be performed for trophodynamic analyses instead of whole gastrointestinal preparations. This method has been used very successfully not only with large predatory fish, but also in very small fish species. In addition, there are now numerous computer vision techniques for image analysis that are freely available on the web and can be used, for example, to analyse swimming behaviour or size/growth, but also to identify species down to the individual (based on body pigmentation and other features (e.g., scars)) of a shoal. In many cases, this alternative method could eliminate the use of markers, especially since many studies show that the intervention can lead directly or indirectly to death or that it can result in behavioural changes in the animals.

(Continued on next page)
For the replacement of animal experiments, cell models are a good basis. Up to date, around 900 fish cell lines from 200 fish species are listed at the cellosaurus database (https://www.cellosaurus.org/). These cell lines are suitable for basic research, e.g. investigation of the effect on climate changes (temperature increase), but also for applied research. As an example for applied research, the successes in ecotoxicology can be mentioned, as since 2019 the fish cell line RTgill-W1 from rainbow trout can be used for ecotoxicological screening instead of in vivo tests - ISO standard 21115:2019. Also in fish virology, cell culture from fish are a very often-used model system.

Discussion

Progress toward implementation of 3R principles has been significant in recent decades. Research on alternative experimental models and methods continues to be developed and expanded so that even fewer experiments will need to be performed on fish in the future. It is hoped that by publicizing these numerous alternatives to in vivo studies, animal numbers will decrease in future.

EFFECTS OF NEONICOTINOID INSECTICIDE AND ITS ACTIVE SUBSTANCE ON ANTIOXIDANT BIOMARKERS OF EARLY LIFE STAGES OF GRASS CARP (Ctenopharyngodon idella)

A. Strouhová*, J. Velíšek, M. Šandová, A. Stará

University of South Bohemia in Ceske Budejovice
Faculty of Fisheries and Protection of Waters
South Bohemian Research Center of Aquaculture and Biodiversity of Hydrocenoses
Research Institute of Fish Culture and Hydrobiology
Laboratory of Aquatic Toxicology and Ichtyopathology
Zatísi 728/II, 389 25 Vodnany, Czech Republic.
Email: astrouhova@frov.jcu.cz

Introduction
Neonicotinoids are synthetically produced compounds, originated from nicotine, they have been launched on the market since 1990s. Neonicotinoids are highly effective against a wide range of pests. They accounted for nearly 23% of the global insecticide market in 2016 (Morrissey et al. 2015; Casida 2018; Klingelhöfer et al. 2022). Neonicotinoids are classified as systemic insecticides and neurotoxins acting on the central nervous system of organisms (Wang et al. 2018). They work in insects and mammals as nicotinic acetylcholine receptor (nAChRs) agonists, especially for the subtype α4β2 (Tomizawa and Casida 2005). Given the low toxicity of neonicotinoids to standard test species, they were not expected to significantly impact the aquatic ecosystem until later studies showed that this assumption was not correct (Morrissey et al., 2015; Sánchez-Bayo et al., 2016).

Flupyradifurone is the only representative of the new butenolide insecticide group. It received an EU authorisation in 2015 and has been classified by the Insecticide Resistance Action Committee (IRAC) as Group 4 - NACHR agonists. Group 4 includes nicotine, neonicotinoids and sulfoximines, in addition to butenolides. All the insecticides from this group principally share the same binding site on the nicotinic acetylcholine receptors (NACHRs) and therefore are considered to share the same mode of action. Sub-classification is based on structural differences of the insecticide molecules (IRAC, 2023). However, PAN Europe (2016) counters that, although the structure of flupyradifurone (and sulfoxaflor) is different, they are still neonicotinoid insecticides. For this reason, flupyradifurone should be treated accordingly by the regulator, considering its systemic and the harm it could cause to non-target organisms. Studies most often deal with the effect of flupyradifurone on bees, bumblebees, or other pollinators. Several studies also follow up on the effectiveness of flupyradifurone against pests. Only a few authors have so far researched the effect of flupyradifurone on non-target aquatic organisms. Most often, these are studies that compare the effects of pure flupyradifurone and other neonicotinoid substances.

Material and methods
The pure insecticide flupyradifurone (99 %) and the insecticide Sivanto Prime, which contains 17.1 % of the active ingredients flupyradifurone, were chosen to assess the effect of neonicotinoids on grass carp. Used concentrations of flupyradifurone were determined as 0.1; and 1 % of median lethal concentration (LC50) for grass carp larvae, stated by Zhong et al. (2021). Concentrations 0.21 and 2.1 mg.l-1 were used. Concentrations of Sivanto Prime used in trial were determined to match the flupyradifurone content of the product (17.1 %). Concentrations 1.23 and 12.3 mg.l-1 were used. Each concentration was performed in duplicate.

The Fish, Early-life Stage Toxicity Test on grass carp was performed according to OECD methodology no. 210 (OECD, 2013). The test started 6 hours after eggs fertilization (hpf) and lasted for 28 days. Mortality was monitored every 24 hours when the bath was changed. Larval growth and development were assessed every 7 days. At the end of the test, 6 fish were collected from each test group to assess the effect of the used substances on the oxidative stress and antioxidant biomarkers of the individuals. Biochemical analysis of proteins, lipid peroxidation (LPO), glutathione S-transferase (GST), reduced glutathione (GSH), catalase (CAT), superoxide dismutase (SOD) and acetylcholinesterase (AChE) was performed on the larvae samples.

Results
Flupyradifurone and also Sivanto Prime affect levels and concentrations of oxidative stress and antioxidant biomarkers. Significant changes (p<0.5) in grass carp larvae were observed in tested groups, especially in larvae exposed to Sivanto Prime.

(Continued on next page)
Conclusion
The toxicity of neonicotinoids varies for different species. The fact that standard test organisms are relatively resistant to their effects also contributed to their worldwide spread. Only a few studies have compared the effect of active ingredients in pesticide products and pesticide products themselves. However, pesticide formulations may have a very different effect than the active ingredient alone. Although the test substance may not have a direct effect on the mortality of the test organisms used, it may affect the development, growth or immunity of the organism.

3 Chinese Academy of Agricultural Sciences (CAAS), Beijing, China
4 Zhejiang Gongshang University (ZJSU), Hangzhou, China

This Sino-Norwegian collaborative project is at the forefront of scientific research in utilizing molecular, physiological and high advanced methodology to quantify the challenges with feed additives in combination with high fat diets (HFD). The overall objective of the Feed2Food project is to investigate the molecular mechanism behind the intestinal damage caused by a common anti-mold feed additive, sodium propionate (SP) under high fat diet conditions. We will also evaluate potential health issues associated with SP-induced translocation of intestinal microflora and microbial lipopolysaccharides (LPS) on fish and human consumers. Our previous study and the published scientific reports have showed that the widely used anti-mold feed additive SP induced intestinal injury in zebrafish under high fat diet conditions. This may impair intestinal barrier to an extent leading to microbial and lipopolysaccharide (LPS) translocation over the intestine. We therefore identified the molecular mechanisms behind the damaging effect. Our study then has focused on monitoring the possible secondary biological hazards that can pose a health challenge for both fish and the consumer. Results from the fish trials conducted in Norway and China with SP added to the feed as a novel ingredient are in progress and expected to be presented at this Aquaculture conference. The outcomes from this project will generate improved knowledge on the comparative effect and mechanisms of specific feed additive and lipid levels following HFD feeding, which is important for the information on potential health hazards to fish and consumers and development of future commercial aquaculture diets. We trust that this is the first of many investigations into possible damaging effects of novel feed stabilizers in the fast-growing aquaculture. This project can benefit all stakeholder groups and is essential for achieving a sustainable aquaculture. The Sino-Norwegian consortium consisting of Norway (NIBIO, NTNU) and China (CAAS, ZJSU), will work together and contribute to food safety through this Sino-Norwegian cooperation. This study is planned to be presented at this conference as an oral presentation.
EVALUATION OF BRAIN FUNCTION FOLLOWING DIFFERENT STUNNING METHODS IN NILE TILAPIA (*Oreochromis niloticus*)

Erika Sundell*, Per Hjelmstedt and Albin Gräns.

Department of Animal Environment and Health
Swedish University of Agricultural Sciences
Email: erika.sundell@slu.se

**Background**

Nile tilapia (*Oreochromis niloticus*) is an important aquaculture species and was the third most produced species globally in 2020 (FAO, 2022). The most common killing procedures for this species include asphyxiation, exsanguination through gill cutting or decapitation and/or direct evisceration (Lines and Spence, 2011; Robb and Kestin, 2002). To meet requirements of humane slaughter and provide strong animal protection, an efficient stunning prior to killing is crucial (WOAH, 2019). Yet all of the above-mentioned methods are merely killing procedures that do not include any form of stunning and therefore will compromise the welfare of the fish (Robb and Kestin, 2002). For a stunning method to be efficient, it should induce immediate loss of consciousness and the unconscious state should be irreversible, or at least persist long enough for death to ensue before consciousness is regained (WOAH, 2019; EFSA, 2004). Efficiency of stunning methods for Nile tilapia is largely unknown and there is an urgent need for validation and/or development of humane slaughter methods for this important aquaculture species.

**Material and methods**

Unconsciousness was determined by absence of visually evoked responses (VERs) in the electroencephalogram (EEG) of the Nile tilapia (Figure 1). EEG was obtained by inserting two 21G needles, soldered to 1.5 mm shielded wire electrodes acting as positive and negative electrodes, approximately 1 cm posterior to the eyes and 0.5 cm lateral to each side of the sagittal suture. A 29G needle electrode that served as the ground was placed subcutaneously at the tail. To study VERs, or lack thereof, EEG was measured in a dark room where a strobe light delivered repeated 20:480 ms light:dark episodes. The EEG signal was analyzed using the 13-32 Hz frequency range (Figure 1) as this is associated to conscious, waking states in many animals including fish (Bowman et al., 2019; Verhoeven et al., 2015). The different stunning methods assessed were i) percussive stunning, ii) live chilling, iii) electrical stunning and iv) a combination of electrical stunning followed by throat cut and placement in ice slurry. EEG was recorded before, during (when applicable) and after the stunning procedure. Percussive stunning was achieved using a handheld pneumatic bolt gun and live chilling was carried out by replacing the warm water with ice slurry. For electrical stunning, 1 second stun durations was initially performed to verify that the electrical exposure managed to induce an immediate loss of consciousness (Cook et al. 1995). When this was verified, 30 second stun durations using similar settings were applied to evaluate if the unconscious state could be prolonged by prolonging the stun duration. For the combinational procedure (i.e., combining electrical stunning with throat cutting and placement in ice slurry), a 30 s electrical stun duration was applied before the fish was throat cut and placed in ice slurry.

![Figure 1. The beta wave frequency of the electroencephalogram (EEG) in a representative fish prior to and post percussive stunning. A) show the EEG before- and B) show the EEG immediately after stunning. The hatched orange line represent the light flash as registered by a custom made solar panel (the y axis is not in scale) and the pink solid line represent the average beta wave frequency of the EEG during one minute. Clear VERs are present prior to stunning whereas no distinguishable pattern in the EEG can be seen after stunning (i.e., the fish is deemed to be unconscious).](image-url)

(Continued on next page)
Results
Percussive stunning rendered all fish immediately and irreversibly unconscious. However, this required handling, air exposure and restraining the fish, which, each on its own is stressful. Also live chilling rendered all fish unconscious but had a long induction time (4.92±2.26 min). Electrical stunning for 1 s managed to induce immediate loss of consciousness when an electric field strength of 8.2 V_{RMS} cm^{-1}, a current density of 0.68 A_{RMS} dm^{-2}, a frequency of 50 Hz sinusoidal alternating current (AC) and a water conductivity of 753 µS cm^{-1} was used. When prolonging the stun duration to 30 s using similar electrical parameters (i.e., 8.2 V_{RMS} cm^{-1}, 0.68 A_{RMS} dm^{-2}, 50 Hz sinusoidal AC and 753 µS cm^{-1}), fish lost VERs for at least 30 s. When electrical stunning using similar settings (i.e., for 30 s using 8.2 V_{RMS} cm^{-1}, 0.62 A_{RMS} dm^{-2}, 50 Hz sinusoidal AC and 753 µS cm^{-1}) was followed by throat cutting and ice slurry immersion in two fish, VERs came back after 80 and 96 seconds, respectively. However, when the strength of the exposure was increased (electric field strength and current density of 14.2 V_{RMS} cm^{-1} and 1.07 A_{RMS} dm^{-2}, respectively), VERs did not come back within 30 minutes after the electrical exposure when it was followed by throat cutting and ice slurry immersion.

Conclusion
Here, we show that when combining electrical stunning with throat cutting and ice slurry immersion, an immediate and irreversible loss of VERs can be accomplished. Also percussive stunning using a handheld bolt gun is efficient in rendering the fish immediately and irreversibly unconscious. However, the latter method require handling and could benefit from a pre-stunning procedure, such as electrical stunning. These results show that electrical stunning followed by both percussive stunning or throat cut and immersion in ice slurry have the potential to ensure humane slaughter of Nile tilapia. However, the electrical exposures needed to guarantee that the effect persists long enough for death to ensue is largely depending on the stun-to-kill time of the selected killing procedure. Collectively, our results shows that humane slaughter of Nile tilapia is possible. If the outcome of our study is implemented this may aid in safeguarding the welfare of billions of tilapia at time of slaughter.

Introduction
Denitrification is a biofiltration process which is commonly applied in RAS to control nitrate concentrations by converting nitrate-nitrogen (NO$_3$-N) to nitrogen gas. This process requires high amounts of organic carbon, which is commonly supplied by external carbon sources that increase farm operational costs. Faecal waste can be used alternatively as an internal carbon source for denitrification but its insufficient carbon bioavailability often limits NO$_3$-N removal. The quantity of bioavailable faecal carbon depends on diet digestibility and the respective faecal composition. Lately numerous alternative ingredients have been used in aquafeeds, frequently resulting in increased indigestible carbohydrate fractions. As such, faeces capacity to act as an internal carbon source for denitrification may vary with diet composition (Meriac et al., 2014). In this respect, the present study aimed to explore the effect of dietary carbohydrate on the denitrification potential of a marine RAS using internal faecal carbon sources.

Materials and methods

In vitro trial: Settleable feaces originating from a preceding feeding trial (Syropoulou et al., 2022) testing six dietary ingredients (shrimp shell meal; SSM, feather meal, insect meal; IM, seaweed, single-cell meal, dried distillers grain with solubles; DDGS) on European seabass were collected. Faecal material was incubated in anoxic batch reactors under isocarboxic conditions for a 14-day period. Abiotic parameters including NO$_3$-N were monitored daily and faecal samples were obtained every 24 h for the first three days (Day1, 2, 3) and every alternate day onwards. Samples were immediately analyzed for volatile fatty acids (VFAs) to determine the degree of fermentation (Letelier-Gordo et al., 2017). Data was normalized to the Day0 values and was expressed per unit of organic matter (OM) faeces and per unit of feed, respectively.

In vivo trial: Four identical RAS equipped with an up-flow sludge blanket denitrification reactor (DR), were stocked with juvenile European seabass (1.78 ± 0.02 kg/RAS). Fish were fed over a six-week period with two of the aforementioned six diets (IM, DDGS) in duplicate. Feeding level was gradually increased until Week2, when a fixed amount of 50 g feed/RAS/day was established. During the trial, presetttled faecal waste produced per system was constantly fed to the respective DR. NO$_3$-N levels in the outlet of the fish tanks were analyzed weekly, whereas in the inlet and outlet of the DR at the end of the trial over a 24-h scheme. Finally, after the completion of the experiment, both faeces and DR sludge were analyzed for their nutrient composition in order to create nutrient balances on a DR level.

Figure. A) Volatile fatty acid (VFA) production (mean ± SD, n =2) in faecal samples fermented in the in vitro trial, with lowercase letters indicating for significant differences (p<0.05) as obtained by multiple comparisons (time × diet) over the whole timespan of the experiment. B) Nitrate-nitrogen (NO$_3$-N) removal (mean ± SD, n =2) for the two diets tested in the in vivo trial.

(Continued on next page)
Results & Discussion
Degree of fermentation, expressed as VFA production per kg OM feed, was influenced by OM digestibility, faecal removal efficiency via settling and carbon bioavailability of faeces. Even though, fish fed with SSM excreted a low amount of faeces, faecal quality improved faecal removal efficiency and thus more material was available to be fermented per kg OM feed. Additionally, faecal carbon bioavailability was highest for this diet which explains the highest VFA production not only per kg OM feed (Figure A) but also per kg OM faeces. Among the tested diets, IM produced the second highest amount of VFAs whilst DDGS the second lowest. Additionally, the two diets yielded a highly different VFA profile, with propionate being produced only from IM faeces and lactate only from DDGS faeces. Due to the higher amount of VFAs produced in the *in vitro* trial along with the more favorable VFA profile, we hypothesized that IM would act as a more efficient internal carbon source for denitrification in RAS between the two. However, when denitrification efficiency was studied in the *in vivo* trial, no significant differences were found for NO$_3$-N removal between the two dietary treatment groups (p>0.05; Figure B). This discrepancy between trials might be attributed to their different experimental duration, indicating that possibly long-term anaerobic digestion of faecal material may allow for better utilization of faecal carbon. Moreover, nutrient conditions differed upon case, since NO$_3$-N was soon depleted in the *in vitro* trial, whereas NO$_3$-N was constantly supplied to the DRs in the RAS setup. This likely resulted in the development of different microbial communities with different capacities to utilize faecal carbon. Additional microbial data will help identify the reason of this inconsistency. In conclusion, the present study showed that batch fermentation of faecal material is not a good indicator for the potential of faeces to act as an internal carbon source for denitrification.

Introduction

In common carp (*Cyprinus carpio*) farming, the use of complete feeds is expected to increase in the future. An important component of fish feed is fish meal, which is made from small, less valuable marine fish. As a result of overfishing, the stock size of marine fish is drastically reduced, so the price of fishmeal as well as of artificial fish feed is constantly rising. Partial substitution of fishmeal can be solved by mixing microalgae into the food, which contain the nutrients necessary for fish in the right quantity and quality. In our experiments, common carp fry of different age-classes was reared in ponds. During rearing, we examined and evaluated the effects of feeding cereals, traditional artificial feed and algae-enriched feed on growth of common carp fry and fingerling.

Materials and methods

Experiments were carried out in fry, fingerling and on-growing ponds of Szegedfish Ltd. during the breeding seasons of 2021 and 2022. During samplings, we collected data on body length and weight of the fish.

Conditions for the experiments related to advanced fry rearing

The experiment took place in June 2022. Carp fry were reared in six ponds, the size of which was one hectare each. In two ponds, fish received traditional fry feed, and in four ponds, we fed the fish with algae-enriched fry feed. The algae concentrations in the feeds were 1.0% and 3.0%, respectively. At the end of the fry rearing period, the body length and body weight of 30 fish from each pond were measured.

Conditions for the experiments related to fingerling rearing

Experiments were carried out in two 10-hectare rearing ponds in the 2021 breeding season. We stocked 300,000 advanced fry into both ponds in the first week of July. In the control pond, we fed the fish with traditional rearing food, and in the “algae” pond, we fed the fish with algae-enriched food. The concentration of algae in the food was 3.0%. During rearing, we measured the body length and weight of 50 individuals on two occasions (July 27 and September 8). The data for the control and the “algae” pond were compared with a two-sample t-test (P < 0.05).

Conditions for the experiments related to rearing of two-summer old common carp

The experiments were carried out in three 40-hectare ponds in 2022. We stocked 150,000 one-year-old fry in all three ponds, the average weight of which was 65 grams. The fry were fed in the three ponds with cereal feed, traditional formulated feed, and formulated feed enriched with algae (1%), respectively. We only fed formulated feed or algae-enriched feed during the last four weeks of the rearing season. At the beginning and middle of the breeding season, these fish were also fed with cereal grains. During rearing, we measured the body length and weight of 30 individuals on one occasion. The data were compared using one-way analysis of variance (F-test) (P < 0.05).

Results and conclusion

Figures 1–4 summarize the results of the evaluation of data recorded during the rearing of different age-groups of common carp in earthen ponds.

(Continued on next page)
Based on our experiments, it can be concluded that feeding algae-enriched feed had positive effects on the growth of all three investigated age groups. At the same time, it should be noted that the tests were carried out in relatively large rearing ponds, which greatly limited the number of replicates that could be used. The results come from single sampling times, so it cannot be ruled out that the measured differences balance out in the later stages of the rearing season. In any case, supplementing fish feed with algae does not have any negative consequences, so it can be a good alternative to replacing fishmeal in the future.

Introduction
Aquaculture is currently the most rapidly growing sector of animal production and until now, fishmeal has been the main source of protein used in compound feeds. Unfortunately, the high demand for fishmeal has pushed up its price and overfished the natural fish stock. For this reason, alternative sources of protein that can be used in compound feeds are being sought. One such alternative are plants of the genus *Lupinus*, characterised by high environmental tolerance and a favourable amino acid profile (Abraham et al., 2019). Many studies have been carried out to assess the possibility of using lupins in aquatic nutrition with promising results (Szczepański et al., 2022). However, there is currently no literature data on the use of lupins in the feeding of sturgeons. Thus, the aim of this study was to assess the feasibility of using innovative feeds, composed on the basis of lupin meal, in Siberian sturgeon (*Acipenser baerii*) nutrition, while taking into account both the economic and animal welfare aspects of sustainable aquaculture.

Materials and methods
The study was carried out as part of the project no. 0001–6521.1-OR0700001/17/20 founded by Operational Program ‘Fisheries and Sea’ (2014–2020) financed by the European Maritime and Fisheries Fund.

The feeding experiment lasted 125 days. The fish were divided into four groups. In the reference group (R), the sturgeons were fed with a commercial feed dedicated to the breeding of sturgeon fish, while in the control group (0L), a composed feed with the addition of fish meal as the main protein source. Groups 5L and 10L were experimental groups using composed feeds with inclusion of white lupin meal at levels of 5 and 10%, respectively. After 125 days, the fish were killed, weighed, total length and standard length measured. Samples from liver, anterior and spiral intestine from twelve individuals from each group were collected (n=48) for histological (HE staining) and biochemical analysis. In livers, the activities of alkaline phosphatase (ALP), acid phosphatase (ACP), superoxide dismutase (SOD) and glutathione peroxidase were examined. In anterior and spiral intestine, the activities of ALP, ACP, amylase, trypsin and lipase were evaluated. The obtained results were statistically analysed.

Results
At the end of the experiment, distinct differences in the mean body weights (BWf) of the fish were observed, with the largest differences (P < 0.05) noted in R group compared to 5L and 10L groups (Table 1). Sturgeons in R group had the highest average total length compared (TL) to the other groups (P < 0.05) (Table 1). The gastrointestinal tract sections showed no significant histopathological changes. The longest intestinal folds (IF) with the proportionally largest absorptive area were found in the 10L group. The livers of all fish were characterized by severe steatosis, with the largest hepatocytes (HA) observed in the 0L group. In anterior intestine, a significant decrease in lipase activity (U/mg) was observed in 10L group compared to other groups. In the liver, significant decreases in alkaline phosphatase (ALP), acid phosphatase (ACP), superoxide dismutase (SOD) and glutathione peroxidase were examined. In anterior and spiral intestine, the activities of ALP, ACP, amylase, trypsin and lipase were evaluated. The obtained results were statistically analysed.

Conclusion
Based on the performed analyses, it can be concluded that feeds with lupin meal inclusion are less suitable for feeding young Siberian sturgeon compared to commercial feeds and generally those with fish meal as the main source of protein. However, the lack of histopathological changes and the absence of enzymatic disturbances may suggest the need for further studies using older fish.

Introduction
Aquaculture sector is thriving as a response to the rapidly increased demand for seafood products. The sector is using, 18 million tons of wild fish that are targeted for fishmeals and fish oils in aquafeeds (FAO 2020), thus affecting the sustainability of marine ecosystem. This has led the research to focus on environmentally sustainable sources of proteins and lipids as replacements of fishmeal and fish oil. Microalgae biomasses seem to be potential feed ingredients containing sustainable amounts of essential amino acids, essential fatty acids, vitamins, and pigments, that could be produced with a low environmental footprint (Nagappan et al. 2021). This study aims to investigate the effect of dietary inclusion of algae meal on the growth performance, amino acid composition and fatty acid composition of the white muscle of gilthead sea bream (Sparus aurata).

Material and methods
The experimental trial was conducted at the Department of Ichthyology and Aquatic Environment, University of Thessaly, in Volos, Greece. Briefly, 360 individuals S. aurata (initial mean weight 6.43±0.04g) were distributed randomly to six 250l tanks. Two experimental diets were formulated to be isonitrogenous, isolipidic, and isoenergetic with diet 1 (PA) consisted of 8% Phaeodactylum tricornutum, and diet 2 (HA) consisted of 8.23% Schizochytrium limacinum. Each diet was assigned to triplicate groups of 60 fish per group. The trial lasted 45 days, after 15 days of acclimatization. The fish were fed three times per day ad libidum. Fish were weighted individually at the beginning and end of the experimental trial under anaesthesia. Feed consumption was recorded daily in order to evaluate accurately values for feed utilization.

Results
The results showed that weight gain, feed consumption, specific growth rate and survival did not have statistically significant differences (p>0.05) between fish fed the diet consisted of Phaeodactylum tricornutum (PA) and the diet of Schizochytrium limacinum (HA). Fish fed with PA had statistically significant (p<0.05) lower feed conversion ratio and higher protein efficiency ratio (Table 1).

Amino acid composition revealed a strong positive correlation, highly significant (p<0.05) between diets and the white muscle of fish in each treatment. Moreover, fatty acids analysis showed a significant decrease (p<0.05) of eicosapentaenoic acid (EPA) and an increase (p<0.05) of docosahexaenoic acid (DHA) in white muscle of seabream fed the HA diet, compared to the PA treatment. Arachidonic acid (ARA) of white muscle was unaffected (p>0.05) between the dietary treatments.

(Continued on next page)
Discussion

The results of this study showed that the inclusion of algae meal in *S. aurata* diets did not affect growth performance and amino acid deposition. The lower FCR and higher PER exhibited in fish fed the PA diet denotes a better protein utilization of *P. tricornutum* diet than *S. limacinum* by *S. aurata*. In terms of aquaculture sustainability, the substitution of fish oil with heterotrophically produced microalgae in salmon feeds proved the nutritional feasibility of low trophic level organisms such as algae in aquaculture fish feed (Kousoulaki et al., 2017). In accordance with the results of this work, fishmeal replacement with the microalgae *P. tricornutum* in started diets of *S. aurata* showed that SGR was not affected (p>0.05) and there was an increase of saturated fatty acids in fish (Atalah et al. 2007). Moreover, the inclusion of 2.5% *P. tricornutum* in finishing diets of giltfileb sea bream did not significantly change growth, feed utilization parameters and muscle fatty acid profile (p>0.05) (Ribeiro et al. 2017). Furthermore, the 2.5% inclusion of *Schizochytrium* sp. as lipid source and especially DHA source in microdiets of *S. aurata* had no negative effect on larvae (Ganuza et al. 2008). In contrast to the aforementioned authors, Eryalçin & Yildiz (2015) reported that the replacement of fishoil with dried *Schizochytrium* sp. meal had a negative effect on growth of seabream although the DHA was increased.

The differences found in the fatty acid profiles on the muscle tissue of fish are characteristic to the fatty acid’s profiles of each algae species as *S. limacinum* is known for being richer in DHA and poorer in EPA compared to the *P. tricornutum* and *S. aurata* has been used successfully in the diets of seabream and other species, mainly for fishoil replacement. According to Santigosa et al. (2021), the growth performance of seabream fed 3.5% *Schizochytrium* sp. oil as replacement of fishoil was unaffected and fillet fatty acid composition was in accordance with the diet fatty acid composition, suggesting that dietary microalgae could lead to an environmentally friendly final product rich in n-3, n-6 fatty acids. The dietary inclusion of algae meal (*Phaeodactylum tricornutum* and *Schizochytrium limacinum*) does not influence growth performance but there is an effect on FCR, PER, amino acid deposition and fatty acid composition of the white muscle of seabream (*Sparus aurata*) follows the fatty acid and amino acid composition of the two algae suggesting they can be used and produce a final product rich in n-3 and n-6 fatty acids. Algae meal biomass is promising ingredient to move the formulation of sea bream feed to a more sustainable future.

Introduction

As the aquaculture industry continues its decade-long growth, ensuring the supply of sustainable alternative feed ingredients is an urgent need. A promising new protein source is dried cells harvested from cultures of monocellular microorganisms, notably yeast. Yeast production has the advantage of being highly sustainable, requiring little space or resources, and enable valorising agro-industrial side-streams (Sharif et al., 2021). Yeast contains a high protein content, and the amino-acid composition is generally well-adapted to satisfy most nutritional requirements of fish (Agboola et al., 2021). Moreover, yeasts are a good source of prebiotic compounds with benefits for health, digestive function, and general performance (Petit et al., 2019). Therefore, this study aimed to assess the effect of dietary replacement of plant-based ingredients with yeast (\textit{Candida utilis}) on stress response and plasma metabolite profile of hybrid African catfish to evaluate impacts on farming performance, health, and welfare.

Materials and methods:

Fish (initial body weight 77.7±0.25 g) were allocated between 3 isoenergetic and isonitrogenous diet treatments (in triplicate tanks) in freshwater RAS. All diets contained 5\% of fishmeal alongside plant-based ingredients (PBI) [soymeal, wheat gluten, and soybean protein concentrate] which were partially substituted with yeast in the other diets: Diet 1 (control, 0\% yeast); Diet 2 (10\% of yeast corresponding to 12\% of PBI replacement); Diet 3 (20\% of yeast, 25\% PBI replacement). During the feeding trial (10 weeks), feed was delivered to satiety. Water temperature, stocking density, and photoperiod were 27.3°C, 17 kg.m⁻³, and 12:12 L/D. At the end of the trial, 18 fish from each group (N=6 per tank) were sampled, from which 9 were euthanatized (pre-stress) while the other 9 were subjected to acute stress challenge (ACT, 15 min of crowding (800 kg.m⁻³), followed by 45 min of recovery before euthanasia. Plasma cortisol was measured using ELISA, and ions (chloride, potassium, and magnesium) and metabolites related to energy and lipid metabolisms (creatinine enzyme, triglycerides, LDL and HDL) were quantified using Pentra 400. Data were subjected to One-way ANOVA followed by Tukey to compare diets, and to Student’s t-test to compare between the two stress states (p< 0.05).

Results

Growth performance (final body weight approx. 421 g) showed minor impacts of the various diets, with a slight but not significant increase correlating with increased yeast inclusion levels. Similarly, the ACT only appeared to have very limited effect on the catfish, as shown on the cortisol levels only showing significant increase in Diet 1 and with non-significant reduction of chloride and potassium levels after ACT (except for Diet1). Magnesium showed a large variance in Diets 1 and 2 following the ACT (Fig. 1). On the other hand, metabolites related to lipid metabolism showed significant changes among diets. Triglycerides were significantly higher in Diet 1, both before and after the ACT. Although plasma cholesterol was unaltered (data not shown), the TAG and LDL plasma concentrations significantly decreased while HDL increased with higher inclusion rates of yeast in the diet (Fig. 2).

Discussion and conclusion

Substitution of PBI with yeast did not hinder growth performance. This is encouraging considering that yeast production is more sustainable compared to SM. Catfish is also a prime candidate for alternative protein sources considering their omnivorous diets and efficient abilities to digest a wide range of ingredients. Further, creatinine was found at a lower level in the fish receiving the yeast diets. Elevated plasma creatinine levels are noted to being associated with kidney damage or impaired functions, and these results could point to anti-nutritional factors found in soy ingredients.

(Continued on next page)
Triglyceride were higher in the fish fed the Diet 1. This may be because triglycerides are commonly associated with diets high in grain and cereals. Increased dietary yeast elevated plasma HDL while reducing LDL, suggesting that dietary substitution with yeast impacted lipid metabolism and transport mechanisms. Elevation in HDL, a major lipoprotein in fish, could signal improved cardiovascular performance compared to the control diets. Alternatively, shifts in HDL/LDL proportions have also been linked to oxidative stress, various metabolic disorders, dietary fat levels, or changes in food acquisition (e.g., fasting) (Long et al., 2021; Kjær et al., 2009) and a more targeted approach is needed to elucidate the impacts of yeast substitution in catfish diets and their implication for lipid metabolism.

Cortisol and ion levels showed limited increase after ACT. Since catfish are notoriously rustic, tolerating poor water conditions, it is likely that the stressor type, duration, or intensity may have been insufficient to trigger a marked stress response. Conversely, plasma magnesium levels, a known stress-marker, showed a reduced response to the ACTs with increasing dietary yeast inclusion. However, the results showed strong individual variations (Fig. 1) and it is possible that while most fish were able to handle the ACT with little difficulty, a few were more affected.

The present study not only showed no negative effect of replacing PBI with yeast but was associated with some improved parameters (creatinine enzyme, LDL/HDL ratio), confirming the suitability of this protein source as a feed ingredient in catfish diet. However, changes in lipid metabolism highlights the need of further studies targeting the liver lipid content and profile and molecular mechanisms underlying these changes.

DEVELOPMENT OF EPIDEMIOLOGICAL MODEL FOR PREDICTING CAGE-LEVEL SALMON LICE (*Lepeophtheirus salmonis*) ABUNDANCE

Leif Christian Stige¹, Lars Qviller¹ Saraya Tavornpanich¹,∗

¹ Norwegian Veterinary Institute
Email: saraya.tavornpanich@vetinst.no

Introductions
Salmon lice (*Lepeophtheirus salmonis*) are parasites on salmonid fish and a density-dependent constraint to the sustainable farming of salmonids in open net pens. To control the parasites, fish farmers in Norway are required to count the number of salmon lice in different developmental stages on a subset of the fish each week. Furthermore, they must ensure that the number of adult female lice per fish does not increase beyond a specified threshold level. In this project, we have developed a statistical model with the goal of determining the optimal way to utilize fish farm monitoring data from the AquaCloud system. AquaCloud data platform is a system that has been automatically aggregating data from Norwegian fish farmers since its establishment in 2017 (https://aquacloud.ai). We have focussed on predicting the lice development one week ahead in the absence of any lice treatment. We included data for weeks without treatments and with observations of lice as well as environmental variables (temperature, salinity, oxygen saturation level) in the two weeks preceding the week to be predicted. This initial dataset included 190,528 observations from 242 farms spanning the years 2017 to 2022. These records represented salmonid farming across most regions of Norway, spanning latitudes from 59 to 71°N (Figure 1).

We used data from a random selection of 80% of the farms to train and fit the model (Training data), and then data from the remaining 20% of the farms (Test data) to see how well the model could predict. Initially, we considered various model formulations, to assess possible nonlinearity in associations and using posterior predictive checks to find an appropriate error structure. These analyses suggest that the following nonlinear random-effects model formulation with a negative binomial error structure fits the data well:

Count data for all three stage groups (A, adult females; O, other motiles; S, sessile) were analysed jointly in one statistical model. The total numbers of lice of each stage on the counted fish in a given cage (subscript C) and week (subscript T) were considered to follow negative binomial distributions (equations 1–3):

(Continued on next page)
Predictions of lice abundance in test data set are shown in Figure 2. Black lines show the 1:1 lines where the observed lice per fish equal the predicted. Blue lines show 90% prediction intervals for the true lice levels. Grey lines show 90% prediction intervals for lice counts, also taking into account the counting variability and the uncertainty in the parameter estimates. The widths of the latter intervals are influenced by variation in the number of fish on which lice were counted for each observation event. The model predicted a considerable part of the variation in lice numbers in the test data set, not used in the model selection or model fitting. Specifically, for these “new” data cases, the model predicted 51% of the cage-level variance and 60% of the farm-level variance in adult female lice abundance. Corresponding numbers for other motile lice were 60% and 65%, and for sessile lice 39% and 47%. Prediction intervals were wider for sessile lice than for the other stages (Figure 2).

In conclusion, by using state-of-the-art statistical modelling, the salmon lice prediction model integrates detailed and high-resolution information from a large number of fish farms from large parts of the Norwegian coast. This information enables the development of generic “rules” for how a fish farmer may best use the monitoring data at hand to predict next week’s salmon lice abundance. The insights from this model will be integrated to enhance the existing “lice calculator” web application (http://apps.vetinst.no/lusekalkulator/). This app is designed to be user-friendly for the general public and will assist farmers in automatically predicting the expected number of lice for the upcoming week. Hence, fish farmers may move from the subjective experience-based assessment used today to more precisely predicting lice development. Precise predictions in turn enable timely use of lice treatments, avoiding unnecessary treatments at low lice levels but treating outbreaks before they become too severe.

This research was undertaken under the NewTechAqua (New technologies Tools and Strategies for a Sustainable, Resilient and Innovative European Aquaculture) project, which has received funding from the European Union’s Horizon 2020 Programme under grant agreement No 862658 (https://www.newtechqua.eu/).
NANOPLASTICS ARE BIOACCUMULATED IN FISH LIVER AND MUSCLE AND CAUSE DNA DAMAGE AFTER A CHRONIC EXPOSURE

Introduction
Nanoplastics (NPs), the particle size-fraction under 1000 nm, are potentially one of the most hazardous marine litter, as their physicochemical nanoscale properties allow them to cross biological barriers, including the intestinal wall and the mammalian placental barrier. The detection and quantification of the environmental plastic nanofraction is an ongoing challenge, as the current analytical techniques to detect NPs in complex biological matrices are not fully mature. Nevertheless, the presence of NPs in marine waters has already been confirmed, both in oceanic (Ter Halle et al., 2017) even if its impact is not fully understood. The presence of small plastic particles at the micro- and nanoscales is of growing concern, but nanoplastic has not yet been observed in natural samples. In this study, we examined four size fractions (meso-, large micro-, small micro-, and nanoplastics and in Mediterranean waters (Llorca et al., 2021) including the monomers characterisation by the Kendrick Mass Defect and confirmation and quantification when standards were available. In parallel, the identification of main additives in NPL/MPLs composition, as well organic contaminants adsorbed onto the plastic particles were carried out by analysis of the extracts by LC(C18. Accurately measuring the concentration of NPs is a major challenge, as precise analytical methods are required, accounting for various types of NPs polymers, as well as for a diverse set of complex matrices (soil, sediments, turbid waters and tissues. In the present study, the model fish Carassius auratus (goldfish) was exposed for 30 days to polystyrene (PS)-NPs, attempting to mimic an environmentally realistic scenario. The main hypothesis of this study was that fish can take up PS-NPs from the water after a chronic exposure and accumulate them in internal organs, causing alterations in fish health.

Material and methods
Adult fish (11.16 ± 3.23 cm length and 7.07 ± 0.64 g weight) were randomly distributed in the experimental aquariums, and two experimental conditions were considered: 1) Control group (0 µg/L PS-NPs) and 2) the group exposed to PS-NPs (100 µg/L PS-NPs). Fish were exposed to PS-NPs for 30 days, and sampled after that period of time. Erythrocytic nuclear abnormalities (ENAs) were classified into four categories according to Pacheco and Santos (1996).

Figure 1. Nanoplastics concentrations in fish liver and muscle.

(Continued on next page)
**Results**

PS-NPs were not detected in the gastrointestinal tract of exposed fish. In contrast, PS-NPs were detected in all liver and muscle samples of the exposed fish (Figure 1). In liver, 7 out of 9 samples had concentrations levels ranging from 2.23 to 265.89 ng/g liver wet weight; in the other two liver samples PS-NPs were below the limit of detection. In 6 out of 9 muscle samples, PS-NPs were detected at concentrations ranging from 9.58 to 18.64 ng/g of muscle wet weight. The concentrations of PS-NPs were significantly higher in the liver and muscle of fish exposed to PS-NPs for 30 days when compared to the control group. A significant increase in the total number of ENAs, a genotoxicity indicator, was found in the group of fish exposed to PS-NPs, when compared to control. The number of erythrocytes presenting reniform nuclei and micronuclei was significantly higher in fish exposed to PS-NPs than in control fish. However, lobed, and segmented nuclei values were similar in both groups of fish.

**Conclusions**

The data from this study suggest for the first time that: 1) fish chronically exposed to 44 nm PS-NPs internalize these emergent contaminants from the water. PS-NPs are then distributed in the organism, potentially through blood, and bioaccumulate in internal organs, such as the liver and the muscle. 2) Higher levels of PS-NPs were found in the liver when compared to the muscle. No bioaccumulation was found in the gastrointestinal tract which agrees with the main function of this organ, i.e., absorption. Considering that fish consumption is increasing steadily worldwide, the fact that PS-NPs are bioaccumulated in fish muscle, the edible part of the animal, means that these contaminants may be ingested by humans, presenting a potential threat to human health. 3) PS-NPs induced genotoxicity in fish blood cells, which can escalate to mutagenicity and is related to more serious conditions such as cancer or degenerative conditions.

Introduction
Deficiencies of plant nutrients in aquaponics are usually thought to be caused by nutritional imbalances of aquafeeds, being the main nutrient input into the system, even though studies aiming at optimising feed formulation had only limited success (Seawright et al., 1998). Meanwhile, chemical boundaries that limit the solubility of nutrients in water have not been closer investigated until today, even though known to be essential and assessed a long time ago for nutrient management in hydroponics (Sambo et al., 2019). This leaves aquaponics practitioners with hands tied as it remains unclear whether optimised feed formulation can actually contribute to an efficient management of plant nutrients in aquaponic systems.

The aim of this study was to test the hypothesis whether chemical boundaries determine nutrient concentrations in aquaponics and if results obtained in an aquaponic system are comparable with chemical equilibrium models.

Material and Methods
Three independent RAS ($V_{total} = 4500L$) were stocked with juvenile Nile tilapia (IBW = 140.7 g±32.0 g) at a stocking density of 15.4 kg m$^{-3}$. Fish were divided to three tanks per RAS ($V_{tank} = 650 L$). Isonitrogenous and isocalorific experimental diets containing graded levels of potassium (K) and phosphorus (P) (see table 1) were administered to the fish stock at an average feeding rate of ≈ 2.5% d$^{-1}$ kg$^{-1}$. Water exchange took place at 5% d$^{-1}$. Quantities of all inputs (feed, water, chemicals) and outputs (water, solids) were recorded. Water and solid samples for element analysis by ICP-OES were taken bi-weekly. The trial lasted for 84 d.

Chemical equilibrium modelling was done using Visual MINTEQ v3.1. In brief, water analysis data, including pH, temperature and obtained element concentrations, were examined for reaching solubility threshold concentrations of amorphous solids.

Results and Discussion
The evaluation of the results is not yet finished as not all sample analysis results were provided by collaborating laboratories until now. Final analysis of all relevant samples is expected to be finished by end of May.

Introduction
The exploitation of aquatic, living resources, in particular mussels, provides work and income to mussel fishermen and farmers, societal cohesion in fishery-sector dependent communities and low cost, valuable protein-rich intake to consumers. Provided that mussel fishery and aquaculture are sustainably practiced, production, financial and ecosystem services are fully met.

Within the context of the EU and Greece co-funded research project (MIS 5052394) PinnaSOS (www.PinnaSOS.upatras.gr) about enhancement of natural recruitment of fan mussel (Pinna nobilis), certain preliminary actions took place. Namely, experimental transplantation, extensive sampling, monitoring of any living specimens and artificial breeding of the critically endangered, according to IUCN, bivalve species were conducted by a conventionally staffed research team along with a vastly experienced group of mollusk fishermen and farmers.

This study shows that the “participatory” approach used in PinnaSOS, presents a way forward to involve and mobilize local stakeholders, increases the sampling efficiency while in parallel promotes credibility and acceptance by society and funding agencies.

Methods
During the transplantation / translocation phase shell-fishers and mussel farmers made available their vessels and technical expertise. Divers, mostly shell-fishers/farmers, removed the selected specimens and farmers’ vessels made the transportation from one place to another. As it was vital that the byssus thread of the fan mussel remain as much as possible intact, shellfish-divers went through this with remarkable success. Though strange it may sound, they were partly “co-writers” of the research protocol, and they had significant contribution to the selection of sites, being aware of local physical and meteorological conditions (depth, waving, windy regime). On the other hand, it was a mussel farmer who received the transplanted specimens next to his production unit by ensuring no anchoring or stealing could occur and therefore, bias the results.

Second, during the sampling and monitoring phase, fishermen gave continuous information about the current population existence due to their daily employment. Fishermen tend to make the optimum, both in terms of time and space, sampling, as they leave no sampleable area, unfished. Moreover, the dissemination of knowledge about biota, substrate and vegetation was imminent. In addition to this, farmers gave information and space about the potential settlement of fan mussels on or near their marine infrastructures (ropes, boats, production units, etc). Mussel farmers took part in the manufacture of spat collectors and their expertise was of great help. Finally, a significant endowment to the project was the provision of aquaculture equipment and the day-to-day monitoring of artificially manipulated specimens in situ, as well as a problem-solving approach due to the “adoption” of the project.

(Continued on next page)
Results and Discussion
Davis & Wagner (2003) emphasized the need for researchers, when using local experts to gain from LEK, to describe, even briefly the selection criteria. In this case, we ranked our experts based (in descending order) on a) experience, b) willingness to collaborate, c) peer influence and d) (quality and safety of) equipment used. The corresponding criteria for farmers were a) willingness to collaborate, b) size of vessel, c) size of production unit and d) farmed species. Using a wider public to crowdsource data is an emerging technique that still needs elaboration. Choosing who to be your “partner” may substantially affect the project’s outcomes and the transparency and repeatability of results (Drescher et al., 2013).

Even though, that the above-mentioned project is not purely a conservation action, but more of a project trying to solve or mitigate a problem (the mass extinction of fan mussel), proposing possible etiological causes of the incurred disease and to a lesser extent conceptualizing conservation actions and fishery management plans, the framework (participatory process) argued by Buchs et al, 2021) was partly applied. Nonscientific knowledge has the potential to improve understanding of ecosystems and may act complementary with science (Hernandez et al., 2014; Theodorou et al., 2022).

Conclusions
To conclude, nowadays, it seems that issues of research staffing is not only how to build a multi-disciplined team with inter-institutional attributes, committed to work for and achieve the common goal. It is also to engage local experts who can decisively contribute with ecological knowledge and technical expertise.

Acknowledgements
This research is part of the project “Innovative Actions For The Monitoring-Recovering–Enhancement of The Natural Recruitment of The Endangered Species (Fan mussel) Pinna nobilis”, which was funded by the Operational Program for Fisheries and Maritime 2014–2020 (MIS 5052394). This action was co-funded by the European Maritime and Fisheries Fund (EMFF).

Introduction

The aim of the present study is to provide, in the CE Mediterranean, information on species’ biofoulings in the Greek mussel farms, and to describe the best management strategies that will reduce the costs of the end-product while controlling biofoulings’ populations.

The information provided by the professionals consists of one of the most direct approaches to activate the links between mussel farmers and scientists to upgrade the quality of the information and data provided, especially in data-poor areas such as those of shellfish farms.

Material and Methods

Local Ecological Knowledge on changes in the composition of species biofoulings in their installations, as well as production fluctuations over time retrieved from the operating management of mussel farmers empirical knowledge. Working protocols for questionnaire/interviews design based on Theodorou et al. (2022, 2023).

Results

The major problem in the Greek shellfish farms was ascidians and to a lesser extent the sponges. The surface size covered by a shellfish farming unit was also significantly and negatively correlated with the time of appearance of invasive ascidians, where ascidians appeared earlier in the larger units. The problem was more intensive in farm units covering an area between 2.0 and 2.5 ha, whereas it seemed moderate in units over 5.0 ha. This might be explained by the fact that the low-sized farms have built-in routine technologies (e.g., regular cleaning, etc.) as mitigation measures for the establishment of biofoulings. Ascidians also exhibited the highest intensity during the last 20 years, whereas gastropods were the invasive species with the highest intensity in the recently established/operated farms (since 2015). In terms of the final product, ascidians exhibited the most significant impact, whereas sponges showed a moderately negative impact, with the effect of the reduced amount of flesh being the most important.

The inherent challenges in shellfish farms, where management interventions are costly and difficult to implement, the rapid invasive parasite recolonization, and the potential for off-target effects pose regulatory barriers to many mitigation measures. Our results showed that the cost of farming management rises for ascidians and sponges, mostly impacted by damages to maintenance and labor, and to a lesser extent to fuel. The studied invasive species affected the operational cost of production at a rate of 21%-50% peaking from July to September, whereas the months previous (June) or following (October) were identified as the second most significant temporal influence on production. The greatest impact of the presence of invasive species was focused on repairs—maintenance, labor, fuel, maintenance, and service during the harvest season. Extra labor during May-June due to the invasive ascidians added extreme threats to the profitability of a shellfish farm with additional economic costs.

(Continued on next page)
Conclusions

Management interventions can result in significant net economic benefits. Monitoring on mussels’ production could provide an empirical quantitative estimate of the economic impact of invasive species impacts. Although there are many variations of integrated invasive organism management, the basic principles are combined risk assessment and risk management activities based on five main pillars: a thorough understanding of invasive organism ecology, bioeconomic cost-benefit relationships, continuous monitoring at the right scales, active prevention, and reactive control. These principles could be applied to shellfish farming, with experts’ judgment knowledge playing a critical role in a long-term approach to invasive organism management. When it comes to understanding the ecology of invasive organisms, the effects of both bio-pollution and invasive organisms also tend to vary spatially, temporally, and/or demographically. Thus, site-to-site variation factors, such as species’ plasticity to adapt to different environmental conditions, could also help to predict and assess the risk in farmed areas exposed to invasive organisms.

Acknowledgements

This is a part of the project «Development of the best control practices of invasive ascidians in mussel farming infrastructures and remediation of economic effects of invasion» (Code MIS: 5048463) funded by the EU-Greece Operational Program of Fisheries, EPAL 2014–2020.

Introduction

Ascidians (Asciidiacea) are marine invertebrate filter feeders with high spatial activity and are ranked among the most important biofouls (Aldred & Clare 2014). Biofouling (i.e., the dynamic process of attachment, accumulation and development of elements of aquatic flora and fauna on any natural or artificial surface) of ascidians in anthropogenic facilities (e.g., aquaculture), often has detrimental economic and ecological impacts (Tsotsios et al. 2023). Especially in shellfish aquaculture (e.g., in mussel farming), the effects of these invasive species are greater than in other forms of mariculture, as the farmed organism itself acts as a substrate for the biofoulants to settle, creating operational problems in production (Tsotsios et al. 2023). Within Greek marine areas, 75 species of ascidians have been recorded (Antoniadou et al. 2016). Most of them originated from Atlantic, whereas a gradual increase in records of invasive species from the Indian Ocean has been observed (Antoniadou et al. 2016).

Farmers consider ascidian biofouling a major etiological agent of detrimental effects for the viability of Greek shellfish aquaculture (Tsotsios et al. 2023). However, whilst ascidians’ genetic structure elucidation is crucial towards biofoulants’ proper management, such knowledge is not available for Greek marine areas. The aim of this study is to provide the first insights regarding the identification and phylogeny of biofouling ascidian species from Greek mussel culture facilities, using sequence analysis of both mitochondrial and nuclear DNA barcode markers.

Material and Methods

A total of 77 ascidian specimens were collected from four aquaculture mussel farms located in the Aegean and Ionian Seas. Genomic DNA was extracted using the Nucleospin® Tissue Kit (Macherey-Nagel) according to the manufacturer’s protocol. Cytochrome oxidase subunit I (COI) and 18S rDNA gene fragments were amplified using primer sets LCO1490 and HCO2198 (Folmer et al. 1994) and 18S1 and 18S4 (Tsagkogeorga et al. 2009), respectively. Polymerase Chain Reactions (PCRs) contained 1X Kapa Taq buffer, 1.5 – 2 mM MgCl2, 0.2 mM dNTPs, 0.25 µM for COI and 0.4 µM for 18S rDNA of each primer, 1 U Kapa Taq (Kapa Biosystems) and ca. 20 ng of DNA template, in a total volume of 20 µl. PCR cycling conditions consisted of an initial denaturation step at 94 °C for 3 min (COI) or 4 min (18S), followed by 37 cycles of 30 sec (COI) or 40 sec (18S) at 94 °C, 1 min at 48 °C (COI) or 40 sec at 50 °C (18S), and 1 min at 72 °C, with a final elongation step at 72 °C for 10 min. Amplified products were purified using the commercially available NucleoSpin® Gel and PCR Clean-up Kit (Macherey-Nagel) and sequenced on an AB3500 genetic analyzer (Applied Biosystems).

Blast algorithm was employed for species identification of the studied individuals. Manual editing of newly acquired sequences was performed using SeqMan II software (DNASTAR). Clustal Omega was used for the multiple sequence alignment of the COI and 18S rDNA datasets. Individual data sets of COI and 18S rDNA were finally concatenated for a total evidence analysis. For phylogenetic reconstruction of the combined dataset, Bayesian Inference analysis was performed using MrBayes (v. 3.1.2) while the best-fit model according to the Akaike Information Criterion (AIC) was determined by jModelTest software (v. 0.1.1).

Results & Discussion

All individuals were successfully identified at the species level, using both COI and 18S rDNA gene fragments, (Table 1).

Following manual editing and multiple alignment the final dataset comprised 1472 nucleotides (590 for COI and 882 for 18S rDNA). Bayesian Inference (BI) analysis, based on AIC TPM1uf+G model, resulted in a dendrogram with four distinct and well supported clades (1.00), corresponding to the species level (Fig. 1). The species orders formed three robust monophyletic clades following the phylogenetic relationships within the subphylum of Tunicates (Delsuc et al. 2018). Stolidobranchia included the Styelidae (Styela plicata) and Pyuridae (Microcosmus squamiger) families, Aplousobranchia the Clavelinidae (Clavelina oblonga) and Phlebobranchia the Ascidiidae (Phallusia mammillata) families (Fig. 1).

