"Celebrating 50 years of the European Aquaculture Society"

Welcome to Aquaculture Europe 2026

Dear Colleagues and Friends,

It is my great pleasure to welcome you to Aquaculture Europe 2026, taking place in the beautiful city of Ljubljana. This year's theme, "*Aquaculture in Global Change*," could not be more timely. Sitting at the heart of central and southern Europe, bordered by Italy, Croatia, Hungary and Austria, Slovenia offers a perfect point from which to explore adaptation of both freshwater and marine aquaculture to climate effects, understand species resilience, and highlight the health, welfare, nutrition and breeding advances that will carry our sector forward. Over this week in Ljubljana, our plenary speakers, scientific sessions, industry and innovation forums, and exhibition will bring together the full breadth of European and international aquaculture to share ideas, forge collaborations, and chart a course for a more resilient, sustainable future. Again (and we can only be happy for that!) Aquaculture Europe promises a lot, with more than 730 abstracts received, and 170 booths at the exhibition

This edition of Aquaculture Europe also carries special significance: 2026 marks the 50th anniversary of the European Aquaculture Society. Since 1976, EAS has brought our community together in pursuit of a sustainable European aquaculture sector, and Ljubljana gives us the perfect setting to celebrate this milestone together.

I warmly invite all EAS members to join our special EAS50 General Assembly on Tuesday, 29 September, 17:30–18:30 (Gallery 1, Kocka Hall), where we will look back on five decades of achievements and formally welcome the incoming EAS Board. The Assembly will be followed immediately by a dedicated EAS50 reception and buffet dinner for all members — a chance to celebrate this anniversary, and the community that made it possible, together. As key actors of this, we will be happy to share this moment with eleven of our Past Presidents and eight of our Honorary Life Members.

On behalf of the EAS Board, thank you for being part of this milestone year. I wish you an inspiring, productive and enjoyable conference in Ljubljana.

Warm regards,

Marc Vandeputte

European Aquaculture Society President 2024-2026

Background

Feed costs represent a significant portion of the total production expenses in the aquaculture industry. These costs may range from 75% to 90%, especially due to the latest price increase on raw materials, such as fish meal and oil, that are now perceived as unsustainable due to their limited availability (Ariffin Hidir *et al.*, 2026). The use of plant-based alternatives, such as soybean meal, as aquafeed ingredients has reduced reliance on marine-derived ingredients but has also raised ecological and nutritional concerns. This scenario exposes the lack of sustainable, nutritionally adequate, and scalable substitutes for traditional aquafeed proteins, underscoring a broader challenge for the sector (Aziz Atnafu *et al.*, 2026). One promising solution is to use single-cell proteins (SCPs) obtained from the fermentation of filamentous fungi. Their consistent nutritional value (40–60% protein), content of essential amino acids, polyunsaturated fatty acids, vitamins, and minerals, together with the presence of functional ingredients (e.g., mannanoligosaccharides and β -glucan), may provide further health benefits in fish, such as enhancing growth performance and antioxidant defences and, consequently, disease resilience. Moreover, the ability of the fungi to use diverse low-cost substrates and reduce land use and water requirements makes this protein source a potentially sustainable alternative. This includes the possibility of macroalgae waste fermentation, which is widely available in European sea basins and, when discarded from human-destined industries, can be transformed into a value-added product. The AlFunFeed project adopts a holistic perspective linking marine resource valorization with aquaculture nutrition, addressing one of the major challenges for the aquaculture industry: the development of a reliable and sustainable alternative source of protein for aquafeeds.

Objective

AlFunFeed aims to develop and validate SCPs produced from macroalgal processing residues as a sustainable and alternative aquafeed ingredient. The project will optimise SCP-based feed formulations, evaluate their effects on growth performance, nutrition, and fish health in European seabass, while assessing their economic feasibility and environmental sustainability.

Methodology

Fungal SCP variants produced from the fermentation of macroalgal residues will be incorporated into experimental diets for European seabass (*Dicentrarchus labrax*). CIIMAR will perform a two-stage *in vivo* validation, including a pilot feeding trial to screen different SCP sources followed by a validation trial to determine the optimal dietary inclusion level (i.e., 15%, 20%, and 25% SCP). Fish performance will be evaluated through growth, feed utilization and nutrient digestibility, while health effects will be assessed using haematological, humoral, and mucosal immune biomarkers, gene expression analyses and bacterial challenges with a relevant aquaculture pathogen, *Tenacibaculum maritimum*. The integration of these nutritional, physiological, and immunological parameters will enable the identification of SCP-incorporated formulations that can modulate and enhance fish performance and health, thereby contributing to more sustainable aquaculture.

Regarding other partners' roles in AlFunFeed, ODS will be responsible for SCP production and characterisation, the University of Vigo will coordinate and assess digestive function, nutritional profiling and appetite, the University of Thessaly will study the microbiota alterations, and the Università Politecnica delle Marche will be responsible for fish welfare assessment.

(Continued on next page)

Expected outcomes

The project aims to identify and validate fungal SCP derived from macroalgal residues that, when incorporated into aquafeed, can improve European sea bass growth, welfare, and disease resilience. This will contribute to welfare-focused and environmentally conscious aquaculture, to waste reduction, to decreasing the pressure on marine resources, and to lowering the carbon and nutrient footprints of the aquafeed and aquaculture industry.

Acknowledgments

This project has received funding from the European Union's Horizon Europe research and innovation programme (SBEP2024-794 AIFunFeed), and national funds through FCT - Fundação para a Ciência e a Tecnologia, I.P., within the scope of SBEP/0002/2024. <https://alfunfeed.eu/>

Introduction

Individual feed intake (IFI) measurements in aquaculture is challenging to measure because of the nature of the culture system where the fish are reared in group condition. Measuring IFI can enable several advancements in aquaculture development to reduce feed cost and environmental impact, but mainly it is required in selective breeding to select feed conversion ratio (FCR) as a trait. Indeed, the ability to measure IFI is the current limiting factor in achieving appropriate estimation of breeding values for FCR. Current methods are invasive with X-ray imaging and RFID-tag in feeding devices, or neglect social behaviour with individual tanks. Here we propose a new approach in measuring IFI at group condition using computer vision (CV). CV enables the automated interpretation of complex visual data to derive actionable biological insights. The idea is to have a practical method for measuring IFI in groups, to maximize the fish capabilities in feed conversion with selective breeding.

Method

European seabass (200g average) were stocked in 240L aquaria at densities of 10, 15, and 20 individuals to facilitate CV development. Over 5 days, fish were filmed daily for one hour during *ad libitum* feeding, using a custom distributor that placed pellets near the front glass to optimize video recording of feeding events. Initial and final biometry were recorded, and individual fish were filmed separately beforehand to create a gallery set for re-identification (Re-ID) comparison. To detect feeding events, two YOLOv8 models were developed using 300 randomly extracted frames each, for “PELLET” and “OPEN MOUTH” occurrences. The system identifies a feeding event when a tracked pellet disappears and a proximity search simultaneously detects an “OPEN MOUTH” bounding box. This dual-condition logic ensures accurate consumption tracking within the video data. Individual feeding contributions were quantified using two distinct Re-ID approaches derived from the FISHNESS project dataset (Crestel et al., 2026). The first utilized Vision Transformers (ViTs) trained on over 18090 (divided to 80/20 train and test set) full-body images of European seabass representing 4944 individual fish photographed at 2 to 5 different ages. The second employed a Convolutional Neural Network (CNN) focused specifically on the head region, defined from the snout to the opercula. These models allow the CV system to attribute specific feeding events to individual fish within the experimental groups. In parallel several supplementary models are also built in order to integrate the feeding event with the Re-ID model. We built the “EYE”, “FISH” and “HEAD” detection models are built with only 100 frames each with YOLOv8 architecture. The “EYE” detection are used in order to track the fish and assign the Re-ID model identification. The “FISH” model are used to generate crop of the whole fish body and send it to the Re-ID model for identification. The “HEAD” model is similar but crops the head part only. Finally, the whole pipeline works by tracking the eyes of the fish in the aquarium. Where there are head or the whole fish detection by the “HEAD” and “FISH” models within the tracked eye, the bounding boxes are used to crop the frame and send it to the Re-ID model for identification. The IDs are then assigned back to the tracked eye. Then, when there are feeding events detected by the logic explained before, the feeding events are attributed to the closest eye that is detected, tracked and identified. Validation is done manually by carefully evaluating the feed intake output video. Evaluation metrics are based on F1 score as a standard metric. F1 score are calculated

$$\text{as } F1 = \frac{2 \times \text{Precision} \times \text{Recall}}{\text{Precision} + \text{Recall}} \text{ with } \text{Precision} = \frac{TP}{TP + FP} \text{ and } \text{Recall} = \frac{TP}{TP + FN}. \text{ TP means true positive (feed}$$

intake happened and detected), FP means false positive (there are no feed intake but it was detected) and FN means false negative (there are feed intake but it is not detected). For the Re-ID, rank-1 (the percentage of correct prediction of the 1st rank) are used for evaluation.

(Continued on next page)

Results and Discussion

All of the detection models were trained successfully with F1 score of >0.8 . The head Re-ID model with CNN training resulted in rank-1 score of 100% highlighting a probability of overfitting, that requires refinement with more training dataset or parameters tuning. Meanwhile, the whole fish Re-ID model training with ViTs resulted in rank-1 score of 95.7%. This score is also high but not as perfect as the head CNNs Re-ID model. Both model are tested on images from the 80/20 data split. We continue to build the whole pipeline taking into account the fact that the modular nature of the pipeline allows for the seamless integration of refined Re-ID architectures as larger, more diverse datasets become available. The whole pipeline was then applied with the logic explained in the Method section. The preliminary results shows that in Aquarium 1 (with 10 fish), 470 minutes of videos were analyzed, 619 feed intake events detected with 85% attributed to an ID. Fish with ID 711 had the highest feed intake with 186 (30% of the total) pellets eaten while fish with ID 622 had the lowest feed intake with only 2 (0.3%) pellets eaten. Other videos are being processed and analyzed. Preliminary validation of the feed intake resulted in F1 score of 0.8 proving that the pipeline is working. The current analyses shows promising results for this pipeline to be used for IFI measurement in group condition of European seabass. Several limitations such as lack of objective validation method for some modules, model overfitting problems and video processing time are areas that need further development. However, this result acts as a proof of concept that measuring IFI with computer vision is possible and with future developments, it can be a reliable method. Several indirect measurements which have been hypothesized to correlate with IFI (e.g., weight loss at fasting, growth rate, lipid content) can also be proven by this method. Overall, this is the first step in creating non-invasive, high-throughput, group conditioned IFI measurement with CV.

REDUCED CRUDE PROTEIN DIETS IN FERTILIZED EARTHEN PONDS: GROWTH PERFORMANCE, FEED UTILIZATION AND ECONOMIC RETURNS OF NILE TILAPIA *Oreochromis niloticus* IN SUBSAHARAN AFRICA

N.G. Adjei, T. Policar

Faculty of Fisheries and Protection of Waters

University of South Bohemia

Background

Feed protein is the single largest cost driver in pond tilapia aquaculture across sub-Saharan Africa, accounting for 50–70% of variable production costs. In Ghana, commercial diets formulated at 30% crude protein (CP), the prevailing market standard, produce farm-gate tilapia prices roughly five times higher than in Egypt, where 25% CP grow-out feeds are routine practice (El-Sayed, 2013). A 25% CP grow-out pellet remains absent from the Ghanaian commercial market. Fishmeal prices have risen by approximately 30–40% over the past decade internationally, further widening the cost burden for smallholder pond farmers. In fertilized pond systems, natural phytoplankton can supply 50–70% of total protein requirements even when complete commercial diets are provided (Schroeder, 1980), yet controlled field evidence validating reduced-CP diets under commercial pond conditions in West Africa has been lacking.

Materials and Method

A 16-week pond trial was conducted at Konama Farms in Kokoben, Atwima Nwabiagya District, Ashanti Region, Ghana, comparing three commercial extruded floating pellet diets (25%, 28% and 30% CP; 4.5 mm pellet). Sexreversed *Oreochromis niloticus* fingerlings (~60 g) were stocked at 1.6 fish m⁻² across eight fertilized earthen ponds (330–630 m²). Ponds were pre-fertilized with mono-ammonium phosphate (MAP; 2 g m⁻²) and urea (3 g m⁻²) prior to stocking and supplementarily when Secchi depth exceeded 40 cm. Fish were fed twice daily at 2–3% body weight, adjusted after monthly sampling. Growth performance, feed utilization, water quality and enterprise economics were assessed monthly. Data was analyzed by one-way ANOVA with Tukey HSD post-hoc test ($P < 0.05$) using GraphPad Prism v5 and Minitab v17.

Results and Discussion

Fish fed the 25% and 30% CP diets achieved statistically equivalent and significantly superior growth compared with the 28% CP group ($P < 0.05$; Table 1). Specific growth rates (SGR) were 1.27, 1.21 and 1.29 %/day for 25%, 28% and 30% CP, respectively. Feed conversion ratios (FCR) did not differ significantly across treatments (1.99–2.09). Phytoplankton-derived natural food, evidenced by significantly higher chlorophyll-a concentrations in 25% CP ponds (495 ± 42 vs. $427\text{--}441 \mu\text{g L}^{-1}$; $P = 0.0149$), appeared to compensate for the lower dietary protein level, consistent with Schroeder (1980) and Frimpong et al. (2014). Ammonia concentrations remained below the 0.20 mg L^{-1} stress threshold in all treatments (Bhatnagar & Singh, 2010). All other water quality parameters were within acceptable ranges for tilapia culture.