(Continued on next page)
Phylogenetics and population genetic diversity of invasive ascidians have been sporadically evaluated in eastern Mediterranean based on various molecular markers (e.g., Maltagliati et al. 2014). The present study is the first attempt to genetically identify and elucidate the phylogeny of biofouling ascidians invading Greek mussel farming facilities. Investigation of the spread and genetic composition of non-indigenous-cryptogenic ascidians and practices to deal with infestation in mussel farms is necessary to assess the magnitude of the problem in production activities.

Acknowledgments
The present work is a part of the project «Development of the best control practices of invasive ascidians in mussel farming infrastructures and remediation of economic effects of invasion» (Code MIS: 5048463) funded by the EU-Greece Operational Program of Fisheries, EPAL 2014–2020.

Introduction

The exploitation of aquatic, living resources, in particular mussels, provides work and income to mussel fishermen and farmers, societal cohesion in fishery-sector dependent communities and low cost, valuable protein-rich intake to consumers. Provided that mussel fishery and aquaculture are sustainably practiced, production, financial and ecosystem services are fully met.

Within the context of the EU and Greece co-funded research project (MIS 5052394) PinnaSOS (www.PinnaSOS.upatras.gr) about enhancement of natural recruitment of fan mussel (Pinna nobilis), certain preliminary actions took place. Namely, experimental transplantation, extensive sampling, monitoring of any living specimens and artificial breeding of the critically endangered, according to IUCN, bivalve species were conducted by a conventionally staffed research team along with a vastly experienced group of mollusk fishermen and farmers.

This study shows that the ‘participatory’ approach used in PinnaSOS, presents a way forward to involve and mobilize local stakeholders, increases the sampling efficiency while in parallel promotes credibility and acceptance by society and funding agencies.

Methods

During the transplantation / translocation phase shell-fishers and mussel farmers made available their vessels and technical expertise. Divers, mostly shell-fishers/farmers, removed the selected specimens and farmers’ vessels made the transportation from one place to another. As it was vital that the byssus thread of the fan mussel remain as much as possible intact, shellfish-divers went through this with remarkable success. Though strange it may sound, they were partly “co-writers” of the research protocol, and they had significant contribution to the selection of sites, being aware of local physical and meteorological conditions (depth, waving, windy regime). On the other hand, it was a mussel farmer who received the transplanted specimens next to his production unit by ensuring no anchoring or stealing could occur and therefore, bias the results.

Second, during the sampling and monitoring phase, fishermen gave continuous information about the current population existence due to their daily employment. Fishermen tend to make the optimum, both in terms of time and space, sampling, as they leave no sampleable area, unfished. Moreover, the dissemination of knowledge about biota, substrate and vegetation was imminent. In addition to this, farmers gave information and space about the potential settlement of fan mussels on or near their marine infrastructures (ropes, boats, production units, etc). Mussel farmers took part in the manufacture of spat collectors and their expertise was of great help. Finally, a significant endowment to the project was the provision of aquaculture equipment and the day-to-day monitoring of artificially manipulated specimens in situ, as well as a problem-solving approach due to the “adoption” of the project.

(Continued on next page)
Results and Discussion
Davis & Wagner (2003) emphasized the need for researchers, when using local experts to gain from LEK, to describe, even briefly the selection criteria. In this case, we ranked our experts based (in descending order) on a) experience, b) willingness to collaborate, c) peer influence and d) (quality and safety of) equipment used. The corresponding criteria for farmers were a) willingness to collaborate, b) size of vessel, c) size of production unit and d) farmed species. Using a wider public to crowdsourcedata is an emerging technique that still needs elaboration. Choosing who to be your “partner” may substantially affect the project’s outcomes and the transparency and repeatability of results (Drescher et al., 2013).

Even though, that the above-mentioned project is not purely a conservation action, but more of a project trying to solve or mitigate a problem (the mass extinction of fan mussel), proposing possible etiological causes of the incurred disease and to a lesser extent conceptualizing conservation actions and fishery management plans, the framework (participatory process) argued by Buchs et al, 2021) was partly applied. Nonscientific knowledge has the potential to improve understanding of ecosystems and may act complementary with science (Hernandez et al., 2014; Theodorou et al., 2022).

Conclusions
To conclude, nowadays, it seems that issues of research staffing is not only how to build a multi-disciplined team with inter-institutional attributes, committed to work for and achieve the common goal. It is also to engage local experts who can decisively contribute with ecological knowledge and technical expertise.

Acknowledgements
This research is part of the project “Innovative Actions For The Monitoring-Recovering–Enhancement of The Natural Recruitment of The Endangered Species (Fan mussel) Pinna nobilis”, which was funded by the Operational Program for Fisheries and Maritime 2014–2020 (MIS 5052394). This action was co-funded by the European Maritime and Fisheries Fund (EMFF).

E-mail : valentin.thomas@inrae.fr

Introduction
Rainbow trout is one of the most commonly farmed salmonid species across the world and the most farmed fish species in France. Trout are reared in France for the production of large fillets which are consumed fresh or smoked. Thus, the main objectives of genetic selection are to improve growth and fillet’s yield. To assess growth and fillet’s quality various traits are measured, such as body weight, carcass and fillet yields or fat content. Though some QTLs have been found in previous experiments (Blay et al., 2021), we still lack precise information about genes and biologicals mechanisms linked to those traits. Our aim was to estimate genetic parameters of production traits in a commercial line of rainbow trout and to detect and accurately localize associated QTLs.

Materials and methods
The stock was established from 3 generations of a commercial selected line of Les Sources de l’Avance breeding company (Aqualande Group, France) whose breeding program started 12 generations ago. The stock was reared under commercial conditions until harvesting. From the 9th, the 10th and the 12th generations, 2198, 1410 and 824 fish were sampled between 503 and 539 days post fecundation. Fish were measured for fork length (FL, cm), body weight (BW, g), carcass yield (CY), head gutted carcass weight (HGCW, g), head gutted carcass yield (HGCY), viscera weight (VW, g), gut yield (GY), fat content in the muscle (FAT, %) recorded using a Fish Torry Fat-meter®.

Fin samples of 3390 phenotyped fish were genotyped for 57,501 SNPs using the Axiom® Trout Genotyping array by the INRAE genotyping platform Gentyane (Clermont-Ferrand, France). All the parents of phenotyped fish were also genotyped with the 57K array (184, 183 and 80 parents of the 9th generation, 10th and 12th generations).

After SNPs quality control including filtering out SNPs with minor allele frequency (MAF) < 1%, and SNP call rate < 97%; 31,968 SNPs were retained for the analysis.

The 99 sires of the phenotyped fish in 10th generation were also sequenced with the NovaSeq6000® paired-end technology (Illumina 2x150bp) at INRAE sequencing platform Get-PlaGe (Toulouse, France). We used the nfcore/sarek 2.7.1 pipeline to call variants. We retained 10,520,443 bi-allelic SNPs with MAF > 1%. The imputation of the 32K genotypes of phenotyped fish into 10,520K genotypes was performed using FIMPUTE3 software using pedigree information. After imputation we kept 1,231,034 SNPs with a MAF above 10%, a mendelian error rate below 3% and linkage disequilibrium r² between SNPs < 0.9 in sliding 100kb-windows.

Genetic parameters were estimated using BLUPF90 software (Misztal et al., 2014). GWAS was performed for the 8 traits of interest with a Bayesian Sparse Linear Mixed Model (BSLMM) using GEMMA - 0.98.5 software (Zhou et al., 2013).

Results and discussion
Heritability varied from moderate to high values (TABLE 1). The highest heritability was estimated for FAT (0.63 ± 0.03) and the lowest value for FL (0.16 ± 0.02). Production traits were polygenic, the proportion of genetic variance accounted for by the 150 to 500 SNPs with the largest effects ranged from 75 to 95% depending on the trait.

We detected 17 QTLs (TABLE 2) with very strong evidence based on posterior inclusion probability (PIP) of SNPs in BSLMM and associated Bayes Factor (2lnBF > 14). We did not re-detect seven of the ten QTLs found in the previous study based on generations 9th and 10th of the same rainbow trout line (Blay et al., 2021).

(Continued on next page)
For FL, 3 QTLs were identified, among them the QTL at 7.1 Mb on chr 22 was also detected for BW and entirely located in the slc39a10 gene. For BW, 4 other QTLs were detected on chr 4, 5 and 8. The QTL on chr 4 (with peak SNP at 20.2 Mb) was located within rcan2. The 2 QTLs on chr 8 and 22 were previously identified in the same trout line (Blay et al., 2021). The QTL on chr 8 spanned the region of map3k7 and bach2b genes. For HGCW and HGCY a common QTL was identified on chr 6 in a region where top3b and ppm1f genes are annotated. All the other QTLs were in intergenic regions.

**Conclusion**

Thanks to imputation on over 1 million SNPs, we significantly refined the location of 2 QTLs previously identified, as well as we detected 15 new QTLs. These results will be validated in an ongoing study by genotyping the 13th generation of the Aqualande’s line to confirm the associations between genotypes and production traits.

EVALUATING AND SELECTING FISH POLY Cultures: HAVING THE BIG PICTURE THANKS TO AN INTEGRATIVE ASSESSMENT

M. Thomas*, N. Amoussou†, A. Pasquet† and T. Lecocq†

†Université de Lorraine, INRAE, UR AFPA, 54000 Nancy, France
E-mail: marielle.thomas@univ-lorraine.fr

Introduction
Fish polyculture is any production in which at least two fish species are reared in the same rearing system at the same time, with the objective of producing several products with economic value. Such practice is a potentially interesting option for future aquaculture developments by benefiting from the coexistence of taxa and/or interactions among species. Regardless of the systems in which polyculture is applied (i.e. traditionally in ponds or more recently in recirculated aquaculture systems, RAS), it requires compatibility and complementarity occur among the fish species farmed together (Thomas et al., 2021). Thus, fish species to be combined must be able to live in the same production system at the same time, without detrimental interactions (such as predation), benefiting from different resources with little, or, even better, no competition for resources (e.g. trophic, spatial), or developing commensal or mutualistic interactions. These prerequisites for polyculture design were used to identify species to be combined with pikeperch reared in RAS. The aim is to define a strategy to identify the species combinations that best meet the challenges of production and fish welfare for the aquaculture of the future.

Materials and methods
Several polyculture approaches were applied in RAS. Fish combinations were selected on the basis of their compatibility and complementarity. Pikeperch were combined with sterlet, with tench, or with sterlet and tench in a first experimental series and, with common carp, with black-bass, or with common carp and Eurasian perch in a second series. Pikeperch were also reared in monoculture as a reference system. All these experiments were carried out at the Experimental Platform for Aquaculture (UR AFPA, Lorraine University) in France. They were applied in experimental units with a strict control of physico-chemical parameters and a daily fish monitoring. To evaluate polyculture scenarios, several biological traits classified into two categories were measured (Amoussou et al., 2022a):

i) production data (survival rate, mean final weight, weight heterogeneity, specific growth rate and Fulton Condition Index), and

ii) welfare data (behavioral traits [agonistic and flight] and physiological traits [cortisol, hematocrit, glucose, serotonin and dopamine]). Multi-trait analyses were then conducted to evaluate the fish polyculture scenarios. Finally, a ranking procedure was also developed to select polyculture scenarios (Amoussou et al., 2022b).

Results
Our experimental works reveal that all studied species were impacted by polyculture, but they are not equally affected. From an aquaculture viewpoint, polyculture could result in beneficial or detrimental impacts on fish production and welfare depending on the species. Our results also demonstrate the value of a multi-traits evaluation based on an integrative analysis to better address the impacts of the polyculture. Differences are measured in the expression of some traits related to fish production or welfare. The application of the ranking procedure makes it possible to consider a variety of stakeholders’ expectations, with or without weighting, and thus result in a variable classification of polyculture scenarios.

Discussion and conclusion
Assessment of any polyculture scenarios requires all species to be considered. The objective is to exclude situations in which one species takes advantage of the rearing conditions to the detriment of another. Polyculture only makes sense if all species take advantage of these rearing conditions. A multi-trait assessment is useful for a balanced assessment between production and welfare objectives, with possible adjustment according to the varying and changing expectations of stakeholders.

PRODUCTION DATA, BIOMASS ESTIMATION AND AI – A COCKTAIL FOR IMPROVED SUSTAINABILITY AND PROFITABILITY IN AQUACULTURE

Diogo Thomaz
Innovasea Hellas
Dervenakion 47
Corinth 20 100
Greece
diogo.thomaz@innovasea.com

Aquaculture is an increasingly important sector in global food production. However, its growth is threatened by the high cost of feed, which accounts for up to 70% of the production costs. Feed conversion ratio (FCR) is a key indicator of the efficiency of aquaculture production and refers to the amount of feed required to produce a unit of fish biomass. Improving FCR is crucial to increasing profitability, sustainability, and environmental performance. Artificial intelligence (AI) and production data can be leveraged to optimize feed management, while biomass estimation cameras can improve feeding accuracy and reduce wastage.

AI can be used to analyze production data and identify patterns that can inform feed management decisions. Feeding is a complex activity in that feed ingestion by fish depends on many factors, environmental, genetic, husbandry, nutritional, behavioral, etc. By analyzing these variables, AI systems can optimize feeding regimes to improve FCR and fish growth. Advanced farm management software will help feed these AI models and deliver continuous improvement of feeding and growth models specific for each farm.

But a feeding regime can only work when farmers have a good notion of the biomass in each pen. Biomass estimation cameras can improve the accuracy of feeding by estimating fish size and quantity in real time. This data is then used to adjust feed delivery rates and reduce overfeeding, which can lead to poor water quality, disease, and mortality. Innovasea has developed its BiomassPro solution to reliably estimate fish weight distribution in several farmed species, with more than 97% accuracy for most species and up to 99% accuracy in others. In addition to enabling more precise feeding, these cameras also help farmers forecast production yields, optimize harvest schedules, and reduce fish waste.
In many marine and freshwater broodstock facilities, fish are tagged so they can be individually handled according to the plans of facility managers. Similarly, in many public or private research organizations working fish reproduction, genetics, pathology, or nutrition, tagged fish are used and tracked individually. Managing data from these activities using non-standard applications such as Excel or Google spreadsheets is far from ideal. Data is complex, multi-dimensional and difficult to track as fish are moved between tanks or pens.

The Cloud-based software service Aquanetix Broodstock, developed with support from the NewTechAqua project, allows users to record all types of events linked to individual fish, such as samplings for weight or length, treatments, transfers between tanks, and more, as well as events linked to the group of fish in a tank, such as water parameters and feedings. The software keeps full traceability of both, groups of fish and individual fish, allowing researchers and broodstock and hatchery managers to find the clear cause-effect relationship between treatments and performance. Much of the flexibility in the application is due to the possibility for users to define custom sampling types, that can be complex variables with many dimensions (for example the shape of fish, or others such as microsatellite haplotypes or specific treatments). The user can then record these samplings over time and link them of individual fish.

Data can be recorded using automated systems such as water parameter monitoring sensors, input by hand using the Aquanetix mobile app or uploaded easily from standard applications used by the main PIT tagging hardware companies. Analysis can be done using the reporting and BI platform linked to Aquanetix or easily exported into a number of formats for analysis in specialized applications.

Aquanetix Broodstock not only allows users to collect and track data from individual fish but stores it in a standard format that can be retrieved and analyzed against future research trials. The data belongs to the organization and is not lost when researchers or broodstock managers move on to new positions.

NewTechAqua is a project funded by the European Commission. This project has received funding from the European Union’s Horizon 2020 Programme under grant agreement No 862658.
INNOVATION FIRST! MANAGING OPERATIONAL RISK IN AQUACULTURE TECHNOLOGY DEVELOPMENT

SINTEF Ocean, Postboks 4762 Torgarden, NO-7465 Trondheim, Norway
E-mail: trine.thorvaldsen@sintef.no

Introduction
Norway is a leading producer and exporter of Atlantic salmon, and open sea-based cages in the coastal zone has been the leading technology since the 1970s. In recent years, new production systems have been emerging, for both coastal and offshore locations. This may require adjustments in the regulatory framework, which has been described as fragmented.

In daily operations, employees at the fish farm and vessels have a responsibility to handle a range of operational risks to ensure personal safety, fish health and welfare and the environment. Studies find that workers are exposed to several hazards in their work environment, and may experience dilemmas related to for instance personnel safety and production or fish welfare and profits (1,2)health complaints and concerns, sickness absence, subjective health status and job satisfaction.

Results
The survey data show that physical and ergonomic exposures are the most common, and several workers report psychosocial exposures such as stress and lack of control in their workday. The most frequently reported health complaints were musculoskeletal (neck/shoulder/arm pain, back pain, hand/wrist pain, knee/hip pain.

Reducing risks, as well as utilization of new areas, were prevalent in the call for “development licenses”, a temporary license aimed to spark innovation introduced in 2015 (3). A total of 104 applications were submitted by the deadline in 2017. Criteria for being awarded development licenses targeted some risks (e.g., salmon lice, escapes, waste) and not others (e.g., occupational health and safety). Furthermore, concepts had to be unique, which may also introduce unique risk scenarios that must be handled.

It was the Directorate of Fisheries (DF) who were responsible for the call and assessment of applications. Even though it is required to assess all risks in the operation of the farms, the Food Safety authority (FSA) (responsible for fish welfare), Norwegian Labour Inspection authority (NLI) and Norwegian Maritime authority (NMA) (responsible for occupational health and safety) had no formal role in the assessment processes.

While the criteria guided applicants towards tackling certain risks through technological innovation, the fish farmers who operate the farms must consider all operational risks in their risk management to ensure safe operations. The question guiding this study is: How were operational risks managed in selected innovation processes?

Material and methods
The research question is addressed through material from 44 semi-structured interviews with fish farmers and suppliers who have applied for development licenses, as well as interviews with authorities, organizations, and other key stakeholders. Interviews were conducted between January 2021 and January 2022.

Additional materials included publicly available documents such as consultation response, response letters to applicants, media coverage and other documentation from the projects.

Results
Interviews provided knowledge regarding applicants’ approach to risk management in the innovation processes, including what type of competence they saw as important at different stages. In addition to the fish farming companies and suppliers, universities, research institutes and consultant agencies also provided advice for several of the projects.

Interviews showed that risk assessments were used to identify operational risks. The call asked for descriptions of how the project would affect fish welfare, and how this could be measured. Several projects were concerned with the welfare of the fish, fish mortality, how the fish would handle the new technology and making sure the personnel could perform operations and maintenance. Here, previous research was seen as an important source. The licenses’ purpose was to test the technology, and one informant underlined that the licenses did not give them any chance to do a large-scale scientific study regarding the welfare of the fish. The Food Safety Authority also addressed issues regarding fish welfare stating that consideration of fish welfare and fish health has not been adequately addressed when licenses for production have been developed and awarded, pointing out the animal welfare law requirements of ensuring animal welfare in all technology.

(Continued on next page)
Occupational health and safety were not mentioned as a criterion in the call for licenses. However, and especially for offshore concepts with harsher weather conditions and increased distance from shore and potentially having to use helicopter transport, personnel safety in operations was addressed in the innovation processes. Concepts with more stable work platforms as less use of vessels in operations, compared to traditional net cages with plastic collars, were seen to reduce risk for workers. While the interaction with regulators varied among applicants, some contacted the NLI and the NMA to discuss concerns regarding risk management related to regulations for work hours. Following the innovations aimed for offshore locations, the government also started working on new regulatory requirements for occupational health and safety applicable for offshore aquaculture, aiming to finalise regulations in 2023.

Interviews show that the applicants applied different strategies to manage operational risks throughout the development licenses innovation process. New technologies can reduce risk, but also introduce new risks. To ensure safe operations and compliance with regulations, all risks must be handled when the farms are in operation. When technological innovation is first on the agenda, it is therefore crucial that the operational risks are identified and managed throughout the innovation processes.

**Literature**

Phenomics is a 21st century approach to quantifying an organisms’ observable characteristics with high dimensionality, however while they are increasingly applied in agriculture and medicine, they are not widely adopted in aquaculture. Here, we present new approaches to the study of developing aquatic embryos, incorporating both open-source bioimaging hardware and analytical software. A key strength of phenomics when applied to developing organisms is the ability to acquire high-dimensional longitudinal data at an individual level. We will present the automated analysis of both commonly used phenotypic measures such as heart rate, but also the ability of ‘machine proxy traits’ to measure complex organismal physiology as the integration of energy across a series of frequency spectra. These approaches have broad potential applicability to aquaculture, including breeding, sensitivity assessment and the use of embryos as biosensors within culture facilities.
GENOME EDITING FOR GENETIC IMPROVEMENT IN FINFISH AQUACULTURE

Alan Tinch*, Klara I. Verbyla, Debbie A. Plouffe, Simon Hill and John T. Buchanan

The Center for Aquaculture Technologies
8445 Camino Santa Fe, Suite 104
San Diego, CA, 92121 USA
E-mail: atinch@aquatechcenter.com

Increasing ability to harness the power of genomics is forcing a rethinking of aquaculture genetic improvement strategies. Successful breeding programs will always be built on the careful selection of the next generation of broodstock, detailed record keeping, and accurate collection of phenotypic data. Genomics allows this base of phenotypic selection to be enhanced, and ultimately accelerated to increase genetic gain per generation. This is currently done in finfish at the most sophisticated level through the use of Genomic Selection. However, another exciting technology is on the horizon that will fundamentally change how we deliver genetic improvement. This technology is Genome Editing.

Genome Editing is a technology that can thought of as “precision breeding”. It will be an important tool in the future toolbox for genetic improvement in aquaculture. The current state of the art in Genome Editing in aquaculture is impressive and on the cusp of significant commercial application. The basic concept is that enzymatic tools (such as CRISPR technologies) can be used to create variants in specific DNA sequences that create a desired phenotype (such as sterility, monosex, rapid growth, or disease resistance). The technique does not involve adding new DNA, so is not transgenic and does not create a GMO. It simply involves understanding the genomics and underlying genetic variant that is needed for a trait to be expressed, and harnessing natural processes to create that variant rather than sorting through many thousands of broodstock and many generations to achieve the same effect.

The power of genomic research is that we are beginning to understand the exact genes involved in performance traits, and how variation in those genes leads to improved performance. Harnessing the power of Genome Editing allows us to transfer this knowledge to application in commercial breeding programs for heritable, quantum advances in genetic improvement. Importantly, sterility will be a requirement in most applications of GE in aquaculture as a method of biocontainment to prevent escape to the environment, or the inadvertent application of genetically improved animals.

This presentation will provide background on how genome editing works, an update on regulation, and how this tool may be used to improve aquaculture genetics in the very near future.
THE EFFECT OF COPPER ON APPETITE, GROWTH AND HEALTH IN FARmed ATLANTIC SALMON: THE IMPORTANCE OF NUTRIENT SENSORS AND THE MICROBIOTA-GUT-BRAIN AXIS

Ingvill.tolas@ntnu.no

A major challenge in fish farming in cages is the formation of biofouling, i.e organisms and algae growing on the pens. This may compromise water circulation, undermine disease management and cause bacterial diseases to spread in the pens. To prevent biofouling, nets are frequently coated with antimicrobial copper alloys, which results in the release of copper into the surrounding water. Copper released from net coating is considered the largest source of environmental toxicants caused by the fish farming industry and it creates an environment in which the farmed fish within the net pen as well as species in the surrounding waters are subjected to chronic copper exposure. Given that copper exposure has been shown to cause reduced growth and feed conversion rate in numerous fish species, it is of high industrial interest to gain knowledge about copper toxicity as it relates to farmed Atlantic salmon.

Based on previous studies in both mammals and fish, we hypothesize that the reduced growth observed in fish exposed to copper in part is owed to an accumulation of copper in the gastrointestinal tract, which in turn affects the composition of the gut microbiota. The gut microbiota plays an important role in the host organism, partially due to its ability to convert feed ingredients like, starch, chitin and fibers into various forms of short chained fatty acids (SCFAs). The variants of SCFAs generated is determined by the composition of both the food and the gut microbiota. Following their formation, SCFAs bind to nutrient receptors in the intestines, the best characterized of which are «free fatty acid receptor 2» (FFAR2) and «free fatty acid receptor 3» (FFAR3). Activation of these receptors contribute to the regulation of peristalsis, immune response, appetite, feed intake and more. The wide repertoire of functions is owed to the many possible combinations of fatty acids, receptors and cell types linked to different signaling pathways, and a shift in any of these variables can potentially have a profound effect on the host organism.

Most of the available knowledge surrounding the symbiotic relationship between the gut microbiota and host organism is derived from mammalian studies. While this relationship has also been demonstrated to be present in fish, available information regarding the processes involved is still limited. To investigate the underlying biological mechanisms in Atlantic salmon, we have analyzed its genome using in silico tools and identified several variants (paralog genes) of FFAR2/FFAR3. Early analysis shows substantial similarity between the receptors in salmon and in humans, with the characteristic seven transmembrane alpha helix structure preserved. We are currently working to characterize these receptors with regards to sequence, structure and expression pattern. We will investigate their role in nutrient sensing, how they are affected by copper exposure and how they correlate with growth, feed intake, the composition of the gut microbiota and SCFA, and expression of appetite regulating neuropeptides in the brain.

Introduction
Accurate comprehension of reproductive processes is essential for the design of aquaculture strategies aimed at optimizing yield and ensuring sustainability. Despite its pertinence, the estimation of fecundity and the dynamics of energy allocation to reproduction remains challenging, both at the farm and individual levels (Chary et al., 2022).

Bioenergetic models provide a mechanistic framework for elucidating many biological processes. Dynamic Energy Budget theory (DEB), for instance, proposes that an organism assimilates energy, storing it as reserves and subsequently expending it to fuel growth and reproduction. Under this paradigm, a fish’s reproductive capacity at any given time depends upon the available energy reserves for this purpose (Kooijman, 2010).

This work is framed in the long-term objective of developing a DEB model capable of mechanistically elucidating principal reproductive processes, thereby facilitating estimations of energy investment in reproduction. The specific objectives of this study encompass 1) developing an ultrasound-based technique for quantifying gonadal and hepatic dimensions, and 2) establishing a statistical model capable of generating precise and accurate estimates of organ weights from ultrasound measurements.

Materials and Methods
European sea bass (*Dicentrarchus labrax*) serves as model species. A sample of 47 mature female individuals was selected for experimentation. These fish were housed at the IRFAP-LIMIA facilities within marine floating mesh cages. At the start of the study, the individuals weighted on average 2,383g ± 524g. Over the span from November 2021 to May 2022, aligning with the species’ spawning season (Pawson et al., 2007), biweekly samplings were conducted on each individual, involving ultrasound measurements of gonadal and hepatic structures. Echographic assessments employed an ultrasonic probe equipped with a linear array, operating at frequencies of 7.5-10 MHz, a focal depth of 25-35 mm, and a signal amplification (gain) of 85%. For gonads, 11 measurements of the left lobe were undertaken, capturing total length, and height and width at five equidistant points along the longitudinal axis. For the liver, three measurements (length, height, and width) were recorded. Before echographic procedures, individuals were anesthetized using phenoxyethanol in a dose of 1,000 ppm.

During the course of the experiment, 35 out of the 47 individuals were sequentially sacrificed to calibrate the method. Ultrasound measurements were consistently taken the day before sacrifice. Post-mortem examinations involved dissection, organ weighing, and identical measurements as those obtained through echography, but done using a calliper. Organ volume was estimated after approximating organ shape to a simple 3D shape. For gonadal lobules, the volume was approximated using a combination of truncated cones with ellipsoid bases, while for the liver, a triangular prism shape was utilized. The estimated volumes for each organ were subsequently compared with their respective weights (obtained during necropsy) using linear regression.

Results
The regression models for gonadal lobes and liver yielded a p-value below 0.001 for the slopes of their respective regression lines. The correlation coefficients were $R^2 = 0.95$ and $R^2 = 0.48$ for gonadal lobes and liver, respectively.

The proposed model for estimating the weight of left gonadal lobes from ultrasound measurements is formulated as $W = 1.028V - 5.263$, where $W$ (g) is the estimated weight of the gonadal lobe, and $V$ (cm$^3$) denotes its volume. The proposed model for estimating liver weight from ultrasound measurements is expressed as $W = 0.725V + 12.681$, with the same variables.

(Continued on next page)
These models were applied to describe the gonadal and hepatic size changes for the 12 fish monitored over the full experiment (nearly 6 months). For these fish we describe clear between-fish differences in the temporal dynamics of the gonad size along the reproductive season.

Discussion

The obtained findings underscore the reliability of ultrasonography for in vivo measurements of internal organ dimensions and weight, specifically gonads and liver, within adult D. labrax specimens. The handling protocol has been validated as safe for fish welfare, thus allowing long-term, non-invasive monitoring.

Both volumetric reconstruction methods for gonadal lobules and liver demonstrate suitability in predicting organ weights. However, while gonadal lobe volume estimates displayed a robust correlation with the volumetric measurements derived from ultrasonography, liver weight estimates appear comparatively less precise. This discrepancy could be attributed to the more irregular shape of the liver, and its deeper intra-abdominal location.

The established association between ultrasonography-derived volume estimates and actual measurements of organ weight offers a means of precisely estimating organ weights exclusively through ultrasonography, facilitating repetitive measurements throughout the fish’s lifespan. The potential of repeatedly estimate organ weights on an individual basis holds promise for characterizing species’ reproductive dynamics. The resultant dataset, generated through this methodology, holds potential for improving bioenergetic models, particularly those derived from DEB theory. The overarching aim is to incorporate data of gonadal and liver weights alongside other variables, culminating in a comprehensive DEB model that mechanistically explicates core reproductive processes, which, ultimately, may contribute to improve the sustainability of aquaculture practices.

METABOLIC CHANGES IN IN VITRO MODEL OF MARAENA WHITEFISH Coregonus maraena DUE TO TEMPERATURE INCREASE

Katrin Tönißen¹, Julia Brenmoehl², Bianka Grunow¹

Introduction

Global climate change causes increasing water temperatures and decreasing oxygen levels, which leads to changing or destroying aquatic habitats. Additionally, the direct contact of the fish with the changed environment leads to physiological changes in the species, which can be studied using cell culture systems. In vitro models represent an essential tool in aquaculture-related research and a flexible system for investigating the effects of altered biotic and abiotic factors at the cellular level.

The maraena whitefish (Coregonus maraena) is an ecologically important species in the region of the Baltic Sea. Due to extensive fishing, habitat fragmentation, and eutrophication, these populations have declined sharply. Today, this vulnerable salmonid species is on the IUCN Red List. The effects of rising water temperatures on the already vulnerable species are not yet been well studied. In studies conducted by our working group, we have succeeded in establishing a cell line (CMA-fin1) derived from maraena whitefish (Grunow et al. 2021, Kaya et al. 2022). The aim of the present work was to use this in vitro model to examine the impact of increasing temperatures on growth and energetic parameters of CMA-fin1 cell line. Additionally, the use of cell lines helps to reduce the number of animals used in research in accordance with the 3Rs principle.

Materials and Methods

The proliferation of CMA-fin1 cells was analysed and compared at two different temperatures, at 20°C (control) and 25°C (high temperature). For this, all cells were cultivated in Leibovitz-15 Medium (L-15, Gibco) with 10% fetal bovine serum (FBS) and 1% (v/v) penicillin/streptomycin. Growth and vitality were measured after 6 days by trypan blue staining and image-based automated cell counting (EVE™ Plus, NanoEnTek).

To conduct a comparative analysis (20°C vs. 25°C) of morphological cell changes, we visualized actin by Phalloidin-iFluor 488 Reagent staining. Additionally, mRNA abundance of selected temperature and stress-related genes was measured by quantitative reverse transcription PCR (RT-qPCR). To measure parameters related to mitochondrial function and glycolysis, we used the Seahorse XF Cell Mito Stress Test Kit and Glycolysis Stress Test Kit (Seahorse, Agilent Technologies). The tests were performed after 24 h for cell attachment. The detection of lactate dehydrogenase (LDH) is a tool for determining the status of necrosis of cells. The enzyme activity was measured by Cytotoxicity Detection Kit (Roche Applied Science) in the supernatant of the CMA-fin1 cells.
USE OF GLYCERIDES OF SHORT CHAIN FATTY ACIDS (BALANGUT®) IN GILTHEAD SEA BREAM (SPARUS AURATA) JUVENILE CULTURE: EFFECTS ON MUCOSAL HEALTH AND DISEASE RESISTANCE

Introduction
Modifications in diet composition, especially those addressing the reduction of traditional ingredients, may induce side effects on fish performance, feed utilization and health. Particularly, fish gut integrity and functionality has been demonstrated to be directly affected by those replacements, especially in relation to alterations in gut morphology, gut microbiota and impaired gut associated lymphoid tissue (GALT) immunological response, altogether facilitating the appearance of inflammatory processes and disease outbreaks. In this sense, functional ingredients, such as glycerides of short and medium chain fatty acids seem to be an accredited solution to reduce the above-mentioned health-related effects.

Materials and methods
Feeding trial: Four experimental diets were formulated to meet the nutritional requirements of gilthead sea bream. One of the experimental diets was devoid of the functional ingredient (Control diet) while the remaining diets were supplemented with glycerides of short and medium chain fatty acids (BalanGut® AQ P; BASF, Germany) at 0.3% (BG0.3), 0.5% (BG0.5) and 1% (BG1), replacing standard carbohydrates (wheat meal). Diets were formulated in a basis of a 15% fish meal, 5% poultry meal and a 6% fish (46% CP, 16% CL, 21.4 MJ/kg feed). The experimental trial was carried out at the facilities of the Parque Científico-Tecnológico Marino (PCTM) at University of Las Palmas de Gran Canaria (Telde, Canary Island, Spain). Gilthead sea bream juveniles of own production were randomly distributed into fifteen 500 L open flow-through water system tanks at an initial density of 3.7 kg·m⁻³ (30 fish/tank). Fish average initial weight and length were 62.41 ± 1.39 g and 14.23 ± 0.07 cm, respectively (mean ± SD). Diets were assayed in triplicate and fish were fed to apparent satiation three times a day, six days a week for 8 weeks. Two sets of three tanks were fed with the control diet and used as negative and positive controls for the challenge test.

Challenge test: After 8 weeks of feeding, 25 fish/tank were transported to the Marine Biosecurity (MBS; PCTM-ULPGC) and challenged by intraperitoneal injection against Vibrio anguillarum (10⁷ cfu/ fish, strain 507) along 10 days. Fish survival was recorded daily and described by Kaplan-Meier curves for each dietary treatment. V. anguillarum was confirmed as the causative agent of all the naturally dead fish.

Results
Fish accepted well the experimental diets, which had no effect on fish survival neither condition factor along the feeding trial. After 8 weeks of feeding, dietary supplementation did not significantly affect (p>0.05) fish weight gain, SGR and FCR (Fig. 1). However, although not significant (p>0.05), it increased SGR in an 8-12% after 4 weeks of supplementation in relation to fish fed control diet. Similarly, functional diets optimized in a 13-17% and in a 5-8% the FCR after 4 and 8 weeks of supplementation (Fig. 1). Graded functional additive supplementation did not affect (p>0.05) ACH50, lysozyme, bacteriolytic and bacteriostatic activities compared to fish fed control diet. However, fish fed BG0.3 diet presented a relative increase in ACH50, serum bacteriolytic and serum bacteriostatic activities of a 12%, 27% and 8%, respectively, compared to the control group. At the end of the challenge against V. anguillarum, fish fed BG0.5 and BG1 diets for 8 weeks presented higher survival (p<0.1) than fish fed the BG0.3 and control diets. (Fig.2). In terms of submucosa width, for anterior gut fish fed BG0.5 presented thinner (p<0.05) anterior gut submucosa compared to fish fed the control diet, whereas for posterior gut and rectum intestinal regions all the dietary levels fed reduced (p<0.05) gilthead sea bream submucosa thickness. In terms of gut mucus production, fish fed BG0.3 and BG0.5 diets for 8 weeks presented smaller (p<0.05) goblet cells than fish fed control diet along the whole intestine.

(Continued on next page)
Conclusions

The overall results obtained in the present study, profile the use of glycerides of short and medium chain fatty acids (BalanGut® AQ P; BASF, Germany) at 0.5% as a potential functional ingredient to promote gilthead sea bream gut health and disease resistance against *V. anguillarum*, when included in practical diets for this fish species.
COMPARATIVE GENOMICS OF THE OLFACTORY GENE REPERTOIRE IN SENEGALESE SOLE (*Solea senegalensis*) AND OTHER FLATFISH

Introduction

The evolution of flatfish (order Pleuronectiformes) towards a sea-bottom lifestyle has involved sharp morphological changes, such as the acquisition of a flattened shape (“flatfish”) and the characteristic bilateral asymmetry. Pleuronectiformes is a highly diverse polyphyletic group resulting from a quick adaptive radiation (around 700 species), dated back to the Pliocene (~70 MYA), and which has adapted to a wide variety of benthonic environments (Lü et al., 2022). Flatfish have evolved into compact genomes (500-700 Mb) with a low proportion of repetitive DNA elements (< 8%), which has facilitated assembly and annotation, so currently, Pleuronectiformes are among the fish with most confident and wide genomic resources (Robledo et al., 2017).

The particular environmental characteristics of the sea-bottom, like the low light radiation and low temperature, needs from specific adaptations to enhance vision (green light), as well as enhancement of alternative sensory systems, such as the olfactory system, as it has been hypothesized (Figueras et al., 2016). The early development of olfactory organs in fish underscores the essential role of the sense of smell in their interactions with conspecifics and the environment. In order to investigate the evolutionary history of the genes related to olfaction and better understand the evolution of the olfactory system in this group, we performed a comparative genomics study on some relevant flatfish species with chromosome-level assembly and well-annotated genomes pertaining to 5 different families: *Solea senegalensis* (Soleidae), *Hippoglossus hippoglossus*, *Reinhardtius hippoglossoides*, *Verasper variegatus* (Pleuronectidae), *Scophthalmus maximus* (Scophthalmidae), and *Cynoglossus semilaevis* (Cynoglossidae) using two bilateral and pelagic related teleosts as outgroups: *Oryzias latipes* and *Danio rerio*. We aim at identifying contractions or expansions in olfaction-related genes that could be eventually associated to specific evolutionary pressures, thus providing new insights into the role of olfaction in the adaptation these unique fish in their habitats. Additionally, our analyses have focused specifically on the Senegalese sole, an emerging aquaculture species in Europe that still faces challenges in captive reproduction, where chemical communication mediated by the olfactory system might be involved.

Material and Methods

The transcriptomes were downloaded from Ensembl. The longest protein for each gene was selected using a custom Python script. Orthology relationships were determined using OrthoFinder (Emms & Kelly, 2019). Phylogenetic relationships were represented using FigTree v1.4.4.

(Continued on next page)
Results
A total of 184,534 genes from the 8 species were grouped into 20,151 orthogroups, of which 7,074 are single-copy orthogroups, and therefore represent single-copy genes across the whole teleost phylogeny. The species tree placed zebrafish and medaka as sister branches out of the Pleuronectiformes cluster, consistent with the teleost phylogeny (Figure 1A). Further, grouping of families in the order was also consistent with previous reports. We did not observe a common evolutionary trend in olfaction-related genes in flatfish, suggesting species-specific adaptations of the olfactory system. Nevertheless, some expansions in genes related with sensory perception were detected. Particularly, the Senegalese sole showed a high number of genes in some orthogroups related to sensory perception through olfaction unlike the remaining species of the order (Figure 1B). Additional analyses are required to further investigate the evolutionary patterns of olfactory genes in flatfish and to better understand the species-specific adaptations of the olfactory system. Furthermore, the role of the olfactory system in reproduction, as an essential aquaculture trait, should be explored.

Introduction
Among other abiotic factors, water temperature is key for fish culture. Temperature changes during culture have a notable impact on multiple physiological processes in fish and other animals. Fish reared in ponds may have a more direct effect from water temperature change than fish reared in cages. Nevertheless, the cold temperatures during winter period affect fish performance in both production systems. Total production of gilthead seabream (*Sparus aurata*) in Europe and other Mediterranean countries in 2021 was estimated at 321,912 tonnes (APROMAR 2022 report), a 12.6% higher that reported in 2020. The main production method in Europe is cage culture. There are numerous reports and articles documenting multiple pathological effects of the low culture temperatures on the fish health during winter, i.e. malfunctions of digestive system, metabolism depression and plasma biochemistry changes (Ibarz et al., 2010). In order to counteract these effects, different nutritional strategies could be applied to help maintaining fish health, growth and survival, including the use of certain nutrients such as phospholipids (PLs) (Teodosio et al., 2021). PLs have been successfully used to improve the growth, survival, reduction of skeletal deformities and increase stress resistance in farmed fish (Kokou et al, 2021). Being a structural component of cell membranes, PLs (and cholesterol) are directly related to membrane fluidity. From the different PL molecules, phosphatidylcholine (PC) is the most abundant phospholipid class in the soy and legume products. PC is the type of PL mostly included in fish feed formulations. However, PL from marine origin (algae oils) are nowadays being evaluated as marine dietary PL source. The aim of this study was to investigate the inclusion of marine origin PL and terrestrial origin PL by the incorporation of i) an algae oil (Marine diet), replacing 91% of the fish oil and ii) soy lecithin (Terrestrial diet), without substitution of fish oil, against a Control diet without PL supplementation, in grow out diets for gilthead seabream cultured at low temperatures and close to the commercial size.

Material and Methods
A total of 162 fish with an initial weight of 277.85 ± 3.03 g were cultured at a stocking density of 12.5 km/m² (18 fish per 400-liter tanks) and a temperature of 16.0 ± 1.3°C, simulating winter conditions, in a recirculation aquatic system (RAS) at the facilities of Testing Blue S.L. (Puerto Real, Cádiz). Three formulated diets (Table 1) were evaluated by triplicate tanks. Diets were isoproteic (45% protein) and isolipidic (18% lipid). The fish were hand-fed twice a day, six days per week, until apparent satiation, during a 60 days feeding trial. Growth, daily feed intake, feed conversion ratio and condition index were evaluated. At the end of assay period, plasma and bile samples were taken for biochemical analysis (nutritional metabolites, total bile acids, osmolality). In addition, tissue samples were obtained for the calculation of somatic indices and histological study of the intestinal epithelium (foregut, midgut and hindgut). Transepithelial electrical resistance of the epithelium in the foregut was evaluated by *ex vivo* electrophysiological techniques (Ussing chamber), as well as the possible improvement in the electrogenic transport of amino acids in the midgut of fish fed with the different diets.

Results and Discussion
No significant differences were found among fish groups for biometric, somatic indices and plasmatic cholesterol, triglycerides and lactate. However, differences were observed in total bile acids (TBA) values in plasma of fish fed with the Marine and Terrestrial diet, but not with respect to the fish fed the Control diet. Regarding bile analysis, no significant differences were found among fish groups for production (µl/g fish), osmolality and TBA values. Bile cholesterol values of fish fed with Marine diet were statistically higher \((p=0.006)\) than those showed for fish fed with Terrestrial diet, but not differences were observed with respect to Control group. The histopathological study of the liver did not indicate any alteration or difference between groups. Likewise, no differences were detected in the histological evaluation of the foregut, midgut and hindgut of the fish fed with the different diets. Regarding the electrophysiological results, significant differences were observed in the epithelium intestinal resistance values between Control and Terrestrial group \((p=0.004)\).

Only fish fed with Marine and Control diets showed electrical resistance values higher (200 and 160 Ω.cm², respectively) than usual for healthy gilthead seabream (120 Ω.cm²) (Fuentes et al., 2006). Therefore, these results suggest that the replacement of fish oil with algae oil could have positive effects on gilthead bream cultured at low temperatures.

Introduction
Aquaculture is a productive area in continuous growth, where the constant search of new potential cultured species is a key factor for its industry development. Thus, inside the genus Seriola that include 12 species, the greater amberjack (Seriola dumerili) is considered the one of the species with the highest potential for aquaculture (Corriero et al., 2021). However, actually, there are many biological and zootechnical aspect to optimize for its industry expansion. Among this factor, the study of stress in fish has significantly increased in the last years, mainly due to its close connection to animal welfare. Based in the growing researches aimed to the use of dietary additives in fish stress mitigation (Herrera et al., 2019), the purpose of this study was to evaluate the effects of the inclusion of a relaxing additive (RELAQUAX) provided by BEDSON S.A. (Málaga, Spain) in the daily aquafeeds about the growth performance, metabolism and welfare of Seriola dumerili cultured to a medium stocking density, established in a previous trial, and later subjected to a thermal challenge under RAS conditions.

Material and Methods
Greater amberjacks were obtained from natural spawning at the ECOAQUA Institute from University of Las Palmas de Gran Canaria (Canary Islands, Spain) and transferred to CTAQUA facilities (Cádiz, Spain). Then, a total of 540 individuals (~144 g) were distributed in a RAS system with 9 tanks of 400 L (60 fish per tank), which constituted the 3 experimental groups (in triplicate). Fish were fed three daily times, until visual apparent satiety, with i) standard aquafeed without experimental additive (Control diet), ii) standard diet with 1 g of RELAQUAX/kg aquafeed (D1), iii) standard diet with 2 g of RELAQUAX/kg aquafeed (D2) during 69 days under control cultured conditions (22 ºC, O2 saturation, 12L:12D). After this period, fish were maintained with the same diets for an additional period of 21 days more at 14 ºC water temperature, simulating winter Mediterranean conditions. After both feeding/thermal trials, a biometric sampling was done, and samples from plasma, liver, muscle and water from each experimental tank were taken. Somatic and zootechnical indices were also calculated.

Results and Discussion
For both assays periods, 69d at 22ºC (pre-challenge) and 21d at 14ºC (challenge), no significant differences were observed in the growth parameters, somatic and zootechnical indices of fish regarding the experimental diets ingested. However, similar to results showed in Fernández-Montero et al. (2018), significant differences were observed in Specific Growth Rate (SGR) and Feed Intake between the fish fed with the same diets during pre- and thermal challenge periods (Table 1), with worse SGR values in fish cultured at low water temperature. Even so, an improved Feed Conversion Ratio (FCR) at lower temperatures was more evident in fish fed with the D1 diet during thermal challenge compared with those fish fed D1 during pre-challenge period. These results would be indicative that a dietary inclusion of the experimental additive to 1 g/kg doses could help to maintain, or even improve, the FCR in fish cultured under low temperature for short time periods.

(Continued on next page)
In terms of somatic indices, the Hepatosomatic Index (HSI) showed significant differences attending only to cultured temperature, with an increase in liver weight in those fish groups subjected to thermal challenge, in line with a liver lipidic accumulation from muscle and perivisceral fat for attending an increased energy demand caused by the adaptation to thermal changes, in agreement with Ibarz et al. (2007). Regarding to intermediary metabolism, the results denoted the absence of negative effects of the dietary inclusion of the experimental relaxing additive in the energy mobilisation which can be invested in growth performance. Attending to temperature effects, a thermal drop caused a metabolism orchestration characterized for a decline in plasmatic levels of triglycerides and glucose, while lactate levels increased in plasma and liver. In contrast, muscle lactate levels decreased concomitantly with increased glycogen levels. This could suggest an increased metabolic recirculation, through the Cori’s cycle, in response to thermal stress produced by low culture temperature. Curiously, cortisol analysis did not show significant differences attending to diet supplementation, existing a direct correlation between circulant cortisol levels in plasma and those detected in the water collected from experimental tanks (Figure 1).

The analysis of the combination of results obtained in the present study seem to indicate that a dietary inclusion of the experimental additive tested have not detrimental effects in growth, health and welfare of fish species with high growth potential, as S. dumerili. However, it is considered important to carry out further assays that complement the results presented herein with this and others cultured species.

Table 1. Effect of supplemented diets and rearing temperature on growth performance and feed utilization of S. dumerili. Asterisk (*) within a row denote significant differences (p < .05) between fish fed same diets in pre-challenge (69 d to 22 °C) and challenge (21 d to 14 °C) periods.

Figure 1. Cortisol levels in plasma (A) and water (B) of S. dumerili fed with supplemented diets and submitted to different water temperatures. Asterisk (*) over the box denote significant differences (p < .05) between fish fed same diets in pre-challenge (69 d to 22 °C) and challenge (21 d to 14 °C) periods.

In terms of somatic indices, the Hepatosomatic Index (HSI) showed significant differences attending only to cultured temperature, with an increase in liver weight in those fish groups subjected to thermal challenge, in line with a liver lipidic accumulation from muscle and perivisceral fat for attending an increased energy demand caused by the adaptation to thermal changes, in agreement with Ibarz et al. (2007). Regarding to intermediary metabolism, the results denoted the absence of negative effects of the dietary inclusion of the experimental relaxing additive in the energy mobilisation which can be invested in growth performance. Attending to temperature effects, a thermal drop caused a metabolism orchestration characterized for a decline in plasmatic levels of triglycerides and glucose, while lactate levels increased in plasma and liver. In contrast, muscle lactate levels decreased concomitantly with increased glycogen levels. This could suggest an increased metabolic recirculation, through the Cori’s cycle, in response to thermal stress produced by low culture temperature. Curiously, cortisol analysis did not show significant differences attending to diet supplementation, existing a direct correlation between circulant cortisol levels in plasma and those detected in the water collected from experimental tanks (Figure 1).

The analysis of the combination of results obtained in the present study seem to indicate that a dietary inclusion of the experimental additive tested have not detrimental effects in growth, health and welfare of fish species with high growth potential, as S. dumerili. However, it is considered important to carry out further assays that complement the results presented herein with this and others cultured species.

Introduction

Vaccination is the most powerful and safe prophylactic method to avoid pathologies and outbreaks caused by microorganisms, but the administration of vaccines can generate an episode of stress and a transient lack of welfare (Khansari et al., 2018; Vargas et al., 2018). The aim of this work was, first to determine the welfare conditions of the fish during one of the welfare critical points in the production process, i.e., vaccination, and secondly, to determine the attenuation capacity of di stress, discomfort, or deleterious health effects, through two specific products based on carvacrol and thymol plant extracts, applied in the moments or phases just prior to the vaccine administration (Montero et al., 2003).

Material and methods

Sea bass, Dicentrarchus labrax of 9-11g body weight were stocked for 1 month in a RAS facility of CTAQUA (Cadiz) under stable conditions of 22ºC, 3.5% salinity, 12:12 photoperiod and 9 kg/m3 density. After that time fish were treated with 30 ppm of either two products obtained from carvacrol and thymol extracts, or not treated for 10 minutes and then a subgroup of either treatment groups were vaccinated with a commercial vaccine ICHTHYOVAC VR/PD from Hipra (Spain). After vaccination fish were sampled at 1 hour, 24 hours and 21 days and the following samples were obtained: Plasma, mucus, brain, head kidney, liver, skin, gills, intestine, and spleen. The physiological response was measured at plasma (cortisol, glucose, and lactate) and the levels of cortisol were also measured in the skin mucus. The genomic stress response was measured by gene expression of selected stress genes (glucocorticoid receptor, corticotropin releasing hormone, heat shock protein 70) in different tissues, and particularly in the mucosal ones (skin, intestine and gills).

Results and discussion

Figure 1: Effect of plant extracts on the expression levels of the stress associated gene gr in two tissues: Skin and intestine compared to the basal expression of controls (horitzontal line)

Figure 2: Effect of plant extracts on the expression levels of the stress associated gene gr in two tissues: Skin and intestine compared to the basal expression of controls (horitzontal line)

(Continued on next page)
One of the products used in this work showed the most effective performance in terms of mitigating the stress effects of the vaccine. Thus, plasma cortisol showed less responsiveness after the E carvacrol-thymol plant extract treatment product. When cortisol was measured peripherally in the skin mucus the results showed the same trend, i.e., low cortisol levels with the same product (Figure 1), and the same for plasma glucose and lactate (results not shown).

In terms of gene expression, the E plant extract product also showed mitigating effects as not only levels were similar to the vaccinated controls, but the levels were even lower than the non-vaccinated controls (see figure 2).

Overall, the results show that carvacrol-thymol plant extracts are able to reduce the stress responsiveness of sea bass to the vaccination response, both at the gene and the hormonal and metabolic level. Further analysis looking at inflammatory cytokines such as Interleukin-1-beta also showed a lower degree of induction of such response (data not shown). As vaccination is one of the critical points of the production process in fish farms, the reduction of such responsiveness by these extracts involves positive effects, as less stress mediators such as stress hormones or proinflammatory cytokines will diminish the risk of imbalances and will help to overcome the critical but unavoidable stress episodes such as vaccination.

Introduction
Gilthead sea bream (Sparus aurata) is a teleost fish found in the Mediterranean Sea. It is economically important and natural stocks are subject to intensive exploitation. However, intensification of its production has been accompanied by an increased occurrence of parasitic diseases (Sitjà-Bobadilla, 2004). Sparicotyle (syn. Microcotyle) chrysophrii is one of the most pathogenic ectoparasites for the seabream aquaculture and research efforts are focused on identification of therapeutic and preventive agents. The use of medicinal plants as aquafeed supplements provide a sustainable way of fish protection in a cost effective way. Several studies have proved that medicinal plants have extensive antimicrobial, immunostimulant, antioxidant, anti-stress, and growth-promoting properties including thymus essential oil extracts. Aim of the present study was the assessment of Thymus vulgaris feed supplementation effects on sea bream (Sparus aurata) and the fish immune responses in natural Sparicotyle chrysophrii infection.