The comparatively lower growth in the 28% CP group may be attributed to two factors. Elevated recruitment biomass from incomplete sex reversal intensified intraspecific competition between grow-out stock and unintended recruits, suppressing individual growth rates. Additionally, the 28% CP diet may have been less complementary to the amino acid profile of available natural food than the 25% or 30% CP diets, reducing effective protein utilization. The interaction between dietary and natural food protein sources in fertilized ponds needs further investigation across a broader CP range.

The 25% CP treatment generated approximately 19% return on investment, compared with 6–9% for the higherprotein alternatives. Fishmeal prices currently stand at approximately \$1,700–2,000 per tonne internationally, substantially above levels recorded in the early 2010s, which amplifies the per-kilogram savings achievable by reducing dietary CP. At current input prices, switching from 30% to 25% CP feed saves approximately $\$0.35 \text{ kg}^{-1}$ of feed, translating to over $\$0.33 \text{ kg}^{-1}$ of fish produced across a full grow-out cycle. Applied to Ghana's estimated 80,000 ha of viable pond area, this represents a sector-wide annual cost reduction in the order of tens of millions of dollars.

(Continued on next page)

Table 1. Growth performance, feed utilization and economic returns of Nile tilapia (*Oreochromis niloticus*) fed diets with varying crude protein (CP) levels in fertilized earthen ponds.

Parameter	25% CP	28% CP	30% CP
Growth performance			
Final body weight (g)	299.6 ± 20.3 a	277.1 ± 11.6 b	305.4 ± 12.6 a
Weight gain (g)	239.8 ± 10.8 a	217.3 ± 2.04 b	245.6 ± 3.04 a
SGR (%/day)	1.27 ± 0.03 a	1.21 ± 0.01 b	1.29 ± 0.01 a
Daily weight gain (g/day)	1.89 ± 0.09 ab	1.74 ± 0.03 a	1.94 ± 0.02 b
Survival rate (%)	93.7 ± 3.79	93.7 ± 5.03	93.0 ± 0.00
Feed utilization			
Feed conversion ratio	2.07 ± 0.10	2.09 ± 0.37	1.99 ± 0.13
Protein efficiency ratio	1.93 ± 0.10	1.74 ± 0.31	1.73 ± 0.11
Feed intake (g/fish/day)	2.42 ± 0.55	2.61 ± 0.28	2.62 ± 1.34
Economic analysis(per hectare)			
Feed cost (USD kg ⁻¹ feed)	\$0.51	\$0.72	\$0.86
Feed cost as % of total cost	40%	48%	51%
Production cost (USD kg ⁻¹ fish)	\$2.42	\$3.10	\$2.76
Net profit (USD ha ⁻¹)	\$1680 (~19%)	\$617 (~6%)	\$1034 (~9%)
a, b: values in the same row with different superscripts differ significantly ($P < 0.05$, Tukey HSD). Feed utilization parameters: no significant differences among treatments ($P > 0.05$). Initial body weight: 59.78 ± 9.52 g (all treatments). Stocking density: 1.6 fish m ⁻² ; fertilized earthen ponds, Kokoben, Ghana. USD conversion at GHC 3.95 per USD.			

Conclusion

Nile tilapia in fertilized earthen ponds achieve commercially equivalent growth and feed utilization on 25% CP commercial diets as on the 30% CP industry standard, at substantially lower cost and with no detrimental effect on water quality. These results support the commercial introduction of 25% CP grow-out pellets in Ghana and comparable sub-Saharan African production systems, with direct relevance to the current global push for sustainable, cost-competitive aquaculture feed formulation.

EVALUATING THE EFFICIENCY OF SELECTIVE BREEDING PROGRAM IN COMMON CARP UNDER FISHPOND MANAGEMENT: A COMPARATIVE STUDY IN PROGENY ORIGINATING FROM MALES OF SELECTED AND NON-SELECTED POPULATIONS OF AMUR MIRROR CARP

Gyamfua Afriyie.^{1*}, Martin Prchal¹, David Gela¹, Jérôme Bugeon², Martin Kocour¹

Introduction

Selective breeding is applied in aquaculture to enhance desirable performance traits. In Czechia, an experimental selective breeding program for faster growth in common carp, Amur mirror carp (AMC), reared under fishpond management started in 2017. In 2022, we decided to compare performance and morphometry of progeny established from males of the first selected generation (G1) and non-selected one (G0) and to match realized heritability and genetic gain with those estimated in previous study (Prchal et al., 2024).

Materials and Methods

A total of 50 males (25 from selected and 25 from non-selected population) and 15 females of non-selected population were used to establish experimental stocks via artificial spawning and individual sperm insemination. Fertilization rate, hatching rates (from inseminated and fertilized eggs), and percentage of malformed larvae were compared between the two groups. Phenotyping was performed four times during the 2-year fishpond culture period at the end of two growing seasons and two overwintering periods. Data on growth-related traits and survival were determined and corrected using an internal control (Linhart et al., 2002). In two-year-old carp, muscle fat content, fillet yield predictors E8 (abdominal fillet thickness) and E23 (abdominal depth) were also measured. The genetic gain and realized heritability (h^2) of the weight at the end of the second overwintering (C2A–C2S) were calculated. Fish digitization was done at the end of the second growing season. Seventeen landmarks were marked using ImageJ and a specifically designed macro to align each fish horizontally and collect the landmark coordinates. Truss network of relative values, 36 in total, was generated. All data were statistically analyzed using R Studio and Statistica.

Table 1: Growth performance evaluation

K (Fulton's condition factor) = $10^5 \cdot \text{BW (g)} / \text{SL}^3 \text{ (mm)}$; **C0–C1A**: the first growing season; **C1A–C1S**: the first overwintering; **C1S–C2A**: the second growing season; **C2A–C2S**: the second overwintering; **SL**: Standard length; **K**: Fulton's condition factor; **S.D.**: Standard deviation; **E8/E23**: Fillet yield predictor. Groups with non-identical alphabets are significantly different at $p < 0.05$.

(Continued on next page)

Results and Discussion

The analyses on reproductive success showed the hatching of inseminated eggs ($p < 0.05$) and fertilized eggs differed significantly ($p < 0.05$) between the groups in favor of the selected line. However, the observed fertilization rate (selected = 84.13% and non-selected = 86.51%) and larval abnormalities (Selected = 2.81% and non-selected = 2.72%) were insignificant.

Cumulative survival rate from the larvae to age of two years (C0 - C2S) was significantly higher in the selected line ($20.18 \pm 1.49\%$) compared with the non-selected line ($12.44 \pm 1.49\%$) ($p < 0.05$), representing an improvement of approximately 62% relative to the non-selected line. This result indicates that selective breeding for faster growth rate may have indirect effect on fish survival. The growth evaluation results (Table 1) demonstrate that the selection program exerted a clear and consistent positive effect on weight and SL, throughout the experimental period. The selected group consistently outperformed the non-selected group in weight ($15.91 - 332\text{g}$ vs $14.99 - 306\text{g}$) with 17% genetic gain of the final weight and a moderately high realized h^2 of 0.355. The genetic gain was in accordance with previous study (Prchal et al., 2024). Interestingly, the selected group also exhibited significantly lower fat content ($2.58 - 2.73\%$) compared to the unselected group ($2.69 - 2.89\%$). This finding reflects a favorable shift in nutrient partitioning, whereby selected individuals allocate proportionally more energy toward lean tissue (muscle and skeletal growth) rather than fat storage as improved growth often increases fat content (Bauer & Schlott, 2009).

Morphometric analysis using truss network of corrected relative values comparison revealed that 10 out of the 36 landmarks examined showed statistically significant differences ($p < 0.05$) between the groups. However, the differences, even if significant, were marginal. Nevertheless, it will be interesting to monitor the changes in morphometry of carp stocks over the generations of selective breeding. This study confirms the efficacy of a selective breeding program for a higher growth rate.

GROWTH PERFORMANCE, BIOCHEMICAL, ANTIOXIDANT STATUS AND HISTOPATHOLOGY CHANGES OF *Clarias gariepinus*, RAISED IN A BIOFLOC MEDIUM UTILIZING NATURAL CARBON SOURCES

Introduction

Aquaculture has persistently developed globally under best practices. A good health status from the function point of view is preponderant for both cultured and wild fish species in early development (Mota *et al.*, 2019). Poor health precludes the reduced exponent of the fish to perform its physiological functions, conform to stressful conditions, and prevent disease (Caipang *et al.*, 2015). Lofty intake of protein above 25% by both fin and shellfish is remarkably excreted as ammonia-nitrogen and influence the quality of water. When inorganic nitrogen, total suspended solids (TSS) are high in concentration in culture water, it leads to death of culture species, diseases, accumulation of harmful residues in culture systems (Karunaarachchi *et al.*, 2018), and obstruction of the growth of global aquaculture market (Caipang *et al.*, 2015). To promote efficient fish production, recycling aquaculture system though expensive to maintain, is most preferable. Therefore, it is apropos to utilize non-expendable ecological clues to resolve the problems associated with cost, poor fish production, etc. However, inappropriate husbandry conditions such as poor water quality, crowding leading to accentuated social interactions between similar schemes present in the culture strategies are a potential threat to animal health/welfare. Therefore, biofloc technology (BFT) provides an alternate solution as a consequence of practicing zero-water exchange, waste nutrient recycling (Bossier and Ekasari, 2017) regulating water qualities by microbial communities, promoting fish growth (Hamidaghli *et al.*, 2019) with reduced environmental impact (Bossier and Ekasari, 2017) for sustainable aquaculture. It is a more beneficial system when heterotrophic bacteria, a nitrogen conversion agent is stimulated by adjusting the C:N ratio in the culture system by the addition of carbonaceous plant-based material or equivalent inorganic carbons for sustainable fish production to achieve sustainable development goals (Bossier and Ekasari, 2017). It has also offered practical solutions to effective water quality control (Avnimelech, 2007) and improvement of fish growth in the healthy culture system (Lananan *et al.*, 2014).

Materials and Methods

A 28 days preliminary trial was conducted to evaluate the affect of biofloc technology application on *Clarias gariepinus* juveniles with emphasis on the growth performance and impact on physiological status. A total of two hundred and seventy juvenile *Clarias gariepinus* were randomly distributed into six plastic bioreactors groups (A-F) in triplicates with equal volume of inoculum, maintained in 30 L tank with constant aeration. Addition of organic carbon sources (CN 10:1, 20:1) were evaluated to stimulate rapid growth of microbial dynamics biomass whereas, no carbon sources were added in the control systems. The CN ratios (cassava and wheat) of 10:1 and 20:1 were; cassava (CA 10:1, 20:1) groups C, D, and wheat flour (WH10:1 and 20:1) groups E and F, respectively. Meanwhile, the normal controls, group A (inoculum, no carbon addition) and B (no inoculum, no carbon) had 50% water exchange and received only fish feed at 3% body weight.

Result

The physicochemical parameters maintained the tolerable limit for catfish farming. Significant weight gain, specific growth rate, Length Weigh Relationship (LWRs), survival rate, and floc volumes were observed at the end of experiment. Observed changes in the catalase, superoxide dismutase, glutathione peroxidase, and malondialdehyde activities in the gill were between day 14 and 21. Significant levels (p1 of *C. gariepinus* juveniles within 28-days. inclusion of C:N ratio of cassava and wheat flour in biofloc tank is beneficial for the growth and health parameters of *Clarias gariepinus*.

Discussion

The adjustable C:N ratio of cassava and wheat flour in flocculation is essential, efficient, and indicated a positive reduction of inorganic nitrogen and noxious metabolites produced in the culture system of African catfish, *Clarias gariepinus*. It is pertinent to observe the peculiar attributes of natural carbohydrates sources such as locally available, not harmful to the cultured fin and shellfish, and cheap. Fish culture using BFT is more beneficial for better growth performances with a reduced pathophysiology change. CA 10: 1 and WH 20:1 is better utilized in *Clarias gariepinus* culture compared to CA 20:1 and WH 10: 1. There is a need to investigate other cheaper sources of carbohydrates such as white yam tuber (*Dioscorea rotundata*), water yam (*Dioscorea alata*), cocoyam (*Xanthosoma sagittifolia*, *Coloca sia esculenta*) and relevant agricultural by-product as natural carbon sources in culture of finfish in a biofloc media.

⁴ PTI SosEcoCir (CSIC) Interdisciplinary Thematic Hub on Sustainability and Circular Economy

Introduction

Hediste diversicolor is characterized by its ability to elongate and desaturate long-chain polyunsaturated fatty acids from substrates of low nutritional quality (Villena et al., 2025). This, alongside its high protein content, makes it a potential alternative ingredient for the aquafeed industry in a context of sustainability and circular economy. The production of *H. diversicolor* biomass for use as feed in aquaculture—whether in its raw form or as meal—requires optimizing its cultivation, which makes it essential to have access to a suitable feed at the lowest possible cost. This study evaluates diets formulated from agri-food industry by-products in terms of growth performance and the resulting fatty acid profile.

Materials and methods

After a preliminary selection process of raw materials derived from waste products from the wine, beer, cider, and aquaculture industries (Aguado-Giménez et al., 2025), along with the inclusion of other raw materials typical of the aquaculture feed industry (to ensure an adequate protein intake), we formulated four diets for *H. diversicolor*. Table 1 shows the proportions of each raw material used in each of the four diets and their basic nutritional composition.

A growth trial was performed using ad hoc experimental units (EU) and following the experimental apparatus described in Aguado-Giménez et al. (2023), at a density of 2,000 individuals m⁻², a temperature of 18 °C, and a salinity of 35‰, for 2 months. Specific growth rate (SGR), Survival Rate (SR) and the resulting fatty acid (FA) profile were assessed.