Materials and methods
Two experimental diets containing different amounts of Thymus vulgaris (T) essential oil extract (0.25% T and 0.50% T) and a positive control diet were used. The feeding trial was continued over a period of two months. At the end of the feeding trial macroscopic examination of fish gills revealed a natural infection with Sparicotyle chrysophrii parasite in 0.50% T tanks. Fish were collected from each tank, their mucus was isolated, weight and length were measured, and blood was drawn by the caudal vein. All gills were examined by microscopy. Head-kidney, spleen, liver and gill tissues were removed aseptically and stored at – 80 °C. All animal handling and sampling procedures were conducted in accordance with Greek and EU laws and regulations.

To assess the S. chrysophrii infection effects on sea bream fed with 0.50% T experimental diet, mucus and plasma samples were used for biochemistry and immunological parameters assessment, according to well established protocols. Non-specific immune parameters (i.e. nitric oxide, lysozyme, myeloperoxidase, complement C3, proteases and anti-proteases), antibody responses (total antibodies, immunoglobulin M, anti-microcotyle and anti-T.maritimum antibodies), oxidative stress (CYP1A1, metallothionine (MTT)) and metabolism markers (glucose, alkaline phosphatase (ALP) were determined. Total RNA was extracted from fish spleen, head-kidney, liver and gills, and real-time PCR assays were carried out to analyze the expression levels of genes related to antioxidants (SOD1, GPx1), cytokines (Il-10, TGFb1, Il-1b, TNFa), antibacterial peptide (Hepcidin) and heat shock protein (GRP75).

Results and Discussion
The 0.50% T diet had no effects on fish weight, length and splenosomatic indexes compared to the control group. The total protein amount, the nitric oxide levels, and C3 in serum was stable, however serum lysozyme was significantly lower as well as mucus total protein and nitric oxide in fish fed with 0.50% T diet. Cytochrome 1A1 was significantly lower in experimental diet but metallothionine, glucose, and alkaline phosphatase were stable. All tested genes expression was unaffected by the experimental diets.

(Continued on next page)
The *S. chrysophrii* infection had no effects on fish weight, length and splenosomatic indexes on 0.50% T diet group. The total protein amount in serum was stable, however the mucus total protein was significantly lower in the infected fish. Glucose and alkaline phosphatase levels weren’t significantly altered by the infection both in serum and mucus. Non-specific immune responses were assessed in fish serum and plasma by measuring the levels of nitrite ions, lysozyme, complement C3, myeloperoxidase, as well as protease and anti-protease activities. No significant differences were found in serum nitric oxide, lysozyme and C3 levels; however, mucus nitric oxide levels were slightly lower in infected group. The myeloperoxidase levels were also not altered by the experimental diets. The remaining parameters (proteases and anti-proteases activities) were not affected by any of the experimental diets. The total antibody levels remained stably low, however the IgM levels appeared to be lower in the infected group. Both cytochrome 1A1 and metallothionine had a decreasing trend without significant differences. Those results indicate a mild systemic immune response of sea bream to *S. chrysophrii* infection.

Gene expression profile was analyzed in four different organs to evaluate the modulation of immune-, oxidative stress- and metabolism-related genes in sea bream infected with *S. chrysophrii*. The studied genes in sea bream spleen were related to cytokines (IL-1β, IL10, TGFb1, and TNFa), oxidative stress (SOD-1 and GPx1) and metabolism (hepcidin and GRP-75). All analyzed genes were differentially expressed more intensively in head-kidney as expected at least for immune genes. Infection seems to suppress expression of all tested genes in all other organs, except IL-10 which remains stable at all tested organs. The suitability of *T. vulgaris* as efficient food supplement for immune status improvement was investigated and the results indicated that it could be used as dietary additive since it appears to have some potential as a natural immunostimulant. Serum and mucus tested parameters revealed that *S. chrysophrii* didn’t influence 0.50% T fed *S. aurata* non-specific immune and oxidative stress profile. Moreover, gene expression levels in spleen, liver and gills seem to be down-regulated by the infection, but slightly up-regulated in head-kidney. Overall, even though the experimental diets considered to be beneficial for fish immune system, natural infection with *S. chrysophrii* revealed poor immune responses in *T. vulgaris* fed sea bream.

GILTHEAD SEA BREAM SKIN MICROBIOTA SHAPES PROACTIVE AND REACTIVE BEHAVIOUR IN FISH UNDER HIGH STOCKING DENSITIES

S. Toxqui-Rodríguez1,2*, F. Naya-Català1, P.G. Holhorea1, J.A. Calduch-Giner1, A. Sitjà-Bobadilla2, M.C. Piazzon2, J. Pérez-Sánchez1

Introduction
The intensification of aquaculture production must deal with inadequate stocking densities that increase the risk of health issues and welfare status due to a variety of stressful conditions such as feed competition, aggressive interactions and reduced O2 availability. In gilthead sea bream facing changes in water O2 concentrations, mitochondrial bioenergetics of blood cells are finely adjusted at the transcriptional level (Martos-Sitcha et al., 2017). Likewise, different O2 status and rearing densities changes induce different tissue-specific expression patterns of genes related to energy metabolism and endocrine growth (liver > muscle > blood) (Martos-Sitcha et al., 2019). All this evidences the fish plasticity to cope changes in the environment, and several components of the Gh/Igf system have emerged as hypoxic imprinting genes during critical early life stages (Naya-Català et al., 2021a). There is now a large body of evidence linking changes in mucosal microbiota communities with fish health and welfare, affecting both local and systemic physiological functions (Naya-Català et al., 2021b). However, it remains to be unravelled how changes in mucosal microbiota composition are linked with changes in physiological traits and welfare indicators in a broad sense. Thus, this study aimed to assess how high-stocking densities in concurrence with reduced O2 availability affect host physiological traits, with focus on skin microbiota and associated shifts in other behavioural and welfare indicators, using a gathered biomarker approach.

Methods
Two-year-old gilthead seabream (450-500 g) were pit-tagged and distributed in 3,000 L tanks to achieve three different initial rearing densities (low, LD: 6 kg/m3; medium, MD: 12 kg/m3; high, HD: 22 kg/m3). Fish were fed close to satiety with a commercial diet from May to June (8 weeks) under natural photoperiod and temperature conditions. The concentration of dissolved O2 varied from 6-5 ppm in LD fish to 5-4 ppm and 4-3 ppm in MD and HD fish, respectively. At the end of the trial, 10 fish per group were randomly selected for the continuous and simultaneous recording of swimming activity and respiration rates over 48h, using implanted AEFishBit devices (Calduch-Giner et al., 2023). The same fish were used for assessing external damage using a scoring system from 1 to 5. Also, from the same fish, samples of skin mucus, blood, liver and white skeletal muscle were taken for microbiota, biochemical and transcriptional analyses. For skin microbiota profiling, the 16S rRNA v1-v9 regions were sequenced with the ONT MinION device and processed with an in-house pipeline. Muscle and liver gene expression was assessed by qPCR array layouts designed for the simultaneously gene expression profiling of two tissue-specific panels of 44 genes each.

Results
At the end of the trial, welfare scores of epidermal status varied among the three groups (P < 0.05), showing the worst status fish held at HD and gradually improving with the decrease in density. However, correlation analysis indicated that external damage appears associated with an active feeding behaviour. Concerning skin microbiota, discriminant analysis showed that the skin microbiome of the three different groups differed in bacterial abundance, and LEfSe analysis revealed six strong microbial markers for these experimental conditions, being the abundance of Alteromonas and Massilia largely increased in the HD group, though a closer look evidenced an opposite trend for these two discriminant taxa. At the transcriptional levels, five genes related to growth (igf1, igf2), lipid metabolism (cy7a1), and oxidative metabolism (cs, cox1) were positively correlated with a higher abundance of Alteromonas within the HD group. Otherwise, seven differentially regulated muscle genes related to growth (ghr1, ghr2, igf2), antioxidant defence (grp170, grp75), and energy metabolism (sirt1, hif1α) were positively correlated with a higher abundance of Massilia. This integrative behavioural, metagenomic and transcriptional approach supported stressful mediated responses that serve to alert and adapt the system in different ways. Hence, a higher abundance of Massilia was connected to a proactive behaviour with increased skin damage and locally regulated growth, while Alteromonas abundance and low cortisol levels appeared related to a reactive behaviour and systemic growth regulation via the liver Gh/Igf system.

(Continued on next page)
Concluding remarks
High-stocking densities had a significant impact on behavioural and physiological traits, that correlated with significant changes in the associated skin microbial population. This gathered biomarker approach served to infer and regulate new operational biomarkers for increased stress resilience in a context of global warming and intensive rearing conditions to cover the increased demand of sea food products.

NOVEL TREATMENT FROM NATURAL HERBAL SOURCES FOR FISH LICE (*Caligus* spp.) PARASITIC ON RABBITFISH (*Siganus guttatus*) CULTURED IN VIETNAM

Ha Nam Tran, Tran Quang Khanh Van, Truong Thi Hoa*

Hue University of Agriculture and Forestry
*Corresponding author: truongthihoa@huaf.edu.vn

The research was conducted to identify the infection level of fish-lice (*Caligus* spp) on Rabbitfish (*Siganus guttatus*) which cultures in Thua Thien Hue province, Vietnam, and to clarify the effect of extraction from Saudau (*Azadirachta indica*) plant on the fish lice. The total of rabbit fish that were used for experiments is 120 fish, and fish were collected in 6 months at two different sites. The extraction of the Saudau plant was collected from leaf, and seed and then concentrated for experiments at ppm (0; 10; 50; 100; 500; and 1000) to evaluate the effect of extraction on fish lice. The results showed that the infection rate of fish lice on rabbit fish is 62.5% and infection intensity averaged at 19.2 lice/fish. Based on the collection data, it was clearly shown that in January, February, and March, fish lice were found much more than in other months (p<0.05). After fish lice were treated with the extraction from leaf and seed for 30 hours, we found that the half effective concentration (EC$_{50}$), and 90% effective concentration (EC$_{90}$) of leaf extraction are 148ppm and 928ppm, respectively. The EC$_{50}$ and EC$_{90}$ of seed extraction are 62ppm and 397ppm, respectively. The results from our research frankly show the potential of using extraction from Saudau leaf and seed to treat the parasite disease caused by fish lice on Rabbitfish.
UNRAVELLING THE ROLE OF MITOCHONDRIAL DNA METHYLATION IN TEMPERATURE-DEPENDANT GROWTH OF NILE TILAPIA (*Oreochromis niloticus*) THROUGH NANOPORE SEQUENCING

Introduction

Thermal plasticity allows organisms to adapt to temperature changes through physiological, developmental, and behavioral responses. This adaptability is crucial for species survival, especially in the face of global warming. In fish, temperature fluctuations in early developmental stages can alter metabolic rate, induce stress, and potentially cause long-lasting developmental anomalies, all of which impact their overall growth, feeding performance, and energy allocation. Mitochondria as cell organelles play a crucial role in generating ATP, which is vital for cellular growth, and its structure and function are affected by temperature (Chung and Schulte, 2020). DNA methylation, is an epigenetic mechanism that modifies gene expression and aids organisms in adapting to temperature fluctuations, impacting growth (Campos et al., 2013). Hence, we hypothesize that fluctuations in temperature may influence the mitoepigenome, subsequently impacting growth. Our prior studies on Nile tilapia (*Oreochromis niloticus*) mtDNA based on bisulfite sequencing identified cytosine methylation (5mC) in a non-CpG context (Nedoluzhko et al., 2021). However, methods like Illumina short reads and bisulfite sequencing are limited to analyzing methylation in 5mC context. Nanopore sequencing offers the advantage of directly detecting additional DNA modifications such as 5hmC and 6mA without the need of chemical or enzymatic treatments. Hence, the aim of the present study was to investigate how thermal plasticity is linked to mitoepigenome changes and growth using Nile tilapia as model, and utilizing nanopore sequencing as the methodological approach.

Materials and methods

Nile tilapia embryos were incubated at three temperatures (24 °C, 28 °C, 32 °C) in triplicate groups. At the opercular stage they were transferred to a common temperature of 28 °C and fed with a commercial diet. After 45 days post fertilization, nine males from each temperature group were randomly selected and fast muscle was carefully dissected. Genomic DNA was isolated and used for construction of PCR-free DNA libraries using SQK-NBD114 kit (ONT, UK). The libraries were sequenced on the Nanopore MinION Mk1C with adaptive sampling. The resultant pod5 files for each sample were used for basecalling and mapping in dorado (v0.3.4, ONT) for 5mC, 5hmC and 6mA. The bam files were used for methylation calling and analysis with modkit (v0.1.13, ONT) and methylKit (v1.26.0; Akalin et al., 2012), respectively. The experimental set-up and workflow are shown in Fig. 1.

(Continued on next page)
Results
The average reads per sample, percent of reads mapped to mtDNA and coverage were 349715, 83% and 419×, respectively. The mitogenome exhibited minimal methylation, and notably, the methylation occurred in non-CpG context. In 5mC context, methylation levels in the mitochondrial H-strand increased from 24 °C (1.2%) to 28 °C (1.9%), then slightly decreased at 32 °C (1.8%). The L-strand showed a rise in 5mC levels from 24 °C (1.1%), 28 °C (1.5%) to 32 °C (1.9%). Regarding the 5hmC context, methylation on the H-strand peaked at 28 °C (5.3%), while the L-strand had its highest at 24 °C (2.6%). In the 6mA context, the H-strand’s methylation decreased from 24 °C (6.8%) to 32 °C (4.9%), whereas the L-strand steadily decreased from 24 °C (1.2%) to 32 °C (0.9%). In both 5mC and 5hmC contexts, the L-strand exhibited higher methylation than the H-strand across all groups. However, in 6mA context, the H-strand had more methylation than the L-strand. Fish mitogenomes at 24 °C were hypermethylated in all contexts (5mC, 5hmC, 6mA) compared to those at 28 °C and 32 °C.

Conclusion
In conclusion, the results indicate that the mtDNA methylation patterns in Nile tilapia was influenced by embryonic incubation temperature. While the L-strand consistently showed higher methylation levels for both 5mC and 5hmC, the H-strand dominated for 6mA. Notably, Nile tilapia mitogenomes were hypermethylated at 24 °C across all examined DNA modifications as compared to the ones at 28 °C and 32 °C. This highlights the intricate relationship between temperature and mtDNA methylation in fast muscle of Nile tilapia. Methylation data generated from nanopore long-read sequencing will constitute a valuable resource for future research on the mitoepigenome related to muscle growth, metabolism and thermal plasticity in farmed fishes.

ASSESSING BAY-SCALE EFFECTS OF AQUACULTURE OPERATIONS ON THE DISTRIBUTION OF PELAGIC FISHES AND PREDATORS

M. Trudel

Fisheries and Oceans Canada
St. Andrews Biological Station
125 Marine Science Drive
St. Andrews, New Brunswick, E5B 0E4, Canada
E-Mail: marc.trudel@dfo-mpo.gc.ca

The aquaculture industry has grown rapidly in Canada during the last three decades, and represents a significant source of employment and revenue for coastal communities. However, this development has altered both the physical and biological attributes of aquatic ecosystems at multiple scales and could displace vulnerable species that utilize these areas as critical habitats. As the aquaculture industry is expected to expand further, there is an increasing need to better understand bay-scale impacts of aquaculture on ecosystem functions and services before aquaculture sites expand into new areas. The objectives of this project are to assess long-term and bay-scale impacts of aquaculture operations on the distribution and abundance of pelagic fishes and other large predators in coastal marine ecosystems. Four complementary approaches are used to determine their distribution and abundance of pelagic fishes and large predators in three separate Bay Management Areas (BMAs) in Southwest New Brunswick and a reference area: 1) stationary hydroacoustic devices, 2) acoustic receivers, 3) water environmental DNA, and 4) high resolution thermal imaging drones. A summary of the key results of the project will be presented and discussed.
MODELLING THE DISPERSION OF THE INFECTIOUS SALMON ANEMIA VIRUS (ISA V) FROM ATLANTIC SALMON FARMS IN THE QUODDY REGIONS OF NEW BRUNSWICK, CANADA, AND MAINE, USA

F. Ding, N. Gagné, D. Ditelecadet, B.K. Quinn, and M. Trudel

Fisheries and Oceans Canada

Outbreaks of disease caused by the infectious salmon anemia virus (ISA V) are an important threat to Atlantic salmon aquaculture production. Pathogen dispersal from an infected farm into the surrounding ocean poses further risks of infection to wild fish and other farms but is difficult to predict. This study aimed to build a framework using ocean circulation and particle tracking models in conjunction with a dynamic infection model and virus inactivation model to simulate the waterborne dispersal of ISA V from Atlantic salmon farms in the Quoddy Region (QR, New Brunswick, Canada and Maine, USA). Using a particle tracking method, simulated particles were released from hypothetically infected farms at rates estimated by a dynamic infection model, and were then advected by modelled currents. Inactivation of viral cohorts by ambient ultraviolet (UV) radiation and natural microbial communities was simulated during advection. Simulations were conducted on thirteen farms in the QR area to demonstrate this modelling system. Maps showing hypothetical spatiotemporal changes of viral concentrations in ambient water were produced for farms under simulated worst-case scenario outbreaks. The advection distances of infectious particles were calculated. A farm connectivity matrix in terms of viral infection was produced, with mutual and asymmetrical connectivity patterns identified between farms. Factors that impact the simulation of viral shedding and inactivation, hydrodynamic effects on dispersal, model application to aquaculture management, and future development were discussed. This framework provides an approach and opportunities to simulate waterborne viral transmission by considering the biology and epidemic features of significance for pathogens and dynamic ocean conditions.
Introduction

Accurate biomass estimation serves as a cornerstone for effective fish farm management, enabling optimized feeding strategies, health assessment, disease control, and resource allocation. By precisely quantifying the total mass and average weight of fish within a farming system, farmers can make informed decisions that promote efficient production and minimize environmental impacts. Given the labour intensiveness of counting, weighing, and sorting fish manually computer vision solutions are on the rise. By applying artificial intelligence algorithms, this technology empowers fish farmers with real-time, data-driven insights into their fish batches.

While hardware costs and computing power have been reduced in many applications, they are still the limiting factor in biomass estimation due to the three-dimensional information necessary. Elaborate methods such as 3D-image synthesis, stereo-vision cameras or special sonar systems are technologically high-end solutions best suited for intensive industrial farms. For a wide-spread application of AI-based biomass estimation in the aquaculture industry a more technically and financially feasible solution is needed.

Animal Welfare Assessment and Control System

Urban Blue offers a software solution which enables land-based aquaculture farms to monitor key farm aspects and manage, analyse, and visualize this data to enable a better system operation. The Urban Blue system is a combination of a computer-based platform, hardware sensors and a mobile phone app allowing to assess the system (pumps, tanks, valves) and manage the operational workflow (task, routines, lists).

Together with the Zurich University of Applied Science Urban Blue has launched the Innosuisse innovation project AWACS (Animal Welfare Assessment and Control System for fish farms) in order to develop an automated assessment of fish-based parameters. The goal is to provide the aquaculture industry with a comprehensive solution allowing fish-farms to constantly monitor, automatically assess and visually analyse fish health and welfare. As part of this project a biomass model was develop using computer-vision and regression models to calculate the weight of a fish based on a lateral picture (Fig. 1) (Aftab et al. 2023).

Figure 1: Biomass model using computer-vision algorithms to define the fish species and calculate the body weight from a lateral picture.
Biomass modelling in a 3D-environment

This model was further developed to calculate the body weights from single frames extracted from videos from underwater cameras. In order to maintain the simplicity of the model, which later ensures applicability, the information about the third dimension was calculated from the camera’s focal length. By increasing the aperture of the camera, the depth of field decreases, leaving any object in front or behind a given distance blurry (Fig. 2). Object detection enables the computer to find fish in the frame and define their blur value excluding fish that are not within the focus area, leaving only fish with a known horizontal distance from the camera lens (Alphonse & Sriharsha 2021) with increase in concern about public safety and security, human movements or action sequences are highly valued when dealing with suspicious and criminal activities. In order to estimate the position and orientation related to human movements, depth information is needed. This is obtained by fusing data obtained from multiple cameras at different viewpoints. In practice, whenever occlusion occurs in a surveillance environment, there may be a pixel-to-pixel correspondence between two images captured from two cameras and, as a result, depth information may not be accurate. Moreover, use of more than one camera exclusively adds burden to the surveillance infrastructure. In this study, we present a mathematical model for acquiring object depth information using single camera by capturing the in-focused portion of an object from a single image. When camera is in-focus, with the reference to camera lens center, for a fixed focal length for each aperture setting, the object distance is varied. For each aperture reading, for the corresponding distance, the object distance (or depth).

Data reduction increase data quality and ensures simplicity

The concept of detecting and excluding objects with high blur values allows to screen the videos and to select only those frames where a fully visible fish with a low blur value is detected (Fig. 3). By consequence these fish are in a known distance from the camera, allowing to apply the previously develop biomass model where length and height of the fish are used to estimate their body weight.

The reduction of data from a fully day-long video with 30 fps/sec to a subsample of several hundred high-quality single frames with fish suitable for the biomass model considerably increases the quality of the biomass estimation and drastically reduces the computing power and digital storage necessary. Further, the concept reduces the costs and handling of the hardware.

Introduction
Zinc (Zn) is a vital micromineral crucial for various biological functions and metabolic processes in fish (Lall and Kaushik, 2021). Zn is an integral component of copper-zinc superoxide dismutase (CuZnSOD), an antioxidant enzyme that defends against free radicals. Zn has a significant role in the bone metabolism and maintaining the normal bone homeostasis in fish (Nguyen et al., 2008). Additionally, Zn is a cofactor for alkaline phosphatase, an enzyme involved in this process for promoting mineralization (Yamaguchi 2010). The use of plant-based ingredients in fish feed to reduce fish meal has become common in aquaculture, but it can lead to Zn deficiencies due to lower Zn content in plant-based ingredients (NRC, 2011). Additionally, the presence of anti-nutritional factors in plant-based ingredients can reduced the absorption of minerals in fish (Kumar et al., 2012). This may cause Zn deficiency to fish, leading to reduced growth, short body dwarfism, cataracts, oxidative stress, poor mineralization, an increased incidence of skeletal anomalies, and increased mortality in fish (Izquierdo et al., 2017; Lall and Kaushik, 2021). On the other hand, excessive Zn can cause toxicity to fish, reducing the capacity of antioxidant defenses, increasing oxidative damage, and competing with other minerals such as Fe, Mg, Mn, Ca, P (Huang et al., 2018). The present study aims to assess the impact of different Zn levels in plant-based diets on growth, bone health, and antioxidant status in gilthead seabream juveniles.

Materials and methods
Six plant-based experimental diets containing low levels of fish meal (FM, 10%), and fish oil (FO, 6%), were formulated with six different levels of Zn. A diet without supplied Zn was used as control (contained: 46 mg Zn/kg). Other five diets were supplemented with Zn sulfate heptahydrate (ZnSO₄·7H₂O), containing 50, 56, 63, 71, and 89 mg Zn/kg. A total of 378 initial fish (body weight: 72.67 ± 0.08 g, total length: 16.37 ± 0.02 cm) virtually selected without anomalies, were randomly distributed into 18 tanks (170 L/tank/21 fish). Fish were manually fed with approximately 2% of body weight in three times per day until apparent satiation, the experiment period was 101 days. Fish body weight and total length were measured every 2 weeks. At the end of trial, fish were collected for determining growth performance, liver TBARS values, vertebral column mineral analysis, skeletal anomalies and gene expression.

Results and Discussion
After 101 days of feeding, gilthead seabream juveniles fed diets with different levels of Zn (46, 50, 56, 63, 71, 89 mg/kg) presented no statistically significant (P>0.05) differences for growth performances and no mortalities were recorded (Table 1). While, dietary Zn level for increase growth defer vary with fish species and developmental stages, such as early stage of gilthead seabream require higher dietary Zn levels for optimal growth (Tseng et al., submitted) Liver TBARS value showed significantly lowest (P<0.05) in fish fed with non-supplemented diet (46 mg Zn/kg) and increased in fish fed with the elevation of dietary Zn levels (Figure 1), indicating an increased risk of lipid peroxidation. Whereas vertebral mineral composition (Zn, Se, Mn, Cu, Fe, Ca, P and Ca/P ratio) was not significantly (P>0.05) affected in all treatments. In fact, vertebral Zn content was maintained at plateau levels between 44.33 to 47.67 mg Zn/kg. Except the cobalt content was significantly highest in fish fed with dietary Zn level at 46 mg/kg, and reduced as the dietary Zn levels increased. In term of bone health, fish fed with non-supplemented diet (46 mg Zn/kg) showed the lowest incidence of total skeletal anomalies although no significantly differences was determined among the groups. Interestingly, fish fed with non-supplemented diet (46 mg Zn/kg) showed a significantly (P<0.05) highest on expression of vertebrae which was reduced with increasing dietary Zn levels. A similar tendency was also found in other bone-related gene including bmp2, on, alp expression. Similar findings were observed in gilthead seabream larvae fed with optimum dietary Zn levels (Tseng et al., Submitted)

(Continued on next page)
Conclusion
Gilthead seabream juveniles growth and survival was not affected by dietary Zn levels from 46 to 89 mg/kg. Fish fed with a non-supplemented diet (46 mg Zn/kg) showed reduced lipid peroxidation, increased vertebral cobalt content, up-regulated bone biomarker and antioxidant gene expression, alongside fewer skeletal anomalies. Conversely, those fed with Zn-supplemented diets led to increased lipid peroxidation, reduced vertebral cobalt content, lower bone biomarker and antioxidant gene expression, and more skeletal anomalies. Vertebral Zn content maintained at plateau level (44.33 to 47.67 mg Zn/kg) and along with the results, suggesting a Zn dietary level at 46 mg/kg would be sufficient to cover the requirements in seabream juveniles when fed with practical plant-based diets.

Introduction
Selective breeding is commonly accepted to be the foremost approach to drastically amplify the aquaculture production and the quality of aquaculture products. Meagre (*Argyrosomus regius*) is a fast-growing sciaenid species which recently presents a rising interest to the Mediterranean aquaculture diversification and industry sustainability. However, the study of genetic parameters on economically important traits in meagre is nowadays limited and the aim of the current work is to identify genetic markers associated with body weight and phenotypic traits at different growth timepoints.

Materials and Methods
We used juveniles originating from a hormone-induced spawning event of thirteen broodstock, reared together to 297 Days Post Hatching (DPH) until grading was performed and small- and big-sized fish were transferred to different cages. At 394 DPH, 600 fish from each cage were randomly selected, individually tagged with a Passive Integrated Transporter, fin-clipped and transferred into a single cage. Weight was measured on all the surviving offspring at 394 DPH (BW1), 770 DPH (BW2) and 978 DPH (BW3). Additionally, length was measured on all surviving offspring at 770 and 978 DPH (Len2 and Len3, respectively), and last deformities were recorded.

Fin clips sampled from all broodstock and offspring fish were used for DNA extraction and library preparation for double-digest random amplified DNA sequencing (ddRAD-seq) using enzymes *Sbf*I and *Nla*III (Nousias *et al.* 2022). Four libraries were prepared and sequenced on Illumina NovaSeq PE150 aiming at 400-500 G raw data per library. Genomic information was filtered using plink (SNP call rate>80% MAF>1%, HWE<10\(^{-6}\)). After quality control, 4650 SNPs remained and used to perform the parentage assignment using the Apparent software (Melo & Hale, 2019) in R. Then, heritability of each body weight using the restricted estimation of maximum likelihood method (REML) was performed and a univariate animal model was used in AIREMLF90, which is illustrated by the formula,

\[ Y = \mu + Zu + e \]

where \( Y \) corresponds to the vector of the phenotype, \( \mu \) is the mean, \( Z \) is the incidence matrix, \( e \) is the residual, \( u \) is the additive genetic effect using the Genomic Relationship Matrix (GRM) and it is described as \( \sim N(0, G \sigma_a^2) \) (\( G \) is the GRM and \( \sigma_a^2 \) is the additive variance).

Furthermore, a Genome Wide Association analysis was performed for the body weight using GEMMA, which is illustrated by the following linear model,

\[ Y = W \gamma + Z \upsilon + e \]

Where additionally, \( \gamma \) is the vector of SNPs, \( W \) is the regression coefficient of the SNP effect, and \( Z \) is the corresponding design matrix. The thresholds of significance of the \( p \)-values after Bonferroni correction were 4.69 for the 0.05 and 4.66 for the 0.1. The proportion of phenotypic variance (PVE) explained by the statistically significant SNP was calculated as described in Shim *et al.* (2015).

*(Continued on next page)*
Results & Discussion

Based on a strict parentage assignment, 93% of the fish were identified belonging to 23 families. The number of offspring ranged from 1 to 251 per family while per parent was 2 to 376. The average number of markers per chromosome was 194 SNPs (range from 121 to 242).

A high genomic heritability (0.53 (0.06)) of the body weight was estimated only for the early stage (BW1). Additionally, a QTL was detected in chromosome 8 (Papadogiannis et al., 2022) which explains approximately 2.01% of the phenotypic variation. Even though the QTL has a minor effect, it is notable that there is an increasing trailing of the p-value of SNPs in this chromosome when only 214 SNPs appeared.

Interestingly, GWAS for body-weight and length at later stages did not show significant association with any marker. Last, GWAS for the pughead deformity, a rare skeletal anomaly, detected a QTL in chromosome 13.

Introduction
Marine fish farming holds great significance in Mediterranean aquaculture, and it is primarily carried out in open seas, subject to varying environmental conditions and the risks of infection by parasites and pathogens. To thrive under these challenging circumstances, the ultimate objectives are to ensure robustness and expedited growth. In the pursuit of these objectives, the use of bioactive compounds with immunostimulant and growth-enhancing properties is gaining recognition (1,2). However, identifying such compounds necessitates novel screening approaches to evaluate their effectiveness in achieving robust and rapidly growing marine fish populations, in the face of environmental oscillations and disease risks. In this study, the impact of bioactive compounds obtained from olive (Olea europea) and Spirulina platensis (Arthrospira) processing by-products on the growth hormone (GH) signaling pathway and myogenesis in gilthead sea bream (Sparus aurata) and European sea bass (Dicentrarchus labrax) juveniles was studied.

Materials and Methods
Fifteen experimental feeds were formulated with the addition of varying concentration of each bioactive compound in a standard feed formulation and were screened in vitro for the presence of antinutritional factors and the levels of dietary protein autohydrolysis and digestibility in each fish species. Based on the results in vitro, two feed per species were selected for a feeding trial. For each species three groups of fish in duplicate were fed with control feed (commercial) and two experimental feeds, Diet 1 (D1) and Diet 2 (D2). At the beginning and at the end of the trial, tissues (white muscle, liver) were collected from eight individuals per condition per species and immediately stored in RNAlater. Following that, RNA was extracted from tissues and cDNA synthesis was carried out. For the growth hormone signaling pathway, the expression levels of three genes were investigated in liver. Two of those genes were growth hormone receptors (ghrI and ghrII) which bind GH, and their levels are analogues to the ones of GH, while the third gene was the insulin like growth factor 1 (igf1), which is one of the outcomes of GH signaling to the liver and is involved in mediating growth and development. For myogenesis the expression levels of two genes mylpfa and mylpfb were determined in white muscle. The genes mylpfa and mylpfb are coding for white muscle myosin light chain 2 and are markers for different types of muscle growth (3). The gene mylpfb is a marker for hyperplasia, which is the recruitment of new muscle fibers, and it is the dominant isoform in early development of the fish, whereas mylpfa gene is a marker for hypertrophy, i.e the growth of already existing muscle fibers, the dominant form of muscle growth after fish development. Primers were designed for the genes of interest as well as two reference genes (per tissue - per species) and gene expression was measured using real-time PCR. A Wilcoxon signed-rank test was used to determine whether there were significant changes in the expression levels between the condition. At the p0.05 level, differences were considered significant.

Results and Discussion
No significant differences were observed in fish growth of D1 and D2 groups compared with the control group as indicated by fish weight and length in both species. A trend for heavier and more elongated fish was observed in seabream that were fed on the experimental feeds. On the contrary, a drop in weight and length of seabass fed with D2 was observed. Experimental feeds did not impact the GH signaling pathway in seabass. In seabream, ghrII expression was up regulated in both experimental diets compared with the control, whereas igf1 and ghrI expression was not affected by diet. Myogenesis molecular markers, mylpfa and mylpfb were downregulated in both D1 and D2 groups in seabass. In seabream, while no differences were identified in the expression levels of mylpfb, up regulation of mylpfa gene was observed in both experimental feeds compared with the control, with the differences being statistically significant.

(Continued on next page)
In conclusion, the bioactive compounds assessed in this study had no impact on seabass growth, yet they had a negative effect in myogenesis regulation. Then again in seabream both experimental diets appeared to elicit a response of the GH growth signaling pathway and they clearly affected myogenesis by promoting hypertrophic growth of white muscle. Furthermore, it is possible that clear differences in seabream growth (weight, length) were to be observed in the fish with the experimental diets, if the experiment had been prolonged. The study provided evidence of the possible beneficial properties of bioactive compounds of olive and spirulina in seabream growth, and underlined the differences in nutrient utilization and metabolism between seabream and seabass.

Introduction
The sustainability of marine fish farming in open seas is challenged by varying environmental conditions and disease risks. Fish robustness and accelerated growth are paramount and bioactive compounds with growth-enhancing properties are gaining increasing attention (1). This study investigates the effects of digested oligosaccharides derived from Spirulina’s processing on the growth hormone (GH) signaling pathway and myogenesis in gilthead sea bream (Sparus aurata) and European sea bass (Dicentrarchus labrax) juveniles. Origin and properties of oligosaccharides are known for their prebiotic like properties promoting growth, by improving intestinal morphology, increasing gut absorptive area, microvilli density and height, and villi structure complexity in sea bream (2). An effect was also seen in the antioxidant capacity of sea bass, indicating a positive effect on the reduction of hepatic reactive oxygen species production (3).

Materials and Methods
An experimental diet was formulated with the addition of 0.05% of digested oligosaccharides in the formulation of the control diet. The two diets were compared based on their in vitro properties; their digestibility of dietary protein was determined in vitro by pH-stat titration according to the method developed by Dimes & Haard (4). Protein digestibility of each feed was measured in the presence of a standard quantity of crude extract of digestive enzymes prepared by the pyloric caeca of either gilthead sea bream or European sea bass. Autohydrolysis rates of each feed were measured with crude enzyme extracts being replaced by distilled water. Enzymatic hydrolysis was calculated by subtracting autohydrolysis from protein digestibility. The presence of antinutrient factors was assessed by measuring Kunitz Trypsin Inhibitor (KTI) against trypsin activity and Bowman-Birk Inhibitor (BBI) against chymotrypsin activity (5). Two groups of European seabass and gilthead seabream were fed either control or experimental feed containing digested oligosaccharides. Tissues (white muscle and liver) were collected from eight individuals per condition per species at the beginning and end of the trial, stored in RNAlater and used for RNA extraction and cDNA synthesis. The expression levels of three genes (ghrI, ghrII, and igfI) in the liver, related to the growth hormone signaling pathway, were investigated. Additionally, the expression levels of mylpha (hypertrophy) and mylpfb (hyperplasia) genes, associated with myogenesis in white muscle, were analyzed. Real-time PCR was used with two reference genes per tissue per species. The Wilcoxon signed-rank test was used to identify significant changes in gene expression levels between conditions, with significance set at p < 0.05.

Results and Discussion
The in vitro digestibility assay revealed that, autohydrolysis, enzymatic hydrolysis and total dietary protein digestibility were higher in the experimental diet compared with the control. On the contrary, all examined markers (igfI, ghrI, and ghrII) in the liver, related to the growth hormone signaling pathway, were significantly upregulated in seabass fed on the experimental diet compared with the control. A higher hepatosomatic index (HSI) was observed in seabream fed on the experimental feed in the case of seabass. No response of the GH signaling pathway to the experimental diet was observed in seabream. On the contrary, all examined markers (igfI, ghrI, and ghrII) were significantly upregulated in seabass fed on the experimental diet compared with the control. In seabass, the expression levels of mylpha gene were significantly lower in the experimental diet compared with the control. In conclusion, the bioactive compound assessed in this study, had no impact on seabream at any level checked. Then again it seems that the active compound had a negative effect on the regulation of myogenesis in seabass. The combination of the GH pathway up regulation with the downregulation of myogenesis and a higher liver mass in seabass fed on the experimental feed, suggests that while the feed was ingested by the fish, there was a need for higher levels of digestive enzymes, probably caused by the elevated antinutritional factors of the active compound. The fact that even higher levels of BBI were tolerated by seabream, underlines the differences in nutrient uptake and metabolism between the two species.

Introduction
Fish and seafood waste ranges 30-50% and is attributed mainly to spoilage and quality deterioration during post-harvest handling, packaging, storage and transportation. Novel and efficient packaging solutions to improve food quality and shelf life and reduce food waste while not raising the amount of packaging waste is a significant challenge for improving the sustainability of food supply chains (Tsironi and Taoukis, 2018). At the same time, environmental sustainability plays a crucial role for the selection of appropriate packaging materials for food products (Ladakis et al., 2020). According to the EU Directive 2019/904 on the reduction of the impact of certain plastic products on the environment, food packaging materials will contain at least 25% and 30% recycled plastic from 2025 and 2030, respectively. Biodegradable polymers have been developed with the aim to increase the sustainability in the food packaging sector. Biopolymers have been considered promising materials for this purpose. The properties and overall performance of the developed materials depend on formulation and processing parameters. In active packaging, the traditional role of packaging is accompanied by the conservation role of antimicrobials, antioxidants, and other components (Oreopoulou and Tsironi, 2021). Novel processes, such as cold atmospheric plasma (CAP) can modify the barriers and enhance the protective effect of the packaging materials (Pankaj et al., 2014).

The objective of the study was to evaluate the applicability and environmental sustainability of conventional and alternative packaging materials for fish and seafood, considering their recyclability, biodegradability and preservative effect on packed products.

Materials and methods
The tested packaging materials were conventional or recycled polyethylene (PE) and polypropylene (PP), polylactic acid (PLA), cellulose, gelatine, chitosan and alternative combinations of biopolymers. CAP treatment was applied using an atmospheric pressure cold plasma jet (kINPen® IND, neoplas GmbH, Germany) supplied with argon at a flow rate of 4 L/min and a conical probe of 16 cm diameter for uniform plasma application onto the film surface. Gas (O₂) permeability and water vapor transmission rate (WVTR) were evaluated using standardized methods (ASTM F2622, ASTM E96/E96M). Wettability of the packaging materials was characterized based on the determination of the contact angle (Theta Flow Optical Tensiometer, Biolin Scientific). Fresh farmed fish fillets were packed using the different packaging films and stored isothermally at 2°C. Quality evaluation was based on microbial spoilage (enumeration of total viable count and Pseudomonas spp.) and sensory evaluation. Computational estimation of environmental impact, according to the Life Cycle Analysis (LCA) methodology using LCA GaBi software, was made.

Results
CAP modified OTR, WVTR and wettability of conventional and alternative polymers with the increase of treatment time. Appropriate processing conditions, resulting in better barriers and higher hydrophobicity, were selected for the materials used for fish packaging. Considering the limit of acceptability of 10⁷ cfu/g for total viable count (ICMSF, 1986) the shelf life of fish fillets at 2°C ranged 8-10 days. No significant differences were observed in the shelf-life of fish using the different packaging materials. Based on the results of the study, the maximum environmental benefit would be achieved by replacing conventional polymers with recycled materials and at the same time increasing their recycling rates. The partial or overall replacement of conventional polymers with edible or biodegradable materials proved as an effective to decrease environmental impact of fish packaging.

Discussion and conclusion
The application of novel processing methods and packaging materials offers a great potential for more environmentally friendly packaging systems resulting in lower emissions and sustainable fish and seafood products.

Introduction
During the last decade, joint efforts by the packaging and the food industries aimed to reduce the amount of petroleum-based polymers and food packaging waste. Biopolymers have been considered promising materials for this purpose. The properties of the developed materials depend mainly on formulation and processing parameters. Edible packaging systems may also be used as thin layers of materials to coat or wrap food products, aiming to extend their shelf life and reduce the required polymers for food preservation (Tsironi and Taoukis, 2018). The performance and preservative effect of several alternative food packaging materials is being investigated for a wide range of food applications. Novel processes, such as cold atmospheric plasma (CAP) can be used for the surface modification of polymers, with the aim to modify the polymer properties and create active materials with potential antimicrobial and/or antioxidant activity (Pankaj et al., 2014).

The aim of the present study was to evaluate the quality and safety aspects of alternative edible and non-edible packaging systems, considering their bioactivity, toxicity, and antiviral activity potential.

Materials and methods
We report the development and testing of alternative biopolymers, including edible materials, such as carboxymethyl cellulose (CMC), pectin, chitosan, and non-edible films, such as polylactic acid (PLA), polyhydroxybutyrate (PHB), polyethylene (PE). Standard methodologies and model systems, determined by the current legislation, regarding putative effects on the cell viability by the migration of substances from the packaging materials to the packaged food was used (Commission Regulation (EU) No 10/2011). In brief, carboxymethyl cellulose-based membrane (possible edible) or the classical plastic membrane of low-density polyethylene (LDPE), were used to assay putative cytotoxicity by the migration of substances to solvents simulating food contact. The approved for food packaging LDPE membrane served as control. Specific dimensions of the above membranes were weighted and incubated in pre-weighted glass vials using different solvents. Based on the current legislation, the solvents used simulated the contact to aqueous (dH2O), alcoholic (10% ethanol in dH2O), milky (50% ethanol in dH2O), fatty (95% ethanol in dH2O) or acidic (3% acetic acid in dH2O) foods. The incubation was carried out for 10 days at 20 °C or 4 °C to resemble the room temperature or the refrigerator conditions of food storage, respectively. At the end of the incubation period, the remaining undissolved membrane-related material was withdrawn, the organic part of the solvents was evaporated under a stable nitrogen stream while the water part was completely dried in fridge-dryer. The remaining was weighted, rediluted in dimethyl sulfoxide (DMSO) and used to perform cell-based viability assays (resazurin-metabolism assays). A piece of carboxymethyl cellulose-based membrane was completely dissolved in dH2O with the use of vortex and used also in cell-based viability assays. Bioactivity was assessed in terms of antimicrobial and antioxidant activity. The evaluation of the antiviral activity on the surfaces of the tested packaging materials was performed using different viruses (Vaccinia virus, Norovirus, Adenovirus, Poliovirus, and SARS CoV-2) according to standard test methods (ISO 21702:2019).

(Continued on next page)
Results
To check for putative effects on cell viability due to substances which are possibly released by the CMC- or LDPE-membranes in the different solvents, serial dilutions of the DMSO-dissolved remaining of each sample were applied on Caco2 and Huh7 cells. Similarly, Caco2 and Huh7 cells were treated with different concentrations of the dH2O-dissolved CMC-based membrane. Treated cells were incubated for 72 h and then the cell viability was determined by the resazurin-based assay. Our results showed that the CMC-membrane had no negative effects on the cell viability with any of the solvents used and in any conditions of incubation. Similarly, with the used concentrations of the dH2O-dissolved CMC-based membrane no negative effects on the cell viability were observed. The results of the study showed the potential of the tested biopolymers as alternative packaging materials, appropriate for fresh and perishable food products, such as fish and seafood, in terms of migration and toxicity, according to the EU regulation for food contact materials, and their bioactivity for the development of active packaging materials. In addition, Vaccinia virus, SARS CoV-2, and Adenovirus exhibited low reduction rates in their titers (5%, 4.5%, and 3%, respectively) when tested using the selected non-edible packaging surfaces. In contrast, no antiviral effect was observed either for Norovirus and Poliovirus on the edible surfaces or for all the tested viruses on the non-edible surfaces.

Discussion and conclusion
The application of processing methods, such as cold plasma, and the incorporation of bioactive components into (bio) polymers offers the potential for effective active packaging for improving quality and safety of fish and seafood products. Moreover, the lack of negative effects on cell viability of CMC-based membrane with all solvents used and with any conditions of incubation (room temperature or refrigerator) suggests that this membrane can be used to wrap food of any composition to extend its shelf life and to reduce the required plastic material for its preservation.

Introduction
The effects of climate change (CC) are a contemporary reality that will have increasingly negative and severe consequences in the near future. One of major component of CC is constituted by heat waves (HWs), extreme climate events that can cause massive mortality of organisms, especially in coastal habitats. HWs are increasing in frequency, intensity and severity and represent a serious threat, not only for species living in coastal habitats, but also for all human activities connected to those habitats, such as clams aquaculture. To counteract the negative effects of these stressors on clams it is necessary to identify stress markers and to investigate the physiological and molecular mechanisms triggered by them. One of the consequences of thermal and oxidative stress is faster ageing caused by an impairment on telomeres, which are non-coding DNA sequences that protect chromosomes. The length of these protective structures is generally associated with lifespan and some evidence has shown a significant decrease in their length following thermal stress. In this work, we evaluated the telomere length of clams subjected to a simulated HW. We demonstrated that HW had a tangible effect on the dynamics of telomeres, which appear to shorten following HW. However, much remains to be understood about how this occurs.

Materials and Methods
To evaluate the impact of HWs on the Manila clam (*Ruditapes philippinarum*) at physiological and molecular level, we purchased, from the hatchery SATMAR, a batch of clams that were produced from the same mass spawning event, to ensure that all animals had the same biological age (thus preventing bias in telomeres due to differing ages). After 14 days of acclimatization at 20°C, clams were divided into two groups: treated and control. The treatment consisted in mimicking for 15 days an HW which naturally occurred in the Venice lagoon in the past years, with water temperatures oscillating daily from 31°C to 35°C, while controls were kept at 25 °C. After 15 days, the HW was terminated and all animals underwent a resting phase (25°C for 18 days) at the end of which the gills from 40 control and 40 treated clams were sampled to analyze the impact of HW on telomere length. After the extraction of high molecular weight DNA from the gills, a protocol was applied for the amplification, via qPCR of the telomeric DNA and of a reference gene (GAPDH) and for the subsequent calculation of the relative telomere length of the telomeres. (T/S ratio)

Results
Exposure to HW significantly reduced the treatment population by 60%, with a mortality peak on the 15th day of HW and a more reduced but constant mortality over the following days.

We then tested whether there was a link between clam length and survival rate to understand if larger or smaller clams were more resilient. However, no correlation was found among these parameters. Finally, we looked at telomere dynamics and found that while in the control population a positive correlation existed between shell length and telomere length, an opposite trend was observed between HW-exposed clams: in fact, HW-surviving clams that were longer in length had shorter relative telomere length. These results suggest an important change in telomere dynamics following HW stress, that should cause the erosion of telomeres (i.e. shortening). However future experiments are needed to properly quantify the the extent of this shortening.
HEAT PRIMING TRIGGERS SURVIVAL MECHANISMS IN MANILA CLAMS EXPOSED TO HEAT WAVE

*Department of Comparative Biomedicine and Food Science, University of Padova, Viale dell’Università 35020 Legnaro, Italy

Email: carmenfederica.tucci@phd.unipd.it

Introduction
Aquaculture is one of the growing sectors in the world and 60% of world aquaculture production is made up of bivalve, especially clams, oysters, mussels and scallops. However, climate change and associated extreme weather events such as heat waves (HWs) are seriously threatening coastal environments, the species that inhabit them and all human activities connected to those habitats. Since the vast majority of global clam aquaculture is produced in coastal areas it is essential to find solutions to counteract the negative effects of these stressors on clams. Possible mitigation strategies lie in heat-priming. Heat priming consists in the exposure of animals to a sub-lethal stressful condition which renders them less vulnerable to a subsequent lethal exposure with the same stressor. In this study, we tested the effect of priming on Manila clam, *Ruditapes philippinarum*, at physiological and transcriptomic level, highlighting some mechanisms that could be triggered by this innovative treatment.

Material and methods
To investigate the effect of priming, we used 500 individuals generated from SATMAR, one of the biggest hatcheries in Europe, and, after an acclimatization period of 10 days at 18 °C, we divided them into two groups: primed and controls. The first group was left for 7 days at a temperature of 30°C, while the control group was kept at 25°C. After a resting period of 15 days (both groups at 25 °C), both groups were exposed to a simulated HW for 7 days where the temperature of the aquariums went daily and gradually from 31 to 35 °C. Survival of animals was monitored for the following 15 days (where temperatures were back at 25 °C) and, finally we measured the condition index -CI (a parameter which gives a general indication of the well-being of the clam), and the hepatosomatic index -HSI (to evaluate the energy reserves stored in the body). In addition, digestive glands were collected and stored in RNAlater to study the transcriptomic response.

Results
At the end of the experiment, the primed clams had a near 100% chance of survival, while the clams that did not receive treatment before the HW had 70% chance of survival. This confirmed the fact that priming improves the survival of clams after HW. However, it emerged that, after the HW, primed clams have a lower CI and HSI. Transcriptomic analysis revealed that primed clams had 32 differentially expressed genes (24 down regulated and 8 up regulated) compared to the group that was only exposed to HW. Despite the low number of differentially expressed genes, specific functional groups emerged from the functional analysis via Gene set Enrichment Analysis. Specifically, entries related to the development of endothelial and epithelial cells and tissue organization are up regulated. Furthermore, entries related to the synthesis of molecules involved in carbohydrate and lipid metabolism such as pentose-phosphate shunt, regulation of ketone biosynthetic process, NADPH regeneration, regulation of lipid metabolic process were up-regulated in primed clams. These results highlights a reorganization of the organ responsible for the stock of energy reserves and the metabolic processes that are triggered following priming. Other up-regulated pathways via GSEA were related to the response to viruses and bacteria (response to cytokine, defense response, type I interferon signaling pathway). Taken together, these results indicate that priming is able to trigger defence responses to stress, directing the clams energies towards processes that guarantee a better response in terms of survival to HW.
REARING OF EUROPEAN SEABASS (*Dicentrarchus labrax*) IN AQUAPONIC SYSTEMS: EFFECTS OF ENRICHED BLACK SOLDIER FLY (*Hermetia illucens*) PREPUPAE MEAL ON FISH LIVER

I. Tucciarone1*, L.F. Pulido-Rodriguez1, A.C. Lira de Medeiros1, G. Secci1, M. Zarantoniello, I. Olivotto, G. Parisi1

Introduction
As the global human population is projected to reach 9.7 billion by 2050, concerns about the future food supply have intensified. Aquaculture is expected to play a crucial role, with an estimated 62% of seafood production coming from aquaculture by 2030. However, to meet sustainability criteria and European Union requirements, aquaculture must limit organic pollution and water consumption, maintaining high production standards. Insects, particularly black soldier fly larvae, have gained attention for their environmentally friendly characteristics. They can be reared on organic waste with low water input, aiding waste biodegradation and aligning with the circular economy concept [1]. Black soldier fly prepupae meal (*Hermetia illucens*; HI) is rich in protein, essential amino acids, vitamins, and minerals, making it a potential ingredient for aquafeed. However, the fatty acid profile lacks certain essential long-chain polyunsaturated fatty acids (PUFA) for fish, raising concerns for marine species. Despite this nutritional drawback, several studies aimed to use the full-fat HI, exploiting the property of the black soldier fly larvae to modulate their fatty acid profile based on their feeding substrate. In this regard, it has been demonstrated that the inclusion of microbial dried biomass from marine protists or cyanobacteria, such as spirulina (*Arthrospira platensis*), in the insects’ growth substrate represents a valid procedure to improve HI’s nutritional value in terms of both long-chain PUFA and antioxidant molecules content. In addition, the inclusion of spirulina-enriched HI in diets intended for both fish and crustaceans resulted in positive responses in terms of fish growth performance and welfare. In this context, this study examined the effects on the biochemical profile of fish liver of the partial substitution of fish meal with spirulina-enriched HI in the diet of European seabass (*Dicentrarchus labrax*) juveniles, reared in aquaponic systems to further promote sustainability in aquaculture.

Materials and Methods
Three different diets for European seabass were designed, aiming to meet their nutritional requirements. The control diet (HI0) contained conventional marine-derived ingredients (40% fish meal and 12.5% fish oil) along with vegetable ones. The other two diets, named HI3 and HI20, were based on the control diet by substituting 3 or 20 % of fish meal with spirulina-enriched HI, respectively. Two hundred and seventy E. seabass juveniles were acclimated for two weeks in a 1000 L tank with controlled water parameters. After acclimation, the fish (initial weight: 19.3±0.1 g) were divided into nine media-based aquaponic systems (600 L fish tank and 120 L hydroponic unit) with 30 specimens per tank. The trial lasted 90 days during which fish nearly tripled their weight (final weight: 60.5±0.6 g). Fish were fed the experimental diets at 2% body weight, with diet adjustments every two weeks. At the end of the trial, all fish were euthanized, individually weighed, and livers were collected for the following analysis: (i) histological analysis was performed to determine hepatic lipid and glycogen deposition; (ii) spectroscopic (FTIR) analysis aimed to evaluate the biochemical composition of the liver tissue; (iii) chemical analyses in which livers were singularly homogenized then analyzed for the total lipid content, oxidative status (as conjugated dienes and thiobarbituric acid reactive substances) and antioxidant capacity (2,2-diphenyl-1-picrylhydrazyl). Data were subjected to one-way ANOVA followed by Tukey’s multiple comparison test. Significance was set at *p* < 0.05.

Results and Discussion
Liver serves as a significant lipid storage site in various marine fish species, including E. seabass. However, the use of full-fat HI in aquafeeds has a notable drawback due to its unbalanced fatty acid profile. This imbalance often results in increased saturated fatty acid (SFA) content and a high n-6/n-3 ratio, which have been linked to the promotion of hepatic lipid accumulation. As expected, in the present study, despite the absence of pathological alterations observed in the liver parenchyma, the histological analysis of the HI20 group showed a significantly higher fat accumulation compared to the other dietary treatments. This outcome was further corroborated by the FTIR analyses, which revealed an increase in both the total lipids and fatty acids content in livers from the HI20 group. Additionally, both the histological and spectroscopic

(Continued on next page)
analyses indicated that liver energy storage in this group could primarily rely on fatty acids rather than glycogen. However, chemical analyses did not show significant differences among the experimental groups regarding total lipid (all around 11%) and SFA (ranging from 251.89 to 327.38 mg of FA/100 g fresh tissue) contents. The contradiction found between the results obtained using different analytical methods can probably rely on their different sensitivity. Indeed, in the case of the total lipid analysis, the liver was homogenized by blending before analysis while for histological/spectroscopic analyses, whole liver samples were fixed without homogenization. Thus, the heterogeneous spatial distribution of lipids in the liver may have affected the results [2].