Results and Discussion

SR was very close to 100% with all diets. SGR was significantly lower with the SUB_2 diet. The other diets resulted in very similar SGR values, which were slightly higher with SUB_1 and SUB_AN (Figure 1). *H. diversicolor* significantly transformed the dietary fatty acid profile into biomass richer in PUFAs and omega-3 fatty acids (Figures 2-4). Polychaetes fed the SUB_1 and SUB_2 diets had a fatty acid profile distinct from that obtained with the other diets (Figure 2), characterized by a higher content of LC-PUFAs, particularly those of the ω -3 series. In general, worms fed any of these diets showed a significant increase in the proportion of PUFAs, particularly EPA and ω -3 series as a whole, compared to their respective diets (Figures 3-4).

Of the four formulated diets, diet SUB_1 was selected to enhance *H. diversicolor* biomass production for subsequent experiments involving its inclusion in marine fish feed. This diet provided the best balance between growth performance, fatty acid profile, and compliance with circular economy criteria.

Table 1: Ingredient and nutritional composition (%) of the four formulated feeds. RoWL: rose wine lees; BSG: brewer’s spent grain; BFL: biofloc waste.

	RoWL	BSG	BFL	Soy meal	Meat meal	Protein	Lipids
SUB_1	70	20	10	-	-	31.89	4.33
SUB_2	70	30	-	-	-	33.22	4.83
SUB_VEG	50	20	10	20	-	34.21	5.52
SUB_AN	50	20	10	-	30	34.11	5.70

Introduction

The thick-lipped grey mullet (*Chelon labrosus*) is a low trophic candidate for the diversification of aquaculture species in Europe. As in other marine species, considerable mortalities have been reported during larval rearing. Some authors have linked survival problems to the presence of microorganisms (Kusuda et al., 1986). Egg disinfection is a routine procedure used to reduce the bacterial, viral, and fungal load on the surface of eggs in species such as salmon, trout, turbot, etc. Disinfection protocols must be optimized for each species. Numerous studies support the effectiveness of iodine as a disinfectant (Hirazawa et al., 1999).

Material and methods

Eggs were obtained through natural spawning induced by hormonal treatments applied to females (Besbes et al., 2020). Eggs were collected using 335 μ m mesh nets at the outlet of the broodstock tanks. From a single spawn, batches of 5 ml of eggs, were used for disinfection trials. Disinfection process was carried out using an iodine-based solution (1.116 % p/p) in 1 L beakers. The procedure was: 100 ml per liter concentration for 10 minutes contact time, and three subsequent rinses of 5 minutes each with clean water. The eggs were at an advanced morula stage prior to the onset of gastrulation at the time of disinfection (6–10 hours post-fertilization at 16°C). The experimental control consisted of eggs from the same spawn subjected to the same procedure but without the use of iodine.

Two assays were performed using both disinfected and control eggs:

1. **Hatching rate and larval survival in 3 ml-well cell culture plates of control and disinfected eggs:** The plates contained embryos incubated with 2ml of sterile sea water that were checked to assess hatching and larval survival rates. The hatching rate was calculated as the total number of hatched larvae divided by the total number of incubated eggs, and larval survival was evaluated daily.
2. **Comparison of the microbiota associated with control and disinfected eggs:** Blood agar Petri dishes supplemented with NaCl were prepared from the egg batch: three dishes containing 60 untreated eggs per plate and three dishes with 60 disinfected eggs per plate. Samples were analyzed for specific identification using the Vitek 2 system (Biomérieux, Madrid, Spain), which employs colorimetric reagent cards that are incubated and automatically interpreted after performing a Gram stain, a catalase test using 3% hydrogen peroxide, and a coagulase test with rabbit plasma.

Figure 1. A. Hatching rates of untreated (control) eggs and eggs disinfected with iodine. The figure shows the results as the mean $\pm$ standard error. B. Kaplan–Meier survival curves of embryos disinfected and not disinfected (Control) with iodine.

(Continued on next page)

Results and discussion

As shown in figure 1, no significant differences were found in either the hatching rates (Mann-Whitney, $p>0.05$) or the survival curves (Mantel-Cox, $p>0.05$) between control eggs (untreated) and those disinfected with the iodine solution. Regarding the identification of flora associated with the eggs and the effect of disinfection, all control batches tested were positive—by identification using the Vitek method—for *Aeromonas salmonicida* / *Bordetella* spp. In contrast, all batches disinfected with Buffodine, following the manufacturer's instructions, showed a complete absence of bacterial growth.

In conclusion, the authors recommend a disinfection with 100 ml l⁻¹ of iodine-based solution for 10 minutes followed by three rinses with seawater to reduce significantly the bacterial load in *Chelon labrosus* eggs without affecting the hatching rate or subsequent survival of the larvae. This methodology is simple and easy to implement as a routine. However, these are the first published data about disinfection in this species, and it would be desirable to test the efficacy of this compound for viruses and fungi, the efficacy of other compounds, or the possible adverse effects of disinfection at different embryonic stages.

MOLECULAR DETECTION OF SULFONAMIDE (Sul1) RESISTANT GENE ISOLATED FROM BACTERIA IN *Chrysichtys nigrodigitatus* (Lacepede, 1803) FROM OGUN RIVER, AKOMOJE IN ABEOKUTA, OGUN STATE

Akinyemi, A. A.

Department of Aquaculture and Fisheries Management
Federal University of Agriculture Abeokuta
PMB 2240, Abeokuta, Nigeria
akinyemiaa@funaab.edu.ng

The study was carried out to investigate the antibiotic sensitivities of bacteria isolated and identified from *Chrysichtys nigrodigitatus* and their antibiotic susceptibility pattern determined. A total of 45 samples of skin, gill and intestine of *Chrysichtys nigrodigitatus* were obtained from Ogun River, Akomoje in Abeokuta, Ogun State and analyzed microbiologically. The mean values of characteristics measured for the body weight, total length, and standard length for the 15 fish samples are 147.99 ± 66.41 , 26.55 ± 5.55 and 20.05 ± 4.13 respectively while the physical and chemical parameters of Ogun River, Akomoje during the study is presented as follows; Water Temperature (29.0°C), pH (7.8), Dissolved Oxygen (4.9mg/l) and Ammonia (2.3ug/dL). The total mean bacteria count in the gill samples was $1.06 \pm 0.20 \times 10^6 \text{CFU/g}$, while in the intestine samples is $1.36 \pm 0.27 \times 10^6 \text{CFU/g}$ and in the skin samples it is $0.77 \pm 0.21 \times 10^6 \text{CFU/g}$. All the samples collected showed bacterial growth on Eosin methylene Blue (EMB) and Salmonella-Shigella Agar. The 45 samples gave 135 isolates; 28 (15.3%) *Escherichia coli*, 30 (22.2%) *Staphylococcus aureus*, 34 (25.2%) *Bacillus sp*, 30 (22.2%) *Salmonella sp*, 13 (9.6%) *Pseudomonas auregenosa*. Five isolates were selected characterized by molecular method using 16S rRNA gene sequencing. The antibiotic test of these isolates revealed their sensitivity to ciprofloxacin, pefloxacin, and tarivid. It was indicated that all the bacterial isolate was susceptible to Ciprofloxacin and Sparfloxacin. *Escherichia coli* were also susceptible to Pefloxacin, Ciprofloxacin and Tarivid. *E. coli* was also resistance to Streptomycin, Augmentin and Amoxicillin, Gentamycin, Septrin and Chloramphenicol.

QUALITY, SAFETY AND NUTRITIONAL COMPOSITION OF AQUAPONIC LETTUCE, PAK CHOI, CHERRY TOMATO AND TILAPIA COMPARED WITH MARKET PRODUCTS

Introduction

Lettuce (*Lactuca sativa*), pak choi (*Brassica rapa* subsp. *chinensis*), and cherry tomato (*Solanum lycopersicum* var. *cerasiforme*) were cultivated in greenhouse aquaponic systems at Sultan Qaboos University. Tilapia (*Oreochromis niloticus*) reared in the system were also analysed. Equivalent market samples were purchased for comparison. Crop and fish samples were analysed for microbiological quality, heavy metals, pesticide residues, and macro- and micronutrient composition. Additional analyses of fish feed, source water, aquaponic water, and hydrostones were conducted to better understand nutrient pathways and possible contamination sources.

Materials and methods

Lettuce (*Lactuca sativa*), pak choi (*Brassica rapa* subsp. *chinensis*) and cherry tomato (*Solanum lycopersicum* var. *cerasiforme*) were cultivated in greenhouse aquaponic systems. Tilapia (*Oreochromis niloticus*) from the aquaponic system were also analysed. Market samples of the same products were purchased for comparison. Crop and fish samples were analysed for microbiological quality, heavy metals, pesticide residues, and macro- and micronutrient composition. Supporting analyses were also conducted on fish feed, source water, aquaponic water and hydrostones to better understand nutrient dynamics and possible contamination pathways within the system.

Results and discussion

Across all vegetable samples, *Escherichia coli*, *Salmonella*, and *Listeria monocytogenes* were not detected, while *Staphylococcus aureus* occurred only in lettuce at very low levels, not associated with toxin formation. Heavy metals were below detection limits and pesticide residues were below the limit of quantification in all crop samples. Nutritional differences were crop-specific. Aquaponic lettuce contained higher magnesium, calcium, potassium, sulphur, and iron, whereas market lettuce contained higher nitrogen, phosphorous and nitrate. In cherry tomato, aquaponic fruits had higher Phosphorous but lower calcium, zinc, and iron than market fruits. Pak choi showed the fewest differences, with only magnesium and total nitrogen differing significantly between sources. Tilapia from both aquaponic and market sources showed a favourable microbiological profile. Supporting analyses further showed that fish feed contained no detectable heavy metals and no quantifiable pesticide residues, while source water and aquaponic water showed no detectable heavy metal or pesticide contamination. Source water also showed a favourable microbiological profile, and hydrostones contained high iron but no detectable arsenic, lead, cadmium or mercury.

Overall, aquaponics produced foods with strong microbiological and chemical safety and nutritional profiles broadly comparable to market products. The findings further suggest that leafy vegetables may be better suited than fruiting crops to low-input coupled aquaponic systems, where nutrient supply may not fully match the higher demands of fruit production. These results support the potential of aquaponics as a sustainable food-production strategy for arid and water-limited regions.

DIGITAL APPROACH TO OPERATION OF AQUACULTURE INSTALLATIONS

Mr. Aland, PA

DNV – Det Norske Veritas
Veritasveien 1
1363 Høvik, Norway
e-mail: per.arild.aland@dnv.com

INTRODUCTION

The so-called “smart” concept of operations is developing to be an increasingly common solution for marine aquaculture. Real time monitoring of asset condition combined with securing a reliable remote operation where the integrity of “autormote” performance is considered a competitive advantage. The fish farming industry is in the middle of a major transition as vessels and installations are transformed into sensor hubs, generating data, and linking in an expanding interconnected web.

DIGITAL APPROACH MERGED WITH REMOTE OPERATIONS

For Smart operations the term digital asset management is often used where inspection as well as operational decisions are based on continuous data streams supplied by sensors on board the fish farm.

Digitally driven condition-based maintenance yields improved reliability by continuously assessing the condition of the fish farming installation. The objective is to identify potential issues before they become major problems and take proactive measures to prevent failures and unplanned as well as expensive repairs. Digital asset management will help improve efficiency and reduce operational costs. For example, by identifying equipment that needs maintenance or replacement. the digitally driven operational monitoring is based on the scheme of capturing information, analysing data collected, learn plus synthesis, and finally act accordingly.

The integrity of these solutions is mainly based on the reliability of sensors and their locations on board. Operational onboard servers together with data transfers solutions and intermediate digital storage are also essential aspects in the utilization of digital management infrastructure. Stability and performance of software applied to process/analyse collected data represents a significant risk and needs to be assessed. Finally safe data transfer and cyber security are vital items in the overall digital performance.

Autonomous and remotely operated fish farms, ranging from remote control operation to fully unmanned installations, marks a major advancement in the aquaculture industry. These solutions can deliver a wide range of benefits including improved personnel safety due to reductions in crew, increased operational efficiency, reduced emissions, and reduced operational and maintenance costs. A broad risk assessment processes for the qualification of autonomous and remotely operated marine technologies with a set of functional requirements need to be established to maintain required safety level for these solutions. This approach is deliberately flexible in nature, and it is essential to creating the space for future innovation, while also drawing on experience from general ocean industry in project development within the autonomous shipping space over the past decade.

While digital asset management can offer several benefits, there are also a number of potential risks and challenges associated with relying on this technology. Together with data security risks and technical issues, challenges related to data quality is a major concern. The monitoring system relies on high-quality, accurate data to provide meaningful insights into asset condition and performance.

This is still early days for autonomous and remotely operated aquaculture installations. Advances in research, technology, and legislation, as well as experience from projects, is expected to lead to significant developments in “autormote” technology in the future

CONCLUSION

Smart-digital is an efficient concept that most operators are chasing, but how well can you trust the status and “green lights” on your operational dashboard? The industry is expected to put great effort into assuring the integrity of the data-streams continuously feeding information to our operational decision-making tools.

There are several efficient methods to mitigate the risks introduced as advanced digital technology is applied in operations of fish farming installations. One of the most rational approaches includes focus on sensor reliability, integrity of operational onboard servers together with robustness of data transfers solutions.

OPERATIONAL CONCEPTS OF NEW-TECH FISH FARMING INSTALLATIONS

Mr. Aland, PA

INTRODUCTION

Aquaculture market projections uncover a large supply-demand imbalance in the next three decades. Focusing on fin fish supply specifically uncovers that output level is close to a saturation point for traditional areas with traditional aquaculture. As a result of the current situation fish farming is growing out of sheltered, near-shore areas and moved to more exposed locations and further offshore. Several innovative solutions are being tried out in ocean fish farming in the process of industrialization.