Finally, lipid oxidation results revealed that conjugated dienes (CD) (mean value: 0.54 mmol kg\(^{-1}\) fresh tissue) and thiobarbituric acid reactive substances (TBARS) (mean value: 0.11 mg MDA-eq. kg\(^{-1}\) fresh tissue) contents in the liver were not significantly influenced by diets. These aspects reflected a good health status of the liver since, when it is inflamed, TBARS usually tend to increase. The same positive results have been found for the antioxidant capacity which did not differ among groups. In conclusion, the marginal impact on the liver underscored that the enriched full-fat HI is a viable and eco-friendly option as an aquafeed ingredient for rearing E. seabass juveniles. Indeed, diets did not adversely affect the biochemical composition and health status of the liver. Thus, further studies could test higher inclusions of enriched HI. Further studies could also help to shed light on the discrepancy in the results for lipid deposition liver found with the analytical methods used. In addition, this feeding trial represents an example of how the rearing of a commercially significant fish species can be carried out using more sustainable aquafeeds and farming techniques, like aquaponics. This approach promotes the adoption of circular economy principles and zero-waste concepts in aquaculture, contributing to a more environmentally conscious and efficient industry.

Introduction
The Italian shellfish industry is a significant contributor to both the volume and value of the national fisheries and aquaculture production.

The sector is mainly composed by three branches: Clams, Mussels and Oyster.

The clam (Tapes philippinarum and Tapes decussatus) industry continues to present a satisfying production level, as Italy is stably the leading European producer. Oyster (Crassostrea gigas and Ostrea edulis) production is relatively recent to Italy, yet it presents great potential for development as the country has the capacity to breed high-quality products, and the demand for internal consumption is primarily met through imports.

On the contrary, the Mussel (Mytilus galloprovincialis) industry is currently experiencing a challenging period, with a diffused difficulty to get enough revenues to remunerate the productive factors and make structural investments.

Considering that shellfish production plays a central role in the current European food strategies, the sector’s primary challenge is thereby to identify a sustainable development pattern, able to ensure a conservative use of resources and the food safety, while meeting the growing demand for seafood.

Framework
This paper is part of the dissemination process of the VALUE-SHELL project, financed by the Italian Ministry of Agriculture, Food Sovereignty and Forests. The project has been financed as part of the institutional and technical-scientific support activities for the implementation of the National Strategic Plan of Aquaculture.

Purpose/scope
Moving from the findings gathered during the VALUE-SHELL project, the purposes of this paper are to present the main problems and needs of the Italian shellfish sector, to highlight the current state of the industry and to suggest sustainable intervention actions. Policy recommendations should be addressed to solve or mitigate current weaknesses and support the development of the opportunities and the potentials of the sector.

Materials and methodology
The study was conducted during 2022 through a desk research on molluscs’ industries structures and the different typologies of public interventions and support.

To assess the needs of the sector it was used a collaborative approach, consisting of interviews to stakeholders, such as local administrators and research centers, and focus group meetings with the fundamental participation of small/medium producers, often organized in cooperatives.

Stakeholders have been singularly interviewed about the main sectorial problems from their professional point of view.

Producers were consulted by organizing five focus group meetings on a territorial basis (Liguria, Emilia-Romagna, Sardegna, Puglia and Campania). The realization of the focus group meetings has been made possible by the collaboration of AMA (Mediterranean Aquaculture Association), the most representative molluscs producers association in Italy.

Moreover, an additional focus group meeting has been conducted within the EATIP experts to share the main results of the project and acquire more knowledge at European level.

Problems and needs emerged during the project’s activities has been categorized according to their prevalent nature within the four sustainability pillars (environmental, economic, social, and institutional).

(Continued on next page)
**Results**

The collaborative process allowed to confront the problems and needs experienced by producers from different areas and overall situations.

From a sustainability point of view, the main reported critical aspect regards the Institutional side, due to the lack of a specific aquaculture law governing the sector and the current fragmentation of competences among different entities. In this field, the most relevant issues concern the bureaucratic concessions of marine areas for aquaculture use and the ongoing process of delimitation of the AZA (Allocated Zones for Aquaculture), an instrument that could solve the conflicts between different spatial uses and grant to shellfish producers the ability to plan mid and long-term investments.

With regards to the economic sustainability, some structural characteristics do create issues in the overall economic performance. Between those should be named the increased production costs and the difficulty to introduce income integration by aquaculture tourism and offer diversification.

Environmental sustainability does involve the relationship between shellfish production and the environment on which it is carried on. Main problems from this aspect comprehend global warming, the need for ecosystem equilibrium in the sea populations (predatory species) and measures to reduce both sea pollution and cementing of coastal freshwater springs.

For the social sustainability, from the focus group meetings emerged a diffused fear on the generational turnover, also connected to the scarcity of adequate professional training and scholastic sectorial education.

The project, both in its policy review and in the collaborative meetings components, found out the main bottlenecks in the sectorial policies that do not allow to completely fulfill the producers’ needs.
THE IMPACT OF FERTILIZER SAVINGS ON QUALITY OF LETTUCE (LACTUCA SATIVA) IN AQUAPONICS. COMPARISON OF AQUAPONIC, FERTILIZED AQUAPONIC AND HYDROPONIC NUTRITION

Introduction
Aquaponics is a promising technology due to its efficient transfer of nutrients from fish waste to plant biomass, resulting in reduced fertilizer and water usage. However, the nutrient content in aquaculture water varies greatly and may not be optimal for plant growth, which can affect plant yield and quality. Scientific literature on this topic is inconclusive and exhibits a high level of disparity. The objective of this study was to compare plant growth and quality aspects in aquaponic, fertilized aquaponic, and hydroponic nutrition systems.

Materials and methods
The experiment was done in three runs. After the first run, the light photoperiod was increased from 11 to 18 hours of daylight to achieve more realistic lettuce weight for commercial production. Experimental set-up was placed indoors in a climate chamber allowing environmental control. Each experimental treatment was implemented in three technical repetitions placed in individual growing chambers. Lettuce, green butterhead variety of Salanova Aquino (Rijk Zwaan) was grown. The total number from all the runs was 229 lettuces. Aquaculture water (aquaponic treatment) was sourced from professional recirculating aquaculture system (RAS) at the Leibnitz Institute of Freshwater Ecology and Inland Fisheries. RAS was placed in the nearby greenhouse, with total water volume of 16 m³, 4 fish tanks stocked with Oreochromis niloticus (tilapia) and Colossoma macropomum (red bellied pacu), kept separately with total weight of 182 kg. Used feed was Aller Aqua Claria Float 2mm (45 % crude protein, 12 % crude fat, 25,1 % NFE, 6,4 % ash, 3,5 % fiber, 0,9 % phosphorus). Aquaponic fertilized treatment was prepared using Hydrobuddy program (programmed and designed by Dr. Daniel Fernandez, available at www.scienceinhydroponics.com). Water from RAS was analyzed on ICP and Ion chromatography. Aquaponic water was supplemented with nutrients to obtain similar concentrations as for hydroponic 70% or 80% Howard-Resh solution, depending on nutrient content of aquaculture water, primary targeting for comparable NPK (nitrogen, phosphorus, potassium) content. Hydroponic treatment was prepared with 1:1 tap and distilled water. After mixing, pH was adjusted to the same level in all treatments, either lowered by nitric acid (6,5% HNO₃) or raised by sodium hydroxide (2M NaOH). After 30 days, lettuces were cut at the basis and weighted. Bottom defective leaves were removed before sampling. For nitrate content analysis samples were oven dried at 85°C for 24 hours, grinded to powder, extracted by boiled water (1/100, w/v; 0.1 g of samples and 10 ml of deionized water (conductivity < 0.055 µS cm⁻¹; Adrona, Latvia) and samples were placed to 1 min in ultrasonic bath. Nitrates were determined by means of capillary ion-exchange chromatography with suppressed conductivity (capillary high-pressure ion chromatography - HPIC). Dionex ICS 4000 and ICS 6000 (Thermo Scientific, USA) system equipped with Dionex IonPac AS11-HC 4 µm (Thermo Scientific, USA) guard and analytical columns were used. For sensory analyses whole lettuces were stored fresh at 4°C for 27 hours, until assessed by experienced sensory panel. The sensory profile was assessed using intensity scales (0-100 mm) which were transformed into numerical scale for statistical analysis. Each evaluator assessed 9 samples for 9 descriptors. To determine microbiological parameters: total counts of bacteria, Aeromonas, coliform bacteria, Salmonella and Listeria, standard media and methods were used in accordance with relevant ISO standard.

(Continued on next page)
Results and conclusions

Our study found that lettuce grown in aquaponic treatment exhibited a 30% decrease in growth (112.2 ± 27.2 g) compared to fertilized aquaponics (164.4 g ± 47.1 g) and hydroponics (160.7 g ± 44.1 g). Surprisingly, the suboptimal nutrient composition in aquaculture water did not exert a significant influence on the quality traits, sensory profile or microbiological status of the lettuce. The fertilized aquaponic treatment resulted in significant savings in fertilizer usage, with nitrogen savings of 93%, phosphorus by 7%, and potassium by up to 12%, compared to hydroponics. The limit of nitrate content in the lettuce was not exceeded in either treatment. For sensory analyses statistically significant differences were not observed in the descriptors examined. Aquaponic lettuce exhibited the highest rank in overall acceptability (74.3), intensity of taste, crispiness and intensity of aftertaste, however the differences were not significant. Aeromonas bacteria were detected in all treatments, with an average concentration of 1.52 log CFU/g on the leaves and 3.11 log CFU/g on the roots. The presence of Aeromonas was not specific to treatments utilizing aquaculture water. Notably, the lettuce roots exhibited a higher bacterial load. Coliform bacteria were found at relatively high levels, with average values of 4.6 log CFU/g on the leaves and 6.69 log CFU/g on the roots, reaching up to 5.6 log CFU/g on the leaves and 7.7 log CFU/g on the roots.

This study provides a comprehensive evaluation of the quality of aquaponic lettuce. The results indicate that aquaponics offers a viable solution for sustainable agriculture by reducing reliance on synthetic fertilizers, producing high-value end products, and environmental sustainability. Aquaponics is a sustainable agricultural system that eliminates the need for synthetic fertilizers by utilizing organic fertilizer derived from fish feed. The method of fertilized aquaponics does not compromise the quantity, quality, sensory or microbiological properties of the resulting product when compared to hydroponics. When no fertilization is applied, aquaponics still maintains comparable quality and sensory traits, although the biomass yield is reduced by 30%. The absence of fertilizer usage in aquaponics can lead to a decrease in nitrate content in lettuce, which can be beneficial. However, it is important to note that aquaponic lettuce may have lower levels of certain nutrients, such as iron. Overall, the aquaponic method effectively saves the use of fertilizers, mainly nitrogen, phosphorus, potassium, and other essential nutrients, without presenting any risks to consumers.

The authors would like to acknowledge Ministry of Agriculture of the Czech Republic (QK 21010207) and METROFOOD-CZ research infrastructure project (MEYS Grant No: LM2023064; LM2018100) for their financial support of this research.
INTERACTIONS BETWEEN BIOPHYSICAL FACTORS, TECHNOLOGY, PRODUCTION STRATEGIES AND ECONOMIC OUTCOMES IN OFFSHORE SALMON AQUACULTURE

Ragnar Tveterås*, Tord Ludvigsen, Bård Misund
University of Stavanger Business School
4036 Stavanger, Norway
Email: ragnar.tveteras@uis.no

Introduction

Offshore oceans provide biophysical environments and risks that are new to the salmon farming industry. New innovations are required in several stages of the value chain. This paper analyses biophysical challenges and risks, and implications for technological innovation, investments, production strategies and financial returns. We examine different smolt size and offshore production cycle choices, accounting for a range of biophysical and technological constraints and opportunities. Our analysis show that production strategies have significant effects on production costs and returns on investments, and implications for the competitiveness of offshore aquaculture and opportunities for sustainable growth. The design of government regulations that affect production strategy and capacity utilization will ultimately play a critical role for the economic sustainability of offshore aquaculture. Here, we examine the impacts of tax regimes.

Empirical analysis

Offshore aquaculture requires investments in an entire value chain, starting with onshore production of salmon fingerling, smolt. This value chain will have a different configuration than the present inshore value chain, with new production and logistics stages. Figure X depicts the conventional inshore value chain, which today represents almost all salmon production, together with alternative offshore value chains. In two of the value chain alternatives an additional production and sea transportation stage is added, postsmolt production in sea. Furthermore, the offshore value chains at several stages require new knowledge and innovation, and involve new risks. These risks are related to biosecurity, fish health and welfare, technological performance and economic performance.

It should be recognized that total investments and production costs in an efficient inshore value chain will be lower than in an offshore value chain. An offshore farm producing 20000 tonnes of salmon may require value chain investments of approximately 5 billion NOK (500 USD, exchange rate 10 NOK/USD), while an inshore value chain producing the same quantity may require investments of only 1.5 billion NOK. The difference in investments is driven mainly by the offshore installation, but also higher share of post-smolt production and specialized vessels increase investment costs.

The economic analysis:
1) Assess suitable production cycles based on temperature, current and waves.
2) Use the TGC growth model for the different production cycles taking temperature for the different production cycles into account and find new salmon weights as a function of time.
3) Creates a model involving both the number of smolts and the weight of the growing fish as a function of time.
4) When the potential biomass minus the maximum allowable biomass (MAB) from government is positive, the surplus of the MAB is harvested. All the biomass needs to be harvested prior of the planned fallowing.
5) The production cost for each identified production cycle is found.
6) Net Present Value analyses are undertaken with and without resource tax and with sensitivity analyses. Figure 1 shows one example of an NPV profile with different tax regimes, building on proposals from the Norwegian government.

Conclusions

Our analysis shows that the production strategies of offshore salmon aquaculture value chains have significant consequences for cost productivity and financial returns. Capacity utilization in terms of biomass is a critical factor. The size of the smolt or post-smolt released into the farms have significant effects on economic performance. Finally, the design of the tax regime is critical for the investment decision, involving investments typically in the order of 500 MEUR for a value chain serving one offshore farm.

Introduction
Minerals play a central role in the growth, development, and health of aquaculture species. Anti-mineralizing agents, such as bisphosphonates, and citrate, help prevent mineral accumulation in unwanted areas such as soft tissues or organs (Li and Uitto, 2013), in some case calcitonin, and vitamin K₂ also act as factor used to reduce vessel ectopic calcification. Excessive doses of anti-mineralization agents can hinder mineral deposition in fish bones and result in skeletal abnormalities, increased susceptibility to diseases, and higher mortality rates, particularly during the early stages of fish development in aquaculture species. In animal models, anti-mineralization agents are used to inhibit ectopic deposition of minerals that can contribute to pathological conditions. For example, anti-mineralization strategies can significantly prevent the formation or growth of mineral-based structures that could potentially obstruct or harm organs. The present study aims to assess the anti-mineralogenic effect of vitamin K₃, in its menadione form, in an aquaculture context using gilthead seabream (Sparus aurata) and in a biomedical context using zebrafish (Danio rerio).

Materials and methods
In vivo experiment #1: Gilthead seabream larvae (initial length 6.26 ± 0.42 mm, body dry weight 0.28 ± 0.41 mg) of 21 dph (days post hatch) fed increasing levels of vitamin K₃ (Table 1) were analysed for growth performance, skeletal anomalies, vertebral mineralization, and expression of bone markers.

In vitro experiment: Giltihed seabream mineralogenic cells VSa13 induced for mineralization (Pombinho et al., 2004) and exposed to increasing levels of vitamin D₃ (cholecaciferol) and vitamin K₃ (menadione) (Table 2), were analysed for cytotoxicity, extracellular matrix (ECM) mineralisation and expression of bone markers.

In vivo experiment #2: Embryos of the zebrafish mutant grate (model for Pseudoxanthoma elasticum (PXE) characterized by the abnormal calcification of soft connective tissues and the fragmentation of elastic fibers) were exposed to different levels of vitamin K₃ (Table 3) and analysed for the expression of mineralization markers.

(Continued on next page)
Results and Discussion

Larvae fed increasing levels of vitamin K₃ exhibited a reduction in complete vertebral mineralization (Figure 1A), but also an increase in abdominal kyphosis and a reduced survival rate. A downregulation of bone gamma-carboxyglutamate protein (bglap), a gene central to bone mineralization, was observed with increased levels of dietary vitamin K₃. In vitro data showed an increase in ECM mineralization in cells exposed to higher levels of vitamin D₃ and lower levels of vitamin K₃. Conversely, ECM of cells exposed to high concentrations of both vitamins was significantly less mineralized. However, ECM of cells exposed to high vitamin D₃ and low vitamin K₃ was significantly more mineralized, indicating a possible antimineralizing effect of vitamin K₃. In this regard, mutant zebrafish embryos exposed to increasing levels of vitamin K₃ exhibited an increased expression of matrix Gla protein (mgp), a gene coding for an inhibitor of tissue mineralization, and a reduced expression of osteocalcin (Figure 1B), as seen in gilthead seabream larvae. Our dataset agrees with observations reported by Elshaikh et al. (2020) and confirmed that excessive intake of vitamin K₃ can disrupt mineral deposition, leading to imbalanced bone mineralization. It also indicates that vitamin D / K ratio has to be optimized for achieving optimal matrix mineralization during bone development, as proposed by Ziemińska et al. (2021).

Conclusion

Increasing levels of vitamin K₃ reduced the mineralization of gilthead seabream vertebrae in vivo and bone matrix in vitro, and upregulated mgp expression in mutant zebrafish embryo providing strong evidence for an anti-mineralization effect of vitamin K₃. Optimizing levels of vitamin K₃ in fish diet may enhance skeletal status of farmed fish thus their health and welfare. In human, it could also contribute to the advancement of therapeutic approaches for ectopic calcification disorders.

Introduction

Analyzing telemetry data and translating it into meaningful indicators of fish welfare remains a challenge, as it is necessary to distinguish between typical and atypical behavior.

Entropy approaches can be used to analyze telemetry data and detect changes in fish behavior, providing valuable insights into fish welfare. Telemetry is an important tool for studying fish behavior and allows for the real-time monitoring of fish movements. However, analyzing telemetry data and translating it into meaningful indicators of fish welfare is a challenge. Entropy-based methods, which use information theory to quantify the complexity and unpredictability of animal behavior, provide a more comprehensive understanding of the animal state.

By analyzing data probability density function with entropy approaches, it is possible to identify atypical behavior that may indicate compromised welfare. These methods can detect irregularities in fish behavior and provide insight into the animal’s state.

Results and Discussion

Typical behavior is not a single type of distribution, but rather a set of distributions. Entropy analysis is an effective method for identifying atypical behavior in fish welfare assessment, as it provides a more robust evaluation of telemetry datasets than classical statistical analysis. Entropy analysis allows for continuous monitoring of behavior and can identify when fish start behaving atypically. It can also determine which fish and which values are atypical or typical. By analyzing the variability of feeding behavior, social interactions, and behavior in response to different environmental conditions or stressors, entropy analysis can provide insights into the complexity and variability of fish behavior and promote more effective management practices. Entropy approaches can help to improve telemetry data analysis and provide objective indicators of fish welfare for management and regulatory purposes.

THE CURRENT STATE OF HUNGARIAN AQUACULTURE EDUCATION, CHALLENGES, FUTURE OPPORTUNITIES AND SOLUTIONS

Béla Urbányi1*, Szvetlana Lengyel1, Emese Békefi2, Zoltán Bokor1, Rita Fekete1, Julianna Kobolák1

Introduction
The European Aquaculture Society held its annual conference in the Italian coastal town of Rimini in September 2022. The motto of the conference was “Innovative solutions in a changing world”, using the word “challenges” in a different context, but strongly indicating the need to analyse the socio-economic-environmental impacts and the importance of developing strategies for solutions. The increase in energy prices in the sector, the extreme rise in feed materials, and consequently in feed prices, created a dark atmosphere at the conference. This was compounded by the unpredictability of consumer markets, the unpredictability of the price sensitivity and tolerance of the buying public, and the cluelessness of the sector players in the face of a lack of skilled and trained labour. These problems affect all aquaculture subsectors, be it marine or freshwater, traditional or advanced (precision systems), production, or processing.

A special section of the conference focused on the state of education in the sector: a factual presentation of the present and a realistic view of the future. The consensus was that action is needed because the sector is threatened by a shortage of manpower, which cannot be offset by technical solutions and increased mechanisation, especially in the current economic situation. Although the aquaculture sector in Hungary is predominantly characterised by freshwater fish production, it can be said that it is facing the same major problems as the sector as a whole.

Background
The young generation has a very different experience of education today than even those who were in the classroom 10-15 years ago. This is partly due to the increasing demand for digital technologies in an accelerated and globalised world, and partly due to the impact of Covid, the online education at home. Young people are inundated with a constant stream of information from online platforms that they cannot and do not want to absorb: they decide whether to be interested or move on based on impulses acquired in seconds. Online education has reduced the social sphere and the opportunities for personal contact, the full impact of which we have yet to measure. It can therefore be said that reaching effectively the next generation, is a human and professional challenge.

The aquaculture sector needs to attract young people who are motivated, interested in the profession (who love it) and practice-oriented. On the other hand, young people who are not influenced by family or friends in their environment find themselves in serious competition with other, more attractive and well-communicated industries. It has become clear that a paradigm shift in aquaculture education and training marketing is needed as soon as possible. We need to attract the interest of young people to the sector with buzzwords that capture the imagination of a thinking teenager (they learn about it at school, they often see it on social media, they get news on their smartphones, etc.): environmental pressures, climate change, the importance of local food, etc.

In addition to the economic environment, the educational environment is constantly changing, to which some sectors (automotive, information technology, biotechnology) have reacted quickly. The traditional education system does not provide young people (primary and secondary school) with enough information on the importance, let alone the beauty, of agriculture, especially aquaculture. The young generation cannot be expected to turn to aquaculture of their own accord. Action must therefore be taken, involving all stakeholders, be they for-profit businesses, educational or research institutions, sectoral stakeholders, or regulatory bodies. There are already good examples of this, which should be adapted to the sector’s environment and specificities, and the processes should be regularly monitored and restructured, and improved, incorporating feedback.

Conclusions
To summarize, the situation in aquaculture education is mixed, with plenty to do and plenty of work to be done. However, these tasks can and should be developed in a structured way, in agreement with and with the involvement of the relevant stakeholders. (Continued on next page)
The first and most important step is to raise the profile of aquaculture as a profession and/or vocation among young people:
- introducing the basics of aquaculture in public education courses, e.g. in a biology or natural science subject (nature studies, environment);
- organising summer camps for primary and secondary school pupils, where young people can learn about the industry through a variety of practical activities;
- teacher training: to familiarise teachers with the aquaculture sector through study trips for teachers with a biology or science degree;
- summer student placements in aquaculture companies, where young people can gain knowledge and experience in the sector;
- raising wages in the sector to bring them on par with other agricultural sectors.

In order to increase the sector’s popularity and attract interest, it is necessary to renew and update the training courses offered in the sector. Main tasks (not exhaustive):
- identify the labour market requirements of the practical (for-profit) partners for each level of training,
- develop the basis for funding outside the school system and, in some cases, within it (adult training), and a system for allocating partner contributions and, where possible, funding from grants, in addition to public funding,
- developing the interaction between theoretical and practical curricula, and preparing training places to carry out the tasks required,
- integrating digital learning opportunities and new teaching methods into traditional training systems,
- adopting good practices from abroad and adapting them to the national system,
- developing the marketing of training courses, using uniform campaigning and marketing tools (coordination),
- development and implementation of a comprehensive training strategy for fisheries (aquaculture) and angling, and wide communication.

Our primary interest is to find the answers to these questions as soon as it is possible through a common reflection that could provide the basis of a new educational concept which we believe is one of the key factors for the survival of the aquaculture sector.

The work is supported by the iFishIENCi project (European Union’s Horizon 2020 research and innovation programme under grant agreement No 818036).
GENERAL INFORMATION OF THE SERBIAN POND FARMING SYSTEM BASED ON A PRACTICAL CASE STUDY

Majo Milošević¹, Zoltán Bokor², Árpád Hegyi², László Lengyel³, Béla Urbányi²*

¹Saint Nikola Fish Farm, Torontálszécsány, Serbia
²MATE, Institute of Aquaculture and Environmental Safety, Department of Aquaculture, Gödöllő, Hungary
³Horticulturists’ Association, Zenta, Serbia
E-mail: urbanyi.bela@uni-mate.hu

Introduction
Like other carp-producing countries in Europe, Serbian pond farming has a long history and a strong tradition. To understand the background of the production and the functioning of the farming technology, we can get an idea of how a pond farm works. These ponds are known locally as the Óbecse fish pond system, and are located close to the Serbian-Hungarian border. The fish ponds were established in 1968 and are located between the cadastral municipalities of Óbecse and Bácsföldvár. The fish ponds cover an area of 650 ha and are supplied with water by the Ferenc-canal with gravity water control. The used water is discharged into the “Old Tisza” after the end of the production technology. The average annual production of the pond system over the last 20 years is 450 - 500 tonnes of market size carp, 150 tonnes of market size silver carp, 50 tonnes of grasscarp, 3 - 3 tonnes of European catfish and pikeperch, 120 - 150 tonnes of two-summer old carp juvenile and 30 - 50 tonnes of one-summer old carp fingerling.

Background
In Serbia, two types of production technology are used: two-year and three-year production systems (Table 1).

The two-year production system is used for intensive pond fish farming systems, using only extruded feed concentrates. The three-year production system is a traditional cereal-based feeding system, where concentrates are used only in the first year of rearing, and only cereals are fed to the stock in the second and third years.

Agrotechnological operations:
- It involves drying out the pond and keeping it dry due to oxidation processes that take place in the pond sludge. Drying out during the summer period involves resting the structures for 15 to 20 days. In winter, the duration of this process is doubled (30 to 40 days). The mineralisation of organic matter in the sludge is doubled at higher temperatures.
- Liming or disinfection: this is mostly carried out with burnt lime and, according to the original technology, there is an initial or zero liming (after the pond is fished, the remaining wild fish are destroyed). Each depression must be controlled, and disinfection is successful if the water is clear and transparent after treatment. The dose applied is 1,5 - 3 t/ha.
- Continuous liming or disinfection is carried out every 15 to 20 days throughout the production process at a dose of 50 to 100 kg/ha.

In small and intensive ponds, aerators are used to enrich the water with oxygen, both deep and surface aerators. In case the amount of feed exceeds 40 - 120 kg/ha, aerators should be operated during the night (mostly between 18 - 06 h).

Conclusions
European carp producers are divided on the future of feeding: the use of cereal-based feeds and complete feeds will be determined primarily by economic factors.

(Continued on next page)
A good example of the use of complete feeds is what our Serbian fish farmers in Vojvodina territory are using in their pond farming systems. Due to the strong pressure from cormorant, they have been forced to rapidly increase the population of one-summer- and two-summer old carp, which they feed with complete feeds.

The results show that the grain-based feeding (2.5 - 7.0 kg FCR) resulted in an average of 5.0 kg, which is similar to the Hungarian results (based on literature data, 4.0 kg of grain can produce 1.0 kg of fish meat).

The results obtained with complete feeding are thought-provoking. The FCR of 1.78 kg of feed to produce 1.0 kg of fish meat is an excellent result, which supports the argument that there is a justification for feeding complete diets for certain carp age classes.

Serbian pond farmers are also struggling with water quality problems, which can only be alleviated by continuous monitoring and control. The KHV is also present in Serbia. Its management and prevention is a priority task and issue of everyday production organisation.

It is interesting to consider how the 2-year carp production system, the current input material prices and the drastic changes in the weather condition could be introduced into the production technology of other European countries.
OVARIAN DEVELOPMENT IN AFRICAN CATFISH (Clarias gariepinus) JUVENILES FED VARYING LEVELS OF COCOA BEAN MEAL

Introduction

African catfish (Clarias gariepinus) is a widely cultivated freshwater fish species in the world. In addition to poor nutrition and adverse environmental conditions, the high variability and unpredictability of fish reproductive performance pose significant challenges to the mass production of fingerlings and overall productivity (Uedeme-Naa and Nwafili, 2017). To address these challenges, the use of plant and organic feed additives to improve gonadal maturation and egg viability has gained attention in aquaculture (Al-Khalaifah et al., 2020). Cocoa (Theobroma cacao) products have been shown to possess a wide range of health benefits and are rich in bioactive compounds, which have shown positive impacts on fish growth, health, and reproduction (Al-Khalaifah et al., 2020). There is a paucity of information on the effect of cocoa bean meal (CBM) on the reproductive development of catfish. Therefore, this study aimed to investigate the effect of varying dietary levels of CBM on the ovarian development of C. gariepinus.

Materials and methods

A total of 200 female C. gariepinus post-fingerlings, 9 weeks old and with similar body weights (23.12 ± 0.71 g), were procured from the Fish Multiplication Centre of the University of Nigeria, Nsukka, and used for the study. The fish were acclimatized in a concrete pond for 3 weeks and were then randomly divided into five treatment groups (T1, T2, T3, T4, and T5) in a completely randomized design with four replications. Each replicate was kept in a 100 L basin with 10 fish each. Five iso-nitrogenous (35% crude protein) and iso-caloric (2.51 Mcal/Kg) diets were formulated, with CBM at inclusion levels of 0, 10, 20, 40, and 50%, respectively, for T1, T2, T3, T4, and T5 diets. The fish received the diets for 9 weeks at the rate of 3.5% of the total biomass. The water was changed twice every week to ensure optimal quality. At the end of the study, fish samples were collected from each replicate, weighed, and taken to the laboratory for further processing. The fish were stunned, dissected, and the gonads were harvested, weighed, and fixed in Bouin’s fluid for 24–48 hours before proceeding with histological analysis, as described by Cevaco et al. (1997). The Gonadosomatic index (GSI) was estimated as described by Çek et al. (2001). The fish ovarian developments were assessed on gross morphologically and histologically, as adopted and modified from earlier characterizations and classifications (Cek et al., 2001; Saka and Adeyemo, 2015). Body weights, ovarian weights, and GSI measurements were subjected to analysis of variance using IBM SPSS (Version 21), and mean differences were separated using Duncan’s New Multiple Range Test procedure, accepted at the 0.05 probability level.

(Continued on next page)
Results
The results of the study showed that feeding fish with CBM at 10% dietary inclusion (T2) resulted in a significant improvement (P<0.05) in body weight (BW), ovarian weight (OW), and GSI values compared to the other groups. The OW and GSI values in the control, T3, and T5 groups were similar (P≥0.05). The OW and GSI values in T4 were similar (P≥0.05) to T2 and those of the other groups. Moreover, the inclusion of cocoa bean meal in the diet of *Clarias gariepinus* catfish improved ovarian growth and development, as reflected in the gross morphology of the ovary. At week 9, the ovaries of the fish in T2 and T4 were observed to be better developed (stage IV) than those in the other treatment groups. The ovaries of the fish in the control group were in stage II of ovarian development, while those of T3 (20% CBM) and T5 (50% CBM) were in stage III of ovarian development.

The study observed a group synchronous type of ovarian development in the fish ovary. The results of the histology studies revealed that CBM caused a general improvement in the follicular development of the catfish ovaries. While oocytes in all developmental stages were observed in all groups, T1 showed the least development, with the secondary growth phase being predominant. On the other hand, the ovaries of T2, T3, T4, and T5 fish predominantly had oocytes in the maturation phase (stage 6). Additionally, ovaries of T2 (10% CBM) showed the optimum maturation, with sparse levels of oocytes in the secondary growth phase.

Conclusion
From the observation of this study, it can be suggested that CBM inclusion in fish feed can facilitate ovarian maturation. However, optimum ovarian maturation can be achieved with 10% CBM inclusion in fish meals.

COMPARATIVE ANALYSIS OF THE ENVIRONMENTAL SUSTAINABILITY OF MACROALGAE, OYSTERS, AND LOW TROPHIC LEVEL FISH NATIVES TO SOUTH AMERICA

Suellen A. Alves, Wagner C. Valenti*

*São Paulo State University – UNESP
Aquaculture Center and Fisheries Institute
Via de Acesso Prof. Paulo Donato Castellane
s/n, Jaboticabal, SP, Brazil. Zip code: 14884-900
E-mail: w.valenti@unesp.br

Introduction
According to the UN (2019), there are predictions that we can reach up to 10 billion people in 2050. Aquaculture can help overcome the protein deficit generated by the high population. For this, the production of aquatic organisms should increase, and thus, it is essential to use effective production systems to prevent adverse effects on the producer, the environment, or society (SAAD et al., 2018). In this way, farming low trophic species may be more sustainable than farming high trophic species. In this study, environmental sustainability indicators of producing organisms (macroalgae), filter feeders (oysters), and allochthonous food ingesters (low trophic level fish) were comparatively analyzed using a benchmark framework.

Materials and methods
Secondary data were compiled for 19 environmental sustainability indicators (Valenti et al., 2018) previously obtained for seven aquaculture systems. Five are monocultures. They include the farming of the macroalgae Hypnea pseudomusciformes (Pereira et al., 2021), the oyster Crassostrea gasar in tropical (Sampaio et al., 2023) and in subtropical regions (Miraldo, 2015), the fish tambatinga, a hybrid of Colossoma macropomum and Piaractus brachypomus (Gilson, 2019), and tambaqui, Colossoma macropomum (Dantas, 2017). Two are integrated systems: tambaqui in hapa inside Amazon river prawn (Macrobrachium amazonicum) ponds (Tambaqui IMTA-Hapa) and tambaqui and Amazon river prawn both free in ponds (Tambaqui IMTA-Free) (Dantas, 2017). These seven systems were used as models to assess the environmental sustainability in low trophic species aquaculture. The benchmark tool was applied, establishing reference values for comparing indicators between the systems.

Results
Macroalgae showed the highest sustainable score for ten indicators, tropical and subtropical oysters for seven, and tambatinga for one. Tambaqui IMTA-Hapa received the lowest score for eight indicators, subtropical oyster for six, tambatinga and tambaqui monoculture for three, and Tambaqui IMTA-Free and tropical oyster for two.

Discussion
Environmental sustainability showed different patterns in the culture of organisms from different trophic levels. Considering the culture models used in the present study, environmental sustainability seems to decrease as the farmed species’ trophic level increases. Integrated low-trophic fish farming systems did not show environmental sustainability superior to monocultures, as could be anticipated. Nevertheless, comparison between production systems is complex due to their large variations. The tremendous biological differences between cultivated species require very different culture systems. In addition, there are various levels of intensification, feeding, and management to maintain water quality. The sustainability indicators measure common points in different farm systems necessary for sustainability analysis. The difficulty in comparing them in an integrated way arises from using variables of various dimensions and unities. Therefore, a standardization and integration technique is needed. Generally, the benchmark analysis met this need. It effectively showed the differences between the indicators in the various analyzed systems in a more accessible and standardized way.

Conclusion
The benchmarking framework carried out with seven aquaculture systems indicated that macroalgae, tropical, and subtropical oyster cultures are more environmentally sustainable than low trophic level fish cultures. The cultures of these extractive organisms do not depend on the supply of an allochthonous diet and are performed at sea. Integrated low-trophic fish farming systems have not shown environmental sustainability much superior to monocultures as expected. Indeed, the culture designs and the species used play a preponderant role in the sustainability of the aquaculture systems.

(Continued on next page)
Using the benchmark framework proposed in the current study effectively ranks the production systems according to each indicator, allowing quick visualization. The magnitude of the differences in an indicator in the various systems is somewhat masked by standardization when there is a substantial asymmetry in the distribution of the numerical values. Modifications in the standardization formulas should be studied to make it easier to see the differences.

SILVER NANOPARTICLES SYNTHESIZED IN PLANT EXTRACT AGAINST ACUTE HEPATOPANCRAETIC NECROSIS OF WHITE SHRIMP, MINIMUM INHIBITORY CONCENTRATION ESTIMATED BY MULTIPLE MODELS

Wenceslao Valenzuela Quiñónez, Luz del Carmen Rubí Félix-Peña, José Adán Felix-Ortix, Ely Sara Lopez-Alvarez and Nadia Vazquez-Montoya

1Facultad de Ciencias del Mar, Universidad Autónoma de Sinaloa, Mazatlán, México
2Instituto Politécnico Nacional-CIIDIR Unidad Sinaloa, Departamento de Acuacultura Guasave, México

Worldwide, Mexico is the sixth place in production of farmed white shrimp (Penaeus vannamei). This activity has suffered great economic losses due to the acute Hepatopancreatic Necrosis disease (AHPND) which is caused by a strain of Vibrio parahaemolyticus. For control, the first option is the application of antibiotics in food, causing changes in the environment and bacterial communities, this has caused greater virulence and resistance of pathogenic bacteria. An alternative treatment is silver nanoparticles (AgNPs) generated by green synthesis, which have been shown to have antibacterial capacity, by destroying the cell membrane or passing into the interior of the cell. However, the doses at which these are effective are still unknown. For this reason, the objective of this research is to calculate the minimum inhibitory concentration (MIC) using the Gompertz, Richard and Logistic model of AgNPs-Ep biosynthesizes against a strain of V. parahaemolyticus, and to test the effect of applying different doses and concentrations of those synthesized from Euphorbia prostrata (Ep) on V. parahaemolyticus causing (VpAHPND) in white shrimp. Aqueous and ethanolic extracts of Ep were obtained, after which an analysis of phenols and flavonoids was carried out. In the antibiograms, the AgNPs with 20% alcohol extract (Ep) and 30% alcohol extracts were the treatments with the highest inhibition 18±1.73 and 17.67±2.08 mm (well dilution) for V. parahaemolyticus. A microdilution in broth was carried out and the inhibitory agents (aqueous extracts, ethanolic and AgNPs-Ep) and 20 μL of Vibrio inoculum, the MIC was taken as the lowest concentration of antibacterial agents that inhibit the growth of Vibrio. Finally, extract concentration with inhibition was (OH at 10% was 57-73; 20% from 65-81 and 30% from 32-65 mg/mL) and nanoparticles (from AgNPs-EpOH of 10-30% was 6.2 ug/mL). The calculation of the inhibitory concentration of V. parahaemolyticus was determined within the previous intervals of the optical density (OD) tests. Emphasized the usefulness of modified templates: Gompertz, Richards and Logistic. The Akaike index (AIC) was used to choose the winning model to calculate the models and inhibition curves of V.parahaemolyticus with different concentrations of Ep and AgNPs-Ep.
DEVELOPMENT AND APPLICATION OF AN INDIRECT ELISA TEST FOR TILAPIA LAKE VIRUS (TILV) DETECTION IN Oreochromis niloticus

Anisha Valsalam*1, Kooloth Valappil Rajendran, Jeena Kezhedath¹, Neeraj Sood², Radhakrishnan Naveenkumar¹, and Megha Kadam Bedekar¹

²National Bureau of Fish Genetic Resources, Lucknow, India
Email: ashina96@gmail.com

Introduction
Tilapia lake virus (TiLV) is an emerging virus that causes large-scale mortalities in tilapia farming and considered a threat to the global aquaculture industry with devastating economic losses. A serological test for detecting Tilapia lake virus (TiLV) in Oreochromis niloticus might be helpful for epidemiological studies. For which an indirect enzyme-linked immune sorbent test (iELISA) was developed for the detection of TiLV antigen in tilapia tissue and mucus using polyclonal antisera against TiLV.

Materials and methods
The TiLV-positive tilapia samples were collected and the inoculum was prepared for the production of polyclonal antisera against TiLV in rabbit. The iELISA test was developed with the optimization of each step using the polyclonal antisera. The developed immunodetection test (iELISA) was validated against the existing reverse transcription-polymerase chain reaction (RT-PCR) based molecular detection method. The sensitivity and specificity of the developed iELISA were evaluated following the establishment of the cut-off value and optimisation of antigen and antibody concentrations. The iELISA test was applied for an epidemiological screening of TiLV in the field samples.

Results
The study discovered that the sample concentration of 50 µg/well was optimum and the dilution of the polyclonal antibody was appropriate at 1:4000 (Fig. 1) and the enzyme conjugated secondary antibody was appropriate at 1:65,000. The optimised iELISA showed high analytical sensitivity with average specificity. The Positive Likelihood Ratio (LR+, LR-) was 1.75, and the Negative Likelihood Ratio (LR-), 0.29. The test’s estimated Positive Predictive Value (PPV) and Negative Predictive Value (NPV) were 76.19% and 65.62%, respectively. The developed iELISA’s accuracy was calculated to be 73.28%. When samples from the field (India) were used for an immunological survey, using the developed iELISA, 155/195 fishes tested positive, suggesting a 79.48% positive rate for the TiLV antigen. The mucus had the highest positive rate of TiLV (92.3%) than all the tissue samples tested. By adopting a non-invasive approach to collect mucus as a sample for iELISA, the newly developed iELISA demonstrated sensitive detection and may be useful for thorough assessments of TiLV infections and monitoring disease status even from samples that appear healthy.
FIGHTING THREATS WITH MANY OTHERS: CHARACTERISATION OF THE LARGE NF-κB INHIBITORS FAMILY IN SALMONID FISH

E-mail: muilekom@fbn-dummerstorf.de

Introduction
The evolutionary ancient family of NF-κB (nuclear factor kappa-light chain-enhancer of activated B cells)/Rel transcription factors is activated by environmental and endogenous cues including viral and bacterial pathogen-associated molecular patterns (PAMPs) or cytokines. The activated NF-κB pathways play a major role in immune and stress responses. The inhibitors of NF-κB (IκB) regulate the activity of NF-κB through a dynamic interplay with their antagonists, IκB kinases (IKK). In mammals, the family of NF-κB inhibitors comprises nine members with different or mutual affinities for the various combinations of NF-κB/Rel dimers. In lower vertebrates, a detailed analysis of the family is still lacking. This study provides the first characterisation of the entire NF-κB-inhibitor family in a salmonid fish (rainbow trout, Oncorhynchus mykiss).

Material & methods
The different NF-κB inhibitors in rainbow trout (Oncorhynchus mykiss) were identified using the NCBI-database. We conducted structural analyses using phylogeny, synteny and 3D-modelling of proteins to characterize the canonical iκbα and iκbε proteins, the nuclear iκbδ and iκbζ proteins and bcl3. Additionally, comprehensive iκb overexpression studies in CHSE-214 cells were performed for functional analyses of iκbα and iκbε.

Results
In this study, six nfkbia, two nfkbie, two nfkbid, two nfkbiz and two bcl3 genes in rainbow trout were identified. The sequence identity of ohnologous nfkbi-encoded iκb proteins from rainbow trout ranges from 82% to 100%. The two pairs of the iκbα ohnologs a1/a2 versus b1/b2 share about 60% identity. However, the comparison of the iκbα paralogs a1/a2 or b1/b2 versus c1/c2 revealed a sequence identity below 30%. A phylogenetic analysis across the amino-acid sequences of all IκB proteins from human and fishes revealed that this pair of ohnologous iκbα sequences (c1 and c2) cluster with the human IκBβ factor, while the other two pairs of iκbα ohnologs (a1 and a2 as well as b1 and b2) cluster with the human IκBα factor.

Functional analysis revealed significantly higher transcript levels of nfkbia-a, compared to the transcript levels of nfkbia-b and nfkbia-c, in immune tissues and immune-cell fractions. Also, the expression of nfkbie-a1 was significantly higher than for nfkbie-a2 in different immune tissues. With regard to tissue-specific expression patterns, the levels of nfkbia-a and nfkbie were significantly higher in immune-relevant tissues including head kidney, gill and spleen, but there was (almost) no differential expression of other nfkbi genes between tissues. Confocal imaging indicated a distinct localisation of iκbα and iκbε constructs in salmonid fish cell model. The concentration of iκbα was higher in the cytoplasm compared to the nucleus, whereas iκbε factor seem to be evenly distributed across cytoplasm and nucleus (Figure 1).

The overexpression of iκbα and iκbε robustly reduced the basal NF-κB activity down to a 0.09-fold and 0.06-fold, respectively, compared to the non-transfected controls (Figure 2). Stimulation of the non-transfected CHSE-214 cells with the fungal cell-wall component zymosan doubled the NF-κB activity (2.0-fold) compared to the basal state. Increasing amounts of the overexpressed iκbα and iκbε factors from rainbow trout lowered this stimulated nf-κb activity in a dose-dependent fashion compared to the non-transfected cells.

Furthermore, stimulation with zymosan increased the transcript levels of characteristic inflammatory markers such as il1b and cxcl8, but also nfkbia. Nevertheless, the transcript levels of the induced immune genes in non-transfected cells versus cells expressing iκbα or iκbε were not significantly different after stimulation with zymosan.

(Continued on next page)
Discussion and conclusion

In this study, we describe the iκb family in rainbow trout which comprises each multiple gene copies coding for iκbα, iκbε, iκbδ, iκbζ and bcl3. We compared canonical iκbα and iκbε proteins, the nuclear iκbδ and iκbζ proteins and bcl3 and identified various structural differences. Our comprehensive overexpression studies in fish cells confirmed a NF-κB-regulation potential of the iκb factors investigated and reveal the first functional results on iκbε in lower vertebrates.
THE ROLE OF AQUACULTURE IN CIRCULAR FOOD SYSTEMS IN EUROPE

Anne-Jo van Riel1,2*, Killian Chary1, Ollie van Hal2, Marit A.J. Nederlof1, Geert F. Wiegertjes1 and Imke J.M. de Boer2

Introduction
Designing circular food systems is seen as a promising way to reduce the pressure of food systems on ecosystems. In circular food systems, biomass from arable land and water bodies is prioritised for human food and other basic needs, rather than animal feed (Boer & Ittersum, 2018; Muscat et al., 2021; van Zanten et al., 2019). Along this paradigm, farm animals, including aquaculture species, should not consume human food, but instead convert by-products from crops, livestock, and fisheries that are inedible for humans into edible biomass.

Previous research on food system modelling has primarily focused on livestock, while aquaculture can also play an important role in circular food systems. In aquaculture, species from a wide range of trophic levels can be cultivated, opening various opportunities for upcycling of food system by-products.

Our aim is to determine the role of aquaculture in circular food systems in Europe. We will use circular food system modelling to gain insights into which aquaculture species could be produced, how much aquatic food can be produced when animals are fed exclusively with food system by-products and what by-products can be recycled as fish feed.

Materials and Methods
We used a resource allocation model to allocate by-products (including by-products from fisheries), food-waste (derived from the EAT-Lancet diet) and grass resources to livestock and aquaculture species (fig 1.) to maximise animal source protein (objective). Livestock systems included in the model were based on van Hal et al., (2020) and van Selm et al., (2022), whereas we developed individual growth models for four commonly produced species in Europe: Atlantic Salmon (Salmo salar), European seabass (Dicentrarchus labrax), gilthead seabream (Sparus aurata) and blue mussel (Mytilus edulis). To this end, we used DEB modelling to estimate the growth and energy requirement of each species for different water temperature conditions representing marine-producing areas in Europe. Preliminary results of the model on what by-products can be recycled as fish feed and which aquaculture species could be produced will be presented.

Figure 1 schematic overview of the resource-allocation model used in this study
ANTIMICROBIAL ACTIVITY OF OVOTRANSFERRIN AGAINST AHPND-CAUSING Vibrio parahaemolyticus

Introduction
As the shrimp aquaculture industry is growing exponentially to meet increasing demands, it needs to overcome certain challenges. One of the challenges that come with intensification of aquaculture is the emergence of pathogens. Acute Hepatopancreatic Necrosis Disease (AHPND) is a bacterial infection caused predominantly by Vibrio (V.) parahaemolyticus. As the use of antimicrobials to fight infections is strongly discouraged due to the emergence of antimicrobial resistance bacteria, the search for alternatives is essential. Transferrins are a family of natural antimicrobial and immunomodulating glycoproteins, which have been shown to be effective against multiple pathogenic bacteria. Ovotransferrin (ovoTF) is an easily accessible transferrin, extracted from egg white. The aim of this study is to investigate the in vitro antimicrobial activity ovoTF towards AHPND-causing V. parahaemolyticus.

Methodology
Three AHPND-causing V. parahaemolyticus strains with different origins were used for these experiments. Different concentrations, ranging from 0.001 mg/ml to 10 mg/ml, of ovoTF were tested for their effects on growth curves, and concentrations ranging from 0.125 mg/ml to 1 mg/ml were tested for their effects on swimming and swarming motility, surface hydrophobicity and biofilm formation, and caseinase, lipase and phospholipase secretion. Live/dead flow cytometry was used to assess the ability of ovoTF to kill the bacterial cells. Furthermore, as ovoTF is able to act as a serine protease, its effect on the PirAB toxins produced by V. parahaemolyticus was investigated.

Results
Our results showed that ovoTF was able to delay growth of the bacteria significantly at a concentration of 0.1 mg/ml, and even inhibit growth at higher concentrations. Furthermore, biofilm formation by the bacteria is inhibited, which can be partly explained by the observed lower cell surface hydrophobicity after addition of the ovoTF. Swimming motility was inhibited, while swarming motility was induced. Secretion of lipase was inhibited by higher concentrations of ovoTF, while caseinase production was induced. On phospholipase secretion, the transferrin did not seem to have a significant effect. Results of live/dead flow cytometry and the degradation assay are to be included.

Clearly, ovotransferrin is putting the bacteria under pressure in vitro and from the growth assays, it can be concluded that it has a strong antibacterial effect on the AHPND-related V. parahaemolyticus. Together, these in vitro results indicate that ovoTF is a promising anti-microbial protein, and should be further investigated in vivo for its use as a natural compound for controlling AHPND in farmed shrimp.
SUCCESSFUL REPLACEMENT OF *artemia* BY CYOPRESERVED BARNACLE NAUPLII in EUROPEAN SEABASS LARVAL REARING

Introduction

Live feeds have a key role in the larval rearing of marine fish. Their key advantage relative to dry feeds is that they can live together with the fish larvae in a tank and elicit their predatory behaviour, while providing high-quality bioavailable nutrients. The drawback of using them is the necessity to produce them simultaneously with the fish larvae, with risks of culture crashes that may jeopardize the production of fish larvae by lack of prey. Moreover, some of the most widely used live prey, *Artemia* and rotifers, often have a poor content in essential fatty acids (EPA and DHA), and have to undertake an additional step of enrichment to provide the desired nutrients to the fish larvae. Planktonic A.S is producing CryoPlankton, which are cryopreserved barnacle nauplii, stored in liquid nitrogen, and which can be revitalized after thawing followed by a short incubation in seawater. They have a good EPA+DHA content and provide an “off-the-shelf” solution for live feed provision to larval rearing, relieving the cost of live feed production and securing the daily provision of feed. They have shown good performance for the larval rearing of ballan wrasse *Labrus bergylta* (Malzahn et al., 2022). Thus, the present experiment aimed at testing their use against the standard “clearwater” protocol for European sea bass, which relies on a ten days dark phase followed by first feeding with newly hatched, non-enriched *Artemia* (Chatain, 1994).

Materials and methods

European sea bass fertilized eggs were produced on Nov 15, 2022 by artificial fertilization of 8 females and 15 males from a 3rd generation West Mediterranean seabass line selected for fast growth at Ifremer (Palavas-les-Flots, France). Nine experimental tanks of 0.5m³ were each stocked with 33632 live fertilized eggs, leading to an estimated 30269 hatched larvae on Nov 18, 2022. These larvae were subjected to three rearing protocols, each in triplicate:

• Control: Clearwater rearing of sea bass with *Artemia* only. This protocol is the standard at Ifremer. It included a dark phase of 10 days post-hatching (dph) for vitellus resorption, before direct feeding with newly-hatched, non-enriched *Artemia* nauplii (AF, Inve) until 29 dph. Enriched *Artemia* (BF, Inve, 24 h post-hatching enrichment with Easy-DHA from Selco) were given from 25 to 56 days post-hatching (dph). Fish were weaned to dry feed (Biomar Larviva Pro-start) at 57 dph after co-feeding from 36 to 56 dph.

• CryoPlankton only (Cryo-Dry). In this protocol, there was no dark phase and fish were fed as soon as the mouth opens at 5 dph, and until 12 dph with CryoPlankton Small (cryopreserved *Balanus crenatus* nauplii from Planktonic A.S., Norway), then from 10 to 42 dph with CryoPlankton large (cryopreserved *Semibalanus balanoides* nauplii from Planktonic A.S., Norway). They were weaned to dry feed (Biomar Larviva Pro-Start) at 43 dph after co-feeding from 25 to 43 dph.

• CryoPlankton and enriched *Artemia* (Cryo-Art). In this protocol, there was no dark phase either, and fish were fed as soon as the mouth opens at 5 dph, and until 12 dph with CryoPlankton Small, from 10 to 31 dph with CryoPlankton large, and with enriched *Artemia* from 25 to 56 days post-hatching. They were weaned to dry feed at 57 dph after co-feeding from 36 to 56 dph.

The temperature was set to 16°C from 1 to 45 dph, was progressively increased to 22°C at 69 dph, then remained constant at 22°C. The photoperiod was set at 12L/12D, after a dark phase (0L/24D) until 9 dph for the Control, and immediately at hatching for the other two treatments. Salinity was decreased from 35 ppt at 0 dph to 25 ppt from 9 to 46 dph, when it was released to natural salinity (35-39 ppt). CryoPlankton was thawed for 5 minutes in natural seawater, rinsed for 10 minutes with seawater on a 100 µm sieve, then revived for 1h in 6°C, 25ppt seawater. All live feeds were distributed 12h/day with a peristaltic pump. Standard length (SL) was measured with ImageJ on pictures at 5, 10, 14, 24, 46 and 75 dph. Sample size was 30 fish/tank except at 14, 46 and 75 dph where it was 50 fish/tank. In addition, we estimated % swimbladder inflation on the pictures at 14 dph. At 75 dph, in addition, all fish were sorted for swimbladder inflation by flotation in 40ppt seawater, and the total number of fish per tank was estimated by weighing after a mean weight was estimated on a minimum number of 1500 fish per tank. The individual body weight (BW) of 50 fish per tank was measured to the nearest 0.01g. Data were analysed using mixed models with treatment as a fixed effect and tank as a random effect using lme4 in R. For swimbladder inflation and survival we used a logit transformation of the data.

(Continued on next page)
Results

At 5 dph, before the first feeding of the Cryo treatments, the average SL of the larvae was 5.18 mm, and there was no difference between treatments (P>0.60). Treatments started to diverge at 10 dph, where both Cryo treatments were larger than the Control (P<0.01; Figure 1). The same divergence was apparent at 14 dph (P<0.05) but became marginally significant (P=0.051) at 24 dph. At 46 dph, the Cryo-Dry treatment was similar to the Control, while the Cryo-Art treatment was larger (P<0.01). At 75 dph, both Cryo treatments had higher SL than the Control (P<0.001). This was also true for BW, which was 278±8 mg in Cryo-Dry, 269±8 mg in Cryo-Art vs. 178±8 mg in the Control.

Survival at 75 dph was higher in the Control (38.4%, 95%CI[37.0-39.9]) than in Cryo-Art (32.9%, 95%CI[31.6-34.2]) and in Cryo-Dry (28.9%, 95%CI[27.7-29.7]) but the biomass per tank was 20-28% higher (P<0.01) in the Cryo treatments (2761±72g in Cryo-Art, 2599±72g in Cryo-Dry) than in the Control (2163±72g).

Swimbladder inflation at 14 dph was lower in Cryo-Dry (75.0%, 95%CI[64.0-83.4]) and Cryo-Art (82.9%, 95%CI[73.3-89.4]) than in the Control (97.5%, 95%CI[93.1-99.1]). However, at 75 dph, the proportion of fish with uninflated swimbladders was negligible (lower than 0.3%) in all treatments.

Discussion

At the end of the larval rearing, both Cryo treatments clearly outperformed the Control in terms of growth (+56% for Cryo-Dry, +51% for Cryo-Art). The difference started to appear at 10 dph, where the Cryo treatments had been fed for 5 days with CryoPlankton Small while the Control was still growing on its reserves, waiting for its mouth to be large enough to ingest AF *Artemia*. At 46 dph, the Cryo-Dry treatment had regressed to the level of the Control, however we must note that contrary to Cryo-Art and Control, which were at the beginning of co-feeding Cryo-Dry was at the end of its weaning period, which logically somehow restricts growth. It caught up with the Cryo-Art treatment at the end of the experiment. In terms of survival, the Control was better than the Cryo treatments. This can be related to the percentage of non-inflated swimbladders, which was more important in the Cryo treatments at 14 dph, while there were no uninflated swimbladders in any treatment at 75 dph. As swimbladder inflation is expected to be complete before 14 dph, this means that the uninflated fish in the Cryo treatments died before the end of the larval rearing. Surface skimmers were in place at 7 dph (as usual with the Control treatment), but at that time Cryo fish were already fed for two days, so probably the skimming of fat at the surface layer was not done early enough or with enough efficiency, which should be taken into consideration for practical implementation. Despite the lower survival, the biomass produced was higher with the Cryo treatments, showing the relevance of using CryoPlankton for sea bass larval rearing.

USE OF EXOGENOUS ENZYMES TO IMPROVE THE NUTRITIONAL VALUE OF *Lupinus Albus* AS FEED INGREDIENT IN EUROPEAN SEA BASS (*Dicentrarchus Labrax*) NUTRITION

**Introduction**

The expansion of the aquaculture production has been linked with the need for a rapid increase in the production of aqua feed products. Among alternative ingredients, the plant ones have been extensively studied. The European Union is highly dependent on soybean imports for its domestic use and is highly vulnerable to risks linked to global trade. In this frame, the key of bridging the gap between consumption and demand is to identify alternative forage plant ingredients for sustainable production. For livestock production, forage legumes are promising candidates and highly valued feed components, however, the presence of several antinutritional factors (ANFs) still limits their use in feeds (Kaushik et al., 2018). The digestibility of many ingredients can be improved with inclusion of exogenous enzymes due to their ability of breaking down the complex cell wall structure that encapsulates nutrients present in plant based feed (Ojha et al., 2019). In addition, by increasing access to protein for digestive proteases, carbohydrases can act as enhancers to improve nitrogen and amino acid utilisation (Tahir et al., 2008). Aim of the present study was to evaluate the replacement of soybean meal by lupin meal treated with exogenous enzymes in European sea bass nutrition.

**Materials and methods**

Lupin seeds (*Lupinus albus* cv. Tennis) were grounded to produce lupin meal. A product fermented by *Aspergillus niger* containing several exogenous enzymes (*Synergen™*, Alltech Inc) was added at 0.05%. Moisture of lupin meal was adjusted to 45% and the lupin meal was treated for 4 hours at 50°C. Four commercial type diets, one control containing soybean meal as the sole plant protein at an inclusion level 15g/100g diet and three diets replacing soybean meal by treated lupin meal at three different levels (7.5 g/100g, 10 g/100g and 12.5 g/100g, Table 1) were formulated to be isonitrogenous (48%), isolipidic (17%) and isoenergetic. European sea bass juveniles (11.2g) were distributed in 12 tanks (50 fish/tank) in replicate groups per diet. The experimental trial was conducted for 83 days in recirculation aquaculture system. Fish were fed *ad libitum* the experimental feeds three times per day. For a 2-week period prior to the end of the trial, faeces were collected, to evaluate nutrients digestibility.

**Results and discussion**

Cooking of legumes is a commonly used process that greatly improves the nutritional value of foods by reducing their ANFs (Patterson et al. 2017). In addition, the use of exogenous enzymes increases nutrient digestibility and bioavailability. In the current study inclusion of lupin meal, treated with exogenous enzymes, revealed positive results. Specifically, fish fed the Lupin1 diet showed significant higher final weight compared to the fish fed the control diet. Even though weight increase did not show significant differences, a trend (P=0.05) for higher weight was observed for fish treated with Lupin1 compare to those treated with control diet. Similar trend reflected also in feed conversion ratio (FCR) and specific growth rate (SGR) for the same groups. The growth parameters evaluated were not affected by the total replacement of soybean meal with treated lupin meal (Lupin3). Somatometric indices were fluctuated at similar levels, however, population fed the treated lupin meal presented lower liposomatic indices. Incorporation of exogenous enzymes treated lupin meal affected the digestibility of nutrients, the retention of protein and the activity of digestive enzymes (results are not shown). The present findings showed that lupin is a promising alternative to soyabean meal in the diet for *D. labrax* when treatment with exogenous enzymes is adopted.

INVASIVE SPECIES FOR SUSTAINABLE AQUACULTURE – USE OF FISHMEAL PRODUCED FROM Lagocephalus Sceleratus IN DIETS FOR THE EUROPEAN SEA BASS (Dicentrarchus labrax)

Introduction
Invasive species, also known as “Lessepsian species”, have rapidly colonised the Eastern Mediterranean basin resulting in environmental and economic impacts on marine life, fisheries and human prosperity. Among them is Lagocephalus sceleratus (Gmelin, 1789), a highly opportunistic fish, which causes damages to fishing gear, catch and local biodiversity. It is a highly-toxic species with no commercial economic value for the Mediterranean market. The lack of predators in addition with the high growth and reproduction rate forecasts the future spread of these invasive species (Nader et al., 2012). This scenario leads to alternative management actions for these species. In addition, the expansion of aquaculture has been linked to the need for rapid growth in aquafeed production, however overexploitation of marine resources for fishmeal production is leading to alternative sources of protein. The objective of the current study was to evaluate the use of fishmeal produced from Lagocephalus sceleratus as a replacement for conventional fishmeal in nutrition of European sea bass.

Materials and methods
Individuals of Lagocephalus sceleratus were transferred to the laboratory of Applied Fish Nutrition of HCMR. LM was obtained after cooking, pressing drying and grinding. The produced LM was treated with two different temperatures to deactivate the tetrodotoxin (TTX) detected in the specific species. Low temperature LM (LT-LM) was treated at 160°C and high temperature LM (HT-LM) at 210°C. Five commercial type diets were formulated to replace fishmeal by unprocessed LM (UnP-LM) and by LM treated with low and high temperature. UnP-LM was used as a negative control to assess the tolerance of European sea bass to TTX. Formulation of the experimental diets are presented in Table 1. All the diets were formulated to be isonitrogenous (47%), isolipidic (17%) and isoenergetic. Micronutrients (essential amino acids, phosphorus, essential vitamins and minerals) were balanced among the experimental diets. The experimental diets were produced by extrusion at HCMR.

European sea bass individuals of 39g initial body weight were distributed in 15 tanks. The experimental diets were tested in triplicate groups of fish. The diets were fed in an open-flow system with controlled and monitored water parameters to the experimental groups over a period of 106 days. Temperature was held at 20°C and O2 at >90% saturation. Experimental population fed ad libitum the produced feeds two times per day and feed consumed (g) was recorded daily. Fish were weighted individually at the beginning, intermediately and at the end of the experimental trial.

Results and discussion
At the end of the experimental trial fish were individually sampled and the Key production (KPIs) and somatometric indices were calculated (Table 2). Most of the production indices evaluated revealed significant differences between experimental population. Specific growth rate (SGR) was significant higher for group fed with unprocessed LM compare to the group fed low temperature LM. No significant differences observed for daily feed intake, although lower feed consumption was observed in fish fed unprocessed LM. Feed conversion ratio (FCR) showed significant lower FCR for fish fed diet UnP-LM. Viscerosomatic index (VSIndex) was similar for all treated populations. In contrast, hepatosomatic index (HSIndex) showed significant differences among experimental fish. Lower performance in KPIs for fish fed diets containing high and low temperature LM is probably associated with the degradation of the nutritional value of the produced LM since the high temperature used to deactivate TTX (160 & 210°C) leads to a higher oxidation status of the meals or feeds, degradation of highly unsaturated fatty acids and a reduction in the nutritional value of the produced LM (Phung et al., 2020). Concluding, further evaluation is required to assess the long-term dietary exposure to TTX in UnP LM.

Introduction
Sustainable aquaculture production requires a greater reduction in the use of fish-based ingredients, and one avenue investigated over the past years is the increase in the proportion of plant-derived digestible carbohydrates in aquafeeds. However, this strategy presents a number of drawbacks for high trophic level teleost fish such as rainbow trout (RT, *Oncorhynchus mykiss*), which show, for still unknown reasons, reduced growth associated with persistent postprandial hyperglycemia and hepatomegaly, when fed diets containing more than 20% of carbohydrates (1,2). Among the factors that may be involved in the apparent glucose intolerance of RTs, one of the major pathways of lysosomal catabolism known as Chaperone-Mediated Autophagy (CMA) attracted our attention. In mammals, CMA is described as a critical player in the turnover of glucose and lipid metabolism-related enzymes, and dysregulation of this function has been shown to lead to significant alterations in liver metabolic homeostasis (3). However, CMA has only recently been identified in fish (4) and no data are currently available regarding its regulation as well as its role in the metabolic specificities of RT. In this work, we first assessed in vitro the existence of functional CMA in the RT. We then studied its regulation upon high glucose treatment and identified the underlying mechanisms. Finally, we studied the impact of silencing either of the two paralogous genes encoding the CMA-essential factor lysosome-associated membrane protein type 2A (LAMP2A) on the overall proteostasis of RT.

Material and methods
First, we established a trout hepatoma cell line (RTH-149) stably expressing a fluorescent reporter (KFERQ-PA-mCherry1) previously used to track CMA in mammalian cells (5), and more recently validated in medaka fibroblasts (4). Then, we exposed the cells either to mild-oxidative stress (H2O2, 25 µM), which activates CMA in mammals (6), or to high glucose (HG, 25 mM). We monitored by advanced imaging both the cellular localization and the half-life of the reporter. Subsequently, we used OxyBlot to analyze the oxidative stress status in cells incubated with HG or H2O2, and we explored the relationship between oxidative stress and CMA using antioxidants and specific mitochondrial inhibitors. Besides, we investigated the role of the nuclear factor erythroid-derived 2, like 2 (NRF2) on the effects of HG on CMA in RTH-149 cells using immunofluorescences, gene expression, in silico analysis, and siRNA-mediated knockdown approaches. Finally, to gain insight into the specific contribution of each of the two RT LAMP2As to the overall proteostasis of RTH-149 cells under an HG condition, we performed comparative quantitative proteomics after transfection with siRNAs designed to specifically target each of the *lamp2a* paralogs (hereafter referred to as si14 and si31, respectively).

Results
Our results showed that upon HG or H2O2 exposure, the KFERQ-CMA reporter accumulated in characteristic CMA-puncta that colocalized with lysosomes (Fig. 1A). Moreover, the half-life of the reporter was substantially shortened under these conditions compared to the CT, suggesting an active CMA-flux and supporting the existence of functional CMA in the RT. Then we observed that these mechanisms underlying the effects of HG on CMA in RTH-149 cells depended on the generation of reactive oxygen species (ROS) (Fig. 1B) at the mitochondrial level. In addition, the results showed that the NRF2 transcription factor mediates the upregulation of CMA by increasing the mRNA levels of both LAMP2A.

Finally, proteomics analysis reveals no significant alteration of any biological process in the cells transfected with si14 and exposed to HG, whereas different processes associated with cellular metabolism and its regulation were identified in si31 transfections (Fig. 1C), supporting a functional divergence between the two LAMP2As during hyperglycemia.

(Continued on next page)
Discussion
These sets of experiments univocally revealed that RT, like medaka, exhibits functional CMA activity, and emphasized, for the first time, the strong responsiveness of RT to HG exposure via the NRF2 pathway. Besides, the result highlighted the role of CMA, especially mediated through the LAMP2A paralogue 31, on the regulation of cellular metabolism upon glucose overload. Altogether, this work underlines the importance of considering this selective autophagy process to understand carbohydrate intolerance in carnivorous fish. Future studies will consider novel approaches for exploiting CMA metabolic impacts through aquafeed formulation to, in the last term, optimize the use of plant-derived carbohydrates and contribute to more sustainable aquaculture.

Introduction
Cell-based models provide valuable support in the search for alternative feed formulations in the aquaculture sector. A powerful in vitro tool should consist of epithelial and fibroblast cells. Indeed, as we recently demonstrated1, subepithelial fibroblasts modulate epithelial cell proliferation and differentiation in the rainbow trout (RT) intestinal mucosa. Moreover, growing data2,3 showed that increasingly elaborated in vitro models that closely recapitulate the morphological and functional features of the native organ, could generate feasible data for the in vitro versus in vivo correlations studies. The H2020-FETOPEN project Fish-AI, aims to develop such an in vitro screening platform based on rainbow trout digestive enzymes and intestinal cells to evaluate nutritional and health values of novel aquafeeds. As part of this project, we developed, characterized, and compared four gradually increasingly complex RT intestinal in vitro platforms from a morphological and functional point of view.

Material and methods
Rainbow trout proximal intestine epithelial cells (RTpi-MI) have been seeded on 1) the culture inserts ThinCert™ (TC) (Greiner BioOne, 0.4 m pore size, cat. No. 665640); 2) the same inserts but coated with the solubilized basement membrane matrix Matrigel® (MM); 3) the same but with the rainbow trout fibroblast cell line RTskin01 previously embedded within the Matrigel® matrix (MMfb); 4) the highly porous synthetic scaffolding Alvetex™ (Reprocell) (AV) previously populated with the same fibroblast cell line (AV). The generation of effective epithelial barriers in vitro has been investigated measuring the transepithelial electrical resistance (TEER) and the apparent permeability (Papp) to 4kDa FITC-dextran (FD4). Moreover, epithelial cell functionality has been assessed by investigating the enzymatic activity of alanine aminopeptidase (ALP), leucine aminopeptidase (LAP), and alkaline phosphatase (AP), 3 well-known enterocytes’ brush border enzymes. Thereafter, the 4 platforms have been characterized for their morphological properties using histological, and immunohistochemical techniques.

Results
All models successfully established an efficient barrier preventing the paracellular flux of FD4 and showing a significant increase of the trans-epithelial electrical resistance (TEER) compared to baseline values of their respective controls (inserts without cells). The value at plateau became higher going from the simple through the more complex models (TC-MM-MMfb-AV). Moreover, the activity of the brush border enzymes alanine aminopeptidase (ALP), leucine aminopeptidase (LAP), and alkaline phosphatase (AP), followed the same gradual pattern, suggesting that the presence of an epithelial and mesenchymal interface significantly boosted epithelial cells differentiation. Morphological analysis showed that RTpi-MI

Fig. 1 Representative pictures of the four platforms after the formation of a fully functional epithelial barrier (TC = ThinCert™, MM = Matrigel®, MMfb = Matrigel® with fibroblasts; Alvetex™ with fibroblasts).

(Continued on next page)
had a flat shape when cultured alone onto TC and MM systems. Conversely, they assumed a more in vivo-like phenotype when fibroblasts were present, acquiring a cubic shape on MMfb and a cylindrical shape on AV with brush border enzymes neatly located on the apical membrane. In addition, fibroblast organization was also different depending on the culture support. While in MMfb they were densely packed with only limited extracellular space from one cell to the other, cells assumed a loose arrangement in AV more like what occurs in the connective tissue. Moreover, fibroblasts that populated the AV scaffolding synthesized and remodelled their own extracellular matrix, indicating a higher degree of cell differentiation.

**Conclusion**
The presence of fibroblasts boosted epithelial cell differentiation and polarization providing a more physiological environment. Therefore, our results indicate that reconstructing the epithelial-mesenchymal interface in vitro is important for the development of intestinal artificial platforms able to generate reliable, predictive data suitable for in vitro/ in vivo correlations studies. This observation suggests that, as we recently observed in vivo, also in vitro fibroblasts may represent an essential source of growth and signaling factors actively involved in the modulation of epithelial cell functions\(^1\). Overall, the platform based on the Alvetex scaffold better recreated the morphological and functional complexity of an artificial the intestinal mucosa therefore it is being tested for its ability to reliably predict the nutritional value of feed formulations.

Introduction
Microplastics (MPs) are emerging as potential contaminants of aquafeeds that represent one of the main exposure routes for farmed fish. When ingested, MPs cross the gut epithelial barrier and are highly bioaccumulated in different tissues and organs [1]. This not only affects fish health but could be a threat for consumers. Several uptake mechanisms have been proposed for their absorption, including endocytosis, transcytosis, and paracellular diffusion. However, the knowledge of this phenomenon in vivo is still fragmentary and largely unknown, so that most pathways are only hypothesized. In this perspective, cell-based organotypic models represent a valuable tool to explore the molecular mechanisms at play. Therefore, a recently developed rainbow trout (RT, Oncorhynchus mykiss) in vitro intestinal platform, consisting of epithelial and connective cells [2], was used to evaluate MPs uptake.

Material and methods
Fluorescent MPs ranging from 1 to 5 µm (amino formaldehyde polymer, peak of emission at 636 nm when excited at 584 nm) were purchased from Cospheric LLC (Goleta, CA, USA). Some preliminary tests have been performed on RT proximal (RTpi-MI) and distal (RTdi-MI) intestine epithelial cells cultured directly onto plastic surface to: i) exclude any aspecific toxic effect; ii) verify MPs uptake; iii) identify the most suitable MPs concentration (12.5 mg/L-1, 25 mg/ L-1, 50 mg/ L-1). MPs were diluted in L-15 culture medium and cells were exposed for 24 hours. Cellular viability was assessed through Neutral Red Uptake (NRU) assay. Since F-actin labelling defines cytoplasm extension and DAPI labels nuclei, their combination was used to determine MPs internalization. The organotypic intestinal platform was made of RTpi-MI and RTdi-MI cells seeded on the upper surface of an Alvetex™ (AV) insert, a highly porous synthetic scaffolding, previously populated with fibroblasts. Platforms were exposed to MPs for 2, 4 and 6 hours, after an effective epithelial barrier was established, as indicated by the trans-epithelial electrical resistance (TEER) value reaching its plateau. MPs uptake and distribution within the scaffolding were evaluated through histological and confocal (Nikon A1R confocal microscope) analysis.

Results
After 24 hours exposure, neither pathological changes nor alteration of cell viability were observed in both cell lines, regardless of the tested concentrations. MPs co-localization with F-actin around the nucleus, demonstrated that MPs internalization followed a dose-response pattern reaching the highest values at 50 mg/L-1 concentration (Figure 1). Since this corresponds to an environmental-relevant concentration [3] it has been selected as the exposure dose in the AV platform. After 2 hours of exposure, MPs crossed the epithelial barrier (Figure 2); after 4 and 6 hours, they progressively reached the deeper regions of the scaffolding, being absorbed in both epithelial and stromal cells (figure 2). Absorption appeared to be more effective in RT proximal intestine cell line than in the distal, suggesting that the latter discourages MPs absorption. This pattern reflects the function of the intestine in vivo whose proximal tract ensures 70% of nutrient absorption.

Conclusion
RT epithelial cells internalize MPs following a dose-dependent pattern. The organotypic platforms seem to replicate the regional absorption differences observed in the intestine, making them a reliable tool to investigate and explore the molecular mechanisms involved in MPs uptake. On this basis, we are now exploring the expression of specific transport-pathway transcripts to identify the one(s) actively involved.

Introduction
European perch, *Perca fluviatilis*, is of high commercial importance in European intensive aquaculture, with an annual production of over 900 t (FAO, 2019). However, the production still fails to meet market demands. One bottleneck is the European perch’s high sensitivity to stress under captive conditions, which reduces immune resistance and at the same time increases the susceptibility to diseases (Milla et al., 2015). It has been hypothesized that the sensitivity to stress, and its impact on immunity, is related to the fish personalities. Therefore, beneficial personalities and stress-coping strategies may be promising targets for selective-breeding programs, which could help to overcome the breeding problems. According to recent research on farmed fish, it is known that bold/shy personalities correlate with behaviour variations in aggressiveness, recovery time, reaction to stress, and foraging (reviewed in Castanheira et al., 2017). Though, there are only limited reports on the relationship between personality and immune competence in fish, although this difference may magnify the resistance to diseases. We analysed the stress coping strategies of the bold/shy personality of European perch after exposure to a stressful condition. Furthermore, we investigated the link between both personalities and the defence against bacteria of the *Aeromonas* genus in vivo.

Material & Methods
One-thousand European perch juveniles were tagged with pit tag sized 7.0×1.4 mm (Loligo Systems ApS, Denmark) and stocked in a separate white tank (net water volume 800 L) within the RAS of the Faculty of Fisheries and Protection of Waters, University of South Bohemia (Czech Republic). To assess the personalities, 900 individuals were subjected to a) open-field test and b) novel-object test (Fig.1.). For the open-field test the fish were transferred into white rectangular tanks (one fish per tank; 37 cm [H] × 57.5 cm [W] × 73.5 cm [L]) and the individual activity (=distance moved) was measured. The novel-object test started right after the open-field test. A small yellow Lego block (LEGO 6176 DUPLO Basic Brick) was placed in the centre of the tank, and

(Continued on next page)
the behaviour of each fish was recorded for 30 min. Three parameters were determined from the video records: (i) the number of fish approaches to the Lego block, the closest distance from the Lego, and the latency of the closest approach to the Lego block. Somatic indices of each fish were calculated.

The top 20 boldest individuals (BI) and top 20 shiest individuals (SI) were subjected to a stress experiment in form of a crowding challenge. Water levels in the tanks were reduced to 5 cm above the dorsal fins of the fish for 30 min. Blood samples from five individuals per group (Bi, SI) were collected from the caudal blood vessels of anesthetized fish (MS-222; 200 μg in 10 L water) at four different time points: at 0 h, and 30 min, 12 h, and 24 h after the water level returned to the original level. Blood analysis included determination of enzyme activities, glucose and cortisol levels as well as ion concentrations. After seven recovery days a 100-μl suspension containing either 5×10^7 inactivated \textit{Aeromonas} ssp. or sterile PBS was injected into the peritoneal cavity of fish from both groups. Head kidney and peritoneal leukocytes were sampled after 1-, 3-, and 7-days post-injection. Tissue/cell analysis comprised cell sorting, phagocytic assays as well as multiplex quantitative PCR (qPCR) of a panel of assays specific for 46 immune-relevant genes on two 48.48 Gene Expression biochips (Standard BioTools) using the BioMark HD system (Standard BioTools).

Results
Testing 900 European perch individuals in an open field and novel object test revealed the top 20 boldest and top 20 shiest individuals. The crowding challenge had only minor effects on levels of glucose, osmolality, and activities of several metabolic enzymes. Remarkably, bold perch had significantly lower basal and crowding-induced cortisol concentrations, in contrast to the elevated cortisol levels across almost all matching SI groups. The phagocytic potential of the head-kidney leukocytes was not statistically different between \textit{Aeromonas} ssp/PBS stimulated BI and SI. The bacterial stimulus led to a proper transcriptional response of the immune system. Moreover, transcript levels of central immune genes were significantly increased in the head kidney (\textit{cc125}, \textit{ighm}, and \textit{Cd74}) and in the peritoneal cells (\textit{Cd74}, \textit{ighm}, and \textit{mmp9}) of BI compared to SI. Additional gene network analysis identified common and opposing patterns of upstream regulators for BI and SI, majorly comprising the typical nf-kb/rel-, stat- und irf-family members (and their associated regulators).

Discussion & Conclusions
We could affirm the existence of different personalities in juvenile European perch reflected by a clear discrimination between active individuals with pronounced exploration behaviour (BI) and rigid/immobile (SI) that took a freeze-hide position. Our data indicate that frozen activity and lower explorative behavior were positively correlated with lower ability in shy perch to cope with stress. We did not find any influence of personality on early innate immune mechanisms. Nevertheless, multiplex-gene expression profiling in the head kidney and peritoneal cells revealed that BI and SI responded differently to the intraperitoneal injection of inactivated \textit{Aeromonas} spp and it seems that the immunity of the SI is at a deficit compared to BI. We assume that selective breeding for a specific fish personality, with careful consideration of possible trade-offs, can be a viable way to improve the production efficiency of commercial European perch farms.

FREEZE-DRIED MICROALGAE PROVE A VALUABLE ALTERNATIVE FOR CULTIVATING EARLY LARVAL STAGES OF Litopenaeus vannamei SHRIMP

Introduction
Early larval shrimp stages rely on microalgae as their main feed. Cultivating these microalgae can be a real burden for individual shrimp hatcheries that focus only on the reproduction and culture of the shrimp itself. Although this is the common practise, ensuring the availability of a constant and large supply of live microalgae is not without challenges. Microalgae cultivation requires constant maintenance, is often space-demanding and requires a considerable investment. Timing of the start and harvest of the culture of utmost importance. Over time, live microalgae cultures may also show variation in their nutrient profile or crash due to biological reasons or contaminating grazers.

Fortunately, advances in cultivating, processing and storing techniques offer promising alternatives. Freeze-dried (FD) microalgae are a reliable and external source that is available all-year-round. The long shelf-life allows an easy distribution from a central production site. The freeze-drying process preserves the biochemical composition of the microalgae and allows for single cell dispersion upon rehydrating the biomass. Today, only a handful of companies specializes in the production of processed microalgae from several species. Despite these advances, the use of processed algae-based products in shrimp aquaculture is still limited and instead focusses on the production and enrichment of live feed (e.g. rotifers and copepods) or inclusion as ingredient in formulated feed. Few publications mention the use of alternative processed algae-products for shrimp larvae.

In the current study, we investigated the potential of the FD form of a selection of microalgae species commonly used in shrimp hatcheries and that have a relevant nutritional profile, as feed for larval penaeid shrimp (Litopenaeus vannamei).

Materials and methods
L. vannamei nauplii (stage 1) were obtained from Imaqua BVBA (Lochristi, Belgium) and stocked in 100-L cylindroconical poly-ethylene tanks filled with 90L of filtered natural seawater, at a density of 140 larvae L-1. Water temperature was set at 29°C, and the light-dark cycle at 12:12 hours. The larval tanks had a 200 µm mesh sieve at their outlet, and were further connected to a filter unit consisting of a protein skimmer and a biofilter, allowing to operate the tanks in batch and later-on in recirculation (RAS). All tanks were connected to the filter units once the larvae reached the mysis 1 stage. Water renewal rate was set at 300% of the tank volume per day. A standard feeding protocol was applied, providing microalgae at around 100 000 cells ml-1 for the zoea stages, and 100 000 towards 50 000 cells ml-1 for the mysis stages. FD microalgae were prepared through a series of blending and hydrating steps before administration to the tanks. Artemia instar I nauplii were introduced from the late zoea 3 stage onwards.

A series of experiments was conducted, wherein the following factors were investigated: microalgae species, microalgae form (live vs FD), rearing system (batch vs RAS) and feed inclusion rate (100% live, 100% FD or 50% of both). Depending on the experimental setup, treatments were performed in triplicate or quadruplicate. Trials were terminated when all treatments reached the postlarval stage (10-12 DPH). Evaluation criteria included survival to the postlarval stage, developmental stage index, fecal production, body fouling and water quality (TAN). All microalgae were supplied by Proviron (Hemiksem, Belgium), including live Chaetoceros muelleri, Thalassiosira pseudonana, Isochrysis sp. Tahitian strain and Tetraselmis chuii, and their FD form, known under the product names ChaetoPrime, ThalaPrime P, IsoPrime and TetraPrime C, respectively.

Results
High survival to the postlarval stage was observed for shrimp larvae fed freeze-dried microalgae: 50.0 ± 8.8 % and 61.5 ± 7.6 % for FD C. muelleri and T. pseudonana, respectively. The highest survival, 70.3%, was observed under FD T. pseudonana. Both diets were supplemented with FD T. chuii for its antimicrobial effect. These survival rates were similar to those of larvae fed live microalgae.

(Continued on next page)
We also observed a substantial body fouling of the shrimp larvae during the zoea stages, more specifically on all antennae and the setae of the maxillipeds and the telson. The most severe fouling was observed on zoea 1 and 2 stages, and consisted mainly of small algae clumps. No more body fouling was observed from mysis 1 onwards. The fouling did not prevent the larvae from metamorphosing to the next developmental stage, as shed molts covered with microalgae clumps were observed. Visual observation showed that some heavily fouled larvae experienced a lower mobility compared to those free of fouling. Additionally, larvae fed FD microalgae also experienced a 1-day delay in development compared to larvae fed live algae. Whether this is the cause of the body fouling has not been validated yet.

**Conclusion, challenges and opportunities**
Live microalgae can be substituted 100% by their freeze-dried counterparts in larval shrimp diets, without affecting survival, albeit with some side-effects including body fouling and a delay in developmental stage. Current and future studies are further investigating the cause of these observations and how further advances in microalgae processing and preparing could mitigate these side-effects.

Introduction

The sustainable extraction and production of food and biomass from the oceans is a priority with increasing attention and awareness. In line with this global interest, aquaculture-related activities in Flanders (Belgium) have been growing over the last two decades. Both industry and government are investing substantially in local aquaculture initiatives. However, they all face one common problem: the lack of starting material (bivalve spat, shrimp postlarvae and seaweed spores) in sufficient quantity and in desired quality, emphasizing their dependence on import or wild-catch. Within this project, we adapted hatchery and nursery concepts for molluscs, crustaceans and macroalgae to local (temperate) conditions, incorporated local North Sea species, and expanded our biological and technological knowledge on hatchery and nursery techniques with a strong emphasis on synergies and integration between the three species groups, in terms of infrastructure, rearing techniques and management.

The final goal was to design an integrated approach of a multispecies hatchery and nursery platform and knowledge center, and promote the development of aquaculture in Flanders, Belgium. The results were achieved by a team of academic and private partners with expertise in sustainable aquaculture (BlueGent), hatchery techniques and live feed (UGent-ARC), seaweed (UGent-Phycology), ecological risk assessment (UGent-GhEnToxLab), microalgae culture (Proviron), shrimp broodstock management and disease testing (Imaqua bvba), bivalve culture (Aquacultuur Oostende), food retailing (Colruyt Group), seaweed cultivation and advanced aquaculture textiles (SIOEN) and offshore solutions (DEME Group).

Approach

For each species group (macroalgae, molluscs and crustaceans), we started by collecting the baseline information and setting up the experimental infrastructure and biological material. We then investigated specific innovations (strain selection, RAS application, alternative feeds, disease control, …). Synergies in facilities and rearing techniques were identified and integrated concepts validated. Based on the experimental data, these synergies were then quantified and the gain in economic and ecological sustainability was valued through an integrated assessment tool. The final result is a first conceptual blueprint for a modular, integrated hatchery and nursery pilot, that forms the basis for a production unit for starting material, service center for experimental validation and knowledge hub for stakeholders.

Main results

A collection of local strains of five commercial seaweeds was built to serve as reliable source for the production of spores. The life cycle of the red seaweeds *Palmaria palmata* and *Porphyra umbilicalis* was further unravelled. Strains of *Ulva* sp. were selected, and the genomic diversity of favourable traits characterized, which resulted in an HD SNP map. Biodegradable cultivation substrates and binders for macroalgae spores were also investigated.

(Continued on next page)
A functional RAS was designed and successfully implemented for the nursery cultivation of two oyster species (*Crassostrea gigas* and *Ostrea edulis*), observing a growth rate close to that of commercial hatcheries. A model on the associated mineral consumption reveals that the addition of Ca and CO$_3$ is vital for culturing bivalves in a closed system. The microbial community profile associated with the mono- and multispecies setup was characterized. The first floating upwelling system (FLUPSY) in Belgium was successfully built and tested in the Spuikom, Ostend. The life-cycle and technical requirements for hard-to-culture microalgae species such as *Isochrysis galbana* and *Skeletonema marinoi* were documented and the first steps towards the upscaled cultivation of these species was undertaken.

The life cycle control of feed requirements for both the tropical *Litopenaeus vannamei* and the indigenous cold-water *Palaemon* prawn has been optimized. Shrimp larvae were successfully reared in a closed recirculating system, with a survival equal to that in batch systems. Freeze-dried microalgae proved a valuable alternative to live microalgae for the cultivation of early larval stages of *L. vannamei*, with some treatments reaching up to 70% survival. This further reduces the dependence on and the investments in a local microalgae culture. The microbial community profile in systems fed with either of microalgae feed forms was characterized. New disease testing tools for shrimp were developed.

The synergies between monospecies cultures were identified to establish experimental multispecies setups that provided insight into the nutrient flow between the system compartments and cultured organisms. Multiple proof-of-concepts on different combinations of resource recycling and species co-culture (integrated multitrophic aquaculture; IMTA) were investigated. An environmental impact and economic feasibility assessment were done for the most relevant scenarios. With the collected knowledge from all mono- an multispecies assessments, a first conceptual blueprint for a modular multispecies hatchery and nursery pilot was developed.

Introduction
Norway is a global leader in salmon farming, with the aquaculture sector expecting to grow in the future to reach consumer demand. Advocates argue farm raised salmon have a low carbon footprint, and aquaculture can therefore play a pivotal role in reducing the carbon footprint of food production. The detractors, on the other hand, argue aquaculture poses an environmental threat as escaped salmon may hybridize with natural populations, and high population densities in pens lead to an increase in local pollution and sea lice occurrence. Furthermore, delousing of the fish is a challenge for fish welfare, the opponents argue. New production systems for salmon fish farming (i.e., land-based, floating closed, semi-closed, and open ocean aquaculture systems) aim to counter these challenges, as well as utilise new areas for production. More knowledge is needed regarding how these new production systems should be regulated, and how they will influence the public perception of the salmon farming industry.

In this study, variables relevant for exploring key future scenarios are co-developed during participatory stakeholder workshops using Fuzzy Cognitive Mapping (FCM), a soft computing framework. Industry stakeholders decide on relevant variables to include in models, how they influence each other, and discuss feedback mechanisms in participatory workshops. Data collected during workshops are then used as the basis for the creation of FCM models (Kosko 1986), which combine fuzzy logic and recurrent neural networks, to produce predictions of changes to the perception of salmon farming in response to potential future scenarios. The results from models (i.e., values that represent the strength and direction of change to the perception of salmon farming in response to different scenarios) were then made interactable and accessible through their integration into a lightweight web application as a first-generation policy action tool.

The application is developed to make the results from this study accessible to diverse stakeholder groups. Thus, a concise description of how the model functions and how to interpret results from the scenarios is included in the app. In addition, information on the relevant variables defined by stakeholders and the fuzzy cognitive map describing the relationship between variables stakeholders defined in workshops is provided to users for easier interpretation of results.

Methods
Stakeholders included in the participatory workshops included industry representatives working with new aquaculture systems in Norway, researchers, and representatives from trade organisations. The variables that stakeholders identified as relevant to Norwegian salmon farming and their interactions were visualized in the freeware Mental Modeler throughout workshops to facilitate the co-production of a map of the system. Connections between variables were quantified on a continuous scale between -1 and +1, where a negative value indicated that if one variable increased, the variable on the receiving end of the “negative” connection would decrease. -1 indicated a strong decrease in the connected variable (and it follows +1 indicated an increase in one variable would also result in the direct, strong increase in the connected variable and values near zero describe weak relationships between variables). These values served as the basis of a semi-quantitative model we used to describe our system and the basis of the creation of the projected future outcomes that were possible to interact with in the web application. Variables and their relationships were calibrated and validated in subsequent workshops.

Models were developed using the FCM package (Dikopoulou and Papageorgiou 2017) in R. Models were fit with the rescale inference rule which is preferred where there is not previous information about a concept-state, and we did not have information on the initial state of the system (Papageorgiou 2011). A sigmoidal transformation function was applied as sigmoidal (continuous) FCMs are recommended for quantitative and qualitative scenarios with complex feedback structures as we found in our system (Tsadiras 2008). The weight matrix consisted of the values obtained from the participatory

(Continued on next page)
workshops. The application was built using Shiny (Chang et al. 2023), an open-source framework for building interactive web applications. One interactive element of the application is in the form of a drop-down menu where users can select what variables to have a positive value in the activation vector. Visualizations and the table of values predicted for each variable in the application show values reached once the model has reached convergence and the system has reached an equilibrium point. The model outputs shown in visualisations from the user’s chosen scenario are based on the stakeholders’ perception of the system if there is a change to the current system. Feedback from stakeholders have been and will be implemented to make the app more user friendly. Specifically, similar variables were grouped together to simplify the interpretation of the results and the app is being developed in both Norwegian and English to match the language needs of different users (from local industry actors to academics). Stakeholders will be invited to give feedback on the application to ensure a user-friendly interface is created as development of the app continues.

**Results & Discussion**

Following the axiom “all models are wrong, but some are useful,” the outputs of the workshops and FCM models in the web application will not be used as predictions of how perceptions will change as Norwegian salmon farming changes. Indeed, the data collected from stakeholders is limited due to the small number of actors it is possible to include in workshops. Outputs from the models may be useful 1) in the context of engaging non-experts in research and 2) for serving as conversational focal points for ideating scenarios and informing decision making. The FCM developed in workshops also serves an important purpose as a simplification of the challenges faced by the Norwegian salmon farming industry, which allows for the visualisation of important and sometimes surprising relationships between identified variables. The app’s value comes from its ability to bridge gaps between researchers and stakeholders and between stakeholders themselves who may have differing opinions on how different variables will affect other variable under future scenarios. Indeed, the app may be used as a policy action tool, and to improve the communication between resource managers, regulators, policy makers, and actors from industry who make critical choices and researchers beyond a traditional scientific article or report. The conversations that result from interaction with the digital tool can thus be used to inform decision makers on how to develop Norwegian salmon farming in coming decades under different scenarios.

Climate change and the overexploitation of the natural resources of the oceans and land for cultivation drive the need for innovative food production within a sustainable, healthy and profitable framework according to EU guidelines. Organic and Innovative technologies, such as aquaponics which is a perfect symbiosis between aquaculture and hydroponics is undoubtedly a solution to alleviate this type of problems. Tilamur is an SME that since 2012 has been working on the implementation of innovative technologies for efficient aquaponics solutions. Since 2021 Tilamur is participating in one of the most ambitious projects in the application of innovative technologies for aquaculture and precision agriculture called Pestnu which has been financed with funds from the EU (Nº 101037128). Over these first 18 months of project execution, Pestnu project has implemented two digital automated analyzers for nitrites, nitrates and ammonium into the fish tank and the nutrients tank for the plants, which provide us in situ with real-time measurements of these types of parameters that are so essential in aquaculture and agriculture. The implementation of this type of technology has provided us with a 60% saving in reagents and analyzes from external laboratories as well as a reduction in labor when collecting daily samples. In the field of agriculture we have installed automatic traps capable of monitoring pests of different insects in real time, an autonomous robot capable of detecting and treating infected plants, satellite technology to monitor the state of water stress and health of the plants at all times. floors. Following the EU guidelines in the field of biostimulant use, the Pestnu project has developed this type of biofertilizers through waste from residual water treatment plants and microalgae cultivation, managing to strengthen the immune system of plants and a saving of almost 50% in fertilizers.
FATTY ACID PROFILE OF RAINBOW TROUT (*Oncorhynchus mykiss*) SUPPLEMENTED WITH DIETARY TRIBUTYRIN: PRELIMINARY APPROACH BY GAS CHROMATOGRAPHY

Introduction

The production of short-chain fatty acids (SCFA) results from anaerobic bacterial intestinal fermentation of soluble fibre carbohydrates leading to an intricate functional cross-talk between diet, gut microbiome and host metabolism. While most studies on aquaculture species focus on the supplementation of SCFA in their salt forms, SCFA delivered as their equivalent triacylglycerol (TAG) forms has huge potential. Tributyrin (TB), the TAG forms for butyrate, rapidly generates the release of 3 fatty acids (FA) along with glycerol following intestinal lipolysis. TB has been well studied, showing the potential to improve animal performance and productivity in land-farmed animals when added as dietary supplement, however its applicability in aquafeeds is less studied (Palma et al., 2023). According to earlier research, supplementing fish and shrimp diets with TB may help to mitigate some of the drawbacks of including plant-based ingredients on aquafeeds. This will be especially challenging for carnivorous species such as rainbow trout (*Oncorhynchus mykiss*), which require the replacement of a significant amount of fishmeal with plant-based proteins to improve diets sustainability. Previous results on *O. mykiss* supplemented with variable percentages of TB did not improve growth or feed efficiency, nor did they reduce feed intake (Espirito Santo et al. 2022). As a preliminary approach, gas chromatography (GC) was used as methodology to assess the effects on fatty acids profile of digesta, intestine, liver and muscle of *O. mykiss* supplemented with TB.

Material and Methods

Four hundred eighty juvenile trout (19.0±0.4 g, mean±SD) were randomly distributed in 12 tanks, connected to a RAS system under controlled conditions (16±1°C; 0.30±1‰; pH 7±1; >95% air saturation; 12 h:12 h photoperiod). Four experimental diets: basal diet (control; TRB0) including 10% fishmeal and 70% plant-based ingredients (44% crude protein, 18% crude fat, gross energy 21.8 MJ kg⁻¹) with inclusion levels of 0.1 (TRB1), 0.2 (TRB2) and 0.4% (TRB4) of a product containing 55% TB (Lucta S.A.) in replacement of silica. After 44 days, three fish per treatment were sampled after 6 h and 24 h of feeding to evaluate the impact of dietary TB supplementation on the FA profile.

Muscle, liver and intestine were collected and tissue extraction was performed by MTBE method (Matyash et al., 2008). Digesta was processed according to Louvado et al. (2020) followed by MTBE extraction. Dried samples were resuspended in 1 mL of hexane and 0.5 mL of methanol. After vortex, 400 μL of sodium methoxide were added. The top layer was filtered with a nylon membrane and 150 μL of the filtered solution was placed in a vial and added 100 μL of the internal standard methyl nonadecanoate (C19:0) (Sigma-Aldrich) with a final concentration of 0.3 mg/mL. The GC was performed in a NEXIS GC-2030 (Shimadzu) chromatograph equipped with a flame ionization detector and a TR-CN 100 capillary column (60 m × 0.25 mm × 0.20 μm). Helium was used as carrier gas at a pressure of 150 kPa at the top of the column. The temperature of the injector and detector was 260°C and the split ratio was 1:25. The initial temperature of the column was maintained at 90°C for 7 min after the injection, increasing 5°C/min to 220°C and held for more 15 min. The data were acquired and analyzed using Lab Solutions data analysis software. FA were identified by comparing the relative retention times with an authentic external standard, Supelco 37 component FAME mix (Sigma-Aldrich). The quantification of FA was based on the internal standard method. The results were expressed in percentage of the total FAME (%).

(Continued on next page)
Statistical analysis and graphic design were applied to fatty acid relative abundances values using GraphPad Prism 6.0 (GraphPad Software Inc., San Diego, CA, USA). A two-way ANOVA was conducted on these values with a Sidak’s correction and multiple comparisons (ntotal=24, nreplicates=3).

Results and Discussion

GC analyses were able to identify and relatively quantify sixteen FA from C14:0 to C22:6n-3 in muscle, thirteen in intestine and liver, and eleven on digesta. SCFA (C1:0 – C5:0) were not detected. Similarly to our results, SCFA were found below the limit of detection on the intestine of zebra fish (Danio rerio) (Cholan et al., 2020). Considering this is a preliminary study, no major effects were found on intestine, liver, and digesta samples (p > 0.05, two-way ANOVA). In muscle, after 6 h, C14:0 and 18:1ω9 cis were the only FA that presented some variations between experimental groups. C14:0 was higher in TRB2 when compared to TRB0, while 18:1ω9 cis was higher in TRB1 when compared to TRB0. Other FA were found only in certain groups, such as C20:0 that was found only in the 3 replicates of the fish with TRB4 diet at 6 h. In digesta, the FA found in higher percentage were C16:0, C18:0 and 18:1ω9 cis. The lack of significant differences between experimental groups in this particular sample could be explained by the high variability observed within individuals.

Conclusion

With this preliminary approach GC could not detect SCFA (C1:0 – C5:0) in muscle, liver, intestine and digesta of O. mykiss supplemented with variable percentages of TB. However, we were able to perform a FA profile on these samples, which did not reveal significant differences in most FA after dietary TB supplementation.

SUPPORTED COVALENT ORGANIC FRAMEWORK TO REMOVE GEOSMIN FROM WATER IN AQUACULTURE

Email: ana.vieira@inl.int

Geosmin, a metabolite of gram-positive bacteria actinomycetes and fungi, is a bicyclic alcohol detected by humans as earthy and mud taste at very low concentrations (from 5 to 50 ng/L, depending on the matrix) [1]. Therefore, for the aquaculture sector, the presence of this compound implies high production costs due to the low acceptance by the consumers.

Covalent organic frameworks (COFs) are porous crystalline materials with long-range order [2,3], which, due to their small pore size (1−5 nm), tuneable structure, and large surface area, have been demonstrated as efficient materials for the capture of different molecules from water, e.g., different types of pharmaceuticals [3,4]. In this work, different COFs with varying pore size and functional groups were tested for their capacity to adsorb geosmin. The conditions were optimized for the material to be able to adsorb concentrations of geosmin far above the detection limit of humans. In addition, geosmin desorption was studied and optimized to allow for the reuse of the COF adsorbent.

Among the tested materials, the COF with best efficiency could adsorb 78 mg of geosmin /g of COF, reaching equilibrium after an incubation of only 30 s. TpBD-Me2 was selected for further characterization. Additionally, geosmin could be removed from each COF by a simple incubation in organic solvent. At least five cycles of reuse were demonstrated without significant efficiency loss.

However, COFs are powders as synthesized and should not be used directly in water as their recovery would be extremely difficult and their release into the environment could lead to some ecotoxicity [5]. To overcome this, TpBD-Me2 was supported on alumina pellets, keeping high adsorption capacity for geosmin.

Introduction

Multiple aquatic invertebrates have the necessary enzymatic machinery for de novo biosynthesis of long-chain (≥C20) polyunsaturated fatty acids (LC-PUFA) including the so-called “omega-3” EPA (20:5n-3) and DHA (22:6n-3). Two distinct types of fatty acyl desaturases, namely methyl-end (ω des) and front-end desaturases (Fed), are known to be involved in animals’ LC-PUFA biosynthesis [1]. Iron (Fe) has a prominent role in LC-PUFA biosynthesis since it is a cofactor involved in the active di-iron centres of all aerobic desaturases [2]. Since expression of desaturases involved in LC-PUFA biosynthesis can be increased by feeding a low LC-PUFA diet, an innovative strategy to enhance the endogenous production of LC-PUFA in aquatic organisms consists of dietary Fe supplementation to guarantee adequate supply under conditions resulting in desaturase activation. Supplementation of Fe has been shown to positively influence LC-PUFA biosynthesis in salmonids [3] but, to the best of our knowledge, has not been yet investigated in invertebrates. The present study aimed to assess dietary Fe supplementation as an enhancer of LC-PUFA biosynthesis in the nereid polychaete Hediste diversicolor, a commercially important species with great interest for aquaculture.

Materials and Methods

First, an in vitro trial was carried out by growing transgenic yeast expressing the H. diversicolor desaturases (two ω des and two Fed) in the presence of specific fatty acid (FA) substrates. For each desaturase, the following treatments were tested: no Fe supplementation (control), supplementation with FeSO₄ (inorganic Fe), supplementation with ProPath® Fe (organic Fe), and supplementation with an Fe chelating agent (chelator). The desaturase activity of transgenic yeast was estimated by calculating the conversion of the FA substrate into the FA product. Second, an in vivo trial with H. diversicolor juveniles was carried out. Briefly, 20 worms (25-50 mg ww) were randomly distributed in nine experimental units (3 units x 3 diets). The worms were fed for 7 weeks on an experimental diet with low LC-PUFA (control), which was supplemented with either FeSO₄ (inorganic Fe) or ProPath® Fe (organic Fe). Worms were fed to 4% of the biomass 5 d per week. Survival and specific growth rate (SGR) were recorded. After 7 weeks, the animals were starved for 24h prior sampling for lipid analysis. Total lipids were extracted and quantified gravimetrically, with an aliquot being transmethylated to fatty acid methyl esters (FAME), and analysed using gas chromatography. The results were processed using principal component analysis (PCA). FA analyses from yeast (in vitro assay) were carried out as described above for worm samples.

Results and Discussion

In the in vitro trial all the H. diversicolor desaturases converted the specific FA substrate into the corresponding product with inorganic and organic Fe treatment exhibiting higher enzyme activity than control. The Fe chelating agent reduced the activity of αl desaturases (Figure 1a). These results suggest that Fe can effectively enhance desaturase activity as previously reported in yeast [4]. At the end of the experiment, no significant differences (p>0.05) in SGR (average of 0.084) nor survival (96.1±4.2 %) were found among treatments. Moreover, the results from the in vivo trial did not show any clear effect of organic and inorganic Fe supplementation on the FA composition of H. diversicolor whereas a clear segregation of the day 0 samples was found (Figure 1b). High levels of 18:1n-9 and 18:2n-6 (23.6 and 19.3%, respectively) on the FA profile of all treatments were found, suggesting a strong dietary effect (34.4 and 15.4%, respectively). Besides, in all treatments, the FA composition of polychaetes showed high levels of PUFA (33.4%) such as 20:4n-6 (ARA), EPA and DHA, indicating bioconversion and trophic upgrading. The reasons underlying the apparent discrepancy between the enhanced desaturase activity observed in vitro and the lack of increased LC-PUFA biosynthesis in worms fed on Fe supplemented diets (in vivo trial) remain unclear. However, it is reasonable to speculate that the Fe enhancing effect on LC-PUFA biosynthesis could not be detected in the present study due to an insufficient capacity of experimental diet to increase the expression of fatty acyl desaturases in vivo. Further analyses on gene expression, as well as FA composition of the polar and neutral lipid fractions, will contribute to clarify the role that dietary Fe supplementation may play as enhancer of LC-PUFA biosynthesis in H. diversicolor.

LESSONS LEARNED: CHALLENGES AND SOLUTIONS FOR FISH HANDLING IN LAND BASED AQUACULTURE

E. Vinje

MMC First Process
Digerneset Naeringspark
6260 Skodje, Norway
E-mail: eivind.vinje@mmcfp.no

Introduction
In traditional sea-based salmon farms, fish is vulnerable to sea lice, predators and various diseases, to mention a few. The current open-pen solutions are not possible to grow further in many countries due to these issues. Land-based aquaculture solves many of these challenges as well as offering other benefits to the fish and environment, but at the same time new risks are present.

Challenge 1: High capex need
For land-based aquaculture, there is undoubtedly a much higher capex demand than sea-based alternatives. To ensure that the project is profitable, it is required to utilize the production capacity optimal. The solution is to design the system to be flexible, allowing fish to be moved from any tank in the system, split on size, and moved back to any two tanks in the farm – and at the same time minimize the required piping.

Challenge 2: Gentle fish-handling solutions
Handling the fish as it grows larger is increasingly complex. Pumping a full-grown salmon is much more challenging than a smolt, making technology from traditional smolt farms not suitable for the larger fish. The solution is to learn from the wellboat industry (live fish carriers) that has evolved over decades to handle big fish. This includes crowding grids, pumping without impellers, avoid sharp bends, keep the fish in water as much as possible, to mention a few.