MAIN APPROACH

The numerous concepts planned and implemented may be split into four main categories: Open trusswork with traditional net or grating, semi-closed units, closed aquaculture installation and submerged solutions. All these concepts may be operated with permanent manning or a combination of remote operation and daily visits. This paper supply a specific description of the main solutions applied in the development of ocean farming:

- Open trusswork. Further development of the traditional sheltered net pen usually with rigid floating collar in steel or concrete. Additional structural arrangements for additional buoyancy, ballasting/de-ballasting and distention of net panels are common features. This category may be split into two sub-sets. One includes operating at the ocean surface only while an increasing number of designs have the option of submerged position to avoid splash-zone dynamics at rough sea states.
- Semi-closed units. These designs aim to separate fish environment from sea for the first few meters of the water column. This separation is established to protect fish from parasites living in the upper levels of the water column. Sufficient water circulation to maintain sufficient growing condition and fish welfare is often a change for these solutions.
- Closed fish farming units. A wide variety of solutions are currently being explored in this category. The ability to control quality of water intake to optimize fish environment combined with possibility to collect fish waste and feed surplus promote the applicability of this solution. Water may be cleaned and re-cycled or filtered before emitting to sea resulting in less environmental impact per unit biomass. Establishing full separation between fish environment and sea results in less parasites and disease in addition to absolute fish control (no escape) and controlled aquaculture emissions to marine environment.
- Submerged fish farming pens. An increasing number of designs have the option of submerged position to avoid splash-zone dynamics at rough sea states. This results in added operational complexity as operations such as feeding, dead fish retrieval and similar needs to be conducted remotely from the surface position.

Concepts and solutions listed have several advantages and weaknesses that must be considered and evaluated. In addition to applying steel and concrete as construction materials, several solutions are currently being built in novel materials such as polymers and composites. To reduce risk, utilizing these solutions special focuses on structural integrity and manufacturing quality is needed. This involves a systematic approach across stakeholders to build trust. This work maps out essential items to be considered as qualification of polymer or composite built installations are qualified for safe operations in a demanding marine environment.

The essential parameters to be taken into consideration assessing performance are considered to be: Oxygen level in sea water, crowding and live transfer of fish, dead fish handling and ensilage processing, logistics of supplies and goods going both on and off the fish farming installation and personnel safety.

ASSESSMENT OF GLYPHOSATE AND ITS METABOLITES' RESIDUE CONCENTRATIONS IN CULTURED AFRICAN CATFISH OFFERED FOR SALE IN SELECTED FISH MARKETS IN IBADAN, OYO STATE, NIGERIA

Selim Adewale Alarape ^{1*}, Fagbohun Adekemi Florence², Adeyemo Olanike Kudirat¹

Introduction

Catfish farming is practiced by around 80% of fish farmers in Nigeria, and it is the most popular variety of fish employed in aquaculture. As a result, the usage of agrochemicals for fish growth and sustainability has increased. On farms, various agrochemicals such as Formalin, Copper Sulphate, Malachite green, and Potassium Permanganate among others have been abused and/or misused (Adeyemo et al., 2011; Alarape et al., 2013). The adverse side effects of glyphosate and aminomethyl phosphonic acid, or metabolites, on soil, water quality, plant, animal, and human health have been studied extensively in recent years due to glyphosate's extensive use and accumulation in the environment and food products (Battaglin et al., 2014). In 2015, the World Health Organization (WHO) categorized the glyphosate herbicide as possibly human carcinogenic based on their most recent findings on its potential chronic negative effects (EFSA, 2015; Guyton et al., 2015).

Materials and Methods

Five adult *Clarias gariepinus* (300 ± 50 g) were collected from each of five active cultured fish markets in Ibadan, giving a total of 25 fish. The fish were pithed, and muscle, liver, and kidney tissues were aseptically harvested, sealed in sterile sample bags, kept on ice, and transported to the International Institute of Tropical Agriculture (IITA) for glyphosate residue analysis. Solid-phase extraction (SPE) and quantification followed Delmonico et al. (2014). Digestion tubes were cleaned with water, distilled water, and 0.5% HCl, then dried. Homogenized tissue samples (0.5 mL) were placed in Pyrex tubes, after which 20 mL of an ammomethyl-phosphonic-nitric acid mixture (5:2:5) was added. Samples were digested for 2.5 hours at 25°C under a condenser, cooled, and diluted to 25 mL with ultrapure water. The mixtures were shaken for 10 min and centrifuged at 5,000 rpm for 5 min. Supernatants were analyzed using Reverse Phase LC (Agilent Technologies) with a C18 column (5 µm, 120 Å, 4.6 × 250 mm) and methanol/water (90:10) as the mobile phase at 1 mL/min for 30 min. The SPE-LC method was validated for specificity, linearity, sensitivity, accuracy, precision, and matrix effect resistance.

Results

The results showed that glyphosate residues were recorded in all the seventy-five (75) fish tissue samples obtained from the selected fish markets in the Ibadan metropolis and all residue concentrations were above both the recommended Acceptable Daily Intake (ADI) of 1.0 mg/kg (1 × 10⁻³ mg/L) and Maximum Residue Limits (MRL) of 0.01 mg/kg (1 × 10⁻⁵ mg/L). Isopropylamine has the highest residue concentration followed by N-Phosphonomethyl and Aminomethylphosphonic Acid (AMPA), while N-Acetyl Glyphosate has the least residue concentration across the sampled markets.

Discussion

The detection of glyphosate residues in the fish organs and muscles in this study confirmed the use of several glyphosate-based herbicides (Force-Up, Vinash, Para force, and Round-Up) on the fish farms (fish as a non-target organism) in Nigeria (Alarape et al., 2024), use of banned pesticides like pyrethroids, organophosphates, carbamates, and organochlorine in agricultural products in Bangladesh (Jallow et al., 2017) and Ghana (Essumang et al., 2009). Although glyphosate-based herbicides were not used directly on fish, environmental contamination may be a possible source of the herbicide residues found in fish in the research location where such herbicides are used on farms close to fish farms. The presence of residues of glyphosate and its metabolites in ready-to-eat fish calls for holistic, systematic, and effective risk management strategies towards monitoring pesticide/herbicide usage in aquaculture production and ensuring the provision of wholesome fish and fish products for the consumers.

VALORIZATION OF INVASIVE CRAB BIOMASS: THE CASE OF THE CHINESE MITTEN CRAB (*Eriocheir sinensis*) AND ITS POTENTIAL AS FEED INGREDIENT IN AQUACULTURE

H Alberts-Hubatsch ^{1*}, Böckmann KM¹, Slater MJ^{1,2}

*corresponding/presenting halberts@awi.de

Introduction

Invasive aquatic species are increasingly recognized not only as ecological threats but also as underutilized biomass resources with potential for sustainable valorization (Arena et al., 2024). In this study, we investigated the biochemical composition and biomass characteristics of the highly invasive Chinese Mitten Crab *Eriocheir sinensis* to assess its suitability within a biorefinery framework. Comprehensive analyses were conducted to determine key constituents, including proteins, carbohydrates, and ash content, alongside the potential for enzymatic protein hydrolysis relevant for industrial applications.

Building on this characterization, we explored potential valorization pathways aligned with established biorefinery concepts, aiming to integrate this biomass into circular bioeconomy strategies (Fricke et al., 2023; Fuchs et al., 2025). Particular attention was given to its applicability as a feed ingredient, considering both nutritional value and processing feasibility.

To evaluate this potential, a preliminary feeding trial was conducted using raw, untreated biomass as feed for shrimp *Penaeus (Litopenaeus) vannamei*. Apparent digestibility coefficients were determined to assess nutrient availability and overall feed performance. The results provide initial insights into the digestibility and suitability of this invasive species as an alternative feed resource in aquaculture.

Overall, this work highlights the dual benefit of mitigating ecological impacts of invasive species while simultaneously unlocking their value as a renewable bioresource. The findings contribute to the development of sustainable management strategies that couple environmental remediation with innovative biomass utilization.

Characterization of Biomass

Biomass of CMC was de-shelled and the pure biomass without carapace/chitin was used for biorefinery approaches. Proximate analysis of CMC showed overall good suitability for feeding purposes in aquaculture, with 53.3 ± 0.17 % crude protein.

The biomass was hydrolysed using four different enzymes, resulting in significantly different degree of hydrolysis (DH, Figure 1), as well as different profiles in aminoacids. All hydrolysates showed good levels of anti-oxidant activity revealed by ABTS and TBAR assays. Here, one-way ANOVA revealed a significant effect of enzyme type on ABTS activity ($F(3,8) = 102.43$, $p < 0.001$). Tukey's post-hoc test showed that Alcalase exhibited significantly higher activity than all other enzymes ($p < 0.001$), while Protamex and Flavourzyme did not differ significantly ($p = 0.129$). For FRAP, a significant effect was observed ($F(3,8) = 4.65$, $p = 0.036$). However, Tukey's test indicated that only Protamex differed significantly from Flavourzyme ($p = 0.044$), with no other pairwise differences detected.

Apparent Digestibility in Shrimp *Penaeus vannamei*

The digestibility of biomass from Chinese mitten crab (CMC) were used in a feeding trial with shrimp. We tested raw biomass (with carapace/chitin; CMC+) of *E. sinensis* and de-shelled biomass (w/o carapace/chitin; CMC-) and a control diet as reference (CTRL). Feces were collected over a 5-week timespan, growth and survival were documented. The AD was calculated for crude protein as well as aminoacids and showed suitable digestibility coefficient. All diets resulted similar survival rates (One-way Anova; $F(2,17) = 0.65$; $p = 0.54$) ranging from 92.4 – 97 % and similar hepatosomatic indices (HSI; $F(2,17) = 0.824$; $p = 0.46$) ranging from 3.2 to 3.4, indicating overall good health status during the experimental time. Growth and SGR were highly different between treatments ($F(2,17) = 12.4$; $p < 0.001$), with Tukey's pairwise comparisons revealing significant differences between treatments with CMC- resulting in highest and the CTRL displaying lowest growth. This is a first indication for the suitability of CMC as feed ingredient for shrimp. However, this study was designed as digestibility trial, so this results need to be confirmed with a growth trial, using isoenergetic and isonitrogenous feeds.

(Continued on next page)

Figure 1 Degree of hydrolysis for four different enzymes used for the protein extraction of Chinese mitten crab biomass

Table 1 Performance data of *P. vannamei* after the 42 day period of the digestibility trial with diets containing either CMC with chitin (CMC+) or without (CMC-) and a control diet (CTRL). Different superscript letters indicated statistical differences (Tukey’s pairwise comparisons, $p \leq 0.05$).

	CTRL	CMC+	CMC-
SGR	1.39 ± 0.22 ^a	1.77 ± 0.17 ^b	2.09 ± 0.31 ^b
Weight gain	9.76 ± 1.57 ^a	12.36 ± 1.21 ^b	14.64 ± 2.18 ^b
survival	0.92 ± 0.11 ^a	0.97 ± 0.07 ^a	0.97 ± 0.05 ^a
HSI	3.28 ± 0.15 ^a	3.24 ± 0.08 ^a	3.43 ± 0.08 ^a

Conclusion

Overall, biomass from the invasive Chinese mitten crab shows suitable nutritional profiles. The biomass can be used as raw biomass, but also shows good potential for biorefinery purposes. Protein hydrolysates of CMC biomass revealed aminoacid-profiles suitable for nutrition in aquaculture as well as good functional properties. A first digestion trial of raw biomass with *P. vannamei* shows its feasibility for the use as aquaculture feeds, but further studies are needed to unfold the whole potential of this underutilized resource.

² Pelagia AS, Norway

*Sissel.Albrektsen@Nofima.no

Introduction

Atlantic Herring *Clupea harengus* and Blue whiting *Micromesistius poutassou* are two of the most important fish species available for commercial fish meal (Fm) production in Norway. Further, side streams from processing of fish have become increasingly important for fish protein concentrate (FPC) and hydrolysate (FPH) production due to their potential as functional ingredients. Raw material handling and processing of Fm can impact their quality. Traditionally, Fm quality has been determined by raw material freshness and protein digestibility. However, focus on improving the robustness of fish during challenging periods have provided incentive to investigate other avenues to improve the quality of Fm and their side streams. In this study we examined the impact of increasing volatile compounds through gentle processing methods of the raw material and their side streams for improving the physiological robustness in Atlantic salmon smolts during adaptation to seawater transfer combined with lowering of the water temperatures.

Material and Methods

Two qualities of blue whiting Fm namely ‘Superior’ and ‘Standard’ were produced by gentle low temperature and conventional steam drying by Pelagia AS, respectively. Herring Fm of high quality was also produced by Pelagia AS, while the added value ingredients; FPH and FPC were produced from the same batch of fresh, high-quality herring side streams by Nofima AS and Pelagia AS, respectively. Seven nutritional balanced and isoenergetic diets were produced where the control diet was a standard formulated salmon feed supplemented with 15 % high quality blue whiting Fm (D1), standard quality blue whiting Fm (D2) and herring Fm (D3). Iso-protein levels of FPH and FPC (about 4 %) were added to the high quality blue whiting Fm (D4, D5) and to combined 50:50 diets of herring Fm and blue whiting Fm (D6, D7), all balanced to reach 35.5 % water-soluble protein. The nutritional added value potential of the diets was evaluated in a controlled 8-week feeding trial with Atlantic salmon immediately after seawater transfer. The fish were adapted to decreasing temperatures from 12°C in freshwater to respectively 10.5°C (at transfer), 9.5, 8.5, 7.5, and 6.5 °C until final fish sampling.