Challenge 3: Good water quality
Increasing the biomass density and at the same time moving the fish often between tanks will stress the water quality in the system. With such a high value in the tanks, giving the fish proper water quality is crucial. The solution is to ensure good water circulation in the tanks, and stable and efficient water treatment. Using circular tanks and correct diameter/height ratio ensures even water distribution and minimized risk of H2S or low oxygen areas. Traditional biofilters are complex and difficult to grow, but there are alternatives with either a hybrid flow-through system, or electrochemical water treatment. A typical hybrid flow-through system will not include biofilter, but CO2 degassing and particle removal, and a higher exchange of water than RAS system. Lately, electrochemical water treatment solutions is proven as an excellent alternative as well.
DAILY CROWDING STRESS AFFECTS WOUND HEALING, WELFARE, AND TRANSCRIPTOMIC RESPONSES IN SURGICALLY TAGGED ATLANTIC SALMON (Salmo salar)

M.I. Virtanen*, M.F. Brinchmann, and M.H. Iversen

Faculty of Biosciences and Aquaculture
Nord University

E-mail: miiro.i.virtanen@nord.no

Introduction
A 20-year average grow out site mortality rate of 17% in Norwegian aquaculture has been observed (DOF, 2022). While approximately 400 aquatic species are being farmed and aiding species diversity, only 25 species have been the subject of five or more published welfare studies (Franks et al., 2021). These findings underline the need to improve and expand our understanding of aquatic animal welfare. Using smart tags embedded in fish offers a novel real-time avenue to monitor and document species-specific welfare (Macaulay et al., 2021). However, the tagging process and the presence of the tag must not disrupt the fish’s natural biological and behavioural patterns. Thus, our study aims to evaluate the potential stress effects over time on the healing process by analysing gene expression in the skin and head kidney. We also present previous observations on physical wound changes and physiological alterations from the same sampled fish (Virtanen et al., 2023).

Materials and methods
In nine 1.0 m$^{-3}$ indoor seawater tanks, 30 ~1kg Atlantic salmon per tank were kept under constant conditions. Sixty-eight days of acclimation were given, and the three experimental groups consisted of: Control, Wound, and Wound + Stress (Stress+). Starting on day 7 up until day 56, nine fish from each group were sampled weekly (three fish per tank, three tanks per group). The Control group was untouched, the Wound group received an abdominal dummy tag, and the Stress+ group had the tag plus a daily crowding stress, where the water level was drained significantly in the tank and then, after 30 seconds at its lowest point, brought back to normal levels. Skin samples were taken weekly from a location 1.5 cm away from the incisional wound (and from a similar location in the control group), along with head kidney samples. Both tissues were analysed using rt-qPCR to examine 14 genes related to cell signalling, immunity, wound healing, and stress. Based on rt-qPCR results skin samples from weeks 1, 4, and 8 were selected and underwent RNAseq analysis.

Results
Regarding physical wound changes, external wounds were sealed by week 5 in both treatment groups, while external inflammation was larger in Stress+ fish than in only wounded fish. Internal wound healing was only seen sealed at week 8 for two individuals in the Wound group; generally, the wound was larger in the Stress+ group. No significant effects were seen on stress responses in the wound group. In contrast, significant increases in ACTH and cortisol production were visible starting at weeks 4 and 6 respectively, and fin erosion was worse in the stressed group starting at week 3. Regarding head kidney transcription, a possible early immune suppressive effect was seen in the Stress+ group compared to the wound group, specifically during week 2 and consistently for il-2 for the first three weeks. For the skin samples, limited differences were seen between the Stress+ and Wound groups, however week four showed the biggest difference within mmp9 and mmp13 being significantly expressed in the Stress+ group. In the head kidney samples, mmp 9 and 13 were still upregulated at the end of the study likely due to internal wound healing. Regarding the RNAseq data, no differentially expressed genes were significant between the two treatment groups at week 1, however by week 8, a major disruption in genes associated with cellular and metabolic processes was observed. Additionally, the most differentially expressed genes were seen at week 1 when comparing treatment groups to the Control group.

Discussion & conclusion
The results show that introducing stress delays wound healing, amplifies the inflammatory response (not seen through cytokines), dysregulates the stress response, and significantly alters gene expression as the combined stress and healing process progresses. Conversely, the tagging process does not create physiological stress (with the first sampling being 7 days post-tagging), and wound healing proceeds in a regulated manner. Practical implications from the study are that tagging can be seen as non-stressful 7 days post-tagging, tags should be positioned away from the wound incision due to the prolonged internal healing process, transcriptional markers identified through RNAseq can aid in early detection of potential issues while possibly suggesting possible avenues to enhance fish skin health and welfare post-tagging. Furthermore, even though some results (like those from rt-qPCR) show only limited effects, all results underscore the importance of providing a stress-free environment for fish during wound healing and tagging where the first three weeks are seen as the most critical time.

Introduction:
Enhanced growth, immunity, and temperature stress resilience are highly sought-after phenotypic traits in aquaculture, yet our understanding of their genetic regulation is extremely poor. Omics approaches, such as proteomics and metabolomics, are powerful tools to understand the effects that nutrition and environmental conditions exerts upon cultured animals, and how the animal responds to external stimuli. Application of omics technologies in aquaculture can enable manufacturing of advanced diets that provide specific nutrients intended to attain enhanced growth, immunity, and resilience that lead to increased production yield while ensuring environmental sustainability and promoting animal welfare and social license.

Methods:
In shrimp hepatopancreas and haemolymph, data independent acquisition (DIA) proteomics and metabolomics were used to elucidate metabolic pathways activated by the inclusion of the microbial biomass Novacq™ compared with a control group fed a fishmeal diet. In salmon, a rapid targeted proteomics method was developed and used to quantify stress in liver of salmon subjected to increased temperatures. In addition, targeted metabolomics was applied to detect modifications to central carbon metabolism in the plasma of thermally stressed fish.

Results:
A strong signature of glycoconjugate metabolism driven by hexosaminidases and arylsulfatases A and B was observed in DIA results for Novacq™ fed shrimp. This was complemented by metabolomics that revealed a significant ten-fold increase in the abundance of the chitin amino sugar precursor N-acetyl D-galactosamine. Joint-pathway analysis indicated that Novacq™ fed shrimp preferred using energy from carbohydrates through activation of the amino- and nucleotide sugar metabolic pathways. In salmon exposed to high temperatures, a multiplexed 55-peptide thermal stress panel revealed many are significantly changed by temperature, with abundance of two different serpin peptides significantly correlated with increased temperature. Targeted metabolomics of plasma revealed significant reductions in key amino acids and vitamin precursors, while significant increases were recorded in purine and pyrimidine nucleotides.

Conclusions:
In shrimp fed Novacq™, combined DIA proteomics and metabolomics pathways revealed mechanisms of energy utilisation, enhanced growth and immune defence stimulation. In salmon at high temperature, two serpin peptides were identified as highly sensitive temperature responsive biomarkers in liver, along with changes to amino acid and nucleotide metabolism in the plasma. Detection in non-invasive tissues such as plasma or mucous will facilitate monitoring the effectiveness of strategies to reduce impacts of stress and improve farmed salmon welfare.
DEUTERATED WATER STABLE ISOTOPE ENRICHMENT AND METABOLIC FLUX ANALYSIS TO TRACE NUTRIENT UTILISATION IN CRUSTACEANS

Introduction:
The efficient utilisation of dietary ingredients is of primary importance in aquaculture nutrition, in order to optimise feeding efficiency, profitability and reduce nutrient loss into the environment. Apparent digestibility of diets and their ingredients are traditionally measured as an indication of ingredient and feed quality, but this does not guarantee the residual absorbed nutrients are utilised adequately. Special consideration of the method in shrimp is needed to account for potential nutrient losses from leaching. Tissue composition and the impact of various dietary assimilated lipid sources has also been extensively studied, but this sheds little light on the metabolic capacity of the animal once the nutrients are ingested.

More recently, the impacts of feed ingredients have been measured using various molecular (gene expression) and omics (RNAseq, proteomics, metabolomics) techniques. A complementary technique is to incorporate inert, non-radioactive stable isotopes into the water (i.e., $\text{D}_2\text{O}$ or deuterated water), and/or enriched within specific feed ingredients ($^{13}\text{C}$ or $^{15}\text{N}$), to track the metabolic transformations over several days of feeding. This technique has been highly successful in fish, to calculate the fractional synthesis rate (FSR) of glucose, glycogen, triacylglycerides (TAGs) and free fatty acids (FFA), or muscle protein synthesis by using alanine as proxy, and define the impact of dietary starch or other ingredients on hepatic metabolism.

Methods:
In this study, the fundamental ability to track nutrient assimilation in crustaceans using stable isotope enrichment was assessed in black tiger shrimp, \textit{Penaeus monodon}, using seawater enriched with 5\% $\text{D}_2\text{O}$. In the first phase, body water (as estimated from hemolymph) $^2\text{H}$-enrichment during residence time in seawater was tracked over time in unfed shrimp. Aqueous metabolites were extracted from shrimp hepatopancreas, muscle and hemolymph from the 48 h group and quantified by $^1\text{H}$ NMR. Subsequently, 12 shrimp were fed twice daily a standard commercial diet over 3 consecutive days in 5\% $\text{D}_2\text{O}$ enriched seawater. The lipid phase was extracted from hepatopancreas and muscle tissue and subjected to both proton ($^1\text{H}$) and deuterium ($^2\text{H}$) NMR to calculate FSR. Protein FSR was estimated from $^2\text{H}$ incorporation into protein bound alanine extracted from muscle tissue.

Figure 1 A) Evolution of hemolymph body water $^2\text{H}$-enrichment with the residence time in tank water enriched with 5\% (mean $\pm$ SD; 5, 10 and 15 min $n = 8$, the remainder $n = 6$). One-way ANOVA followed by Tukey test ($p<0.05$), with significant differences indicated by different letters. B) Partial Least Squares (PLS) scores plot computed with the metabolites concentration in plasma, hepatopancreas and muscle samples ($Q^2 = 0.983$; $R^2 = 0.991$; 1000 permutations: $P = 0.001$).
Results:
Results showed that body water rapidly equilibrated with tank water after 2 hours, which ensured the 3-day feeding duration in the second phase was sufficient for metabolite enrichment. The $^1$H spectra from the 48 h samples quantified 34, 49 and 49 metabolites from hemolymph, hepatopancreas and muscle, respectively, which clearly displayed tissue-dependent distribution. Metabolites detected were mainly amino acids and their derivatives, along with simple sugars, with important roles for succinate, butyrate, choline and amino acids defining tissue clusters.

Using comparative $^1$H/$^2$H spectra from hepatopancreas extracts, fractional synthesis rate (FSR) of TAG bound FA (de novo lipogenesis, DNL), was calculated at 0.16 ± 0.09 % / day. Meanwhile glycerol turnover was high calculated at 3.13 ± 0.9 % / day, demonstrating an enhanced role of glycerol as a metabolic intermediate in shrimp. FA elongation was calculated at 0.43 ± 0.14 % / day while FA desaturation was calculated at 0.32 ± 0.33 % / day. Using comparative $^1$H/$^2$H spectra from muscle extracts, DNL was calculated at 0.08 ± 0.03 % / day. Meanwhile there was no enrichment detected in muscle glycerol, or evidence of elongation or desaturation, supporting the concept that muscle has very limited role in metabolising dietary nutrients in shrimp, where the primary metabolising organ is the hepatopancreas. While the $^1$H/$^2$H NMR analysis quantified low values of $^2$H-enrichment in Ala (0.01-0.07 %) compared with other species, muscle protein FSR was calculated at 0.9 ± 0.3 % / day.

The combined $^1$H NMR-based metabolomics and $^2$H NMR analysis of metabolite $^2$H incorporation while resident in $^2$H$_2$O allows for a comprehensive, undisturbed, non-invasive and non-radioactive analysis of metabolic flux. This involves shifts in metabolite concentrations in different tissues as well as a dynamic interpretation of nutrient utilization, accumulation and turnover.

Conclusions:
While the use of omics methods can provide a snapshot of the impact of dietary ingredients on the animal at the time of sampling, stable isotope enrichment in deuterium captures a movie of all metabolic transformations occurring over several cumulative feeding events and post-feeding transformations. This study establishes a new method for defining metabolic requirements in crustaceans and assessing the impact of dietary ingredients. The collection of $^1$H/$^2$H NMR spectra simultaneously from a single sample and subsequent in vivo metabolic flux analyses (MFA) across multiple tissues places this technique above others for integrated nutritional analyses.
THE ROLE OF FISH AND SEAFOOD IN THE FIRST 1000 DAYS OF LIFE

Summary
Quality nutrition is of critical importance during the first 1000 days of human life, conception until a child’s 2nd birthday. Sufficient micronutrition is vital for supporting early childhood development and minimising long term health risks. Fish and seafood products can contain elevated concentrations of micronutrients in comparison to other protein sources, but the potential of this food group is underexploited in the UK. Understanding of the role of fish and seafood in early childhood development could act as an important step towards informing and improving public health. To further contemporary understanding of the role that fish and seafood currently plays in the first 1000 days of life in high income countries, the following objectives are being investigated:

Objective 1- To analyse the quantity and type of seafood expectant mothers and young children in the UK currently consume in order to identify the scope for improved seafood consumption;

Objective 2- To determine commercially available fish and seafood products with the greatest micronutrient concentrations per GBP (£) to identify accessible products for meeting the key nutritional needs of different income groups;

Objective 3- To examine the level of understanding of the UK fish and seafood safety guidelines for pregnant and breastfeeding women;

Objective 4- To identify the key barriers to seafood consumption amongst expectant mothers and young children and potential mechanisms that might remove these barriers.

Background and Significance
Quality nutrition is of critical importance during the first 1000 days of life. The first 1000 days of life refers to the time from conception through to a child’s second birthday. During this period, significant neurocognitive and physical development occurs that shapes the future health of a child. Micronutrients such as iron, zinc, calcium, magnesium and vitamin D are vital for supporting this early childhood development and minimising long term health risks. Consequently, the demand for micronutrients is increased for mothers supporting the beginning of a child’s life. Severe micronutrient deficiency is rare in the UK and other high income countries but mild deficiencies can still have adverse effects on the health of mothers and babies. There is also a positive correlation between a lack of micronutrient intake and a low socio-economic status so ensuring widespread accessibility to nutritious foods is imperative to ensuring optimal early development for the next generation.

Recognising and informing the public about micronutrient rich, sustainable foods is vital for encouraging healthy diet habits. In the UK, pregnant women receive supplements for folic acid and vitamin D. However, micronutrients are more beneficial to humans when consumed in food, rather than in a supplemental pill. This is due to the surrounding health benefits of food consumption, such as the displacement of less healthy food alternatives, increased protein intakes, and the collective increase of a variety of micronutrients. For example, fish oil supplements do not offer the same health benefits as the consumption of real fish. Seafood products can contain elevated concentrations of micronutrients in comparison to other protein sources. Bivalve shellfish are particularly high in micronutrients, for example containing up to 20 times the amount of vitamin A than beef, pork or chicken. In addition to this, the environmental impact of fish and shellfish production can be lower than other animal production systems. Despite this, in 2019 the National Diet and Nutrition Survey (NDNS) identified the mean consumption of oily fish was 56g in UK adults aged 19-64. The NHS recommends around 140g of oily fish per week. Highlighting the potential for seafood to be a quality, sustainable source of nutrition could be important in improving its consumption.

(Continued on next page)
The barriers inhibiting fish and seafood consumption during the first 1000 days of life have been hypothesised but rarely quantified. Cost, safety, health and environmental reasons will all be investigated in this study. There are many myths and misconceptions surrounding the safety of seafood during pregnancy, particularly the risk of heavy metal poisoning. This research aims to understand these further and ascertain what women themselves believe to be the barriers. This novel approach will also enable direct insight into how to encourage optimal, safe seafood consumption, and in turn informed and improved public health.

Data and methods
In order to address objective 1, the National Diet and Nutrition survey (NDNS) database will be utilised to quantify what women of childbearing age are currently consuming. The NDNS is a database of survey responses on quantitative information of food consumption, nutrient intake and nutritional status of the general population in the UK. This dataset will provide an accurate depiction of dietary choices in the UK which is important because there are upper limits as to how much seafood is recommended during pregnancy and whilst breastfeeding. Advice to women needs to balance encouraging optimal consumption with acknowledging the potential health risks.

Artificial intelligence (AI) tool Beautiful Soup will be used to webscrape data from 10 leading UK supermarkets. This model will enable rolling analysis of fish and seafood prices in the UK and their associated nutritional values. In order to assess product affordability, household food spending needs to be considered. DEFRA’s family food dataset details how much of household income is spent on food shops. This dataset includes information on how much UK equivalised income decile groups spend on their food shop and how much of that is currently spent on seafood products. This will enable the analysis of cost as a barrier to improved fish and seafood consumption during the first 1000 days of life.

An online survey has been granted ethical approval and will be used to assess the changes of diet for expectant and new mothers as well as identify the barriers to improves nutrition and women are encouraged to share their thoughts on potential resolutions. The target is to survey greater than 100 expectant mothers and parents/careers to children under 2 years from a diversity of socio-economic backgrounds. Questionnaires distributed to 50 active Facebook groups will gather data quantifying fish and seafood intake, guideline understanding level and key barriers to fish and seafood consumption for mothers. The survey also asks women to identify mechanisms that they believe have the potential to remove fish and seafood consumption barriers.

Conclusion
The potential for fish and seafood to help supply expectant mothers and children under the age of 2 with the essential micronutrients required for healthy development is significant. Current under exploitation of nutritious seafood in high income countries, such as the UK, means that there is an opportunity to sustainably improve public health. Understanding how to improve seafood consumption in this precious period could help enhance positive health outcomes for a future generation.
VACCINATION CAUSES SALINITY-DEPENDENT GROWTH IMPAIRMENTS IN RAINBOW TROUT (*Oncorhynchus mykiss*)

Nicklas Wallbom*, Erik Sandblom, Henrik Sundh and Elisabeth Jönsson

Department of Biological and Environmental Sciences
University of Gothenburg
Sweden
Email: nicklas.wallbom@bioenv.gu.se

Background
Vaccination enhances survival in farmed rainbow trout (*Oncorhynchus mykiss*) exposed to certain pathogens, but vaccinated fish may develop mild-to-severe side-effects1. Indeed, industry experience testifies that growth may be impaired, resulting in up to 20% lower harvest mass. The growth impairments stem from an initial reduction in appetite, leaving less energy available for growth2. This might be mediated through cross talk between the endocrine systems regulating growth and immunity3. In addition, the reduced growth may result from increased metabolic demands from immune activation or adjustment of homeostatic imbalances. Vaccine-induced effects have primarily been studied in fresh water, while less is known about the effects in sea water, even though salmonids are often transferred to and reared in sea water after vaccination. This knowledge-gap warrants attention, especially considering the observed negative salinity-dependent effect on growth in trout that likely relates to effects on metabolism and appetite4. Thus, as both vaccination and seawater-acclimation may interfere with processes underlying growth, we hypothesized that their combination may lead to additive effects. We therefore analysed the effects of vaccination on growth in rainbow trout acclimated to fresh water or sea water, and compared the effects on metabolism, osmoregulation, and endocrine growth-regulation.

Materials and methods
Rainbow trout were either immunized with Alpha Ject 3000, or sham-injected with phosphate-buffered saline. The fish were fed daily until satiation with ±2% of body weight. Starting 12 days post injection (dpi), salinity was gradually increased to 31 ppt over 10 days for half of the vaccinated and unvaccinated fish, while the other half remained in fresh water. During acclimation, feeding was limited to ±1% of body weight, and then returned to initial levels until the experiment ended at 52 dpi. Length and weight were recorded at 0, 12 and 22 dpi. At 44-50 dpi, the metabolism and aerobic scope of the fish was examined by manually chasing the fish for 5 minutes to elicit a maximal metabolic response, before measuring standard metabolic rate after 48 hours of recovery. Fish were then euthanized, length and weight measured, and blood plasma acquired for measuring concentrations of growth hormone (GH) and insulin-like growth factor I (IGF-I). In addition, the kidney, gill, and intestine were sampled for analyses of Na+/K+-ATPase (NKA) activity.

Figure 1. Effects of vaccination and salinity on growth and metabolism. A. Specific growth rate for weight across treatment groups during the three phases of the experiment (0-12 dpi; 12-22 dpi; 22-50 dpi). Fish were vaccinated at 0 dpi, and the shaded area represents the period of seawater-acclimation between 12 and 22 dpi. B. Specific growth rate for weight across treatment groups over the entire experimental period (i.e., 0-50 dpi). C. Standard metabolic rate (SMR; black) and aerobic scope (AS; gray) at 50 dpi in vaccinated (subscript V) and sham-injected (subscript C) trout acclimated to fresh water (FW) or sea water (SW). Maximum metabolic rate is represented as the combined SMR plus AS. Data were analyzed by two-way analysis of variance and are shown as means ± s.e.m.

(Continued on next page)
Results and discussion

Size was initially uniform across treatment groups (weight and length for all fish [mean ± s.e.m.]: 32.8±0.8 g; 14.3±0.1 cm). Vaccinated fish grew less than sham-injected fish for two weeks after injection (Fig. 1A), which is in line with research showing that initial appetite inhibition can limit growth for two weeks after vaccination\(^2\). However, during the seawater-acclimation phase, the vaccinated fish grew faster than non-vaccinated fish (Fig. 1A), compensating for the initially reduced growth. When the fish were fully acclimated and their feeding rates increased, freshwater trout grew faster than seawater trout (Fig. 1A). This is in line with research showing a negative relationship between growth and salinity in rainbow trout\(^4\).

During this phase, growth rates were numerically lowest in the vaccinated trout acclimated to sea water, although this was not significant. Yet, there was no interaction effect of salinity and vaccination on growth rates when analysed across the entire experimental period (Fig. 1B). However, there was a strong trend for lower growth in sea water (\(p = 0.07\)), where vaccinated trout again had the numerically lowest growth rates (Fig. 1B). While this pattern was similar for both weight and length growth, the effect on length appeared to be more pronounced (data not shown). Over 50 days, this did not cause any differences in condition factor, but may indicate ongoing spinal deformation, which is a known risk of vaccination in Atlantic salmon\(^5\).

We did not find conclusive support for our hypothesis that metabolic differences could explain differences in growth. For example, aerobic scope was similar across treatment groups (Fig. 1C). However, fish in seawater had significantly lower standard metabolic rate than fish in freshwater, and it was numerically lowest in vaccinated seawater-acclimated trout (Fig. 1C). This could be associated with reduced growth rates in fish fed \textit{ad libitum}\(^6\). The analyses of endocrine and osmoregulatory effects are ongoing and will be complemented later. In conclusion, we show that the growth of rainbow trout is compromised following vaccination with Alpha Ject 3000, and the effect was more pronounced in seawater where it appeared to persist for at least 50 days. This may partly relate to metabolic changes, and it remains to be seen if the differences in growth can be explained by endocrine and/or osmoregulatory changes.

A NOVEL VIRTUAL SENSOR FOR RECIRCULATING AQUACULTURE SYSTEMS TO BETTER CONTROL THE DENITRIFICATION PROCESS

Prof. Dr. Uwe Waller, Kai Wagner, Prof. Dr. Anneliese Ernst, Christian Steinbach

SEAWATER Cubes GmbH
In den Hallen 16
D-66115 Saarbruecken,
Email: uw@seawatercubes.de

Introduction

Recirculating Aquaculture systems (RAS) are gaining importance for a sustainable future seafood production. Reasons are the increasing threat to coastal ecosystems and climate change that is imposing thermal distress on organisms in conventional systems.

RAS could be a solution if the water circulation can be largely closed. This requires control over nutrient concentration such as nitrate from ammonia excretion of fishes converted in the biological nitrification. Nitrate accumulating in RAS process water is often controlled by strong water exchange contradicting the sustainable concept of RAS. Without denitrification RAS pollute the environment as open aquaculture installation do.

Heterotrophic denitrification operated with an organic carbon source is an efficient but potentially instable process. The carbon supply to denitrification is crucial to avoid accumulation of nitrite that is an unwanted intermediary product in biological denitrification. By detecting the occurrence of elevated nitrite concentrations in the denitrification effluent the dosage of organic substrate could possibly be adjusted to meet with the demand.

This abstract summarizes company-based research. It describes the discovery of a virtual nitrite sensor that is capable to detect a deficient carbon supply to denitrification. With that a new opportunity is revealed for more sustainable RAS technology.

Material and methods

The investigations were carried out in a precursor model of a SEAWATER Cube. For details refer to Orellana and co-workers (2014, Aquacultural Engineering 58, 20–28). The RAS was fully automated. Process data were saved for later use and evaluation.

The 8 m$^3$ RAS included a subsequent treatment of the denitrification effluent in a floatation to remove excess bacteria biomass, to replenish oxygen, and to oxidise unwanted inorganic and organic residuals (Fig. 1).

The denitrification process was maintained by feeding acetate as carbon source. The acetate dose was estimated from literature data. It was continuously fed into the denitrification by pulses of constant volume (Fig. 1, metering pump).

Nitrate-rich process water was fed into the denitrification whenever the Oxidation-Reduction-Potential (ORP) in the denitrification decreased to values of - 110 mV and below. Water flow stopped at - 90 mV ORP. The effluent water from denitrification was passed into the floatation for clarification and removal of excess bacteria biomass.

Fig. 1: The experimental set up of the denitrification filter and floatation.

(Continued on next page)
The flotation was operated with ozone. The two-point regulator adjusted the ozone feed to maintain an ORP at around +400mV in the flotation (Fig. 2). In this experimental set up a reductive milieu was followed by an oxidising milieu in the flotation delivering nitrate free and oxygenated process water back into the RAS (Fig. 1).

During experiments ORP was continuously monitored. To investigate the effect of ozone, nitrate, nitrite, and carbon feed on the denitrification process and ORP the concentrations were either determined discontinuously ($O_3$, $NO_3^-$, $NO_2^-$) or calculated from mass flow data (carbon source).

To investigate the effect of elevated nitrite on the ORP within the flotation the filter was disconnected from the RAS and nitrite was dosed into the flotation. Subsequently ORP, ozone, and nitrite concentrations were measured.

**Results**

Figure 2 shows a short time section of the registered process data revealing two recurring patterns of the ORP signal in the flotation filter. The typical up and down movement of the ORP signal was caused by switching on and off the ozone generator according to the measured ORP within the flotation filter (Fig. 1, A).

Time by time it was observed that the ORP unexpectedly decreased in the flotation filter. This was likely linked to an incomplete denitrification process. Parallel measurements of nitrite concentrations proved that nitrite concentration in the denitrification filter always had increased when a drop in ORP was recorded.

The untypical ORP pattern slowly disappeared if carbon dosing was upregulated (Fig. 2 A, 17:30). The elevated nitrite concentrations disappeared from the denitrification effluent meaning that the full denitrification process had been restored.

Fig. 3 shows the result of an additional experiment to investigate the effect of elevated nitrite concentrations on the ORP in the flotation.

The results (Fig. 3) shows that ORP in the flotation remained on low levels ($\leq$ 300 mV) when nitrite was present in the water. Nitrite concentrations of around 0.6 mg · dm$^{-3}$ already impeded an increase in ORP. After 18 minutes nitrite had disappeared. Subsequently ORP and ozone concentration abruptly increased at a constant feeding rate.

**Discussion**

Coincidental observations in a process chain of a denitrification biofilter and a flotation led to the discovery of a virtual sensor that allows to observe the function of a microbial denitrification process. The release of nitrite from denitrification due to an insufficient carbon supply led to a marked change of pattern in the ORP signal of the downstream flotation. The virtual sensing of elevated nitrite marks a next level in the control of denitrification which is inevitable in future RAS operations. No other solution is seen as direct measurements of carbon, nitrate, or nitrite concentrations would be more costly.
EFFICIENT GENOME EDITING IN AN Oreochromis mossambicus CELL LINE USING RIBONUCLEOPROTEIN COMPLEXES

Email: s2437587@ed.ac.uk

Introduction:
Aquaculture is the fastest-growing food production sector worldwide (FAO 2020). Nile tilapia (Oreochromis niloticus) has the third-highest production of all finfish species (FAO 2020). However, the recent emergence of Tilapia Lake Virus (TiLV) presents major threats to tilapia production, mortalities up to 90% at several stages of the production cycle (Dong et al. 2017). There are currently no effective treatments. Genetic and genomic technologies have the potential to increase the resistance of Nile tilapia stocks to TiLV. Recent advances in genome editing via CRISPR/Cas technologies have facilitated genome-engineering approaches that have the potential to characterise genes involved in resistance and generate fully resistant animals. Also, extensive progress has been made in utilizing cell lines for studying fish pathogens and host responses, and the potential for enhancing fish health research through the manipulation of these cell lines is significant. The effectiveness of CRISPR/Cas editing using ribonucleoproteins (RNP) in Omb cell lines remains uncertain. Exploring this approach could offer valuable insights into creating models for investigating TiLV diseases in tilapia.

Methods:
This experiment employed two cell lines, namely the Omb wild-type (WT) and Omb-GFP cell lines. TracrRNA-ATTO550 was utilized to assess the transfection efficiency under various electrical stimulation conditions in the Omb wild-type cell line. Cell survival of Omb-GFP cells under different electrical setting was determined using the CellTiter Glo assay. On Day 3 and Day 7, knockout efficiency was evaluated through Sanger sequencing. Additionally, after 14 days post-electroporation, the disappearance ratio of EGFP protein was assessed via flow cytometry.

Figure 1: Efficient editing of Omb cell line by electroporation of Cas 9 RNP. a. Using tracrRNA-atto550 test the best efficiency, test by flow cytometry after 24 h. b,c,d, efficient knock out of GFP in Omb-GFP cell line. The optimal concentration (2µM) of RNP, different electroporation configurations were employed for Omb-GFP cell knock out. Cell survival 24 hours after electroporation was measured with CellTiter-Glo (b), editing efficiency was assessed by Sanger sequencing and ICE analysis at 3 and 7 days post electroporation (c), GFP fluorescence knockdown was measured after 14 days using flow cytometry in experimental (edited) group: 6.62% and control group: 90.3% (d).

(Continued on next page)
Result:
Electroporation of Cas9-gRNA complex leads to efficient editing in OmB (Figure 1). The highest tracrRNA transfection efficiency was 2 μM group (Fig 1a), using that concentration, we optimised electroporation conditions using a GFP expressing cell line. We measured fluorescence as a proxy of cell survival, and observed that 1700V 15ms 2 pulses settings resulted in the highest cell survival (Figure 1B), editing efficiency was measured by Sanger sequencing and loss of eGFP signal also showed 1700V 15ms 2 pulses is best setting (Fig 1c and 1d).

Conclusion
In the current study, the best setting for RNP electroporation was 1700V 15ms 2 pulses, tracrRNA concentration was 2 μM. Editing efficiency was higher in day 7 than day 3, so the Cas9 protein must be still active at room temperature for over one week. Through Cas RNP complex, we can efficiently edit the OmB cell line, needing just about 2 weeks from design to experimental testing of the edits.

Introduction

In subtropical and temperate areas, low temperatures limit shrimp culture to summer and fall. The shrimp biofloc culture rearing system (BFT system) in an enclosed greenhouse is a technological alternative aimed at increasing the culture period in these regions. The shrimp farming sector has developed great interest in the BFT, due to the ability of the bioflocs to provide a stable culture environment by the maintenance of water quality, low feed-conversion rates (FCRs) through the natural food source and high productivity reaching up to 9 kg.m-3 (Samocha et al., 2017). In order to achieve the highest productivity rates, several authors have been testing the effects of high stocking density rates in order to determine which is the most appropriate (Da Silveira et al., 2020; Krummenauer et al., 2011). However, the production efficiency in culture tanks can be boosted by increasing the culture tank’s carrying capacity, which can be described as the maximum biomass of aquatic cultivated organisms that can be maintained in a rearing system indefinitely, usually described as unit of mass per volume unit (kg.m-3) (Timmons and Ebeling, 2010). Anyway, with the system carrying capacity known, the definition of the most adequate stocking density must consider the shrimp desired final individual weight. In addition, for a better efficiency in the use of the available culture structure, it is also possible to use strategies that maintain the shrimp stocking densities closer to the system carrying capacity throughout the production cycle like multi-phase production system (Van Wyk, 1999). The BFT system at high stocking density requires a vigorous and efficient aeration to keep the oxygen concentration within the desirable concentrations, and maintain a high particle density and organic matter in suspension. The dissolved oxygen is the most critical water quality variation in aquaculture. In this scenario, several technologies and practices has been tested and adopted in order to increase the productivity, for example Samocha et al. (2017) described a system with carrying capacity of 9 kg.m-3 with the possibility of using pure oxygen if it needs. These technological advances have greatly increased the aquaculture system’s carrying capacity in terms of maintaining desirable water quality parameters. Considering that, the multi-phase system permits the maintenance of stocking densities closer to the system’s carrying capacity, and the system’s carrying capacity in terms of water quality maintenance is no longer a limit. The present study intended to show the evolution of the stocking densities from Intensive to Hyperintensive culture of shrimps in BFT systems and determine the most adequate maximum shrimp biomass in each stage of a multi-phase system.

Material and methods

The present study aims to define the most adequate highest stocking densities for each stage of a multi-phase system, considering that the system’s carrying capacity is able to maintain the water quality parameters at desired levels. This study was divided into four phases according to the size: Phase 1, shrimp were stocked with initial weight of 0.002 g; Phase 2, initial weight of 1.04 g; Phase 3, initial weight of 6.09 g; and, Phase 4, initial weight of 12.51 g. Each phase lasted for 40 days, and the treatments applied were the different stocking densities. Shrimp for all stages were cultured at high stocking densities in biofloc technology system (BFT). The water quality parameters were maintained within the optimum levels for the L. vannamei development.

(Continued on next page)
Results and discussion

The results of the present study confirm the *L. vannamei* density dependent growth dynamic in all stages of development as reported by several authors (Da Silveira et al., 2020; Krummenauer et al., 2011). The phase 1 or pre-nursery has already been considered intensive culture when the densities reach 2,000 to 5,000 shrimp.m\(^{-3}\). The utilization of the BFT technology in the early stages of *L. vannamei* can generate shrimp juveniles of excellent quality due to the nutritional benefits taken from the presence of bioflocs. In different experiments survival and growth in all treatments and were significantly different (P<0.05). Better results of each experiment are shown in table 1. However, for phase 4 the quadratic model \(y = -1.292e-05x^2 + 0.02852x - 1.513\) indicate that the support capacity reaches the max biomass (14.22 kg) at 1,125 shrimp.m\(^{-3}\).

Conclusion

In summary, the present study confirms the shrimp density dependent growth pattern even when maintaining optimum levels of water quality parameters. In addition, proposes a biological limit of 14 kg.m\(^{-3}\) for the shrimp culture in BFT system. However, the water quality parameters deterioration is the limiting factor for the system’s carrying capacity, and the shrimp stress behavior generated by the lack of space is the biological limiting factor for the shrimp culture maximum biomass (biological limit). In addition, further studies are needed for better understanding of the shrimp biological limit and for technology development aiming to increase the shrimp culture productivity.

GROWING NATIVE OYSTERS (*Ostrea edulis*) IN OPEN WATER IMTA SYSTEMS– A PILOT STUDY

C. Waters1*, P. O’Donohoe1, J. Casserly1, K. Michalek2, and A. McCleod2

1Marine Institute, Rinville, Oranmore, Galway, Ireland
2 The Scottish Association for Marine Science (SAMS), PA37 1OA Oban, Scotland, UK
Email: catherine.waters@marine.ie

Introduction

Integrated Multi-Trophic Aquaculture (IMTA) is defined as a practice that combines appropriate proportions of fed aquaculture species, with organic extractive species and inorganic extractive species to create an environmentally sustainable, economically stable and socially acceptable balanced aquaculture system (EUMOFA 2023). In temperate regions, IMTA systems are uncommon and research into establishing economic and environmental IMTA value chains with appropriate and available species and technologies is essential to achieve commercial scales (Barrington et al 2009). The ASTRAL project is a European Union Horizon 2020 collaborative that focuses on IMTA, it aims to support and promote sustainable production across the Atlantic. ASTRAL IMTA production is carried out in five IMTA labs involving partial inshore recirculation (South Africa), inshore recirculation (Brazil), two open coastal systems (Ireland and Scotland) and one prospective lab (Argentina).

In Ireland, the Marine Institute runs a pilot-scale IMTA lab based in a sheltered bay on the west coast. The lab is exploring the cultivation of Atlantic salmon (*Salmo salar*), native oysters (*Ostrea edulis*), seaweeds (*Alaria esculenta, Saccharina latissima*) and sea urchin (*Paracentrotus lividus*). In Scotland, SAMS is managing an experimental low-trophic aquaculture site exploring the economic and practical feasibilities synergies of growing seaweeds (mainly kelp: *Alaria esculenta, Saccharina latissima*) and shellfish (*Ostrea edulis, Pecten maximus*) alongside within an integrated system designed to reduce material and capital requirements.

Both sites have incorporated native oysters into their IMTA value chains to assess this species suitability for cultivation in an open water IMTA system. Growth performance, mortality and operational constraints were measured as part of this assessment.

Methodology

At the Marine Institute’s Marine Research Site in Ireland, juvenile native oysters were sourced from an oyster bank situated in the same bay as the research site. Approximately 300 oysters were collected by dredging under license, spat was identified and 2 grades were chosen (6 – 18 months old). Oysters were deployed into three locations the Low-Trophic Grid (LTG) and Long-Line (LL), locations enriched by the effluent produced by salmon in adjoining fish pens and a control (Ctrl) location away from the nutrient load provided by fed species. Oysters were mixed and stocked evenly in 6mm mesh round oyster tumblers (AP6 baskets). At SAMS site, 2000 juvenile oysters were sourced from a commercial hatchery and split into two batches – one for subtidal cultivation at SAMS LTA site and the other for intertidal cultivation at a neighboring traditional oyster monoculture site. Oysters were also deployed using the AP6 baskets. At regular intervals (approximately 8-10 weeks), both sites followed the same protocol for the monitoring of progression in shell and tissue growth and recording any mortality.

Results

Initial results suggest that oysters can be successfully grown as part of the open coastal IMTA system. Although growing slowly, native oysters grown in an IMTA system can provide good yield and would be of value in a well-established market.

Oyster survival differed substantially between subtidal and intertidal culture, with mortality rates exceeding 70% in summer in the intertidal.

(Continued on next page)
Practical considerations: The floating AP6 oyster baskets were selected to replace buoyancy required to maintain cultivation materials at the appropriate depth. These baskets must be routinely (every two weeks during the summer months) inverted to expose biofouling to the air for extended periods to minimize the impact of biofouling on buoyancy and flow rates within the baskets. This may not always be possible and careful selection of floating basket types that allow for biofouling to be managed easily whilst maintaining efficient husbandry of oysters is essential to develop efficient cultivation practices. At the more exposed SAMS LTA site two failure modes were identified whilst using the AP6 baskets and these must be corrected if this system is to be scaled.

Potential remediation of these extractive species systems is under investigation and will form part of the outcomes of the ASTRAL project.

PHENOLOGICAL STUDY OF *Palmaria palmata* ALONG THE WEST COAST OF IRELAND

Susan Whelan*, Anna Soler-Vila¹, Mark Johnson² and Maeve D. Edwards¹

¹Irish Seaweed Consultancy Ltd, Galway, Ireland
²University of Galway, Ryan Institute, Galway, Ireland
E-mail: susan.whelan@irishseaweed.com

Introduction

The phenology of the red alga *Palmaria palmata* is described for a number of locations on the west coast of Ireland from January 2020 to March 2021. Increasing demand of *P. palmata* in Ireland for wild collection and cultivation required further understanding of the reproductive cycle and phenology of this species. At present, wild populations are hand-harvested at low tide; this is labour-intensive and does not always provide a consistent product. Hand-harvesting can put pressure on wild populations, with the increasing demand areas can be overharvested. This suggests that the development of cultivation methods such as tetraspore release and on-growing at sea could help ease this pressure on wild populations. This phenological study aims to understand features of selected populations of *P. palmata* along the Irish coastline and the timeline of their reproductive cycles to understand the optimal time to collect fertile biomass for tetraspore release and to increase the chances of a higher harvest return.

Material and methods

Over the year, monthly sampling of approx. 100 individuals from populations of *P. palmata* in two locations in County Galway and additional regular (not monthly) sampling from six populations in Counties Cork, Kerry, Clare, Galway, Leitrim and Donegal. The total length of each individual was measured to the nearest 0.1 mm and weighed to the nearest 0.1 g. Each individual was also inspected for condition, epiphytes, reproductive status, and if reproductive, the percentage of unspent sori remaining in the sori. An estimation of the amount of released ('spent') tetraspores from the sori of individuals was made visually inspecting each specimen in a well-lit area to compare the dark, raised areas of sorus (containing fully mature tetraspores), compared with the pale areas of sorus that had already released tetraspores ('spent sorus'; Figure 1).

Results

An estimation of the proportion of mature tetrasporophytes and males was recorded, with the majority of individuals (71-100%) reproductive from November to April. There was a seasonal trend to the proportion of fertile individuals found, with overall high fertility in the winter and low in the summer. Asynchronous reproductive maturity was observed, with mature tetrasporophytes developing reproductive sori in October, and most abundant in populations by February (79% ± 10.76 SD). Whereas males were developing reproductive sori in November with lower numbers of mature males abundant in January (31% ± 6.86 SD). This was found to be similar across sites. Measurement of the percentage of unspent sori indicates that most tetrasporophytes have a synchronised short (two week) peak release of tetraspores in November to December (Figure 3).

Discussion

To cultivate *P. palmata* in an ethical and sustainable way, wild material used for seeding or vegetative culture ideally would be collected from abundant and healthy populations. Monitoring these populations over time to understand their fertility and reproductive cycles is beneficial knowledge for the harvesters and cultivators. Overall, on the West of Ireland there was a clear seasonal development of the different life phases of *P. palmata* as identified with reproductive sori of tetrasporophytes and males. According to this phenological study, the best time to find fertile material in Irish west coast populations occurs from December to March. By sampling regularly and measuring the amount of unspent tetraspores in sori, a short period of just over two weeks in November into December emerged as the peak release event of tetraspores in almost all tetrasporophytes; this has not previously been observed for this species.

(Continued on next page)

Introduction

Due to the development of intensive fish production and the increasing global consumption of aquaculture products (FAO, 2022), European perch (*Perca fluviatilis*) is currently considered an interesting species for the diversification of European aquaculture (Fontaine and Teletchea, 2019; Gebauer et al. 2021). Furthermore, it can serve as a complementary species to wild stocks in niche alpine markets, thus reducing pressures on wild individuals of the same species (Cooney et al. 2021. In the wild, European perch are opportunistic, schooling predators feeding on a diverse diet (Thorpe, 1977). In contrast, the nutritional requirements under perch aquaculture conditions are currently not fully defined (Bochert, 2022). It therefore becomes necessary to develop formulations for the production of efficient feeds to produce nutritionally complete commercial fish.

The aim of this experiment was to determine the effect of dietary protein content on morphology and enzymatic activity in liver of the European perch (*Perca fluviatilis*).

Materials and methods

The study was carried out as part of the project “Diversification of the productive function of earthen ponds based on semi-intensive rearing of Perca fluviatilis - PROPERCH (no. 00002-6521.1-OR1400004/17/20) co-financed by the European Maritime and Fisheries Fund.

A 12-week feeding experiment was carried out, during which the fish were fed a feed with fish meal (FM) levels of: 44%, 52%, 60% and 68%. On the last day of the experiment, the fish were sacrificed, measured and weighed, and biological material in the form of liver sections was collected from 12 individuals from each of the 4 groups for analysis. Tissue sections were fixed in Bouin’s fluid and then subjected to a standard histological procedure. The sections for biochemical analysis were placed in liquid nitrogen and later homogenates were prepared from them. Paraffin-embedded tissues were sectioned and stained with haematoxylin and eosin (HE) and AB/PAS (Alcian blue - Schiff’s reagent with periodic acid). The stained slides were subjected to microscopic analysis. In addition, biochemical analysis of the activity of the following oxidative stress enzymes was performed: alkaline phosphatase, acid phosphatase, superoxide dismutase (SOD) and glutathione peroxidase. The obtained results were analysed using statistical methods.

Results

The highest body weight was observed in the fish meal-fed group at 68% and the lowest in the group with 44% FM (Kruskal-Walis ANOVA; p<0.05). In contrast, the most favourable FCR values were achieved in the FM52 and FM60 groups, which translated into the Protein Per Growth Rate (PCR), which was also the most favourable in these two groups. Increase in phosphatase activity in individuals fed diets with a fish meal content above 52%. The group with the highest proportion of fish meal in the diet showed increased superoxide dismutase activity. In addition, all study groups had high glutathione peroxidase activity.

Conclusions

The results obtained indicate that the most favourable protein content in the feed for common perch kept in RAS are feeds with a fish meal content above 52%.

RESEARCH TO OPEN UP UNDEREXPLOITED OPPORTUNITIES FOR INNOVATION IN AQUACULTURE

Dr David F. Willer*

1 Department of Zoology, University of Cambridge, Cambridge, UK
Email: dw460@cam.ac.uk

Summary

We present research which aims to help improve the efficiency of thriving aquaculture sectors, create new opportunities in underexploited aquaculture sectors, and provide methodologies to reach a larger consumer market with sustainable and nutritious fish and seafood. Key topics include: nFIFO as a new metric to assess the micronutrient efficiency of fed aquaculture, value chain exploitation and new species opportunities in the bivalve sector, and food preparation and marketing approaches to drive consumption of sustainable fish and seafood.

Improving the efficiency of thriving aquaculture sectors 1, 2

Aquaculture is the world’s fastest growing food sector, and many industries such as salmon farming are thriving. The salmon industry grew by 270% since 1998 to become the most valuable sector in aquaculture at USD $23 billion in 2018. Salmon farming has perhaps unfairly received bad publicity on its use of wild-caught fish in feed, and has in reality made remarkable progress, with Fish-in Fish-out (FIFO) ratios now close to 1:1, having been 4:1 in the 1990s. However, FIFO does not capture the micronutrient content of feed and farmed species.

We have developed a new tool, nutritional Fish-in Fish-out (nFIFO), which enables practitioners to assess the micronutrient efficiency of fed aquaculture systems, and identify scenarios to enhance nutrient rich seafood production. For example, for salmon farmed in Norway in 2020, nFIFO exceeded one for seven of nine dietary micronutrients that are essential in human diets, indicating salmon farms consume substantially more micronutrients than are produced as seafood. We identified a reallocation system by which directing one-third of edible fish in feed for human consumption, we could increase seafood provisioning for people and create new by-products to further support the salmon sector. Application of this research to the salmon industry and to other fed aquaculture sectors can allow us to make more efficient use of limited global fishmeal and fish oil supplies, support further growth in fed aquaculture, and provide a greater quantity of micronutrients from seafood to people.

Creating opportunities in underexploited aquaculture sectors 3, 4, 5

Bivalves are rich in protein, essential fatty acids and key micronutrients, and have a lower environmental impact than other sources of protein. However, conventional bivalve farming has limiting problems making the sector financially less attractive than others such as finfish or crustacean farming. Specifically, problems include food safety in increasingly polluted open marine environments, slow growth rates versus fish, costly processing, transport and storage. Bivalves are also far less popular as a consumer product relative to other meat or finfish products. Aside from a few select nations such as Portugal, most of European food manufacturer, retail and consumer interest in bivalves is weak compared to southeast Asia.

We have performed value chain analyses in collaboration with Europe’s largest frozen food manufacturer, and identified key opportunities that could enable bivalve to become a popular mass-market consumer food. This includes new innovations in depuration, storage, food processing and technology. We have also carried out laboratory trials on terenids, bivalves which could potentially offer an order of magnitude faster growth rate than mussels, clams or oysters. There may be an opportunity to create a new sector in terenid aquaculture, and we have begun to gather critical data including nutritional profile and growth data that underpin further concept development.

Methodologies to reach a larger consumer market 6

Finfish and seafood are one of our richest sources of key nutrients such as omega-3, which play a critical role in child development, brain, and cardiovascular health. Yet consumption of fish and seafood varies greatly by global region, and there are many areas where consumption is markedly lower than recommended or nutritionally beneficial. For example, while consumption of bivalves is as high as 100 kg per capita in Shandong in China, the EU average is below 1kg per capita. While the NHS in the UK recommends around 140 g of oily fish per week, NDNS data show the mean consumption of oily fish in adults aged 19-64 is just 56 g per week.

(Continued on next page)
We are performing research to identify several methodologies which could enable a greater proportion of the consumer market to access and consume nutritious seafood, and most critically in sustainable way. National surveys have allowed us to identify key behavioural levers which could help drive the consumption of sustainable bivalve meat in place of less sustainable meat products. Catering trials have allowed us to investigate the impact of ‘hiding’ bivalve meat in popular consumer dishes in place of conventional meat on consumption patterns. We are assessing ways by which we could get consumers to consume ‘under loved’ components of fish and seafood, such as heads, bellies and viscera, that would otherwise go to non-human uses. In addition, we have performed focus studies to look at how we could provide pregnant mothers and babies, a group who could benefit greatly from the nutrients in fish and seafood, with greater knowledge about and access to fish and seafood.

Introduction

Dietary selenium (Se) supplementation is increasingly discussed in modern fish feed formulations due to its low availability from plant raw materials and its essential role in the antioxidant system of fish (Fontagné-Dicharry et al., 2015). Thereby the effective biosynthesis of selenoproteins from organic Se is dependent on pyridoxal-phosphate as an enzymatic co-factor (Soda et al., 1999). A deficiency of vitamin B6 has been associated with impairments in the glutathione metabolism and antioxidant system (Taysi, 2005). Recent changes in the recommendation for dietary pyridoxine levels in plant-based aquafeed formulations (Hansen et al., 2015) raise the question, if the limited availability of the two micronutrients Se and pyridoxine may induce interactive effects in the glutathione metabolism of fish, especially when exposed to stress. Therefore, a feeding trial was conducted to investigate such possible interactive effects between dietary Se and pyridoxine supplementation in rainbow trout (*Oncorhynchus mykiss*).

Material and Methods

Four diets were designed: CTL, without any Se or pyridoxine supplementation; SEL, supplemented with 4 mg selenomethionine / kg diet; PYR, supplemented with 50 mg pyridoxine hydrochloride / kg diet and SEPY, co-supplemented with similar Se and pyridoxine levels. Groups of 50 juvenile rainbow trout (28 ± 3 g) were randomly distributed in triplicate tanks per treatment and fed one of the experimental diets for eleven weeks. At the end of the feeding period, 8 fish per tank were euthanized and tissue samples dissected. The remaining fish were exposed to oxygen stress (periodic hyperoxia) prior to sampling. Therefore, the dissolved oxygen (DO) level in the tanks was elevated for 8h (09:00-17:00h) per day from 8.5 ppm to 13 ppm (=168 %) DO over a one-week period. The liver samples collected of stressed and non-stressed fish were analyzed for metabolites and gene expression associated to the glutathione metabolism. The collected data was analyzed by repeated three-way ANOVA and is presented as mean ± standard error of means.

Results

Neither Se nor pyridoxine supplementation had any significant effect on fish growth performance (182 ± 3 g). Total liver glutathione levels were significantly lower in stressed compared to non-stressed fish (1351 ± 76 vs 927 ± 57 pg/mg protein). Fish fed diets supplemented with Se showed lower cysteine (Cys) levels in liver tissue compared to fish fed diets without Se supplementation (1522 ± 67 vs 1112 ± 57 pg/mg protein). Homocysteine (hCys) and total glutathione levels were observed to increase with pyridoxine supplementation (8.1 ± 0.7 vs 9.9 ± 0.9 and 1003 ± 66 vs 1275 ± 97 pg/mg protein). However, in stressed fish a significant interaction between Se and pyridoxine was detected as hCys levels were the highest in fish fed PYR, but the lowest when fed SEPY (12.9 ± 1.1 vs 5.7 ± 0.6). In addition, Cys levels were the lowest in stressed fish when fed CTL, but the highest with SEL (1587 ± 257 vs 806 ± 127). The gene expression of antioxidant enzyme glutathione peroxidase (Figure 1) and that of other selenoproteins was only affected by Se but not by pyridoxine supplementation.

**Figure 1.** Relative gene expression of *gpx1a* measured by real-time qPCR (n=6). Data are normalized to fish fed the CTL diet before subjected to hypoxic stress. Unlike superscript letters indicate significant main effects (p < 0.05) according to three-way ANOVA. Interactive effects were not significant.

(Continued on next page)
Discussion and conclusion

The decrease in Cys levels detected with dietary Se supplementation might be a result of the co-metabolization of selenomethionine and methionine through the transsulfuration pathway (Dalto and Matte, 2020). On the contrary, dietary vitamin B6 supplementation seems to elevate transsulfuration as indicated through higher liver hCys and glutathione levels. This might relate to pyridoxal-phosphate being a co-factor of transsulfuration enzymes (Soda et al., 1999). Although vitamin B6 acts as a co-factor for the biosynthesis of selenoproteins through the delivery of Se to the translational machinery, in the present study, no effect of pyridoxine supplementation on selenoprotein gene expression was observed, suggesting that the pyridoxine levels in the non-supplemented treatments might have been sufficient to support selenoprotein synthesis. Nevertheless, interactive effects of Se and pyridoxine on transsulfuration metabolites in stressed fish indicate that both micronutrients play an important role to maintain glutathione homeostasis under stressful conditions similar to observations in mammals (Dalto et al., 2015).

RECOVERY AND STABILISATION OF VERTEBRAL DEFORMITIES IN ATLANTIC SALMON

Lucia Drábiková, Per Gunnar Fjelldal, M. Naveed Yousaf, Thea Morken, Adelbert De Clercq, Charles McGurk, P. Eckhard Witten*

Evolutionary Developmental Biology
Biology Department
Ghent University
Ghent, Belgium
E-mail: peckhardwitten@aol.com

Introduction
Farmed teleost fish commonly suffer an increased rate of vertebral deformities. Vertebral deformities have an adverse impact on fish welfare, growth, and swimming behaviour. Under unfavourable conditions (inappropriate handling stress, increased mechanical load, increased water temperature) vertebral deformities are likely to progress and worsen over time\(^1\)-\(^2\). However, an increased amount of recently published studies observe that deformities can recover and disappear or stabilise over time\(^3\)-\(^5\). Here we present a detailed description of the process of recovery and containment of deformities in Atlantic salmon (\textit{Salmo salar}).

Materials and Methods
Individual animals of Atlantic salmon were followed by x-ray imaging to analyse the development of vertebral deformities in two studies. The first study\(^4\) followed 200 PIT-tagged farmed animals which were x-rayed at three time points: prior to seawater transfer (100 g), six months after seawater transfer (1.1 kg), and 12 months post-seawater transfer (2.3 kg). The second study\(^3\) followed 135 PIT-tagged Atlantic salmon. These animals were x-rayed prior to seawater (50 g), seven months post-seawater transfer (720 g), and 16 months post-seawater transfer (4.5 kg). Further analytics included whole mount Alizarin red S staining, mineralised and non-demineralised histology, and mineral content analysis.

Results and Discussion
Studies detect two broad categories of vertebral deformity which determine further development. Category I. comprises deformities that affect the bone of the vertebral centra. These are characterised by either bent bone trabeculae and replacement of adipose tissue with ectopic cartilage in the bone marrow spaces (hyper-dense vertebrae), by vertical displacement of the vertebral centra, or by mild compression of the vertebrae. Importantly, the intervertebral space between the vertebral centra remain non-deformed and thus category I deformities were observed to recover.

Category II. comprises deformities with alterations in both, vertebral centra and intervertebral spaces. Two studies\(^3\)-\(^4\) show that these deformities can stabilise as long as no more than three vertebrae are affected (stabilisation through vertebral fusion). Stabilised vertebral fusions do not further aggravate, do not affect animal welfare, and are also common in wild Atlantic salmon\(^6\). In cases with damage to more than three adjacent intervertebral spaces, recovery has not been observed. Instead, extended vertebral fusion centra develop.

Conclusions
These studies provide detailed insights into the development of vertebral deformities based on tracking individual animals from freshwater up to harvest size. Surprisingly, several types of vertebral deformities can recover and stabilise over time under favourable rearing conditions.

Introduction
Aquaculture is an established industrial sector of progressively increasing importance for food production as an alternative that minimizes negative impact on climate change. Continuously growing demand of aquaculture infrastructure introduces important yet-to-be-addressed technological and logistical challenges, with reliance solely on human operators becoming unattainable in the future. Robotics and automation could become a leading force on expanding aquaculture operations and resolving scalability issues in a consistent and sustainable way [1]. However, exposed aquaculture settings are among the most challenging domains for robots to operate, due to uncertainty introduced from limited and low-quality sensor readings, lack of static reference caused by changing surroundings due the constant deformation of the fish cage structure, and necessity for real-time decision in environments with currents, surge, moving obstacles, and uncertainty. The ResiFarm project, aims to address such problems regarding scalability and safe operations in exposed aquaculture settings by providing fundamental technologies enabling underwater robots to operate safely, accurately, and resiliently. The potential of different types of autonomous robots is explored for the produced technology, such as ROVs and Underwater Swimming Manipulators (USMs), Figure 1.

Approach
Resilient autonomy depends on solving robustly two fundamental problems in robotics: State Estimation, which is the problem of localizing the robot with its surroundings, and Motion Planning, which is the problem of deciding on efficient and safe actions that the robot could take towards accomplishing a task. Unfortunately, both are becoming more challenging to solve in the underwater domain, and especially in aquaculture settings. The focus of this paper lies on safe and robust motion planning.

Even assuming perfect state estimation — a prerequisite for motion planning — safe autonomous aquaculture operations require addressing simultaneously and in real-time a combination of unique challenges, such uncertainty, unexpected surge and currents, potential control errors, moving obstacles, and moving deformable nets. Several motion planning approaches exist, such as sampling-based, lattice-based, and optimization-based motion planning. We focused on path optimization, due to its computational efficiency, quick replanning frequency, and guarantees, as shown in past work [2].

Such techniques can provide very quickly locally optimal solutions, which are sufficient given the limited on-board sensing range. Though, the most important advantage of these techniques is that user-defined cost functions could be implemented making them highly adjustable to different platforms, and for different tasks, such as for inspection [3].

Towards enabling autonomy, a novel framework, called ResiNav, was developed that guarantees safe navigation in the presence of motion errors due to currents, waves, or imperfect controls, localization and map uncertainty, and detected dynamic obstacles. ResiNav [4] deals with all these challenges in real-time in a holistic perspective by informing the path optimization process with the past experienced conditions, adjusting automatically the clearance needed. The necessary clearance is computed analytically with minimal information and provides a tight worst-case boundary that guarantees safety.

Results
Currently, several motion planning concepts have been tested in simulation. The AquaVis [3] pipeline was applied for cage inspection. Virtual visual objectives were placed on the net, enabling the robot to inspect it from a desired proximity. The robot inspected the net, while also avoiding safely dynamic obstacles executing unknown trajectories in simulation, Figure 2. Additionally, ResiNav has been implemented and rigorously tested for different conditions, environments, and robot velocities in simulation. An example of one test case with strong side current is shown below in Figure 3. We speculate that, almost certainly, a motion planner with such capabilities will be at the core of future safe and robust autonomy applied for operations in exposed aquaculture infrastructure.

(Continued on next page)
Conclusion and Future Work
A collection of approaches is investigated to realize the ambitious goals of ResiFarm, towards robust motion planning, with a subset of them described briefly above. Future focus will be directed towards data collection and testing of robust motion planning concepts in real fish farms (infrastructure provided by SINTEF ACE) using ROVs and investigating extensions to different platforms, such as the Eelume USM. We aspire that the result from ResiFarm would provide fundamental technologies and insights to support scaling aquaculture operations in the future, safely, accurately, and resiliently.

AQUAPONICS PRODUCTION OF WHEATGRASS (*Triticum aestivum*) IN VERMICULITE SUBSTRATE WITH DIFFERENT STOCKING DENSITIES OF AFRICAN CATFISH (*Clarias gariepinus*)

Introduction

The direct production and marketing of aquaponic vegetables is to be considered critical due to the quality and quantity as well as the labour costs compared to the competition of industrial vegetable production. However, there are possibilities to generate profit from vegetable ingredients and metabolites (e.g., vitamins, proteins, essential oils) via secondary value chains that are relatively independent of the expiry date compared to fresh vegetables. Larger quantities can be accumulated by extracting and drying secondary plant constituents and by storing and hoarding them in a pre-stored state. Such extracts can either be used fresh (e.g., wheatgrass smoothies) or dried as powders or tablets as food supplements or cosmetics. Fast-growing plant species are particularly predestined for such an aquaponic value chain, such as herbs (Knaus et al., 2020) or functional-/super-foods like wheatgrass (*Triticum aestivum*; van den Driessche et al., 2018).

Wheatgrass (*T. aestivum*) has been tested with different growing media in aquaponics with African catfish (*C. gariepinus*) before (Xu et al., 2022). Results indicated that fish effluents had beneficial effects on wheatgrass growth, especially in improving nutritional quality for organic produce. It is necessary to reduce the use of synthetic fertilizer in aquaponics. Hence, the aim of the present study was to test the influence of nutrient solution from African catfish recirculating aquaculture systems (RAS) with different stocking densities on the growth of wheatgrass.

Material and methods

Wheatgrass was cultivated in an ebb-and-flood commercial aquaponic system from 23.8.2021 to 03.9.2021 (12 days) in the FishGlassHouse of the University Rostock, Germany. In triplicate, wheatgrass was irrigated with two distinct effluents from intensive aquaculture unit (IAU: 140 fish/tank; 138.78 ± 120 kg/tank) and extensive aquaculture unit (EAU: 35 fish/tank; 25.80 ± 23.29 kg/tank) recirculating aquaculture systems of African catfish (*C. gariepinus*) and tap water with fertilizer (Universol Basis, ICL, Israel) as control. Plant growth parameters and nutrient contents were measured and analysed in order to assess the growing performance of wheatgrass. The system design was identical to Xu et al. (2022).

Table 1: Vitamin levels of wheatgrass (*T. aestivum*) irrigated with different nutrient water sources (control [C], extensive aquaculture unit [EAU], and intensive aquaculture unit [IAU]) and cultivated in pure vermiculite substrate. Different letters within a row indicate statistically different mean values at p < 0.05.

Results and discussion
The shoot length reached the highest value in the IAU (27.07 ± 3.51 cm), comparable to the EAU (26.44 ± 2.81 cm), and significantly lower in the control (23.61 ± 2.89 cm). Furthermore, the SPAD index was greatest in the IAU (27.55 ± 5.78%) and was lower in the control (23.86 ± 5.91%) and the EAU (23.34 ± 4.41%). Generally, experimental groups with fish water irrigation had better growth performance of wheatgrass although the pH value in control was the lowest (6.62 ± 0.06; EAU: 6.69 ± 0.12; IAU: 7.10 ± 0.34), and the EC value was the highest (control: 1701.80 ± 35.81 µS/cm; IAU: 1439.20 ± 56.64 µS/cm; EAU: 993.50 ± 32.57 µS/cm). A significantly higher nitrate level in the IAU (434.50 ± 62.03 mg/L) was assumed to be credited to optimal wheatgrass growth with intensive fish effluent, which had distinct lower values in both the EAU (177.62 ± 52.42 mg/L) and control (177.82 ± 45.79 mg/L).

The majority of the plant nutrients in the wheatgrass had no significant difference among all the groups in the present study. Noticeably, vitamin B₅ (pantothenic acid) reached a significantly higher value in the EAU (and IAU) than the control (Table 1). The difference from the control was probably attributed to the significantly higher pH value in the IAU (slightly above 7), and EAU. This pH value in the IAU may have had a positive effect on the microbial communities and thus positively influenced vitamin production (Ratzke & Gore, 2018) and plant growth.

In conclusion, both aquaculture effluents (IAU and EAU) were beneficial to the growth and vitamin (B₅) content of wheatgrass, although some growth conditions, such as pH and EC value, were better in the control. It was assumed that high nitrogen levels, abundant organic matter, organic metabolites, and certain beneficial microbes in the aquaculture effluents significantly promoted plant growth; meanwhile, microbes that can biosynthesize vitamin B₅ should be investigated and verified further in future experiments.

Introduction
In recent years, there is an increasing number of applications of computer vision in agriculture and aquaculture. The applications include individual tracking, behavior monitoring, species identification, phenotyping and prediction of complex traits based on images or video (Vo et al., 2021). Image data has the benefits of being high-throughput and non-invasive. In image data analysis, one of the most popular methods is neural network, especially convolutional neural network (CNN). However, as CNN has been criticized for its ‘black box’ nature, the lack of interpretability of the image-based neural network can make the results questionable for real-life application. Some methods attempt to understand how CNNs learn by revealing the imaginal features they use to establish the prediction. One of the most intuitive methods is class activation map (CAM). The core function of CAM is to reveal the regions in an image that are most relevant for the prediction. Field experts can therefore use CAM-revealed features as a reference to judge the reliability of the CNN prediction. Ideally, class activation map can make CNN more transparent and promote data driven decisions.

The study aims to investigate the validity of the predictive features of CNNs revealed by CAM from a genetic perspective with a case study. The case study is interested in the physical characteristics of fish that contribute to their critical swimming speed (Brett, 1964). We use individual 3D images and CNN to predict in rainbow trout. With fish physiologist we then defined two new traits based on the CAM features derived from the prediction. At last, we calculated the genetic properties of these new traits in relation to swimming speed and body weights.

Materials & Methods
We conducted swimming test and acquired individual records on for 1037 rainbow trout. Each fish was weighted and measured for length manually and allowed time for recovery. Afterwards, all fish were subjected to imaging through an imaging equipment. Each individual fish was placed towards the same direction when its lateral side was captured simultaneously in two images: one RGB image, and one depth image where each pixel contains the distance information between the camera and the lateral surface of the fish (Figure 1). By combining these two images, we obtained a 3D-colored hologram of each fish with its lateral side up (Figure 2, left).

We also corrected the recorded for body length for each fish. For corrected prediction we used part of the analytical framework for image data proposed by Xue et al. (2023). Predictive features were visualized using gradient weighted class activation map (GradCAM) (Selvaraju et al., 2019). We included the interpretation from fish physiologists and refined the visualized predictive features into two swimming traits. We then annotated these traits on the original RGB and depth images for each individual (Figure 3). We estimated the heritability of these traits and their genetic correlation with corrected using an animal model: , where are the measurements of the traits, is the overall mean of each trait, are the additive genetic effects and are the residuals.

Results
The correlation of the CNN prediction with the real corrected was 0.23. The right side of figure 2 shows the 3D predictive features revealed by GradCAM. The regions highlighted in red correspond to the contour of the fish, the volume of the head, the caudal fin and the volume of a narrow region along the dorsal side. Based on the location of these features and the biological function of the corresponding regions in a fish, two swimming traits were defined in consultation with fish physiologists: One trait is the volume of the head. Another one is the volume of epaxial muscle corrected by body weight, hereafter refer to as the ratio of epaxial muscle. The heritability of head volume and ratio of epaxial muscle were 0 and 0.23, respectively. No significant genetic correlation was found between the volume of the head and corrected . However, the ratio of epaxial muscle had a genetic correlation of 0.35 with corrected .

(Continued on next page)
Discussion
In this study, we built a CNN using 3D images to investigate the relationship between the physical characteristics and the swimming speed of rainbow trout. The predictive features from CAM were narrowed down to two traits by annotation: head volume and ratio of epaxial muscle. Image-based CNN explained only 23% of the variance within corrected but this is enough for the activation map of the trained CNN to provide valuable information for pinpointing novel predictor traits. The results of genetic analysis validate the intrinsic relationship between and the ratio of the epaxial muscle - a trait derived from the activation map features of the trained CNN. The positive genetic correlation makes intuitive sense; if two fish are of the same weight, the one with a higher volume of epaxial muscle swims better. Head volume, however, shows no significant genetic relationship with . The highlighted region of head in CAM might due to variation in its other properties like shape or its relative distance to other highlighted parts. Future study will continue the interpretation of predictive features, also with different animal models.

Efficacy of Different Ratio Between Vitamin C Phosphate and Phytocee (Herb Extract) in Diets on the Performance of White Shrimp, Penaeus vannamei, Under Density Stress Condition, and Disease Challenge Against Vibrio parahaemolyticus

Nattakul Yaemsooksawat1*, Srinoy Chumkam, Orapint Jintasataporn

Department of Aquaculture, Faculty of Fisheries
Kasetsart University
Bangkok, Thailand
E-mail: nattakul.y@ku.th

Introduction
Disease outbreaks and climate change have been an ongoing challenge for some large Asia shrimp aquaculture producers, particularly in Thailand and China. In Thailand, shrimp diseases are the most important causative agents. The currently pathogenic bacteria and viruses are Vibrio harveyi and V. alginolyticus as well as acute hepatopancreatic necrosis disease (AHPND) and early mortality syndrome (EMS) caused by V. parahaemolyticus (Lightner, 2011). Furthermore, stress is universal challenge in animal and it can be defined as the nonspecific response of the body to any demand made upon it. Stress can cause adverse effects in animals like low productivity, susceptibility to disease, organ damage, retarded growth and death. (Chen, 2015). Dietary vitamin C is essential for penaeid shrimp, and its deficiency would induce severe damage, such as the “black death” syndrome. It also acts as a promising nutritional supplement, since it has been already demonstrated that this vitamin, besides functioning as a potent antioxidant such as an immunostimulant in fish and crustacean (Maggioni et al., 2004). Many herb extracts have the function related to vitamin C on animal physiology. Phytocee, herb extract, has the adaptogenic effect which could be understood by examining its ingredient. Withania somnifera, one of the key ingredients has been shown to have anti-stress effects and improve immunity in animals (Singh, 2011). Therefore, the aim of this study was to evaluate the effects of ratio between vitamin C phosphate (vit-C phosphate) and Phytocee on growth performance and survival after pathogen challenge test.

Material and Methods
The experiment was a factorial design with 2 factors of A: 2 levels of vit-C phosphate 35% (0 and 1000 ppm) and B: 2 levels of Phytocee (1000 and 2000 ppm) with 4 treatments and five replication as Table 1.

Shrimp with initial mean weight of 1.4 g/shrimp were randomly distributed into 240L glass aquarium (Total 20 aquariums) that contained 120L of 15 ppt seawater and stocked 30 shrimp per aquarium (250 pcs/m³). During 8 weeks of feeding trial, shrimp were fed experimental diets 3-5%BW, 4 times a day and weighted on week 0, 4 and 8 for determined growth performance and after challenge test by bath treatment against 6.2X10⁵ CFU/ml of Vibrio parahaemolyticus AHPND for 12 days, mortality was recorded.

Results
After 8 weeks of feeding trial, the growth performance of shrimp fed different ratio between vit-C phosphate and phytocee (herb extract) in diets showed that shrimp fed diets of vit-C phosphate 1000 ppm had better growth performance than group of shrimp fed vit-C phosphate 0 ppm (p<0.05). Moreover, shrimp fed diets of Phytocee 2000 ppm had better growth performance than shrimp fed Phytocee 1000 ppm (p<0.05). Hence, shrimp fed Phytocee 2000 ppm exhibited the better performance than group of shrimp fed diet of Phytocee 1000 ppm both with vit-C phosphate 0 and 1000 ppm (p<0.05) when focusing on final weight, average daily gain, and shrimp production (T4>T3,T2,>T1). Feed utilization in term of feed conversion ratio in shrimp fed Phytocee 2000 ppm was lower (p<0.05) than shrimp fed Phytocee 1000 ppm both in shrimp fed vit-C phosphate 0 and 1000 ppm (T4<T2<T3<T1). The results of growth performance and feed utilization were presented in Figure1. The survival rate were not significantly differences (p>0.05). Shrimp fed vit-C phosphate 0 ppm have tended to present the poor survival rate than shrimp fed vit-C phosphate 1000 ppm (p=0.063) both in shrimp fed Phytocee 1000 and 2000 ppm and Phytocee 2000 ppm demonstrated the better survival rate than 1000 ppm. The survival rate was 82.67, 85.33, 86.00 and 88.67% in T1, T2, T3 and T4, respectively. The levels of Phytocee did not affect the survival rate under high stocked density of 250 shrimp/m³ in clear water of indoor condition due to proper culture management resulting exhibited on promote growth performance and shrimp production. After disease challenge by V. parahaemolyticus AHPND immersion treatment, the survival rate of shrimp fed vit-C phosphate and Phytocee showed that shrimp fed vit-C phosphate

(Continued on next page)
1000 ppm and phytocee 2000 ppm had highest survival rate follow by shrimp fed vit-C phosphate 1000 ppm and phytocee 1000 ppm (p<0.05) and the poor survival rate exhibited in shrimp fed vit-C 0 ppm (T4>T3>T2, T1). There, the results indicate the efficacy of vit-C and Phytocee on improving growth performance and survival rate under high stress condition of stocking density and disease challenge and imply that Phytocee has the adaptogenic effect on reducing stress resulting promoting growth performance and survival rate under stress condition.

Reference
Feed accounts for up to 70% production costs in aquaculture. The increase in the use of vegetable and other alternative protein sources, together with the recent aquafeed price increases of up to 30%, calls for the further innovation in lower cost ingredients. However, the optimal nutritional value of the feed should be maintained, and the use of dietary enzymes in aquafeeds have potential to improve the nutritional value of the feed as well as contributing to the sustainable development of aquaculture.

Accordingly, the hunt for new raw materials of sufficient quality and affordable price is very challenging across aquaculture species and their growing conditions. In addition, stakeholder concerns are not limited to the nutritional value of individual raw materials but also include important factors such as sustainability, welfare, and the effect on the environment. A reminder on the benefits of available enzymes to support aquaculture as it grows sustainably is of major interest.

Data from trials with phytases, proteases and enzymes improving the digestion of non-starch polysaccharides, have shown to have significant effects in the performance of the species, the cost of the feed and reduction in phosphorus excretion for example (salmonids, warm water species, Mediterranean species, and shrimp).

A few recent studies show that the use of phytase enzymes (release the phosphorus contained in phytate form in the vegetable ingredients: Phytate P) impact the digestibility and absorption of phosphorus, other minerals and protein. The effect of phytase on the phytate-P, which is poorly digested by animals and is also an antinutritional factor, can improve growth performance in fish species up to 5% because of an increase in phosphorus digestibility up to 65% in rainbow trout and 60% in tilapia. At the same time, these studies demonstrated a reduction in environmental emissions of phosphorus.

Proteases are a key tool to improve the digestibility of ‘low value’ ingredients, increasing the flexibility of the raw material basket: protease inclusion in shrimp and tilapia feeds can maintain animal’s performance with a significant decrease on the use of marine proteins or soy protein concentrates, contributing to control the costs of the feeds and reducing the feed and farm footprints.

Studies demonstrate that the in-feed inclusion of a combination of enzymes, such as phytase, protease and xylanase, can improve energy utilization up to 8% in tilapia when modern formulas are used.

This paper will review the existing data in the use of enzymes in aquaculture feeds, as well identifying current gaps and future needs to support the sustainable growth of aquaculture.
Chlorella vulgaris AS SOURCE OF VITAMIN C FOR PIKEPERCH (sander lucioperca) LARVAE

Introduction
Most animals can synthesize Ascorbic Acid from glucuronic acid, but fish and crustaceans lack the enzyme gluconolactone oxidase necessary for the last step in this biosynthesis (Chatterjee, 1973; Dabrowski, 1990). Therefore, they depend on constant supplies of acceptable amounts of vitamin C through the feed. Currently, fish larvae in aquaculture rely primarily on commercial live feed enrichments to supply the required amount of Vitamin C. Due to the high amount of vitamin C found in Chlorella vulgaris, we looked at the potential replacement of commercial enrichment diets during the first 21 days post-hatching with Chlorella vulgaris.

Materials and Methods
This trial tested the use of Chlorella vulgaris on pikeperch (Sander lucioperca) larvae during first feeding. The trial included three live feed enrichment treatments and one control, fed to the larvae for the first 21 days post-hatching. The first treatment exposed the live feed to the “Selco Spresso” enrichment diet by INVE, while in the second treatment, Ascorbic acid was used on the live feed. The third treatment used Chlorella vulgaris as the live feed enrichment, and the control treatment used Nannochloropsis occulata. After 21 days post-hatching, a representative sample of larvae (100 per treatment) from the four treatments was challenged for 180 minutes in high salinity (15ppt) to test resilience and cortisol levels. Growth, survival, and bladder inflation data were also collected.

Results
Significant differences were found between treatments regarding stress resilience to the salinity challenge and cortisol levels compared to the control treatment and between enrichments. Significant differences were also found in larvae Vitamin C concentration after 21 dph. No differences were found in the growth or survival (average 65%), although chlorella treatment had the highest survival (72%).

Conclusions
The results suggest that using Chlorella Vulgaris in live feed during the pikeperch larval stage, positively enhances stress resilience and could potentially replace the use of more expensive commercial enrichment diets.

Email: Peyman.Yarahmadi@arona-chemie.com

Introduction
Health feed additives are designed to enhance animal immunocompetence and reduce the dependence on chemical treatments, such as antibiotics, in fish farming. This study aims to evaluate the effects of a phytogenic-based additive, SANACORE® GM (Adisseo, France), on the immunocompetence of rainbow trout (*Oncorhynchus mykiss*) in farm testing.

Material and methods
Rainbow trout with an average individual weight of 230g were fed the functional additive (0, 1 and 2 kg/mt) in raceway compartments. Each compartment was stocked at a density of approximately 3 kg/m3 in triplicates. After a cultivation period of 60 days, the fish’s health status was assessed by measuring serum glucose, total protein, albumin levels, serum alternative complement activity, lysozyme activity, and antioxidant activity. Lastly, the additive effect on the community of microorganisms in the fish’s digestive tract was also evaluated.

Results
Supplementation of the functional feed resulted in significant increased antioxidant enzyme activities, serum globulin production, lysozyme activity (P <0.05), and in term complement system activity although showed increase tendency but there was no significant discrepancy (P>0.05). Additionally, the intestinal bacterial counting showed significant reduced populations of opportunistic bacteria such as *Aeromonas*, *Streptococcus*, and *Yersinia* while significantly promoted the population of probiotic bacteria *Lactobacillus* (P<0.05). In conclusion, the findings of this study demonstrated that the SANACORE® GM enhanced the immunocompetence of rainbow trout by elevating immune enzyme activities and antioxidant defense, making fish better prepared to combat infections. A healthier gut microbiome is important to prevent dysbiosis and better deal with stress and disease.
FIRST REPORT OF NATURAL *Nematopsis* sp INFECTION IN *Chamelea gallina* IN BULGARIAN WATERS OF THE BLACK SEA

N. Yordanov1*, Ç. Ürkü2, G. Nikolov1, A. Atanasoff3

1 Trakia University, Faculty of Agriculture, Stara Zagora, Bulgaria

**Introduction**

*Chamelea gallina* (Linnaeus 1758) is a benthic species which has a wide area of spread including the East Atlantic Ocean coasts, the Adriatic Sea, the Black Sea and the Mediterranean (Tanrıverdi et al., 2019). This wedge clam is found intensively in the Western Black Sea and the Marmara Sea, where they play an important economic role (Dağtekin et al., 2023). In addition, *Chamelea gallina* are dietary sources of n-3 LC-PUFA, trace elements (Cr and Fe) and protein (Peycheva et al., 2023). There are significant gaps in knowledge about population and health status of clams in Bulgarian waters of the Black Sea.

In this study we present the first record of *Nematopsis* sp. infection in the wedge clam *Chamelea gallina* along the Bulgarian Black sea coast.

**Material and Method**

The study was carried out in the North Bulgarian Black sea coast near Cape Shabla. The samples were collected by scientific scuba diving, consisting of 30 clam *Chamelea gallina* twice a month, in the period between April 2021 and May 2022. The biometric measurements were undertaken with digital caliper (nearest 0.1 mm) including anterior-posterior length (L), dorsal-ventral length (W), the distance between two valves (D), total weight (TW), wet weight of the soft parts (WWSP), and weight of shell (WS). A total of 720 specimens have been analyzed to detect the changes occurring during reproductive processes by classical histology techniques. First, a section from the tissue (mantle, gonad, gill, digestive gland, and foot) was fixed in 10% neutral buffered. In the next step samples were dehydrated with graded series of ethanol, cleared in xylene and embedded in paraffin wax. Paraffin blocks were cut (4-5 µm) with a microtome (Leica RM2125, Germany) and stained with haematoxylin and eosin (H&E). Slides were examined and described regarding the presence of morphological alterations under a light microscope (Olympus BX51, Germany) equipped with a digital camera (Olympus DP72, Germany).

**Results and Discussion**

In routine classical histological examination among the analyzed clam organs parasites were observed in gills in three of them. The identified as *Nematopsis* sp. parasites were found as gametocysts, and the effects on infected individuals presented tissue damage, intense hemocyte infiltration, especially disruption of the structure of the gill tissue (Figure 1).

**Conclusion**

To our knowledge, this is the first record of *Nematopsis* sp. infection in the wedge clam *Chamelea gallina* along the Bulgarian Black sea coast. Further research is needed for the process of parasitism that may occur simultaneously with other pathogens in different environmental conditions.

Due to sustainable economic development and food security for Saudi Arabia, aquaculture is essential for the national development sectors. In addition, mariculture is more appropriate than freshwater culture due to the limitations of factor policy and natural environment. Therefore, the Saudi Arabian Fisheries Authority (Ministry of Environment, Water and Agriculture) has been promoting mariculture to support sustainable development and food security of national policies. However, the Saudi Arabian aquaculture industry has faced many problems related to the lack of a wider range of aquaculture species, the absence of local hatchery facilities or inadequate production, diseases, and the lack of well-trained personnel. In Saudi Arabia, few institutions and organizations provide vocational training for aquaculturists. In addition, most field work is dependent on foreign labor. Sustainable strategies can be developed to support the aquaculture industry, including the national training center for the private sector and improving vocational training in the public sector. In addition, vocational training can focus on hatchery managers and technicians and the development of new cultured species.
This study estimated the survival, growth, fry production, and farming costs of Sabaki tilapia (Oreochromis spilurus) broodstock in the following five types of outdoor production systems: arena, raceway, cage, concrete pond, and earth pond. Experiments were conducted in triplicate with 300 broodstock per production system. Survival rate, growth performance, fry production and farming cost were monitored. Our results indicated that Sabaki tilapia fry production was feasible under high salinity conditions in the production system types studied; however, the systems showed significant differences in terms of survival rate, growth performance, and fry production. The arena and raceway systems were the most effective and had the highest fry production.

UTILIZING PHOSPHORUS SMARTLY FOR SUSTAINABLE BONE HEALTH IN SALMON FARMING: A GLIMPSE INTO THE FUTURE

Muhammad Naveed Yousaf*, Lucia Drábiková, Per Gunnar Fjelldal, Adelbert De Clercq, Thea Morken, Matthew Owen, Charles McGurk, Alex Obach, P. Eckhard Witten

E-mail: Muhammad.naveed@skretting.com

Introduction
Bone health is an essential aspect of overall health and well-being of fish. Bones provide support to the body, protect vital organs, and store minerals such as calcium and phosphorus. All vertebrates need sufficient minerals for their Ca—P based skeletons. Fish mainly obtain calcium from the water, but not phosphorus as ocean is empty of phosphorus. Dietary phosphorus deficiency is considered a nutritional risk factor for the development of vertebral deformities in farmed Atlantic salmon (Salmo salar, L). Bone health is important not only for fish welfare, but also for farmers, as bone defects (vertebral deformities) may lead to bad fillet quality and eventually downgrading of the fish at slaughterhouses.

Results
Our recent studies have shown no correlation between dietary phosphorus levels and growth in freshwater Atlantic salmon (Drábiková et al., 2021, 2022). The growth of post-smolt Atlantic salmon deficient in phosphorus (with a 50% lower dietary P content) was restricted compared to those reared in seawater with a sufficient phosphorus content, despite no significant differences in the condition factor or feed conversion ratio between the experimental groups (Witten et al., 2016, 2019). Fish fed a low phosphorus diet develop extended areas of non-mineralised bones without having significant effects on the prevalence of vertebral deformities in Atlantic salmon (Drábiková et al., 2021, 2022; Witten et al., 2016, 2019). Excessive dietary phosphorus intake (50% above the dietary P requirement) has no additional benefits in terms of bone mineralization, but ultimately results in water waste. Furthermore, elevated CO2 levels in water can prevent dietary induced osteomalacia (bone softening) in Atlantic salmon (Drábiková et al., 2023).

Conclusion
In conclusion, fish need an optimum phosphorus diet and environment to keep their bones healthy. This is critical for closed aquaculture systems where excess nutrients (phosphorus) build up in the water.

Introduction
Fluctuating conditions, more extreme events and an unpredictable environment are impact from climate change. There is an urgent need to understand how farmed aquatic organisms respond to these challenging conditions. Aquatic animals farmed in the ocean are in direct contact with the environment, without any possibilities to escape unfavourable conditions. These animals are part of an intensive production regime, and stress related to production management are further inducing stress on the animals. How production procedures in combination with fluctuating environmental conditions exert stress on the animals and how the stressors work in combination, is important knowledge when making climate adaptation strategies.

The presented results provide insight into how cells from different organs in Atlantic salmon and Atlantic cod can be used to understand how changing climate conditions in combination with secondary stressors affect fish health.

Methods
Using climate projections from the Intergovernmental Panel on Climate Change (IPCC) we evaluated potential future temperatures at selected Atlantic salmon (Salmo salar) and Atlantic cod (Gadus morhua) farms in Norway. Based on these results we designed a temperature study with Atlantic salmon to evaluate biological impact from temperature alone and in combination with secondary stressors.

Atlantic salmon post-smolt (50g, N=600) and Atlantic cod (60g, N=400) were exposed to different temperature regimes, optimal: 12°C, high: 17°C or fluctuating (only salmon): 12/17°C, conditions. The trial was run for two (cod) and three (salmon) months, with the fluctuating temperature cycling in three rounds. All groups were exposed to different combinations of secondary stress, such as reduced oxygen, pathogens, algae or jellyfish.

Samples of skin, gills, and olfactory organs were collected at different time-points, and microarray, histology, scanning electron microscopy and immunohistochemistry used to evaluate the impact of temperature alone, and in combination with secondary stressors. In vitro models of skin biopsies and scale explants were used to further investigate the functional biology of increased temperature. Migration assays and immunohistochemistry with markers for stress induced genes were used to increase our understanding of the combined stress.

Results and Discussion
Results show no growth different between fish from the different temperature regimes and few differences when looking at the operational welfare scores (OWIs). However, comparing cellular responses in the skin, gills and olfactory organs from fish reared at the three different temperatures revealed altered morphology, changes in immune response and reduced regeneration capacity in fish from high and fluctuating conditions. High temperature and fluctuating conditions were shown to reduce skin integrity, thereby increasing the risk for wounds and secondary infections. After exposure to secondary stressors, such as algae and jellyfish, fish from higher temperature showed increased damages in gills and further reduced migration potential in skin. Results indicate that fluctuating conditions and constant high temperature are challenging for salmon health, but that the biological responses are different.

Conclusion
Fish in production systems are exposed to changing environmental conditions, pathogens, and operational procedures, that may expose the animals to stress either individually or in combination. Our results indicate that biological alterations caused by high and fluctuating temperatures may reduce Atlantic salmon’s and Atlantic cod’s resilience to diseases and production related stress. Understanding how multiple stressors affect the biological performance of farmed species is essential when planning for robust production. Looking into the cellular responses to multiple stressors may help us understand when the fish is vulnerable, what the tolerance thresholds are, and accordingly how the fish may be handled to sustain good welfare and survival.

carlzyu@scsio.ac.cn

As the leading role of mollusk industry in China, oyster aquaculture has witnessed a rapid popularity and sparkling development of triploid seed production and farming over the past few years. In this field the method of triploid production has been the mainstream one by mating tetraploids and diploids. When tetraploidy-inducing approach has been the popular one, the production of tetraploid oyster is still a great technical difficulty. In the past few years, we’ve successfully developed a new technique of oyster tetraploid-induction, and then applied it to commercial production of triploid seeds.

The triploidy performance and characteristics of tetraploids were evaluated using complete inter-ploidy breeding between diploid and tetraploid Pacific oyster or Portuguese oyster. In the Pacific oyster, experiments on two intra-ploidy groups (DD: 2n♀ × 2n♂, TT: 4n♀ × 4n♂) and two reciprocal triploid groups (DT: 2n♀ × 4n♂, TD: 4n♀× 2n♂) were carried out successfully in duplicates. High fertilization rates and D larvae rates were observed in all groups, while the TT and TD groups have a lower hatching rate due to a dysfunction in tetraploid eggs. In grow-out stage, DT hybrids had a higher survival rate than intra-ploidy groups during the whole life history stage. Growth advantage of reciprocal triploid hybrids was evident in both, while DT progeny was always larger than TD in the whole process except in the D larvae stage. As for the two intra-ploidy groups, all tetraploid progeny was smaller than the progeny of diploids, and some tetraploid progeny showed the ploidy loss phenomena as aneuploids and triploids at the grow-out stage.

In the *C. angulata*, artificial breeding was made between diploid (D) and tetraploid (T) to produce DD, DT, TD and TT groups. The results showed that the fertilization rate, cleavage rate, D larval rate and larvae survival rate of DT group were significantly higher than those of TD and TT groups, and the larval growth of DT group was significantly faster than that of the other three groups. In cultivation period, the growth and survival rate of DT in the 2 sites were significantly higher, and the 100% triploid rate was stable. In addition, some triploids in DT and TD groups were fertile and could produce functional gametes. But the proportion of female and hermaphrodite in fertile triploids was higher than that in diploids and tetraploids, and the fertility of triploids was still poor overall. However, some tetraploids in TT group would lose chromosomes during growth and become triploids, diploids or aneuploids. Tetraploid had the slowest growth and the lowest survival rate at the both sites, but its fertility was normal and could produce a large number of functional gametes, which could provide sufficient sperm for large-scale production of triploids. All our data/results demonstrated that the diploid ♀× tetraploid ♂ group have excellent commercial production capacity of triploid for both species in the industry.
**Posidonia oceanica AND FISH FARMING IN THE GÜLLÜK GULF**

G.Yücel Gier, C. Coşkunışık, A.H.Eronat, M.Duman

Dokuz Eylül University Marine Science and Technology Institute Izmir/Turkey
E mail yucel.gier@deu.edu.tr

**Introduction**

Seagrass habitats are important ecological ecosystems. *Posidonia oceanica*, a native species, is essential to the welfare of the marine ecosystems of the Mediterranean Sea (Duarte 2002). Human activities such as eutrophication, coastal tourism and anchoring, destructive fishing methods, effects of coastal development, uncontrolled aquaculture development, coastal constructions and industrial wastes are the prime cause for the decline in density and surface area of *P. oceanica* meadows over the past three decades (Pergent, G. 2006). This study aims to map the fish farm areas and the spatial distribution of *P. oceanica* in the Güllük Gulf using sonar, remote sensing techniques and GIS (Geographic Information System) in an effort to increase the ecological sensitivity of the gulf.

**Material and method**

The study area lies east of the Aegean Sea. This 670 km² Güllük Gulf is a coastal area with a high concentration of touristic activities, fish aquaculture, and second homes. In the study, remote sensing (the Sentinel 2 satellite image 2018) was utilized to illustrate the distribution of fish farms. *Poceanica* data was collected by using side-scan sonar and Stratabox Sub Bottom Profiler. *P.oceanica* data and fish farms data was converted to create a GIS map.

**Result**

Figure 1 illustrates the fish farms and *P.oceanica* distribution in the Güllük Gulf. Meadows are more common in the northern regions of the Gulf. The legislation Turk (MEF, 2007) defines an aquaculture area as Allocated Zone Aquaculture (AZA), which encompasses 21.2% (139.8 km²) of the Güllük Gulf. There are 61 fish farms in the AZA. There is no *P. oceanica* in the AZA region.

![Figure 1 Distribution of P.oceanica and fish farms in Güllük Gulf](image-url)

*(Continued on next page)*
Discussion and Conclusion

The study location, Güllük Gulf, is also located in the Aegean Region and is a coastal area where human activity, tourism, fisheries, agriculture, secondary houses and Güllük port activities are intense. The rapid development of fish aquaculture and tourism has paralleled the urbanization of the Güllük Gulf (Yücel-Gier et al., 2013). Due to the conflict between aquaculture and other sectors, fish farms had to be relocated to areas a minimum distance of 0.6 miles from the land and at the minimum depth of 30 meters according to Turkish legislation passed in 2007 (MEF, 2007). After the relocation aquaculture production increased to 88,000 tons in 2008, present production is 121,000 tons (TUIK 2021). *P. oceanica* is seen outside the AZA in Figure 1 (2018), the aquaculture farms were relocated in 2007. Mapping was done in 2018 so it is difficult to determine the effects of aquaculture on *P. oceanica* prior to 2018.

With the development of remote sensing and sonar imaging techniques, *P. oceanica* data can be collected and processed via GIS; this method enables the making of maps common and widespread. In addition, such maps can be used as an important tool in the sustainability of activities such as aquaculture by selecting the right location and integrating coastal planning.

Introduction
A good knowledge of the potential effects of water temperature on feeding and on-growing process is of primary importance to optimize the fish production. Temperature modulates ingestion, transit, digestion, assimilation, metabolism and ultimately feed utilization and growth rate. These two last parameters, together with the cost of feeds and energy, are necessary data for producers to make decisions. The production in indoor facilities with temperature control is depending on energy cost while in outdoor facilities (ponds and cages) it depends on environmental temperature. The effect of temperature is more noticeable in fast growing fish, as the greater amberjack (Seriola dumerili), a species of great interest for the aquaculture industry worldwide. Currently, its cultivation is expanding in the Mediterranean countries. Therefore, it constitutes a good model to study the consequences of an increased temperature. In this study, we examined the ingestion, digestive enzyme activities, metabolites in plasma and liver, antioxidant response in the liver and the integrity and electrogenic amino acid transport in the intestine, in greater amberjack juveniles growing at three different temperatures. The final aim was to elucidate the mechanisms behind feed utilization that justify the growth differences and to provide a useful informative basis to the productive sector.

Materials and methods
Greater amberjack juveniles (weight 23.35 ± 5.07 g; mean and SD) were randomly distributed in three independent RAS units set to 18, 22 and 26°C of temperature, each one with three 900-L tanks. Juveniles were reared for 58 days under a photoperiod of 12h-light/12h-dark and fed until apparent satiation 3 times a day with a commercial diet (Skretting). Every two weeks, 5 fish per tank were sampled to check their body weight. At the end of the experiment, 16 fish per tank were sampled for assessing feeding and growth performance (weight gain, feed intake, feed conversion ratio) and analytical determinations. Luminal pH was measured in stomach and middle intestine. Activity of digestive proteases (trypsin, chymotrypsin, leu-aminopeptidase, pepsin) was analysed at the actual physiological temperature and pH. Oxidative stress biomarkers (protein carbonylation PC, catalase activity CAT, lipid peroxidation LPO, total antioxidant capacity TAC and mitochondrial reactive oxygen species mROS) were analysed in liver concomitantly with plasma cortisol; metabolites (triacylglycerol TAG, lactate, protein, glucose, glycogen, cholesterol) were also evaluated in plasma and liver. Intestinal integrity, permeability and electrogenic amino acid transport were assessed in using chambers. Differences were checked by ANOVA followed by Tukey’s test.

Results
Voluntary feed intake, final body weight and weight gain increased with the temperature increase from 18 to 26°C (p<0.05). Feed conversion ratio was higher at 18°C than at the other temperatures (p<0.05) (Table 1). Overall, the activities of trypsin and chymotrypsin were higher at 22°C than at 18°C when analysed at their physiological temperature and pH (Fig. 1). Contrarily, pepsin was not detected at the actual physiological pH. In liver, TAG was higher at 18°C, whereas hepatic glucose and glycogen (Table 2), as well as plasma protein and cortisol levels were higher at 26°C. Oxidative stress parameters were higher at 18°C than at the other temperatures, excepting mROS that was similar among treatments. Epithelial electrophysiology showed that tissue resistance was temperature-dependent and the electrogenic amino acid transport was higher at 26°C than at the other temperatures.

(Continued on next page)
The tested temperatures are within the tolerance range described for this species. Ingestion clearly increased with the increase of temperature, but growth and FCR were similar at 22 and 26°C, although weight values were higher at 26°C. Interestingly the level of enzymatic activities was also similar at 22 and 26°C. In addition, the temperature increase modifies the intestinal epithelium selectivity and improves electrogenic amino acid transport from the lumen at least in the mid-intestine.

At 26°C, fish are using primarily TAGs from liver for covering the energetic demand, while at 18°C switched to carbohydrates. The higher plasma protein level reflects a higher synthesis activity for growth. TAGs were less utilised at 18°C, with risk of liver steatosis, or even favouring damage by oxidative stress at the lowest temperature, despite activating antioxidant defences. From a practical view, 22 and 26°C appear as optimal temperatures for on-growing the species, although surely better growth would be obtained at 26°C in longer periods. At 18°C, the low ingestion and the damage derived from the oxidative stress impair the growth capacity.

Discussion

The tested temperatures are within the tolerance range described for this species. Ingestion clearly increased with the increase of temperature, but growth and FCR were similar at 22 and 26°C, although weight values were higher at 26°C. Interestingly the level of enzymatic activities was also similar at 22 and 26°C. In addition, the temperature increase modifies the intestinal epithelium selectivity and improves electrogenic amino acid transport from the lumen at least in the mid-intestine. At 26°C, fish are using primarily TAGs from liver for covering the energetic demand, while at 18°C switched to carbohydrates. The higher plasma protein level reflects a higher synthesis activity for growth. TAGs were less utilised at 18°C, with risk of liver steatosis, or even favouring damage by oxidative stress at the lowest temperature, despite activating antioxidant defences. From a practical view, 22 and 26°C appear as optimal temperatures for on-growing the species, although surely better growth would be obtained at 26°C in longer periods. At 18°C, the low ingestion and the damage derived from the oxidative stress impair the growth capacity.
Introduction
The cereal industry generates large amounts of residual by-products with high potential as feed ingredient for aquafeeds. Such raw materials could help to substitute protein and lipids from less sustainable sources such as soy concentrate, wheat flour or oils and reduce the competitiveness between the production of aquafeeds and the use of food for human consumption. In this study, one of these by-products, corn gluten feed, has been tested in dose-response experiments as ingredients in on-growing feeds for two European species (greater amberjack, *Seriola dumerili*; gilthead seabream, *Sparus aurata*). The final aim was to examine to what extent this more-sustainable and low-cost product can be used as alternate ingredient for fish feeds.

Materials and methods
Corn gluten feed was provided by Roquette (Corex, 18% crude protein). The experimental diets had increasing proportions of this novel ingredient. Diets were manufactured by SPAROS Lda and were tested in greater amberjack and gilthead seabream. The inclusion level increased from 0 to 25% on weight basis (control: 0%, 12.5%; and 25%) replacing wheat flour and rapeseed oil. All diets contained 47% of crude protein and 20% of crude fat. Greater amberjack juveniles (average body weight 92.25 g) were distributed in 9 tanks in RAS and fed until apparent satiation three times a day for 97 days at 22 ºC. Gilthead sea bream juveniles (average body weight 93.36 g) distributed into 9 tanks in RAS were maintained for 57 days at 24 ºC and fed in excess with automatic feeders twice a day. Feeding and growth performance were measured at the end of the trials with both species. Intestinal integrity, oxidative stress biomarkers (catalase activity CAT, lipid peroxidation LPO and mitochondrial reactive oxygen species mROS) in liver as well as fillet composition and organoleptic characteristics were also analyzed in greater amberjack. Statistical differences were tested by one-way ANOVA followed by Tukey’s test (p < 0.05).

Results
Experimental diets were well-accepted by both fish species and the fish grew up in all cases. In greater amberjack, the voluntary feed intake (VFI) was lower, but not significantly different, in fish fed diet with 12.5 inclusion of corn gluten feed than in fish fed the other two diets. Growth parameters and feed conversion ratio (FCR) with the two experimental diets were similar to those of the control diet. The hepatosomatic index (HSI) was also similar among treatments. However, the viscerosomatic index (VSI) was higher with diet containing 12.5% of corn gluten feed (Table 1). Oxidative stress parameters (CAT and mROS) were higher with 12.5%-diet than with the other two diets, but LPO was similar among treatments though with a trend to be lower with the control-diet (Table 2). Organoleptic analysis of fresh and cooked fillet samples revealed no differences among treatments for all sensory attributes and a good acceptance for fillets coming from fish fed diet with the new ingredient. No histological alterations associated to inflammatory processes in the intestine were observed in fish fed the experimental diets. In gilthead sea bream, VFI was significantly lower in fish fed on diet with 12.5% of corex inclusion, but growth parameters and FCR were similar in juveniles fed on the three diets. Likewise, no statistical differences were detected for VSI (Table 3).

(Continued on next page)
Discussion
The inclusion up to 25% of corn gluten feed in diets for greater amberjack and gilthead seabream allowed similar growth and feed utilization than the control, even a tendency for a more favorable utilization of the diet with 25% inclusion was observed in greater amberjack. With the 12.5% corex diet, fish required to activate higher antioxidant defences to prevent damage by oxidative stress. In addition, fish fed with the new ingredient maintained the integrity of the intestinal mucosa as well as the flesh quality. These results support the potential of corn gluten feed to be used as an ingredient for fish diets. This by-product has a good protein content and is also rich methionine, a limiting amino acid in feeds with high proportion of plant derived ingredient. The use of this ingredient would increase the sustainability of growing stage in the aquaculture industry without affecting the zootechnical performances and reducing competition with human food chain resources.

Introduction
The increasing incorporation of plant-based products in fish feed warrants consideration of potential unintended factors, including the presence of new plant toxins. To enhance risk assessments in animal studies, the utilization of early response biomarkers has been proposed. This study aims to explore the interaction between an experimental diet and the gut integrity in juveniles of greater amberjack (Seriola dumerili), focusing on the effects of corn gluten feed as a plant-based ingredient obtained as by-product from the cereal industrial processing. Various biomarkers of exposure and effects were evaluated, including histochemical properties of goblet cells, morphological changes in the posterior intestine (villus length, variations in size and number of goblet cells), and alterations in cell proliferation using the proliferating cell nuclear antigen (PCNA) approach.

Materials and methods
In this study, a cereal by-product, corn gluten feed (Corex, Roquette; 18% crude protein), was evaluated as a novel ingredient in experimental diets for greater amberjack. The diets were formulated by SPAROS Lda and consisted of increasing proportions of corn gluten feed, ranging from 0% to 25% on a weight basis (control: 0%, 12.5%; and 25%). This ingredient replaced wheat flour in the experimental diets maintaining a consistent crude protein content of 47% and crude fat content of 20%. Greater amberjack juveniles with an average body weight of 92.25 g were distributed into nine tanks in a recirculating aquaculture system (RAS). The fish were fed three times a day until apparent satiation over a 97-day feeding period at a water temperature of 22 ºC. At the end of the trials, samples of the distal intestine were collected, fixed in a formaldehyde solution, and processed for histological analysis. Histochemical properties of goblet cells, intestinal integrity, and changes in cell proliferation were assessed in greater amberjack fed with the experimental diets. Statistical differences among the different diet groups were analyzed using one-way ANOVA, followed by Tukey’s test (p < 0.05).

Results
Concerning the histological organization of the intestine, the comparison between the control group and the two experimental diets indicated no relevant differences in the arrangement of the lamina propria-submucosa and muscular layers. In both the control and corex diet groups, the intestinal mucosa displayed a simple columnar epithelium with basal nuclei, basophilic cytoplasm, and a prominent brush border. Furthermore, no histological changes associated with inflammatory processes or variations in villi height were observed among the fish from both the control and corex groups. However, it is important to note that fish fed the experimental diets, especially those with 25% corex inclusion, exhibited an increased number and average diameter of goblet cells along the intestinal epithelium (Figure 1A). On the other hand, the analysis of the histochemical properties of goblet cells revealed that the dietary administration of corex induced modifications in the composition of glycoproteins of mucins produced by these cells. Specifically, there was an increase in the staining intensity of neutral mucins, as well as mucins rich in carboxylated and sulphated glycoconjugates (Figure 1B, C, and D). Additionally, there was an increased affinity for the lectins WGA (Wheat Germ Agglutinin) and SBA (Soybean A.) in the mucinous content of goblet cells. However, no changes were detected concerning the lectins SNA (Sambucus nigra A.), DBA (Dolichus biflorus A.), ConA (Concanavalin-A), and UEA-I (Ulex europaeus A.-I) (Table 1). Finally, the study of cell proliferation revealed that the PCNA index was statistically significantly lower in the corex 25% group compared to the control and corex 12.5% groups.

(Continued on next page)
Discussion
The study found that the experimental diets had no significant impact on the organization of intestinal layers in *S. dumerili*. There were also no significant differences in villi height between the control and corex groups, indicating that the structural integrity of the intestines was not affected. Additionally, there were no indications of histological alterations associated with inflammatory processes in any experimental groups. However, the experimental diets, specially those containing 25% corex, did influence the abundance and size of goblet cells in the intestine. This was accompanied by modifications in the glycosylation patterns of intestinal mucins produced by these cells that would benefit fish by providing an effective immune barrier against potentially gut pathogens, indicating a potential positive impact on gut health. Furthermore, the study of PCNA index, revealed a positive potential influence of the diet with corex on cell division in the intestine. This indicates that this diet may support the homeostatic balance between epithelial cell proliferation and apoptosis, contributing to the overall health of *S. dumerili*. In conclusion, the results suggest that the experimental diets, particularly those with 25% corex inclusion, may promote better gut health and enhance the immune function, ultimately increasing the overall health and performance of *S. dumerili*. These findings highlight the potential benefits of incorporating corex into the diets of *S. dumerili* for better gut health and overall well-being.

Introduction

Fish counting makes it possible to estimate the appropriate amount of feeding and the total volume of product in harvest timing from the fish cage. The number of fish is currently estimated by dividing the total weight of juvenile fish by the average weight of sampled ones when the fish farmer buys them. With this method, the gap between the estimated and actual fish count can be up to 50%.

At first, detecting fish is needed for counting fish in a fish cage. Deep learning methods have proven to work well for such detection tasks. The challenge for training such a model for our objective is collecting enough datasets with significant variations by capturing enough videos underwater. Because water clarity changes when the season, weather, and other environmental factors change, we need to collect enough variations to train the visually based counting method that works in any conditions robustly.

Methods and Results

Our proposed method uses synthetic data generated by the realistic bio-inspired fish simulation and physically based underwater simulation, which is called Foids [1,2]. The simulation considers the density of chlorophyll and sediment, light scattering, intensity, and casting orientation varying depending on the day and time, and the shape and size of the net pen. The Foids algorithm enables us to obtain the training data of the fish school movies on the arbitrarily chosen day, time, and weather (See Fig. A). Furthermore, it is possible to set the number of fish and arbitrarily obtain the 3D configurations of fish. Then, it is a better training dataset than the videos taken in real situations. This paper introduces the fish counting application based on the Foids, in which YOLOv4 [3] (Fig. B) is used for fish detection (See Fig. C). Figure D exhibits the pictures obtained from the field works (upper) and the ones provided by the simulation (lower) for each species. In the simulation, cameras are set on the same points as in the field works carried out in the actual net pen. The result of the fish counting using our method is shown in Fig. E. Our method with deep learning methods, using the synthetic data created by using Foids, reduces the time 98% from the time taken manually, and the difference between them is approximately 3%. We will further develop the method providing the synthetic data set and apply it to estimate the fish size from the videos taken in the fish cage.