Results and Discussion

The feeding trial was carried out with salmon (initial weight: 119.5 ± 0.6 g), showing doubling of fish body weight (final weight: 237.5 ± 6.7 g) and efficient growth in all dietary groups (average SGR: 1.23 ± 0.05 %; TGF: 2,60 ± 0.12). No significant differences in feed intake, growth or feed conversion were found in the total feeding period (ns). Increased feed intake, however, was observed in the initial 2 weeks feeding period (10.5°C) in fish fed diets added FPC (D5, D7), while continued increased feed intake was observed only in fish fed the blue whiting diet D5. During the trial, the feed intake slowly decreased in all dietary groups adapting to the steadily declining temperature. Protein and amino acid (AA) digestibility tended to be higher in fish fed D4-D7 added FPH and FPC (Prot: 92.4 ± 0.9 %; AA: 93.5 ± 0.9 %), while no differences relative to the other diets (D1-D3) was found (Prot: 91.3 ± 0.8 %; AA: 92.5 ± 0.7 %). Whole body crude composition (Protein: 16.5 ± 0.2 %; Lipid: 11.8 ± 2.4 %, Ash: 2.10 ± 0.05 %) was unaffected by the diets (ns). The protein retention efficiency was high in all dietary groups, and no significant differences in PER: 3.32 ± 0.14; PPV: 49.5 ± 2.3 % or BV: 53.8 ± 2.4 % was detected (ns). Lipid digestibility was also high in all dietary groups (ADC lipid: 94.3 ± 0.9 %), and no significant differences detected (ns).

In the sampled fish (n=5/tank), the OWI welfare scores of the skin (scale loss, bleeding, wounds and cataract) revealed high quality (OWI scores ≤ 1.2) and no diet dependent differences (ns). Liver lipid (6.4 ± 0.9 %), HSI (1.44 ± 0.10 %), slaughter yield (85.1 ± 0.7 %) and total tocopherols (868 ± 153 mg/kg) were unaffected by diets (ns). The liver contents of Fe and Cu were weakly elevated in fish fed diets added FPC, while liver Zn, Mn and Se were unaffected by diets.

(Continued on next page)

Figure 1 Free amino acids (AA) and bioactive peptides in muscle and skin

Figure 2 Volatile N-compounds (TVN, TMAO) in muscle and skin

Analyses of free amino acids in muscle and skin showed that nearly 80 and 70 % represented maintenance of the osmotic water balance in the muscle and skin, respectively, independent of the diets, Figure 1. The levels of osmolytes such as anserine was very high in the muscle, while taurine was much higher in the skin, while both appeared to be physiologically well regulated due to the consistent levels and observed differences between skin and muscle of fish from all dietary groups. Addition of the soluble, functional compounds from herring (FPH, FPC) did not seem to affect the tissue composition, while more advanced methods would be required to explore impacts on the physiological regulatory mechanisms.

Summary

Fish from all diets demonstrated efficient growth, feed intake and feed conversion, high protein and lipid digestibility, efficient protein retention and no visual observed differences in skin quality by operational welfare scores (OWI). Distinct differences in the tissue composition of free amino acids and volatile N- compounds in skin and muscle is anticipated to be of physiological relevance for maintenance of osmotic balance but will require further exploring for revealing of the physiological regulatory mechanisms. Additional analyses to study dietary impacts on serum health markers and serum osmolality, amino acid composition in the skin and the muscle, and selected gene expressions in the skin and the gills (qPCR) are in progress and will be presented.

ENVIRONMENTAL DNA-BASED RISK ASSESSMENT OF VIBRIOSIS CAUSED BY *Vibrio harveyi*

M. Alfier¹, Zupičić¹ I.G., Zrnčić¹ S., Oraić¹ D., Kolega² M., Branović Čakanić¹ K., Kolačko¹ I., Grbin¹ D.

¹ Laboratory for Aquatic Animal Diseases, Croatian Veterinary Institute, Zagreb, Croatia

² Cromaris d.d., Zadar, Croatia

Introduction

Vibrio harveyi is naturally present in marine ecosystems and forms part of the normal intestinal microbiota of many marine organisms. Over the past decades, *V. harveyi* has become an important bacterial pathogen of marine vertebrates and invertebrates, including crustaceans, molluscs, and fish, causing high mortality and substantial economic losses in aquaculture. Its prevalence has increased markedly in Mediterranean aquaculture, likely driven by changing environmental conditions and the effects of climate change. Fish are primarily colonized through exposure to contaminated water, with the bacterium initially establishing on the skin, gills, and gastrointestinal tract. Clinical disease usually develops in immunocompromised fish or under environmental and husbandry-related stress. Biofilms on aquaculture tanks and production systems act as reservoirs of *V. harveyi*, promoting bacterial persistence and increasing tolerance to antimicrobial agents and disinfectants, thereby complicating disease control. Environmental DNA (eDNA)-based monitoring enables the detection of *V. harveyi* before the onset of clinical disease, providing an opportunity for early intervention. Early detection of the pathogen in the environment is therefore essential for timely risk assessment and the implementation of effective disease management strategies.

Materials and Methods

To evaluate the applicability of environmental DNA (eDNA) for early monitoring of *V. harveyi* in marine aquaculture, sampling was conducted at a commercial European seabass (*Dicentrarchus labrax*) farm. Seawater samples (1 L) were collected at two depths: approximately 20 cm below the surface (24.3 °C) and 2 m below the surface (24.0 °C), and filtered through 0.45 µm nitrocellulose membrane filters. Biofilm samples were collected by swabbing a 10 × 2 cm area of the cage pipe, while fouling samples were scraped from the waterline using a sterile knife. Gills and digestive glands were sampled from Mediterranean mussels (*Mytilus galloprovincialis*) that were fastened to plastic cage pipes close to the sea surface. Samples of the kidney, liver, spleen, gills, and heart were taken from four European seabass individuals with clinical indications of vibriosis (uncoordinated swimming). DNA was extracted using commercial extraction kits according to the sample matrix. A species-specific quantitative real-time PCR assay targeting *V. harveyi* was developed using genomic DNA from a reference isolate to generate the standard curve for absolute quantification. Results were normalized to tissue weight (copies g⁻¹), filtered water volume (copies L⁻¹) or sampled surface area (copies cm⁻²).

Results

The developed qPCR assay successfully detected *V. harveyi* DNA in seawater, cage biofilm swabs, mussels and clinically affected European seabass, whereas no amplification was obtained from the fouling sample. Fish tissues showed the highest bacterial loads, with gills containing up to 2.3×10^3 copies g⁻¹, while lower concentrations were detected in the heart, kidney, spleen and liver. Seawater samples collected at two depths were positive for *V. harveyi*, with approximately $2\text{--}3 \times 10^3$ copies L⁻¹. Mussels were also positive, with higher bacterial loads detected in gills than in digestive glands. Biofilm swabs collected from cage pipes contained 30–190 copies cm⁻², indicating the presence of *V. harveyi* on cage surfaces.

Conclusion

Quantitative monitoring of *V. harveyi* in environmental samples, supported by analysis of fish tissues and potential reservoirs, provides a valuable approach for early detection of increased pathogen abundance in mariculture systems. This method may facilitate timely implementation of preventive measures before the onset of clinical disease.

This study was funded by the European Union NextGenerationEU and supported by the Ministry of Science and Education of the Republic of Croatia through the project No. NPOO 8 of the Croatian Veterinary Institute entitled „Advancing the Understanding of the Presence and Pathogenicity of *Vibrio harveyi* in Mariculture – ViHMar“

IMPACTS OF ARTIFICIAL LIGHT MANAGEMENT AND CAGE SUBMERGENCE ON THE REPRODUCTIVE PHYSIOLOGY AND WELFARE OF FARMED ATLANTIC COD (*Gadus morhua*)

M. Alix^{1*}, E. Andersson¹, R. Schulz¹, L. Geitung¹, V. Nola¹, P.G. Fjellidal¹, T. Dempster², F. Oppedal¹, B. Norberg¹

*Presenting author: Maud.alix@hi.no

Introduction

Since 2018, interest in Norwegian cod (*Gadus morhua*) farming has seen a significant resurgence, driven by the development of 6th to 8th generation domesticated strains selected for enhanced growth and disease resistance. To ensure the long-term sustainability of this renewed industry, it is essential to address a persistent challenge and long-standing biological bottleneck: early sexual maturation and the potential release of fertilized eggs within open-sea cages, as highlighted in recent environmental risk reports. Spawning in cages might results in a possible risk of genetic pollution of wild Atlantic cod populations, while the maturation process itself is energetically demanding, often compromising fish health and growth performance. Continuous light treatment (LL) is a common management strategy used to delay maturation by interrupting the photoperiodic control of the reproductive cycle, a process mediated by melatonin regulation, which is sensitive to prior diurnal light exposure. While LL is widely implemented, its efficacy remains inconsistent. To address this, combining continuous light with cage submergence represents a promising solution to stabilize the light environment and minimize the intensity differential between day and night.

Material and methods

To investigate enhanced maturation control in Atlantic cod, two sequential trials were performed using a single cohort of fish at distinct stages of the production cycle. The first experiment (EP1) was conducted in 2023-2024 with fish ranging from 200 g to 1.5 kg, while the second (EP2) focused on fish between 1.5 and 5 kg. We tested, in triplicate, surface cages exposed to high-intensity continuous light (LL, 2500 W) with or without net/tarpaulin shading, as well as submerged cages positioned at 30 m depth (shielded from strong natural daylight) under either LL (600 W) or natural light (NL) conditions. Stocking densities consisted of 1200 fish per cage in EP1 and 240 to 480 fish in EP2. Prior to transfer to the sea cages, LL-groups were held in indoor tanks under continuous light, while NL-groups followed a natural photoperiod. Bi-monthly sampling was conducted across all experimental groups to monitor growth performance and collect blood and tissue samples. We employed ultrasound imaging alongside hormonal, histological, and molecular analyses (gene expression) to provide a comprehensive assessment of sexual maturation. Additionally, health and welfare were tracked through parasite prevalence monitoring and the implementation of a dedicated welfare scoring system.

Results and discussion

In both EP1 and EP2, the gonadosomatic index (GSI) of the NL-groups rose during winter and spring, culminating in spawning. During EP1, this was dominated by males due to their earlier maturation compared to females. In contrast, LL-groups in EP1 showed a delayed GSI increase whereas those in EP2 maintained GSI levels similar to initial values throughout the experiment, with no spawning observed by the end of the trial despite fish reaching commercial size. Notably, the submerged LL group in EP1 exhibited no significant GSI elevation, with females showing no initiation of vitellogenesis. However, fish kept in NL-submerged cages in EP1 presented an increase in GSI similar to that observed in NL-surface cages. In EP1, plasma levels of sexual hormones, specifically estradiol (E2) and 11-ketotestosterone (11-KT), mirrored the GSI and histological findings; 11-KT increased in males across all NL groups, while an elevation in E2 was noted in females from submerged NL cages. Corresponding analyses for EP2 are currently ongoing.

Regarding fish health, experimental treatments significantly influenced parasite dynamics, with a notably higher prevalence of *Caligus spp.* observed in submerged cages, particularly in LL-treatments across both trials. Preliminary welfare evaluations, adapted from established Atlantic salmon indicators, suggest that cod welfare was generally maintained within acceptable limits; however, some skeletal anomalies, specifically in the cranial and vertebral regions, were noted.

These preliminary observations suggest that the efficacy of maturation control may be dependent on the timing of implementation in the sea cages within the production cycle. While LL treatment resulted in only partial inhibition for the smaller fish during EP1, initial observations from EP2 indicate a more robust suppression in larger individuals. Although further histological and hormonal analyses are required to confirm these trends for EP2, optimizing light management during the production cycle appears to be a promising path for the industry to prioritize somatic growth over early maturation.

RIDGING THE INTENTION-BEHAVIOUR GAP: DRIVERS OF SEAFOOD CONSUMPTION AMONG YOUNG NORWEGIAN CONSUMERS

F. Govaerts, K. Bergsnev, M. Meland, M. Heide, T. Altintzoglou*

Department of Marketing Research

Nofima, Tromsø, Norway

*corresponding/presenting author: themis.altintzoglou@nofima.no

Introduction and Methodology

Despite a general desire among 70% of Norwegians to increase their seafood intake (Norges sjømatråd, 2023), actual consumption has declined by approximately 12% over the last decade. This “intention-behaviour gap” is influenced by complex factors including price, sensory aversions, and perceived lack of cooking skills (Heide et al., 2023; Bergsnev, 2025). To identify specific drivers for young adults (aged 18–35), a **Choice-Based Conjoint Analysis (CBCA)** was conducted with a representative sample of **n = 1,000**. Participants completed ten choice tasks evaluating cod filet profiles based on three attributes: product form (natural vs. seasoned), sustainability information (e.g., MSC, National Food Safety Authority), and sensory cues (“Scent of the sea”). The study also explored how early childhood experiences shape adult “Green Trust” and consumption habits (Bergsnev, 2025).

Results and Discussion

The conjoint analysis revealed that **sustainability information** was the most critical factor, with a relative importance of **53.6%**. Products featuring the **MSC label** achieved the highest positive utility (0.305), while guarantees from the Norwegian Food Safety Authority also had a strong positive effect, reflecting high trust in national institutional sources (Gullbrandsen, Vormedal & Larsen, 2022). **Sensory cues** were the second most important attribute (33.5%), where the descriptor “Scent of the sea” significantly increased the likelihood of product choice by triggering positive emotional responses (Bergsnev et al., 2024). Interestingly, **product form** (natural vs. seasoned) had the lowest impact on decision-making (12.9%). Open-ended responses confirmed that while health is a primary motivator, price and sensory barriers remain significant (Carlucci et al., 2015). Furthermore, a strong positive correlation exists between **early-life exposure**—such as fishing trips or helping with cooking—and the development of high-frequency consumption in adulthood. These findings suggest the industry should focus on clear, intuitive sustainability signaling and sensory-focused marketing through digital channels and influencers to reach younger demographics.