INTRODUCTION
Seaweeds are considered a source of biologically active substances for fish nutrition. Macroalgae can be utilized for their bioactive compounds especially chlorophyll, carotenoids, vitamins E and C, fucoxanthin, enzymes, mycosporine-like amino acids, polysaccharides and polyphenols that possess antioxidant activities (Vega et al., 2020). The algal genus *Ulva* is often used in Integrated Multi-Trophic Aquaculture (IMTA) and has the potential to both bioremediate aquaculture water and benefit the reared organisms, as a source of anxiolytic substances to combat the stress caused by fish farming conditions (Calheiros et al., 2019). In this study, European sea bass (*Dicentrarchus labrax*) was co-cultured with *Ulva* sp. in an indoor RAS for 12 weeks, and exposed to a hypoxia test in order to assess the effects of *Ulva* on blood parameters and the behavioral stress responses (swimming behaviour, movements, immobilization) of sea bass.

MATERIALS AND METHODS
An indoor RAS consisted of 2 units, the first (*Ulva*-RAS) was used for the co-culture of seaweed *Ulva* sp. and sea bass and the second as a control (Control-RAS) for rearing sea bass without seaweed. In each unit, six separate tanks were divided into two levels. *Ulva* was placed in the upper level of the *Ulva*-RAS. Sea bass was reared in the lower level of both units. Seawater was pumped into each of the upper-level tanks and then it flowed to the lower-level fish-rearing tanks. The effluent from this level was recirculated to the upper-level tanks after passing through the gravel bed biofilter. Rearing conditions were similar in both RAS units in terms of water flow rate, salinity, oxygen, photoperiod and light intensity. Fifty fish were placed in each tank and were fed on extruded pellets, where dietary fish oil content was mostly sardine oil, at apparent satiation, twice a day, five days per week. The rearing lasted 12 weeks. *Ulva* was collected from the Saronic Gulf, sorted and cleaned with seawater, weighed after drying in open air and transferred to the upper-level tanks of *Ulva*-RAS. Seaweed densities were kept at 0.5-1 kg m⁻². *Ulva* was replaced weekly. At the end of the trial, a hypoxia test was performed. From each tank of Control-RAS and *Ulva*-RAS, 10 specimens were selected for blood sampling prior to the hypoxia test (CF and UF group, respectively). Twenty-four fish remained in each fish tank of Control-RAS and *Ulva*-RAS. The oxygen supply was turned off for all the fish tanks. The average initial DO level was 5.7 mg/L and the final was 0.7 mg/L. The experiment for each tank was completed when half of its fish (12), were immobilised at the bottom of the tank. The hypoxia test was video-recorded and the time of behavioural stress responses was noted. Median Immobilization Time (MITₚ₅₀) was estimated as the average time interval during which 50% of the initial population was immobilized in each tank after exposure to hypoxia test. At the end of the experiment, 10 fish from each tank for both Control-RAS and *Ulva*-RAS, were selected for blood sampling (SCF and SUF group, respectively). Blood samples were collected from the caudal vein and stored in heparinized tubes. Plasma was used for the determination of cholesterol (CHOL), low and high-density lipoproteins (LDL and HDL), glucose (GLU), albumin (ALB), alkaline phosphatase (ALP), glutamate oxaloacetate transaminase (GOT), glutamic pyruvic transaminase (GPT), lactate dehydrogenase (LDH), triglycerides (TG), phosphorus (P), cortisol (CORT) and superoxide dismutase (SOD), with commercial kits. Fat content of sea bass was also determined at the end of the rearing period by Soxhlet extraction.

RESULTS
At the end of the sea bass rearing, UF showed a significantly higher fat content than CF. During hypoxia stress test, the time required for 50% (MITₚ₅₀) of the fish to sink and become immobilized at the bottom of the tank was significantly higher in SUF compared to SCF. Under normoxia, UF exhibited significantly decreased levels of ALB, TG, CHOL and HDL and increased levels of LDH compared to Control-RAS and *Ulva*-RAS, were selected for blood sampling (SCF and SUF group, respectively). Blood samples were collected from the caudal vein and stored in heparinized tubes. Plasma was used for the determination of cholesterol (CHOL), low and high-density lipoproteins (LDL and HDL), glucose (GLU), albumin (ALB), alkaline phosphatase (ALP), glutamate oxaloacetate transaminase (GOT), glutamic pyruvic transaminase (GPT), lactate dehydrogenase (LDH), triglycerides (TG), phosphorus (P), cortisol (CORT) and superoxide dismutase (SOD), with commercial kits. Fat content of sea bass was also determined at the end of the rearing period by Soxhlet extraction.

(Continued on next page)
Discussion
Present results showed that *Ulva* induced a reductive stress in sea bass during long-term co-culture, leading to decreased plasma SOD levels and increased LDH levels, associated with mitochondrial dysfunction and obesity. The elevation of SOD levels in SUF group under hypoxia test indicates an activation of antioxidant mechanism that enabled SUF to withstand the hypoxia stress for a longer time period than SCF, along with the prior lipid accumulation during normoxia. Magnoni et al. (2017) reported a decreased lipid peroxidation and an improved aerobic respiration, permitting a more efficient ATP production during hypoxia in fish fed the *Ulva*-diet. Scavenging of •OH in UF by *Ulva* may explain the changes of plasma parameters, indicating decreased OXPHOS and increased glycolysis, compared to CF in normoxia, which were similar to those observed in SCF after the hypoxia stress imposed to CF. On the contrary, the increased OXPHOS and the decreased glycolysis in SUF compared to SCF under hypoxic conditions point out increased cellular H$_2$O$_2$ levels and O$_2$ signaling, probably associated to the prior reductive stress of UF induced by *Ulva* in normoxia. It seems that *Ulva* acted as pro-oxidant in normoxia and as antioxidant in hypoxia on sea bass. These abilities could be attributed to ulvan compounds (García-Márquez et al., 2023) that were available to sea bass through the fragmentation of *Ulva*. It is concluded that *Ulva* in IMTA can ameliorate fish tolerance to environmental stressors like hypoxia that often occurs in intensive aquaculture.

Introduction
Modern aquaculture is moving towards more sustainable aquafeeds, and several alternatives have been proposed for replacing the conventional and less sustainable marine-derived ingredients such as fish meal and oil. On this regard, insects have gained increasing attention due to many beneficial properties. Particularly, the black soldier fly (*Hermetia illucens*) prepupae meal (HM) shows a relative high protein content (ranging from 32-53 %), a well-balanced amino acid profile, and an appreciable content of bioactive molecules (*i.e.*, lauric acid, chitin, and antimicrobial peptides) with immunostimulatory and anti-inflammatory effects. The main drawback is associated to the HM fatty acid profile, lacking in long-chain polyunsaturated fatty acids (PUFA). However, it has been widely demonstrated that the black soldier fly larvae can positively modulate their fatty acid profile if reared on growth substrates enriched with dried microbial biomass. Particularly, spirulina (*Arthrospira platensis*) can represent a valid solution to improve the nutritional properties of HM, being a great source of long-chain PUFA and pigments with antioxidant properties.

In this context, the present study was aimed to test and compare, for the first time, the effects of two experimental diets in which conventional marine-derived ingredients were replaced by 3% or 20% of spirulina-enriched full-fat HM on growth, welfare and quality of giant freshwater prawn (*Macrobrachium rosenbergii*) post larvae and European seabass (*Dicentrarchus labrax*) juveniles reared in aquaponic systems. In both of these species of commercial interest, the use of HM in aquafeed formulations has been scarcely explored and never tested using aquaponic systems.

Materials and Methods
Three test diets were formulated for each species to be grossly isoproteic, isolipidic and isoenergetic. Starting from the control diet (HM0), the test diets were characterized by 3 or 20 % (w:w) of conventional marine-derived ingredients replacement with spirulina-enriched HM (HM3 and HM20, respectively). Considering giant freshwater prawn, 1971 post larvae (initial body weight: 0.10 ± 0.01 g) were divided into 9 aquaponic systems (three systems per experimental group), with 15 lettuce (*Lactuca sativa*) seedlings (density = 10 plants/m²) each. The feeding trial duration was 60 days, during which the prawns were hand-fed the experimental diets, provided at a daily feeding rate of 10% body weight. As regards European seabass, 270 juveniles (initial body weight: 19.3 ± 0.1 g) were divided into 9 aquaponic systems (three systems per experimental group), with 100 saffron (*Crocus sativus*) seedlings (density = 65 plants/m²) each. During the acclimation period, salinity was gradually decreased from 30 to 5‰ to match the salinity of aquaponic systems. The feeding trial lasted 90 days during which fish were daily hand-fed the experimental diets at 2% body weight.

At the end of the trials, for both species, zootechnical parameters were measured and the lipid content, fatty acid profile as well as oxidative status (conjugated dienes and thiobarbituric acid reactive substances) of the edible portions were determined. For giant freshwater prawn post-larvae, hepatopancreas samples were collected for: (i) histological analyses (focused on the middle portion of each hepatopancreas tubule that includes the mature stage of B and R cells) to determine the B and R cells relative abundance, abundance of lipid droplets in R cells, tubule diameter, and height of the epithelium; (ii) molecular analyses (real-time PCR) to analyse the expression of genes involved in molting regulation (*jheh*), chitin and protein digestion (*chit3* and *catL*, respectively), stress and immune response (*hsp90* and *α2m*, respectively). For European seabass juveniles, histological analyses were conducted in liver to determine the hepatic lipid and glycogen deposition and in distal intestine to verify eventual alterations or signs of inflammation in the distal intestine. The expression of genes involved in immune response (*thr1*, *myd88*, *nfkb*, *il1b*, *il10*, *tnfα*) was also assessed in the distal intestine.

(Continued on next page)
Results and Discussion

The experimental diets used in the present study properly sustained survival and growth performance and positively affected the fatty acid profile of the edible portions that did not show significant differences in terms of n3 PUFA among the experimental groups, in both species. The dietary lipid content of each experimental diet intended for giant freshwater prawns led to a massive presence of lipid droplets in R cells, in all the experimental groups, allowing a proper storage of energy sources to sustain the molting processes. However, the dietary amount of saturated and monounsaturated fatty acids that increased with the increasing dietary HM inclusions resulted in an increase in B cells abundance (also supported by the catL upregulation) in the HM3 and HM20 groups, able to produce and recycle fat emulsifiers to counteract their hydrophobic features that slow down the digestive processes. Similarly, as regards the European seabass, the percentage of fat fraction in liver of HM20 group was significantly higher than in the other treatments, representing one more evidence about the role of the HM fat fraction in determining a high hepatic lipid accumulation.

For both the species analysed, the inclusion of spirulina-enriched HM in the diets allowed the transfer of important antioxidant molecules (tocopherols and carotenoids) to the edible portions which possibly played a crucial role in preserving muscle-quality traits, preventing the lipid oxidation.

Finally, in giant freshwater prawn, the hepatopancreas health status was preserved in all the experimental groups, as evidenced by the histological analyses and the expression of immune and stress markers that did not show significant differences among the experimental groups. Similarly, in European seabass juveniles, histological analyses coupled with the expression of genes involved in immune response did not reveal structural alterations and signs of inflammation at the intestinal level, confirming the beneficial role on gut health of bioactive molecules typical of HM or derived from the enriching procedure of insects’ growth substrate with spirulina.

Results obtained in the present study highlighted the suitability of enriched full-fat HM as a proper sustainable aquafeed ingredient for both giant freshwater prawn post-larvae and European seabass juveniles rearing. In addition, both these feeding trials represent an example of how the culture of two species of great commercial interest can be implemented with more sustainable aquafeeds and farming techniques such as aquaponic systems, promoting the valorisation of the circular economy and the zero-waste concepts in aquaculture.

Background
Aquaculture in the Nordic countries is dominated by salmonid (Salmonidae spp) species such as rainbow trout and Atlantic salmon. However, high mortality of fish before slaughter is a serious threat to the financial and sustainability of the fish farming industry, and also comprises a significant fish health and welfare challenge. Fish mortalities often occur during stressful handling events like grading, parasite treatment, and transportation, but the specific reasons behind these deaths are unclear. However, a growing body of evidence indicates that cardiac rupture is the cause of death in many fish. Indeed, salmonid fishes can develop a range of cardiovascular diseases that affect both the heart and blood vessels. For instance, farmed salmonids are reported to have a high prevalence of coronary arteriosclerosis 1, which may constrain blood flow to the heart, making it less resilient to handle stress. The implications of impaired cardiac function due to arteriosclerosis are supported by data from laboratory studies showing that rainbow trout (Oncorhynchus mykiss) with experimentally occluded coronaries display reduced cardiac and aerobic metabolic capacities as well as warming and hypoxia tolerance 2.

Unfortunately, there are currently no effective screening tools for monitoring cardiovascular health to early detect heart diseases in salmonid fish. In human medicine, electrocardiogram (ECG) analyses are widely used for screening and diagnosing various cardiac pathologies, but this has so far not been widely applied in fish. The present study was designed to comprehensively evaluate the suitability of ECG recordings as a screening tool for heart disease in salmonid fish. Specifically, we mapped abnormalities in the ECG following experimentally induced myocardial ischemia in rainbow trout with surgically ligated coronaries.

Material and methods
Fish were anesthetized in freshwater (10°C) containing buffered MS-222 and custom-made ECG electrodes were implanted subcutaneously. One experimental group (coronary ligated) had the main coronary artery occluded permanently by using a silk suture to induce myocardial ischemia, while a second group (sham operated) was treated identically except that the coronary artery was only exposed but not ligated. Experiments were performed on both anaesthetized and unanesthetized fish. Provocation maneuvers were also used to experimentally elevate the fish’s heart rate (i.e., atropine injection and chasing stress) in order to increase the sensitivity for detecting any cardiac abnormalities. After the experiments, all fish were euthanized and the heart was removed and histologically examined to link cardiac electrophysiological properties with heart morphology and pathology.

Results and Discussion
At necropsy, the coronary ligated fish had comparatively pale hearts relative to the vivid red hearts of sham operated fish. While all sham operated fish survived, there was only a 55% survival rate among the coronary ligated fish at 10 days post-surgery. Four out of five deceased fish showed signs of blood accumulation in the pericardial sac of the heart (hemopericardium) at necropsy, and this was likely due to atrial/ventricular rupture. Indeed, one of the coronary ligated fish displayed signs of ventricular aneurysm, which may be an underlying cause of cardiac rupture. Coronary ligation significantly affected ECG characteristics in both anesthetized and unanesthetized fish. Abnormalities in the QRS morphology, which represents ventricle depolarization, included a loss of QRS voltage and prolonged QRS duration as a consequence of myocardial ischemia. The loss of QRS voltage suggests extensive myocardial injury leading to a loss of viable myocardium mass 3, while the prolonged QRS complex duration has been linked to an increased risk of ventricular arrhythmias in humans. In addition, the coronary ligated fish showed atrioventricular (AV) conduction delays, which manifested as 1st and 2nd-degree AV blocks. The 2nd degree AV block typically occurred at high heart rates (Fig. 1).

(Continued on next page)
Conclusion

We show that ECG analyses of both anaesthetized and unanaesthetised fish have the potential to be used for screening and diagnosis cardiac diseases in salmonid fish. Our intention is now to apply this technique under farming conditions as a quick and non-lethal screening tool to predict and reduce the risk of mortality from heart disease in farmed salmonids.

Introduction
Shrimp research has recently focused on the development of practical feeds that use plant proteins as substitutes for animal protein sources (Amaya et. al., 2007; Sabry-Neto et al. 2017; Guo et. al., 2019). According to Davis et al. (2004) and personal communication with shrimp industry partners (Euroshrimp: The Shrimp Network), the use of a purely plant protein feed may be limited by a variety of factors. These include amino acid profile, lower mineral content, low/limiting poly-unsaturated fatty acid content, the presence of antinutritional factors and lower palatability (Amaya et al., 2007). Feed attractants are being considered as a means of improving diet palatability and intake of feed in shrimp fed high percentages of plant material (Browdy et al., 2006). The efficacy of krill meal as attractant has been already proven in shrimp diets however, much research is needed for alternatives and sustainably produced attractants. In this study, we investigated the potential of meal from gammarids and polychaetes, low trophic organisms and can be bred from agricultural by-products and processing residues, as attractants in plant-based diets for white leg shrimp (Malzahn, A.M. et al., 2023; Ribes-Navarro et al., 2022). A controlled feeding experiment was conducted to evaluate the effects of the inclusion of the gammarids, *Gammarus locusta*, *Gammarus pulex* the polychaete *Nereis virens*, and Krill *Euphausia superba* as attractants in white leg shrimp diet. Growth performance, feed intake, survival rate, health and immune responses were evaluated.

Material and Methods
A one-month controlled feeding experiment with Whiteleg shrimp (*L. vannamei*) was conducted with 40 shrimps per tank in quadruplicate. Shrimp with an initial weight of 0.39 ± 0.02 gr were hand-fed four times daily according to the recommended feed rate, expressed as percent of body weight per day (Wyk et al., 1999) in a recirculation aquaculture system (RAS).

Six experimental diets were formulated: a commercial feed (FMD) as positive control with 10-20 % fishmeal content; a negative control (PD) containing no ingredients from marine sources and consisting of 100 % vegetable proteins and no added attractant. In addition, four test diets were produced from PD and with the addition of the 2% attractant (krill meal, gammarid meal (*G. locusta* and *G. pulex*) and polychaete meal (*N. virens*)).

Growth performance, survival rate, feed intake were monitored. At the end of the experiment haemolymph and hepatopancreas samples were taken to determine metabolic parameters (glucose, acylglycerides and total heamolymph protein), immunological capacity (phenoloxidase activity), stress resistance (antioxidant capacity) and nutritional value (fatty acid profile).

Results and Discussion
Preliminary results showed that shrimp fed the *N. virens* diet showed significantly higher weight gain than both gammarid diets. No significant differences were observed between the other diets. Moreover, survival rate did not significantly differ between treatments (Figure. 1). To date, no conclusions are possible since the full data set is not yet available.

Introduction
In this abstract, results are presented from the study of the behavioural change of Atlantic salmon (Salmo Salar) in sea cages when exposed to dynamically changing environments. Several field trials have been conducted in an industrial-scale fish farm to observe and study the behavioural responses of fish towards different influence factors, especially to the structures (obstacles) of various shapes, sizes, and colours. Ping360 sonars (BlueRobotics - Ping360 Scanning Image Sonar) were used to collect relevant fish behaviour data in industrial-scale sea cages. A deep learning-based method was applied to the 360-degree sonar data and used to identify fish swimming patterns around the structures and quantify the minimum distance the fish kept from the structures. Changes in the behaviour of the fish towards structures with different appearance were studied.

This work was financed by the Research Council of Norway through the project: CHANGE – An underwater robotics concept for dynamically changing environments [1] and RACE – Fish Machine Interaction [2].

Materials and methods
The structure was produced in six different versions that varied in shape, size, and colour, and equipped with a stereo camera and two Ping360 sonars: one on the top and one on the bottom, as shown in Figure 1. The Ping360 sonars were set with a range of 5 meters. The structure was placed in a water depth of 8 m in each of the tests conducted in June 2021, October 2021 and September 2022 in an industrial-scale fish farm of SINTEF ACE [3].

The sonar data provide images of a 360-degree view of its surroundings, with the areas of fish having greater intensity. The circular swimming behaviour of fish around structures makes them appear as rings in sonar images. After creating a training dataset via manually labelling fish swimming patterns on a few hundred randomly selected sonar images, a deep learning semantic segmentation UNet++ model [4] was trained to identify fish swimming patterns around structures. The distances between fish and structures can then be estimated by averaging the distance from each pixel on the edge of the parts identified as fish swimming patterns to the structure centre, as shown by the red curves in Figure 2.

Results
The deep learning-based method has been applied to the sonar image of fish accumulated around structures over 1-, 5-, and 10-minute time periods, Figure 2 shows examples of the accumulated fish presence around the cylindrical structures over a 5-minute period and the corresponding fish behaviour quantitation results. When the structures were big cylinders, fish with an average size of 1 kg seemed to stay approx. 1.5 m from the yellow structure and 0.8 m from the white structure. Similar fish-to-structure distances were obtained when the structures were big cubes. When interacting with small cylinders, the same fish maintained approx. 0.9 m and 0.6 m from the yellow structure and the white structure, respectively. Based on our sonar data, fish always stayed closer to the white structures than to the yellow structures if the structures were of the same shape and size.

In September 2022, the fish were of an average size of 1 kg and a population size of 172,563 individuals and stayed approx. 1.5 m away from a yellow cube structure. In June and October 2021, average fish size was 2.5 kg and 5 kg, while population size was 195,832 and 99,243, respectively. The distance to the same yellow cube structure then increased to approx. 2 m and 2.5 m, respectively. In all three cases, the biggest-sized fish had the longest distance to the structure, while the smallest-sized fish had the closest distance to the same structure. This indicates that there seemed to be a relationship between fish size and the distance the fish maintain from the structure.

(Continued on next page)
Conclusion and future work
The colour of structures seems to be affecting fish behaviour, and fish keep shorter distances from white structures compared to the yellow ones. Our results present no evidence that structure shape has an impact on fish, but structure size may have an effect as fish were closer to smaller structures than to the big ones. In addition, fish stayed farther away from the same structure as they got bigger, suggesting that the size of fish themselves can also a factor influencing their behaviour. More studies are needed to confirm these findings and explore further relationships between fish size and fish-to-structure distance.

References
Introduction

In this abstract, methods and technical solutions for real-time simulation and monitoring of farmed salmon (*Salmo salar*) in flexible net cage are introduced. Machine learning-based estimation methods are implemented to combine an individual-based fish model with field measurement data and quantify behavioural changes of the fish when exposed to dynamically changing environments. Fish density distributions in the cage are determined by the simulation results and assimilated echo-sounder data. Fish distributions around a submerged structure such as an underwater vehicle can also be simulated according to the 360-degree sonar data (BlueRobotics - Ping360 Scanning Image Sonar). Field trials and demonstrations have been conducted in an industrial-scale fish farm for instrument testing and verifications of the integrated simulation and monitoring system.

This work was financed by the Research Council of Norway through the project: CHANGE [1].

Materials and methods

A flexible net cage and fish were modelled in the simulation framework, FhSim, which allows a high degree of flexibility to combine different mathematical models, numerical solvers, sensors/observers and relevant estimation techniques for time-domain representation of a complex system [2]. The fish model in FhSim is individual based [3], able to simulate full-scale fish populations (e.g., 200,000 individuals in one cage) in real time. The spatial and temporal fish behavioural responses towards the cage, feed, temperature, light, water currents, waves and other individuals are considered. However, there are several influence factors (e.g., oxygen level and consumption) that are not yet included in the model, and it is notoriously difficult to measure all the environmental conditions and complex interactions in the field.

Therefore, several simulations have been conducted with randomised environmental and behavioural parameters (more than 10,000 samples). These simulation data were used to train machine learning-based surrogate models [4] which were then able to find the most possible behavioural parameters for the resulting fish distributions. As shown in Figure 1, the machine learning-based estimation methods are incorporated into the simulation model to continuously update the behavioural parameters according to measured fish distribution data. The integrated simulation and monitoring system will not rely on accurate environmental inputs that might be difficult to obtain, but can still use the environmental and structural monitoring data when available.

Results

A real-time data collection and communication system has been tested in an industrial-scale fish farm (as shown in Figure 2). The measured fish densities from a multi-beam echo sounder were assimilated with the simulation model for real-time monitoring of vertical fish distributions. The simulation results were shown to coincide with the echo-sounder data and provide more information about the fish, such as the influence of the current and cage deformation on fish distributions and changes in the fish swimming speeds. An extended setup of several echo sounders (both single-beam and multi-beam) in the cage will be tested, as well as the integrated simulation and monitoring system.

Machine learning-based estimation methods have also been implemented to identify and quantify fish distributions around an underwater vehicle or a generalised object, where the 360-degree sonar data were used to parameterize the behavioural changes. These could be extended for real-time fish detection and characterization of the possible interferences to the fish. In combination with the estimated fish distributions in the cage, a bio-interactive control routine can be implemented to ensure fish welfare and increased efficiency in relevant underwater operations (e.g., autonomous underwater data acquisition).

(Continued on next page)
Conclusions and future work

An integrated simulation and monitoring system is being developed and shown to be suitable for real-time applications in an industrial-scale fish farm. The tested instrument setup is preliminary and will be extended for actual use. The machine learning-based estimation methods incorporated into the simulation framework form a basis for hybrid analysis and modelling [5] and relevant digital twin implementations. A holistic digital twin solution for aquaculture structures and farmed fish will improve the ability to monitor, control and document aquaculture productions and facilitate knowledge-based decision making, thereby contribute to the realisation of precision fish farming.

Introduction
Off-flavours are of great concerns in various systems such as aquaculture, drinking water and food production. Geosmin (GSM) and 2-methylisoborneol (MIB) are the most widespread off-flavour compounds in recirculating aquaculture systems (RAS), known for their earthy/muddy smell and extremely low detection threshold for humans. GSM and MIB are secondary metabolites of microbial origin and the main off-flavour producers are Actinobacteria, Myxococcota, and Cyanobacteria (Lukassen et al., 2017). Typically, two distinct routes of GSM and MIB biosynthesis occur in prokaryotes: the 2-C-Methyl-D-erythritol 4-phosphate (MEP) pathway and the mevalonate (MVA) pathway (Lange et al., 2000). The latter pathway also has an auxiliary leucine-dependent isoprenoid pathway. In this study, we investigated microbial communities of 50 samples from five RAS in three Swedish fish farms by metagenomic analysis.

Materials and methods
Two of the sampled RAS were aquaponic systems combining production of rainbow trout with tomatoes or vegetable cultivation, two produced eel, and one produced sturgeon. Three RAS used moving biofilm carriers for nitrification, one used a stationary trickling filter, and one relied on nitrification in gravel bed. Four RAS had drum filters for particles separation and one used sedimentation tanks. Samples of microbial communities were collected from various locations within the system including biofilters, sedimentation tanks, gravel bed, and wall growth. Following DNA extraction, the samples were analysed using shotgun metagenomic sequencing. The raw data were filtered and trimmed by using Fastp (v0.20.0). Then seven batches of metagenomics data were co-assembled into contigs using MEGAHIT (v1.1.3), and the scaffolds longer than 2000 bp were selected for binning with MetaBAT (v2.12.1) to obtain metagenome-assembled genomes (MAGs). CheckM (v1.2.1) was used to evaluate the completeness and redundancy of MAGs. The coverage of MAGs (%) in each sample was estimated using CoverM (v0.6.1). Taxonomic classifications of MAGs were conducted using GTDB-Tk (v2.1.0), and phylogenetic analysis was performed by using PhyloPhlAn (v3.0.3).

Results and discussion
A total of 76 potential off-flavour producers, affiliated with 10 bacterial phyla (Acidobacteriota, Actinobacteriota, Myxococcota, Proteobacteria, Nitrospirota, Planctomycetota, Bacteroidota, Chloroflexota, Gemmatimonadota, Verrucomicrobiota) and 1 archaeal phylum (Iainarchaeota), were identified from 1378 MAGs based on functional genes annotation. After conducting a blast (basic local alignment search tool) search for functional genes responsible for the MEP and MVA pathways, we identified 38 MAGs with complete MEP pathway, 33 MAGs with complete MVA pathway, and 5 MAGs with both complete MEP and MVA pathways (Fig. 1). The GSM and MIB synthase genes (geoA and MIBS) were found in all the 76 MAGs, indicating a high diversity of previously unknown off-flavor producers in RAS. In addition, a large number of bacteria (203 MAGs, affiliated with 16 bacterial phyla) with almost complete MEP or MVA pathways but lacking the final genes of geoA and MIBS were also identified (Fig. 2), suggesting that these bacteria may interact with potential off-flavor producers in RAS by providing precursors or intermediates.

Introduction
Nowadays, biometric systems have numerous applications in different fields. In recent years, various applications of modern computer vision systems have been applied for different tasks like object detection, segmentation, and classification for analysing different fish vertebrates and aquatic animals. There are a lot of applications available for using artificial intelligence automated manners in different research fields of aquaculture studies, like fish welfare, disease detection, and fish behaviour. Fish species identification is the major tool for biologists’ studies to identify and trace these types of species over a period of time. Since machine learning can provide an automated manner to identify each individual fish, these methods can be much easier to use especially for real condition identification tasks. New machine learning approaches, such as different deep neural network architectures, could provide essential and more trustable tools for researching and developing the fisheries industry. Thus, in this article, we present a comparison of different convolutional neural networks (CNN) architectures in the field of individual image-based fish identification. The results of different techniques are discussed. Finally, we provided conclusions from applying different CNN methods of fish identification.

Materials and methods
In recent years numerous artificial neural network architectures have been introduced for different tasks like image classification and recognition. CNN have been used extensively in different image classification tasks like fish species identification. In this research, we used three different CNN architectures for performance review for fish individual identification tasks for Atlantic Salmon. Atlantic salmon identification – The dataset consists of 30 individual Atlantic salmon. The average fish weight was 251±21 g, and the length was 29.5±2.5 cm. The age of the fish was five months. All fish were tagged with PIT (passive integrated transponder) tags. The tagged fish were cultivated in a 2m³ recirculation freshwater tank for six months. Every two months, 4-8 images per fish were taken for each individual (session). Two to four images for each fish from each session were used to create the reference database for identification. All sessions were mixed together to identify the fish at different growth stages. The other images for each individual were used to evaluate the identification task.

We used simple CNN, VGG 16 and ResNet-50 for fish identification tasks. Stacked colour images of all individual fishes were used as the CNNs input for training and testing. A simple CNN can provide an accurate model over simple visual data; However, the pattern of salmon is more complex and change over time, so we need to use deeper networks to train a more accurate model for fish identification. Training different models with ResNet-50 with 23 million trainable parameters and VGG-16 with over 138 million trainable parameters show that using a deeper network can effectively handle the fish identification task for long-term identification. Below you can see the two deep networks used for fish identification.

(Continued on next page)
Results

Fish identification using CNN: A simple CNN architecture with four hidden layers applied over the collected data, and the accuracy rate for identifying the 30 individual fish was 93.4% which corresponds to the high accuracy of individual identification.

Fish identification using VGGNet: The accuracy rate for identifying the 30 individual fish was 95.1%, which shows a better performance than simple CNN for fish identification.

Fish identification using ResNet-50: Finally, the accuracy rate for identifying the 30 individual fish using ResNet-50 using triplet loss function was 99.3%, which shows the best efficiency among the used CNN-based structures.

Conclusion

Identifying individual fish species and other aquatic species by tagging them is one of the most important tools for following up on their footprint in the aquatic habitat to estimate their health, growth assessment, and welfare for the fishing industry. This study showed the ability to use different CNN architectures on the visual data for individual fish identification. The three CNN architectures were evaluated on the salmon dataset. The best metrics result reported for the fish identification by applying ResNet-50 using triplet loss. A high accuracy rate of about 99% showed that it shows the effectiveness of applying this ResNet-50 architecture for fish identification tasks.

Introduction
Aquaculture is increasingly considered as the main source for meeting the world’s growing demand for fish products (FAO, 2022). However, in parallel with the growth of the sector, concern about its sustainability has also grown. In this regard, the SIMTAP project ‘self-sufficient integrated multi-trophic aquaponics systems’ (EU PRIMA 2018) aims to implement and test a multi-trophic aquaponic system to reduce: (i) fish meal and fish oil use for feed (ii) water and energy consumption, (iii) emission of nutrient compounds. These are the main factors identified as environmental hotspots in aquaculture systems (Aubin et al., 2009; Abdou et al., 2017). In particular, the proposed system allows for the recovery wastewater from aquaculture and its use as a nutrient source for hydroponics, achieving a run-off reduction and nutrient recovery effect as well as the co-production of other alternative food and/or feed. In addition, the project aims to analyze its performance in terms of sustainability and, for the environmental pillar, Life Cycle Assessment (LCA) approach is considered the most suitable methodology to apply. In this study, using the LCA method, the environmental performance of SIMTAP systems developed in Italy were analysed and compared with that of a traditional aquaculture inland farm.

Materials and method
The concept behind the analysed SIMTAP system is to utilise wastewater from the rearing of Gilthead Sea bream (Sparus aurata) and European Sea bass (Dicentrarchus labrax) for both a hydroponic halophytic system (for Salicornia, Salicornia europaea and Beta Maritima, Beta vulgaris subsp. maritima), which exploits the dissolved nutrients in the water, and for the breeding of DFFO (polychaetes) that feed on the solid waste from the fish, in order to recycle the nutrient in the water loop.

The functional unit (FU) selected for the LCA (i.e. the reference unit of the study to which all inputs and outputs are referred) was 100 kcal derived from all the outputs of the systems analysed (fish, Salicornia, Beta maritima, polychaetes). This FU was chosen because it expresses the functionality of the food (McLaren et al., 2021) while at the same time allowing the different outputs of the SIMTAP system to be taken into account. We applied cradle to farm gate perspective for the definition of the system boundaries, including the production of the infrastructure and equipment (e.g. pumps, tanks, filters), the production of inputs (e.g. electricity, diesel, liquid oxygen), feeds production and supply and the net nutrient emission due to the metabolism of the fish. To facilitate the comparison of results with a commercial reference system, the scenario inventory was built by upscaling the experimental data and results of the pilot plant to a production farm of 10 tonnes of fish/year. To this purpose, literature data, estimates and questionnaires submitted to experts were also used. In particular, two scenarios were constructed that differ in terms of fish feeding: (I) commercial feed (CF) scenario in which fish are fed with a commercial feed; (II) alternative feed (AF) scenario: in which fish are fed with an alternative feed consisting of locally produced mussels, clams and polychaetes.

The commercial reference farm, used as a benchmark, is a traditional Italian inland farm with a production of about 400 tonnes/year of Sea bream and Sea bass. This farm consists of several ponds, where fish are reared from a size of 3g up to 400-500g. The system is high energy demanding, both for pumping water, blowers and the liquid oxygen consumed.

(Continued on next page)
Results
For the main impact categories analysed in the aquaculture sector (global warming potential, eutrophication, cumulative energy demand, acidification) the two SIMTAP scenarios always have a lower impact than the commercial farm. In more details, the global warming potential is 0.230, 0.247 and 0.266 kg CO$_2$ eq./100 kcal respectively for CF scenario, AF scenario and commercial farm. The cumulative energy demand is reduced by 25% in both SIMTAP scenarios, while the most promising results are in the eutrophication impact category. This category depends mostly on the release of nitrogen and phosphorous compounds into the environment due to fish metabolism. In SIMTAP systems, thanks to the coupling of the hydroponic system (which absorbs the dissolved part of the nutrients) and polychaetes (DFFO that feed on fish faeces, removing the solid part of the waste), eutrophication is significantly reduced (more than 50% reduction). However, the main hotspots of the analysis, as in the commercial farm, remain the high electricity consumption due to pumping water, oxygen consumption and feed supply. Furthermore, since a large surface area is required for the hydroponic system, the impact of the infrastructure required for the system is also not negligible.

Conclusions
Improving the sustainability of aquaculture is a need in the current European context. As demonstrated in this study, following the example of the SIMTAP system, it is possible to improve the environmental performance of aquaculture systems with new diets characterised by the use of locally produced raw materials, the coupling of a hydroponic system to a RAS and the reuse of nutrients. Furthermore, in a context where energy consumption is the main driver, maximisation of the use of renewable energy sources (e.g. solar energy) can lead to significant improvements. It is important to emphasise that the analysis is concerned with theoretical scenarios, so the analysis of the uncertainty of data and results will be a further important step. Finally, in addition to environmental performance, economic and social sustainability should also be assessed for a more comprehensive evaluation of the innovative systems.

Introduction

The development of sustainable, productive, climate-neutral and resilient farming systems is, nowadays, an obliged way to provide consumers with affordable, safe, traceable, healthy and sustainable food, while minimizing pressure on ecosystems. The culture of aquatic organisms is still the fastest growing sector in food production and now provide almost half of all sea food consumed globally. Crustaceans, with a total production of 11.2 million tonnes in 2020 (SOFIA, FAO 2022), represent 13 % of all aquaculture products, with the white leg tiger shrimp (Litopenaeus vannamei) contributing for nearly 52 %. Shrimp farming has been historically practiced in Asia and in the Americas. During the last decade the interest to shrimp culture has arisen also in Europe (Euroshrimp.net, 2020), due to the increasing demand for freshly harvested, sustainably produced shrimps and to the application of highly intensive systems, such as the clear water recirculating aquaculture system (RAS) and the biofloc technology (BFT). Both RAS and BFT are considered eco-friendly and have low or zero-water exchange rates, which improves the efficiency of water use and reduces the risk of introducing pathogens. However, both can be improved and fully integrated in a land-based multi-trophic aquaculture system that allows to produce high quality seafood, additional biomass, and valuable environmental services, ensuring sustainability and circularity.

The BIORAS_SHRIMP project objectives

The main goal of the BIORAS_SHRIMP project (www.bioras-shrimp.eu) is to develop, improve and innovate a bio-secure land-based shrimp culture model to enhance productivity, minimize waste and recover energy and nutrient for additional biomass production, in the view of a circular economy process. In particular, an innovative recirculating aquaculture system (RAS and hybrid RAS-BFT) with improved technology and husbandry efficiency, for shrimp intensive culture, will be developed and implemented in Malta, Norway and Italy. Furthermore, systems for the recovery of waste, co-products and side-products generated by the aquaculture activity, will be developed and tested. Finally, sludge and residual nutrients in the effluent will be used to generate additional valuable biomass and bioactive compounds.

(Continued on next page)
**Research approach and methodology**

The application of the bio-system principles (food first, sustainable yields, cascading approach, circularity, and diversity) is at the backbone of the R&D and methodology proposed. A conceptual layout of the full system to be developed, implemented, and tested is shown in figure 1. As clearly indicated, the rearing units (RAS and Hybrid RAS-BFT) are structurally and functionally connected to the effluent treatment system, in a full circular process able to produce, via separate streams, different valuable end-bioproducts (indicated in the colored boxes): 1) high quality shrimps for human consumption; 2) a bio-fertilizer obtained through the conditioning and thickening processes of the extracted solids; 3) a set of bioactive compounds derived from the aquatic biomasses (algae, plants, cyanobacteria), appropriately cultured in the nutrient-enriched residual water.

**Industrial innovation for shrimp culture**

All outcomes have high potential industrial and commercial impact being innovative products and processes immediately applicable to support a sustainable ecological and digital transition in aquaculture.

**Stakeholders’ engagement**

Our network involves scientists, professionals, and students to develop relevant knowledge, technologies and innovations, skills, abilities and experience to be shared with a wide range of stakeholders, including farmers, researchers, policymakers, Consumer Associations, and other end-users, to facilitate growth and development of the circular aquaculture in participating countries.

**Capacity building opportunities**

A specific work package is dedicated to the organization of a training course based on the results achieved during the project lifetime. The course will describe the general management of the shrimp culture RAS, including the effluent treatment system, additional biomass production and by-products, co-products and side-products potential utilisation and valorisation.

The course will be open for attendance by farmers, technicians, PhD students, representatives of Aquaculture Producers and NGOs.

Introduction
The meagre Argyrosomus regius (Asso, 1801) is a promising aquaculture species and advancing puberty using recombinant gonadotropins could shorten the generation time for selective breeding programs (Zupa et al., 2023). The aim of this study was to assess the effects of recombinant follicle stimulating hormone (rFsh) administration on spermatogonial proliferation and apoptosis in prepubertal meagre reared in indoor tanks through a comparison with adult fish reared in sea cages.

Material and Methods
Prepubertal meagre males (18-months old) reared in indoor tanks at IRTA (La Ràpita, Spain) underwent a six-weeks treatment with increasing doses of rFsh (week 0: 6 µg/kg; week 1: 9 µg/kg; week 2 to week 6: 12 µg/kg); control prepubertal males were injected weekly with 1 mL of saline solution. Prepubertal fish samplings took place before the treatment (week 0; control fish, N = 6) and after 6 weeks of treatment (week 6; control fish, N = 9 and rFsh-treated fish, N = 4). Adult males (6-years old) belonging to a commercial stock reared in sea cages in the Gulf of Taranto (Ionian Sea, Italy) were sacrificed during early (March-April 2021; N = 7) and advanced (June 2021; N = 4) phases of spermatogenesis. Testis samples were fixed in Bouin’s solution and embedded in paraffin wax. Deparaffinized sections were stained with hematoxylin-eosin; proliferating spermatogonia were identified through the immunohistochemical detection of the proliferating cell nuclear antigen (PCNA); apoptotic germ cells were identified through the TUNEL method.

Results and Discussion
The rFsh-treated fish had larger testes compared to both control groups, had larger seminiferous tubules that contained all stages of spermatogenesis and had more abundant luminal spermatozoa (Fig. 1a, b). The testes of adult fish sampled in March-April were in active spermatogenesis with all germ cell types in the germinal epithelium and luminal spermatozoa (Fig. 1c); while in June, all adults were fully mature, showing residual spermatogenetic activity in a thin germinal epithelium and plenty of luminal spermatozoa (Fig. 1d). Anti-PCNA immunostaining was observed in the nuclei of single spermatogonia, spermatogonia in cysts and primary spermatocytes (Fig. 1e), but only single spermatogonia were considered for quantitative analysis. The TUNEL reaction labelled spermatogonia and spermatocytes (Fig. 1f). Fish treated with rFsh showed a significant decrease of proliferating and apoptotic single spermatogonia. In adults, spermatogonial proliferation was significantly higher during the early phase of spermatogenesis compared with the advanced phase in June, and apoptosis significantly increased from the early to the advanced phase of spermatogenesis (Table 1).

The treatment with rFsh stimulated spermatogenesis advancement in prepubertal meagre and induced a significant reduction in spermatogonial proliferation and apoptosis. In adult fish, germ cell apoptosis was low during the early spermatogenesis phase and increased during the advanced spermatogenesis phase. This observation confirms that apoptosis plays a major role in regulating germ cells/Sertoli cells ratio and in preventing aberrant germ cell development during spermatogenesis in adult fish (Prisco et al., 2003; Zupa et al., 2013). Moreover, the present data support our previous hypothesis that in prepubertal meagre apoptosis is involved in the inhibition of spermatogonial survival and progress towards meiosis (Zupa et al., 2023).

In aquaculture various deep-cold liquefied gases are used for different purposes: oxygen (LO2 or LOX) for oxygenation [1, 2], nitrogen (LN2 or LIN) for cooling [3], petroleum gas (LPG) [4] and natural gas (LNG) [5, 6] for energy supply and cooling, hydrogen (LH2) for water treatment [7] or – potentially in the future – also for energy supply.

All these liquefied gases are stored at deep temperature (-150 to -250 °C) and enhanced pressure (up to 20 bar) in liquid state. For the different applications the gases are generally regasified (i.e. vaporized), usually by using ambient air or (sea) water in open rack vaporizers. The used media are cooled, while this (exergetic) cold potential is wasted to the respective environment in most of the application. Though there are approaches to use this potential [5, 6] for cooling, none of those approaches refers to the enormous possibilities of using the very low temperatures and appreciable regasification (evaporation) enthalpies of the liquefied gases (~ 200…400 kJ/kg, depending on pressure level).

In a number of projects – mainly initiated and managed by the small company REGASCOLD GmbH – different heat exchange technologies and equipment were designed, improved and tested for several commercial application sectors [8, 9]. Special focus was given to aquaculture systems, i.e. indoor (RAS) as well as open sea farming. As cooling media (i.e. secondary or refrigerant media), e.g., different thermofluids, propane, water and carbon dioxide were investigated, water and carbon dioxide also in the form of the respective solid state – ice. Special (heat) exchangers were designed and tested, whereas a twisted coil type and a double tube (tube-in-tube) were developed and commercially produced for the industrial applications.

Especially for applications in RAS and indoor aquaculture, a joint project addressed the needs of freeze drying (up to -50 °C, preferably with thermofluid as cooling agent) and water cooling or indoor and room climatization (5 … 15 °C, preferably with water or water ice as cooling agent). The investigations are transferred into a special RAS modernizing and energy efficiency project, which is up to be implemented.

Introduction  
In response to the increasing demand for sea urchin gonads (known as roe or uni) in both Asian and European markets, coupled with concerns about the overexploitation of wild sea urchin populations, this initial study aims to address the necessity for cost-effective protocols within echinoculture. The primary objective of this research was to assess the gonadosomatic index (GI) in *Sphaerechinus granularis* that have been raised in captivity over a five-month period and compare it with that of their counterparts captured from the wild. Additionally, we examined two different methods for inducing spawning: injection of potassium chloride (KCl) and agitation.

Material and Methods  
For this preliminary study, *S. granularis* with test size superior of 50 mm were collected from local wild populations by snorkeling in the subtidal at east Madeira Island (Quinta-do-Lorde; 32°74′11.25″N; 16°70′96.36″W). The broodstock was reared for a five-month period in 200 L tanks with running ambient seawater at water exchange rate of 45 % per hour. Urchins were fed with *Zea mays*, at 0.7 % of the biomass present in the rearing tanks three times a week, and before each feeding the uneaten food and feces were siphoned. After the five-month period gonadosomatic index (GI), was compared between conditioned sea-urchins (n=20) and wild caught conspecifics (n=15). Additionally, two spawning induction methods were evaluated: KCl injection, and agitation, by assessing the spawning response within 30 minutes, and survival up to seven days.

Results  
Results indicate that five-month conditioned sea-urchins GI average was 5.30 ± 2.14, as opposed to wild caught *S. granularis* presented a GI average of 3.34 ± 1.51. In the spawn induction techniques evaluation, the two methods were able to trigger spawning. Mortality was higher with KCl injection method with a mortality rate over 90%. The agitation method showed a significantly lower mortality rate of 10% of the induced urchins, that highlights the potential of this spawning inducing method as an alternative to intracelomic KCl injection without impairing broodstock survival.

Introduction

Aquaculture currently accounts for the majority of seafood produced for human consumption (FAO, 2022). However, the production security of marine aquaculture is still largely dependent on ambient environmental conditions. Climate change is a major driver of shifting environmental conditions which, in turn, drives a global redistribution of marine species as they shift to remain within their ideal conditions (Pinsky et al., 2013; Fredston et al., 2021). This impacts the way in which humans utilise marine resources and the aquaculture industry, where farmed species are unable to track ideal climates, will need to adapt. Environmental changes may lead to production losses in regions where species already live at the edge of their environmental thresholds. Conversely, temperate regions may benefit from an increase in growth rates and a localised diversification of species (Pauly, 1980; Kitchel and Pinsky, 2023). The current and projected development of the industry highlights a growing need to assess future aquaculture suitability in a changing climate.

In this study, we projected the extent to which global marine aquaculture species and regions will experience dissimilar climates in future. To achieve this, we used the climate dissimilarity metric which drives the climate analog approach, identifying regions with similar environments to a current region across time and space (Mahony et al., 2017). Using climate dissimilarity to estimate the difference between present-day conditions and contrasting future climate scenarios can identify countries or regions best suited for marine aquaculture in future, estimating how species may move in response to changing conditions. Here, we determined the climate dissimilarity for 333 marine aquaculture species aggregated into five taxonomic groups. Present-day environments were defined for each taxonomic group based on biologically and aquaculturally-relevant environmental variables, and future projections were made at the end of the century for three climate change scenarios: an optimistic scenario (SSP1-1.9), a moderate scenario (SSP3-7.0), and a worst-case scenario (SSP5-8.5).

Research Outcomes

Under an optimistic climate scenario, regions experiencing climate dissimilarity are concentrated in the Northern Hemisphere, with Arctic regions having the highest proportion of marine aquaculture species facing climate dissimilarity. This highlights the rapid rate of environmental change already being observed in the Arctic (Rantanen et al., 2022). In total, 111 Exclusive Economic Zones (EEZs) were projected to face no dissimilarity, including important aquaculture nations such as Indonesia and the Philippines. Conversely, projections for the moderate and worst-case climate scenarios find that regions experiencing extreme climate dissimilarity are largely within semi-enclosed regions, including the Baltic Sea, the Black Sea, and the Red Sea. Additionally, equatorial regions are projected to experience moderate to extreme dissimiliar climates, with a high proportion of species facing climate dissimilarity. Under the moderate climate scenario, four EEZs face no dissimilarity, while three EEZs face no dissimilarity under the worst-case scenario. However, these EEZs are all small island nations or territories that currently have no commercial marine aquaculture. Regions where species already live at the edges of their environmental thresholds may face losses in aquaculture production with climate dissimilarity. Conversely, opportunities for aquaculture development may arise for high-latitude regions, including those with moderate or greater dissimilarity, as climate change aids in poleward species movement.

Our findings aim to aid governments and industry in establishing adaptive management strategies to mitigate the impacts of climate change, to facilitate the continued growth and sustainability of the aquaculture industry.

ASSESSMENT OF *Salicornia ramosissima* RESIDUE VALORIZATION AS A WHEAT FLOUR SUBSTITUTE IN FEEDS FOR EUROPEAN SEABASS AND WHITELEG SHRIMP

Rui J.M. Rocha*,1, Daniel Jerónimo1, André Barreto1, Ana Nobre2, Jorge Dias2

*Email: ruirocha@riasearch.pt

Introduction

Halophytes like *Salicornia ramosissima* are valuable sources of biomass that can be grown in regions where traditional crops may not thrive. The green tips of *S. ramosissima* are utilized as a human food product, whereas the rest of the plant is treated as residue. To establish a more sustainable and profitable production cycle, the residue must be valorized into by-products, which can be used in aquafeed formulations, reducing reliance on traditional feed sources, and promoting more sustainable practices within the aquaculture industry. The current study aims to assess the feasibility of using *S. ramosissima* aerial by-products, as a substitute for wheat meal, in aquafeed formulations for juvenile stages of European seabass, *Dicentrarchus labrax*, and whiteleg shrimp, *Penaeus vannamei*, evaluating survival (%), relative growth rate (RGR, % day\(^{-1}\)), feed conversion ratio (FCR) and economical conversion ratio (ECR, € spent in feed per Kg of biomass gain).

Methods

Four experimental diets were tested on European seabass in triplicates: a commercial-like diet (CTRL), comprising 16.3% wheat meal, and three experimental diets featuring lignified *S. ramosissima* at inclusion levels of 2.5%, 5% and 10%, replacing wheat meal as an alternative ingredient. European sea bass juveniles (mean wet weight 7.3 g) were kept at 22 ± 0.5 ºC and fed *ad libitum* for 62 days.

Five experimental diets were tested in quintuplicates on whiteleg shrimp: a commercial-like diet (CTRL), comprising 25% wheat meal, two experimental diets containing lignified *S. ramosissima* stems (S) and two containing lignified *S. ramosissima* leaves and seeds (L), both at 5% and 10% inclusion levels, replacing wheat meal as an alternative ingredient. Whiteleg shrimp juveniles (mean wet weight 6.1 g) were kept at 28 ± 0.5 ºC and fed *ad libitum* for 55 days.

Voluntary feed intake was registered daily. At the end of the trials, fish and shrimp were weighted and counted for survival, RGR, FCR and ECR determination.

Results and discussion

No significant differences in survival, RGR and FCR were observed among treatments for European seabass (Table 1). These results suggest that lignified *S. ramosissima* can be used to replace wheat meal in aquafeed formulations for juvenile European seabass in inclusion levels up to 10%, with no detrimental effects to growth performances, survival and FCR. It was possible to observe that in scenarios where *S. ramosissima* was included at a rate of 5%, this by-product could be valued at up to 80% of the value of wheat flour while still maintaining a slightly lower ECR value than the CTRL diet. In the case of a 10% inclusion of *S. ramosissima*, it was observed that this inclusion could be limited to only 50% of the value of wheat flour in order to maintain the desired ECR levels. In this context, it is possible to consider the valorization of *S. ramosissima* aerial by-products. Furthermore, the use of these by-products could reduce the environmental footprint of European seabass production due to the proximity of both industries, in the Mediterranean region.

On the other hand, whiteleg shrimp fed diets containing *S. ramosissima* showed significantly higher FCR values, despite having similar RGR and survival values to those fed the CTRL diet (Table 2). These results indicate that Salicornia by-products might not be a viable alternative to wheat meal in diets for juvenile whiteleg shrimp, as these increases in FCR, in a production scenario, would represent increments of around 20% in feed associated costs, even if considering a reduction in diet price by including Salicornia by-products retailed below wheat meal market value.

(Continued on next page)
Conclusion

Results obtained in this study suggest that *S. ramosissima* aerial by-products can be used to replace wheat meal in aquafeeds formulations for European seabass juveniles. This scenario would allow Salicornia farmers to valorize a residue, that potentially could be marketed at wheat meal retail price, while also contributing to the implementation of a circular economy paradigm in halophyte farming and the aquaculture industry. Based on the European seabass production in 2021, approximately 300,000 tons, it was feasible to estimate that around 15,000 tons of Salicornia lignified biomass could potentially be utilized as an ingredient in aquafeed diets for this production.

Nonetheless, it appears that using *S. ramosissima* by-products as a substitute for wheat meal in diets for whiteleg shrimp juveniles may not be a practical solution. Observations revealed an increase in both FCR and ECR when shrimp were fed diets containing Salicornia, potentially leading to substantial additional feed-related costs for producers.