Introduction

To ensure optimal growth and acceptable fish welfare, dissolved oxygen (DO) concentrations in fish cages need to exceed a temperature-dependent threshold (Remen et al. 2016). As the Norwegian salmon aquaculture industry moves towards larger production units, DO levels are likely to become a more significant concern, and climate change can compound this problem through higher water temperatures. DO concentrations within open aquaculture sea cages depend on the dynamical interplay of factors such as the oxygen consumption of individual fish, spatial distribution of fish biomass in the cage, water temperature, ambient current speed and direction and the flow field within the fish farm. Since DO varies spatially between and within cages, it is insufficient to simply measure DO at a single point in order to assess the availability of oxygen for the fish in the farm (Berntsson et al. 2026). In this study, DO was monitored at multiple locations in a commercial salmon farm, and two mathematical models of high and low complexity, respectively, were evaluated as tools to predict oxygen conditions and to assess the risk of hypoxia inside cages.

Materials and methods

The field study was conducted at a commercial salmon farm in Mid-Norway with 8 cages of 50 m diameter (see Figure 1) stocked with biomass over a 6 week period in May-July 2025. DO and temperature was monitored at 5, 10 and 15 m depth inside one cage stocked with biomass near the center of the farm, at two cage locations without biomass and at a reference location outside of the farm. Current speed and direction was monitored using profiling current sensors at one location near the center of the farm and at a reference location outside the farm. Two mathematical models were used to simulate DO conditions over the study period. One model used simple relations between the oxygen consumption of fish as a function of temperature, the expected vertical distribution of the fish, the current speed and the diameter of the cages in order to estimate DO levels inside cages. The other model was based on Alver et al. (2024), and used a gridded 3D representation of the entire farm to simulate spatial DO distribution as a function of advection, diffusion and the spatially distributed oxygen consumption of the fish. The output of the two models was compared to the measured DO values in order to assess the quality of model predictions. A comparison of the two models was made in order to assess the trade-off of model complexity, computational cost and the ability to accurately predict DO conditions and the risk of hypoxia affecting fish welfare.

Table/Figure 1

Exposure	Gd Concentration (ug L-1)	Parent History	Experiments
Basal (control)	0	Non-exposed	Embryotoxicity assay
Low	14	-	-
Medium	157	Exposed	Embryotoxicity assay after 20 days of exposure

Table 1 This table highlights the parental exposure levels of Gadolinium (14 and 157 µg L⁻¹) and the subsequent larval analysis used for risk assessment in marine aquaculture.

(Continued on next page)

Results

The study period included temperatures in the range 7–13°C and currents generally below 0.2 m/s at the reference location. Ambient DO levels were in the range 7.5–11.5 mg/l, while measured DO inside the stocked cage ranged down to below 6 mg/l. The 3D model generally predicted DO levels best when using current measurements from within the farm, with RMS deviation on the order of 1 mg/l and overall bias of about 0.1 mg/l at 5 m. The low and high complexity models were compared for similar conditions, meaning a simulation test case where all other cages were considered empty. The overall trends for DO estimated by the low complexity model were often similar to the overall trends displayed by the complex model when considering a time scale of days. There were differences however, especially when investigating hourly variations. The simplified model seems to be more sensitive than the complex model to variations in current velocity, which may be a result of the formulation of the simplified model. A significant limitation of the simple model was the difficulty of representing effects of neighbouring cages. As illustrated in Figure 1, downstream cages tend to see lower DO levels than upstream ones.

Introduction

Temperature is a key environmental factor regulating fish physiology and performance, and sudden decreases in water temperature represent a major challenge for warm-water species such as gilthead seabream (*Sparus aurata*) (Ibarz et al., 2010). Dietary protein hydrolysates (PH), as sources of highly digestible peptides and antioxidant amino acids (AAs), may enhance the capacity of fish to cope with the energetic and oxidative demands imposed by cold stress (Siddik et al., 2021; Wei et al., 2017). However, little is known about how PH from different sources modulate hepatic metabolic adaptations to cold stress. Therefore, this study characterised the metabolic and oxidative responses of juvenile gilthead seabream to low-temperature exposure and evaluated the modulatory effects of dietary PH from different sources.

Methodology

Fish were fed four experimental diets for 88 days at 20 °C: a control diet (CTRL) containing 3% commercial PH (CPSP90), and three other diets in which CPSP90 was replaced with PH derived from insect meal (INSECT), fish by-products (FISH), or swine by-products (SWINE). At the end of the feeding trial, fish were either sampled immediately (non-stressed) or exposed to 15 °C for 5 days before sampling (stressed). Plasma and hepatic metabolites, biomarkers of oxidative status, and antioxidant enzyme activities were assessed.

Results & Discussion

As previously demonstrated, replacing a commercial PH with an alternative PH maintained growth performance and feed efficiency in gilthead seabream (Alves-de-Oliveira et al., 2026). Cold exposure induced marked metabolic changes, characterised by decreased plasma cortisol, lactate, cholesterol, and triglyceride levels, together with increased glucose and non-esterified fatty acid levels, consistent with the mobilisation of endogenous energy substrates to maintain energy homeostasis. Metabolomic analyses further revealed significant shifts in carbohydrate and AA metabolism, with distinct metabolic signatures among dietary treatments. Lower hepatic threonine concentrations were observed in FISH- and SWINE-fed fish, whereas INSECT-fed fish showed higher hepatic cholesterol and triglyceride concentrations.

Cold exposure also remodelled the antioxidant defence system by increasing superoxide dismutase and catalase activities while reducing glutathione peroxidase activity, without increasing hepatic lipid peroxidation (LPO). Dietary PH also modulated these responses, with FISH- and SWINE-fed fish showing lower hepatic LPO than CTRL- and INSECT-fed fish despite the stress challenge.

Overall, the results suggest that selected PH can contribute to enhanced resilience to low-temperature stress through the modulation of energy metabolism and redox homeostasis.

Introduction

Insect meals, particularly from the yellow mealworm (*Tenebrio molitor*), are increasingly recognized as sustainable alternatives to fishmeal in aquafeeds. To date, most studies have focused on defatted insect meals, which contain between 4–14% lipid content [1]. The industrial defatting process involves a thermal-mechanical fat removal step [2], which improves shelf-life but may reduce environmental sustainability and alter the meal's functional properties [3]. Insect-derived lipids have been reported to modulate intestinal microbiota and barrier function [4], understanding the impact of dietary lipid composition on gut health is critical. This study evaluated the comparative effects of replacing fishmeal with either full-fat (ffTM) and defatted (dTM) mealworm meal on the digestive enzymes activities, oxidative stress responses and intestinal histomorphology of rainbow trout (*Oncorhynchus mykiss*).

Materials and methods

A single batch of mealworm larvae was either subjected or not subjected to a thermos-mechanical defatting process, resulting in two distinct mealworm meals (TM): a ffTM (crude protein: 51.9%, crude lipids: 32.8%) and a dTM (crude protein: 66.7%, crude lipids: 12.9%). Three isoproteic (45%) and isolipidic (22%) experimental diets were formulated for juvenile rainbow trout. A control diet (CTRL) was formulated to mimic the composition of a conventional commercial trout diet. Two other diets were formulated based on the CTRL diet but incorporated 25% of the full-fat and defatted MMs, totally replacing fishmeal (FFMM and DMM diets). All diets included 11.5% of fish oil (dry matter basis), and rapeseed oil was adjusted to maintain consistent lipid levels across all formulations. A growth trial was conducted with juvenile rainbow trout (11.4 ± 1.5 g). Nine homogeneous groups of 20 fish each were randomly assigned to nine fiberglass tanks (120L), within a recirculating aquaculture system kept at a constant 14 °C. Fish were fed to apparent satiation, twice daily, over an eight-week period. At the end of the trial, whole intestines were sampled for digestive enzymes activities, oxidative stress enzymatic and non-enzymatic indicators and semi-quantitative and quantitative histomorphology analyses.

Results

At the end of the feeding trial, rainbow trout showed an eightfold increase in body weight, with no significant differences in zootechnical growth parameters, regardless of the dietary treatments. Nevertheless, fish fed the FFMM and DMM diets exhibited reduced feed intake alongside improved feed efficiency.

No significant dietary impact was observed on the activity of α -amylase and chymotrypsin activities. In contrast fish fed the DMM diet showed higher lipase and trypsin activities and those fed the CTRL diet

No significant dietary impact was observed in intestinal lipid peroxidation (LPO), total glutathione (TG), reduced glutathione (GSH), oxidized glutathione (GSSG), GSH-GSSG ratio, glutathione peroxidase (GPx) and glutathione S-transferase (GST) activities. However, catalase (CAT) and glutathione reductase were increased and reduced, respectively, in the FFMM and DMM groups relatively to the CTRL group.

No significant dietary impact was observed in most semi-quantitative parameters, except for the size and regularity of the enterocyte vacuole, which were slightly enlarged in the FM groups than in the FFMM groups. The quantitative morphometric parameters analyzed in the anterior intestine did not vary significantly among dietary treatments, with no significant dietary impact on the cross section total perimeter, total area, villi area, lumen area, muscular layer area, villi density, villi height, lamina propria width, muscular layer width, stratum compactum width and submucosa width of the anterior intestine. In contrast, villus width and enterocyte height were significantly increased in the DMM groups relative to the CTRL groups, whereas the number of villi was reduced between these treatments. Furthermore, fish fed the FFMM diet had lower villi density than fish fed the CTRL diet.

(Continued on next page)

Conclusion

Overall, defatted mealworm meal (DMM) increased the villus width and enterocyte height in the anterior intestine and enhanced lipase and trypsin activity compared to fishmeal-based control (CTRL). Despite these morphometric differences, both DMM and FFMM showed a similar impact on intestinal antioxidant activity and redox status. These results suggest that while defatted mealworm meal may be a more suitable direct replacement for fishmeal, the use of full-fat mealworm meal could be considered a viable alternative to reduce the reliance on added vegetable oils in sustainable feed formulations.

*E-mail: damaral@ciimar.up.pt

Introduction

Yellow mealworm (*Tenebrio molitor*) is a prominent sustainable alternative to fishmeal in aquafeeds. However, replacing fishmeal can compromise thermal stress resistance if formulation lack essential nutrients critical for antioxidant defence and membrane integrity [1]. This is particularly relevant for insect meals, which often lack long-chain n-3 polyunsaturated fatty acids [2]. In contrast, mealworm-derived immunostimulants and bioactive compounds can potentially modulate fish immune and oxidative status [3].

This study aimed to characterize the comparative effects of full-fat (ffTM) and defatted (dTM) mealworm meal on the physiological, immunological and inflammatory status of rainbow trout (*Oncorhynchus mykiss*) subjected to a 15-day progressive thermal stress challenge.

Materials and methods

A single batch of mealworm larvae was either subjected or not subjected to a thermos-mechanical defatting process, resulting in two distinct mealworm meals (TM): a full-fat mealworm meal (ffTM, crude protein: 51.9%, crude lipids: 32.8%) and a defatted mealworm meal (dTM, crude protein: 66.7%, crude lipids: 12.9%). Three isoproteic (45%) and isolipidic (22%) experimental diets were formulated for juvenile rainbow trout. A control diet (CTRL) was formulated to mimic the composition of a conventional commercial trout diet. Two other diets were formulated based on the CTRL diet, but incorporated 25% of the full-fat and defatted MMs, totally replacing fishmeal (FFMM and DMM diets). All diets included 11.5% of fish oil (dry matter basis), and rapeseed oil was adjusted to maintain consistent lipid levels across all formulations. The diets were tested in triplicate during an initial 8-week growth trial under optimal rearing conditions. Following this, nine homogeneous groups of 7 fish each (159 ± 15 g) were assigned to 120L fiberglass tanks within a recirculating aquaculture system. The thermal challenge was initiated by raising the water temperature from 17 °C to 23 °C over 7 days. During the subsequent 15-day challenge period. Fish were fed 2% of the initial biomass, twice daily, over a. In this 15-day period the temperature was raised in 5-days intervals until reaching 25 °C. At the end of the challenge blood was sampled to isolate the plasma for the innate immune parameters analyses, livers were sampled for oxidative stress enzymatic and non-enzymatic indicators analyses and head-kidneys were sampled for inflammatory status markers expression.

Results

No mortalities or signs of disease were recorded during the thermal trial, and fish showed a mean 30% weight increase. The haemoglobin (Hb), mean corpuscular haemoglobin (MCH), mean corpuscular haemoglobin concentration (MCHC), mean corpuscular volume (MCV) and red blood cell count showed no significant differences between experimental diets. In contrast, haematocrit levels were significantly higher in the CTRL and FFMM groups relatively to the DMM groups. Furthermore, fish fed the FFMM diet also showed higher white blood cell counts (WBC) than fish fed the DMM diet. No significant difference between experimental treatments was observed on glucose and lactate levels, nor on the lysozyme, protease and anti-protease activities. However, fish fed the DMM diet showed a significantly higher peroxidase activity than fish fed the FFMM diet. No significant dietary impact was observed on the hepatic activities of catalase (CAT), glutathione peroxidase (GPx), glutathione reductase (GR), glutathione S-transferase (GST) total glutathione (TG) and lipid peroxidation (LPO) levels. In contrast, the fish groups fed the DMM diet showed significantly higher reduced glutathione (GSH) levels than fish groups fed the CTRL diet, and significantly lower oxidized glutathione (GSSG) levels than fish groups fed the FFMM diet. Ultimately leading to the DMM groups showing a hepatic reduced - oxidised glutathione ratio (GSH/GSSG ratio) significantly higher than the CTRL and FFMM groups. The expressions of *Hsp70*, *tnf- α* , *il-8*, *tgf- β* , and *Casp3* was not affected by dietary composition. In contrast, *il-1 β* was significantly upregulated in DMM group relative to CTRL.

(Continued on next page)

Conclusion

Under a 15-day thermal stress challenge, rainbow trout fed defatted mealworm meal (DMM) showed higher plasma peroxidase activity, hepatic GSH levels and redox status ((GSH/GSSG)). However, the upregulation of pro-inflammatory cytokines and reduced WBC in the DMM group suggest a complex physiological response. Both ffTM and dTM support high survivability and similar hepatic oxidative protection compared to fishmeal. While defatted mealworm meal (dTM) may offer specific antioxidant advantages, full-fat mealworm meal (ffTM) remains a viable alternative that reduces the requirement for supplementary vegetable oils without compromising the ability of rainbow trout to withstand thermal stress.

TEACHING AQUACULTURE IN PRACTICE – WITH THE ARC MODEL

Making aquaculture understandable and engaging for the next generation

I. Andersson Jupiter and F. Boström

Sweden
idajupiter1@gmail.com

This pre-study explores the potential for adapting the Irish educational concept The aquaculture remote classroom (The ARC) to a Swedish context. The ARC is a mobile classroom that, through experiential learning and interactive activities, introduces students to aquaculture, sustainable food production, and the blue economy.

Through study visits in Ireland, interviews with key stakeholders, and pilot implementations with Swedish students in grades 4 and 5, the concept's potential has been tested in a Swedish setting. The results show that students generally have limited knowledge of aquaculture, but that engagement increases rapidly when teaching is hands-on, concrete, and experience-based.

The study demonstrates that the concept has strong alignment with the Swedish primary school curriculum and considerable potential to increase interest in future food systems. At the same time, a clear national adaptation is required, focusing on local conditions, species, and career opportunities.

The presentation will highlight insights from the pilot work, provide concrete examples of teaching approaches, and discuss the opportunities and challenges of developing engaging learning environments focused on sustainable food production in Sweden.

One of the conclusions

The pilot study shows that there is a need to increase knowledge about aquaculture among young people. If Sweden is to develop future sustainable food production and strengthen skills supply within the blue economy, more students need to have the opportunity to engage with these issues early in their education. Strengthening awareness and understanding at an early stage is also important for building social license, as public acceptance and trust are crucial for the long-term development of aquaculture. A Swedish concept inspired by The ARC could form an important part of this effort.

DECISION SUPPORT TOOL FOR CLIMATE-INFORMED SEA LICE MANAGEMENT IN FAROESE SALMON AQUACULTURE – INITIAL MODEL DEVELOPMENT

Birgitta Andreasen^{1*}, Sissal Vágshéyg Erenbjerg¹, and Gunnvør á Norði¹

¹ Environment, Firum, Faroe Islands

*corresponding/presenting birgitta@firum.fo

Sea lice are currently the main obstacle to increasing production in marine salmon aquaculture across Europe. Treatments for sea lice are also one of the largest contributors to fish mortality and a major factor in the industry's carbon footprint. As ocean temperatures rise due to climate change, sea lice are expected to become an even greater challenge, with faster development rates, increased egg production, and higher infection pressure.

Current models used to guide sea lice management are helpful at the regional level but fall short when applied to individual farms. They are unable to accurately simulate future scenarios that involve changes in climate, farm locations, or production practices, limiting their practical use for producers.

Within the OCCAM project (<https://occamproject.eu/>), Case Study 3 seeks to address these challenges through the development of a Decision support tool (DST) for sea lice management. This tool combines a sea lice population model, already used by the Faroese salmon industry, with a hydrodynamic particle tracking system (FarCoast + LADiM) that will be further integrated into climate models. This enables realistic simulations of how lice larvae move and develop under changing environmental conditions.

The Faroe Islands provide an ideal test case due to the limited number of farms and consistent third-party sea lice data, allowing for accurate model validation.

With this DST, salmon farmers will be able to optimise operations by evaluating farm location, stocking density, production cycle length, and timing—all while accounting for environmental change. In parallel, the tool will support policymakers in setting more effective sea lice thresholds and improving marine spatial planning. This solution offers a practical, science-based approach to controlling sea lice sustainably in a warming world.

The initial model development and our first prototype will be presented.

COMPARATIVE TRANSCRIPTOMIC ANALYSIS OF FAST- AND SLOW-GROWING *Sparus aurata* IDENTIFIES CANDIDATE GROWTH BIOMARKERS

Introduction

The rapid development of aquaculture has positioned it as a vital component of global food systems. Within the Mediterranean basin, gilthead seabream (*Sparus aurata*) has emerged as a dominant cultured species, reflecting both its commercial importance and adaptability to farming conditions. However, growth variability in gilthead seabream still represents a major challenge for Mediterranean aquaculture, as individuals raised under identical conditions often show large differences in growth rate. This stems from multiple factors, including genetic diversity, where inherent differences in genetic growth potential lead to unequal growth rates. Environmental factors, such as water quality and temperature fluctuations further exacerbate these differences, often favoring certain individuals while suppressing others. This inconsistency reduces overall production efficiency by making synchronized harvesting difficult, as fish reach market size at different times. To address these challenges, in most aquaculture companies periodic grading is commonly practiced, where fish are physically separated based on their size to reduce competition and ensure uniform growth within groups. This method offers a practical short-term solution for managing size variation, but it is still labor-intensive and does not address the underlying molecular factors that influence growth. Moreover, conventional gene expression analyses target only a limited group of candidate genes which may not fully capture the genetic landscape regulating growth.

Materials and Methods

Two independent trials were conducted at EPPO/IPMA facilities, where growth differences were identified at initial sampling with mean weights of 14.0 ± 1.8 g (trial 1) and 14.5 ± 2.6 g (trial 2). Then fish were sorted into slow- and fast-growing based on the average batch weight, with density maintained across all tanks. Fish were maintained at a flow-through system and fed a commercial diet, three times per day, until apparent satiety. Trial 1 lasted 100 summer days, while Trial 2 extended for 284 winter days, reflecting seasonal variations. In the final sampling, liver and intestine (in trial 1 and 2) and muscle (only in trial 2) samples were collected from six fish per condition (fast vs slow) for differential gene expression (DGEs) analysis. Total RNA was extracted with a TRIzol GTM reagent, under manufactures instructions, quantified and quality verified by gel electrophoresis before sending for library construction and mRNA sequencing (Novogene Co., Ltd). To select growth biomarkers in liver and intestine, the DEGs in both trials were compared and only the genes differentially expressed in both trials were selected as hits for validation through RT-qPCR. To select growth biomarkers in muscle, the top 5 up- and down DGEs were selected as hits using data only from trial 2.

Results and Discussion

Results show that fast-growing fish outperformed slow-growing ones, demonstrating better growth potential and physiological performance with mean weights in trial 1 of 139 ± 17 g and 194 ± 16 g and trial 2 of 216 ± 54 g and 591 ± 22 g, for slow and fast-growing, respectively. The combination of both trials' biomarkers selection revealed 11 up (including *cacna1d*, *ccbe1* and *hamp*) and 4 down-regulated genes (including *efna2* and *trim21*) in liver and 1 up (*samd9*) and 2 down-regulated genes (*dhrs12* and *irgc*) in intestine, when comparing fast- with slow-growing fish. The top 5 up-regulated genes in muscle were *tmprss9*, *ctxn3*, *nlrp12*, *dpy30* and *znf608*, and top 5 down-regulated genes were *mfap4*, *dhys*, *mdn1*, *lgals3* and *gpr12*. RT-qPCR validation of some genes confirmed the differential expression between fast- and slow-growing fish, concordant with RNA-seq results. These genes play diverse yet interconnected roles in growth regulation, metabolism, immunity, and muscle function. Their differential expression between fast- and slow-growing fish suggests that they could serve as potential biomarkers for growth profiles in *Sparus aurata*. Differential KEGG pathway enrichment analysis between fast-growing and slow-growing fish revealed tissue-specific metabolic reprogramming associated with growth rate. For liver and intestine, only the pathways that are significant in both trials were analyzed, and in muscle all significant ones. In the liver, fast-growing fish showed significant down-regulation of pathways involved in oxidative phosphorylation, potentially indicating a reduced reliance on hepatic mitochondrial ATP production, and cardiac muscle contraction pathway that reflect a systemic metabolic prioritization away from energetically costly maintenance processes. No up-regulated pathways were observed. In intestine, fast-growing fish showed down-regulation of two metabolic pathways, carbon metabolism and biosynthesis of amino acids. This pattern suggests a reduction in endogenous metabolic

(Continued on next page)

processing and amino acid synthesis within the intestinal tissue, potentially reflecting a reliance on dietary nutrient uptake and a more efficient utilization of absorbed nutrients to support rapid growth. In muscle, fast-growing fish exhibited a mixed but overall, metabolically enhanced pathway profile. Several central energy and metabolic pathways were up-regulated, including oxidative phosphorylation, the citrate cycle (TCA cycle), carbon metabolism, peroxisome activity, drug metabolism – cytochrome P450, mitophagy animal, and valine, leucine and isoleucine degradation. Together, these changes indicate increased mitochondrial activity, enhanced energy production, and active cellular remodeling to meet the high energetic demands of fast growth. In contrast, the ribosome pathway was downregulated in muscle of fast-growing fish, suggesting a potential reduction in protein synthesis capacity or a shift toward more selective and efficient translational processes during rapid growth. This coordinated inter-tissue regulation likely enhances energy efficiency, supporting rapid somatic growth.

These results reveal distinct molecular signatures associated with growth capacity in gilthead seabream and that the use of RNA-seq proved to be effective for identifying genes and regulatory networks directly related to growth performance. Future work includes expanding validation efforts and conducting additional trials to further test the predictive value of these biomarkers in a real-life setting.

Introduction

Aquaculture has become an essential sector for meeting the growing global demand for high-quality protein, with species such as European seabass playing a key role in Mediterranean production. Despite advances in rearing, fish are particularly vulnerable to physiological stress, disease and routine husbandry practices, such as transportation from hatcheries to nursery facilities or exposure to bacterial and parasitic pathogens, that can result in high mortality and significant economic losses.

Nutritional strategies that enhance resilience during these challenges are therefore of great interest for the industry. Diets enriched with bioactive peptides have the potential to support the immune system, improve stress tolerance, promote growth and survival, making them promising tools for increasing the robustness and productivity of juvenile European seabass. This study investigates the effects of a diet containing bioactive peptides on European seabass juvenile performance under commercial farming conditions after a stress event, through the expression of stress-related genes.

Materials and Methods

The trial was conducted at EPPO/IPMA (Olhão, Portugal) to assess the effect of bioactive peptides on an experimental diet (FORT) and to benchmark them against a SPAROS commercial diet (CTL) on European seabass juveniles. Fish were subjected to transportation (~48h) from a hatchery in Italy to EPPO facilities, where they were reared in duplicate 3m³ outdoor tanks, natural photoperiod, flow-through system with 200% renovation per hour and fed each diet (CTL vs FORT) three times per day *ad libitum*. Fish average weight was 5.3 ± 0.6 g (Day 0), and they were reared until day 45 with sample collection at day 0, 7, 14 and 45. Liver from 8 fish were sampled at day 0 (after arrival/transportation stress) and at day 7 (one week after the stress event).

After this, fish were subjected to an infection challenge with *Photobacterium damsela* subsp. *piscicida* (via intraperitoneal injection). The challenge was performed in triplicate in 30L tanks. A control group that was injected with only Phosphate Buffer Saline (PBS) was added to analyze the effects of the injection itself. Liver samples were collected 24h after the stress. Water quality parameters were kept within optimal ranges for the species, and routine husbandry ensured stable rearing conditions throughout the trial. Mortality was observed until 14 days after challenge.

Relative gene expression of *hsp90*, *nrf2*, *gr1*, *fosl1* *prdx5*, and *cat* was calculated using the efficiency-corrected mathematical model described by Pfaffl. *Prdx5*, *cat* and *gr1* are key enzymatic components of the antioxidant defense system, *nrf2* is a transcription factor that induces these antioxidant genes, *hsp90* is a molecular chaperone that promotes protein folding, stabilization, and protection against cellular stress and *fosl1* an immediate early transcription factor that regulates stress, inflammatory, and cell survival responses through the AP-1 signaling pathway. Expression levels of target genes were normalized against the geometric mean of the reference genes *ef1a* and *rps18*.

Results and Discussion

The results showed that the experimental diet did not affect growth between dietary treatments (CTL vs FORT). Regarding the bacterial infection, fish mortality occurred between days 3 and 7 post-infection, from both dietary conditions, which is the predicted timeline for bacterial infection. Cumulative mortality after challenge was significantly higher on FORT (~28% mortality) when compared to CTL (approximately 15%; *p*-value < 0.05) and both treatments had higher mortality than PBS treatment (100% survival), suggesting that this dietary formulation did not provide a protective effect against bacterial infection.

(Continued on next page)

Immediately after transport (Day 0), juvenile seabass exhibits an acute stress response, with *fosl1* showing high expression (<0.05) when compared with day 7, indicating that fish were in stress after the transport and recovered after 7 days, as evidenced by the expression of this gene as stress marker. Antioxidant defense genes *gr1*, *cat* and *nrf2* were down-regulated on day 0 when compared to day 7 (p -value <0.05), suggesting a temporary suppression of antioxidant gene transcription during the transport, followed by an up-regulation during recovery. *Prdx5* and *hsp90* expression was not affected.

After the bacterial challenge, gene expression patterns were similar to the effect after transportation, with *fosl1* up-regulation after the stress (injection + infection), suggesting a potential role turning on genes required for tissue remodeling, and structural healing, after stress, and antioxidant defense genes *prdx5*, *cat* and *gr1* being down-regulated after stress, reinforcing the pattern that pathogen challenge in European seabass suppresses oxidative stress gene transcription after a challenge, *hsp90* and *nrf2* expression remained not altered. In addition to the effects of the stressors, dietary treatment also influenced gene expression. Fish fed the FORT diet exhibited consistently lower *gr1* expression and higher *fosl1* expression than fish fed CTL, both before and after bacterial challenge. Considering the higher mortality in FORT diet, these results may suggest that the fish had a reduced capacity to maintain redox homeostasis and suffered a stronger stress response.

Overall, *fosl1* proved to be a reliable marker of acute stress in juvenile European seabass, whereas antioxidant gene expression was down-regulated after the stressors. While the bioactive peptide-rich diet altered the expression of genes involved in redox homeostasis and stress responses, the effects were not associated with improved disease resistance, demanding further investigation into the mechanisms underlying its impact on fish health and survival.

Introduction

European seabass (*Dicentrarchus labrax*) is one of the most produced species in aquaculture production, mainly in Mediterranean production. Despite advances in hatchery technologies, the larval and post-larval stages remain critical bottlenecks due to their sensitivity to nutritional imbalances, environmental fluctuations, handling stress and particularly during the transition from live prey to inert diets.

Early weaning strategies can reduce dependence on live feeds, but their success depends on the nutritional quality and physical properties of the diets, where advances in feed technology - such as fluidized bed agglomeration - enable the production of stable microdiets with improved nutrient availability that are essential for optimal larval development. In parallel, the use of protein hydrolysates from alternative sources (e.g. wheat and whey) has gained attention for their potential to enhance digestibility, growth, and may also improve resistance to handling stress. This study investigates the effects of early weaning using experimental inert diets on European seabass larvae performance alongside the expression of growth- and stress-related genes.

Materials and Methods

The trial was conducted at EPPO/IPMA (Olhão, Portugal) to assess the effect of early weaning using experimental inert microdiets produced by fluidized bed agglomeration technology containing different hydrolysates, and to benchmark them against a control diet. Three diets were tested: Sparos control diet (CTL), a wheat hydrolysate diet (Wheat) and a diet with whey protein sources (Whey).

Fish were reared in triplicate 300-L cylindroconical tanks under controlled zootechnical conditions and fed *ad libitum* with experimental diets under different conditions. Fish were fed from 11 to 50 days after hatching (DAH), and samples were collected at 12, 22, 30, 40 and 50DAH for analysis.

Water quality parameters were kept within optimal ranges for the species, and routine husbandry ensured stable rearing conditions throughout the trial.

Relative gene expression of growth-related genes (*gh*, *myog*, *igf1*, *pparA* and *tgfB*) and stress-related genes (*cat*, *hsp70* and *sod*) was calculated using the Pfaffl method. Expression levels of target genes were normalized against the geometric mean of the reference genes *fau* and *l13*.

Results and Discussion

The results showed that modifications applied during feed production did not negatively affect the growth performance or physiological status of European seabass larvae. Survival and dry weight (22, 30, 40 and 50 DAH) had no significant differences among treatments throughout the trial.

At the molecular level, most of the analyzed genes involved in growth regulation, including *myog*, *igf1*, *pparA* and *tgfB*, were not significantly affected by dietary treatment. *myog* plays a central role in muscle differentiation, *igf1* is involved in somatic growth and protein synthesis, *pparA* regulates lipid metabolism and energy utilization, and *tgfB* participates in tissue growth and cellular differentiation. The stable expression of these genes suggests that the dietary modifications did not substantially alter the molecular pathways controlling these genes, supporting the zootechnical results. Still, a significantly higher expression of *gh* was observed in CTL (*p*-value < 0.05) in comparison with all experimental diets, suggesting an increase in endocrine growth transcript that was not accompanied by differences in *igf1* expression or by improvements in larval growth. One possible explanation is that the *gh* increase may reflect a physiological regulation or a compensatory endocrine response to subtle metabolic differences among diets rather than actual differences in growth performance.

(Continued on next page)

Regarding stress-related genes, the expression of *cat*, *hsp70* and *sod* was not influenced by dietary treatment. These genes are commonly used as indicators of oxidative stress and cellular stress responses, with *cat* and *sod* acting as antioxidant enzymes, while *hsp70* is involved in protecting cells from environmental and physiological stress. Their stable expression suggests that the experimental diets did not induce oxidative damage or cellular stress, indicating that the feed processing modifications did not compromise larval welfare or physiological homeostasis. This results further supports the comparable survival and growth observed among treatments.

Overall, the present study demonstrates that the evaluated feed production modifications did not negatively affect the development or physiological status of European seabass larvae and can be applied. The absence of significant differences in survival, growth performance, and the expression of most growth- and stress-related genes indicates that the nutritional quality and functionality of the experimental diets were maintained despite the production changes. These findings support the feasibility of implementing the evaluated feed production modifications in larval aquaculture without compromising larval performance or welfare. Future studies should investigate whether these results are maintained over longer rearing periods and later developmental stages.

Introduction

The increasing growth of the aquaculture industry generates large volumes of organic side streams, creating a need for sustainable strategies that promote nutrient recovery and circular resource use (Turchini et al., 2019, Wang and Olsen, 2023). Fish sludge and dead-fish silage represent nutrient-rich by-products from Atlantic salmon (*Salmo salar*) production that could be valorized through bioconversion by extractive low-trophic organisms. The ragworm *Hediste diversicolor* is a promising candidate for this purpose because of its ability to utilize organic waste substrates and convert them into biomass containing valuable proteins and lipids for aquafeed production (Wang et al., 2019b, Anglade et al., 2023). This study investigated the suitability of two dead-fish silage protein concentrates as feed sources for *H. diversicolor* and compared their performance with fish sludge, a substrate already considered relevant for polychaete production.

Material and methods

A 137-day feeding trial was conducted using three dietary treatments: fish sludge (Sludge), Category 2-derived dead-fish silage (K2) from salmon that died before slaughter (not approved as a feed ingredient), and Category 3-derived dead-fish silage (K3) from salmon slaughter by-products (approved as a feed ingredient). Twelve tanks were used in total, with four replicate tanks assigned to each treatment. The dietary effects on polychaete performance were evaluated by measuring survival and growth. Additionally, diet samples and polychaete biomass were analyzed for total organic matter, elemental composition, amino acid composition, lipid content, and fatty acid composition. In addition, selected contaminants were measured to assess the potential risks of horizontal transfer.

Results and discussion

All diets successfully supported the survival of *H. diversicolor*, with no significant differences observed among treatments. In contrast, growth varied considerably between diets. Polychaetes fed K2 and Sludge exhibited significantly higher final dry weights and specific growth rates (one-way ANOVA, $p < 0.05$) than those fed K3. Although K3 contained the highest levels of dry matter and nitrogen, these characteristics did not result in higher growth, suggesting that nutrient concentration alone was not a reliable predictor of feed performance. Differences in feed texture, availability, acceptance, and actual feed intake may have played an important role in determining growth outcomes.

Diet composition also influenced the nutritional quality of the produced biomass. Polychaetes fed K2 contained the highest total amino acid concentration (one-way ANOVA, $p < 0.05$), suggesting efficient protein deposition. In contrast, Sludge-fed polychaetes showed the highest total lipid content. Significant differences were also observed in fatty acid composition. Biomass produced on K2 and K3 generally contained higher relative proportions of polyunsaturated fatty acids (PUFAs) and n-3 fatty acids than biomass produced on Sludge (one-way ANOVA, $p < 0.05$). Notably, Polychaetes fed K3 exhibited the highest relative DHA content and DHA:EPA ratio, despite their comparatively poor growth performance. These findings highlight a potential trade-off between biomass production and nutritional quality depending on the feed substrate used.

The contaminant analyses provided valuable preliminary insight into feed safety but were insufficient for a comprehensive assessment. Total arsenic concentrations were higher in polychaetes fed K2 and K3 compared with those fed Sludge (one-way ANOVA, $p < 0.05$). However, the absence of data on inorganic arsenic, dioxins, and polychlorinated biphenyls (PCBs) prevented a complete evaluation of potential health and regulatory risks. The results of these analyses are still pending.

Overall, the results demonstrate that both fish sludge and dead-fish silage can serve as suitable substrates for the production of *H. diversicolor* biomass, supporting the conversion of aquaculture side streams into nutritionally valuable resources. Among the tested diets, K2 showed the greatest potential by combining strong growth performance with a favorable amino acid profile. Further research should focus on optimizing feeding strategies, quantifying feed intake and digestibility, and conducting more comprehensive contaminant analyses to evaluate the feasibility of large-scale implementation.

Introduction

Microalgae are the primary feed source for bivalves throughout their life cycle and remain indispensable for hatchery production (1). However, conventional microalgae production requires a high demand for freshwater, nutrients and energy inputs, contributing substantially to hatcheries' production costs (2). Therefore, more sustainable production systems are needed to ensure a reliable biomass supply. Cultivating microalgae using wastewater, namely agricultural drainwater (excess runoff and percolate discharged from irrigated crop fields), represents a relevant circular bioeconomy approach, enabling nutrient recovery while reducing the need for freshwater (3). Additionally, applying biorefinery processing to this microalgae biomass enables the recovery of microalgal fractions for multiple applications and promotes compound availability, enabling its use as feed ingredients (4). However, information regarding the safety and efficacy of these ingredients for bivalve nutrition remains limited. Therefore, this study evaluated the efficacy of whole microalgal biomass and biorefinery-derived fractions of single- and mixed-species produced in agricultural drainwater as feed ingredients for juvenile *Ruditapes decussatus*.

Material and Methods

Five feeds were formulated for juvenile clams of *Ruditapes decussatus*. The control feed consisted of a pilot microalgae-based formulation for juvenile bivalves (CTRL). Four additional diets were obtained by partially replacing ingredients from the control formulation with microalgae cultivated in agricultural drainwater, either as whole-cell biomass or as biorefinery-derived insoluble fractions (retentate). These experimental formulations included whole cells of *Chlorella* sp. (ChC), *Tetrademus obliquus* retentate (TetR), *Chlorella* sp. retentate (ChR), and a mixed retentate from *Chlorella* sp. and *T. obliquus* (MixR). The biochemical composition (protein, lipid and ash content in % of dry weight) of all diets was determined and is presented as the mean of duplicate analytical runs. Juvenile clams were reared under controlled hatchery conditions for 55 days, with the five dietary treatments using three replicate tanks per treatment. Feeding was performed twice a day. Growth was monitored over time using biometric parameters, such as shell morphometrics (shell length, width and area; fortnightly) and biomass parameters (total wet weight; weekly).

Figure 1 – Individual total fresh weight (g) and shell length (mm) of *Ruditapes decussatus* juveniles over the 55-day feeding trial (DAH). CTRL – control diet; ChC - *Chlorella* sp. biomass; TetR - *Tetrademus* sp. retentate; ChR - *Chlorella* sp. retentate; MixR - mixed *Chlorella* sp. and *Tetrademus* sp. retentate.

(Continued on next page)

Results and Discussion

Biochemical composition across the five formulations revealed that crude protein content ranged from 20.2% to 26.9%, lipid from 13.7% to 17.6%, and ash from 6.2% to 6.9%. Protein values showed high variability between replicates; therefore, no differences were observed between formulations. The MixR feed presented the highest lipid content (17.6%) compared to all other formulations, which ranged between 13.7% and 15.3%. The highest ash content was observed for the CTRL (6.9%) compared to all other formulations, which ranged between 6.2% and 6.5%. Regarding the feeding trial, all diets successfully supported juvenile growth throughout the 55-day feeding trial. From day 28 onwards, clams fed with the MixR began to present higher individual total wet weight and shell length than the remaining dietary treatments (Figure 1). In contrast, growth of juveniles fed ChC and TetR remained comparable to the CTRL feed, while ChR presented the lowest values at the end of the trial. These observations suggest that combining fractions from different microalgal species may provide additional nutritional benefits compared to single-species fractions. The present results indicate that whole microalgal cells and their biorefinery-derived fractions produced in drainwater can be safely incorporated into juvenile clam diets without compromising performance. This study provides one of the first evaluations of whole microalgal cells and biorefinery-derived fractions produced in agricultural drainwater for juvenile bivalve nutrition, supporting the integration of wastewater valorisation, microalgae biorefinery and bivalve nutrition within a circular production approach.

INTEGRATING DUCKWEED INTO INTENSIVE CATFISH CULTURE THROUGH CLOSED-LOOP WATER RECYCLING

Samuel Appelbaum

¹ French Associates Institute
Jacob Blaustein Institutes for Desert Research
Ben-Gurion University of the Negev
Sede Boqer 8499000, Israel

The African catfish (*Clarias gariepinus*) is exceptionally well suited to highly intensive inland aquaculture due to its rapid growth, efficient feed conversion, robustness, tolerance of high stocking densities, and facultative air-breathing capacity. These characteristics make it particularly suitable for compact RAS and tank-based systems, enabling high production efficiency with low water requirements. Moreover, *C. gariepinus* can be readily reproduced under indoor conditions, allowing efficient rearing from newly hatched larvae to fingerlings.

Intensive catfish production, however, generates water containing suspended solids and dissolved nutrients, particularly nitrogen and phosphorus. Although RAS substantially reduce water consumption, efficient recovery of dissolved nutrients remains a challenge.

Duckweed, particularly *Lemna* species, grows rapidly in nutrient-rich water and assimilates dissolved nutrients into protein-rich biomass. Under favourable conditions, duckweed can produce 15-30 g dry matter/m² every 1–2 days.

We propose an integrated system combining indoor RAS, outdoor catfish tanks, and duckweed cultivation within a single closed-loop water-recycling system. Water from both fish-production units passes through mechanical filtration before entering shallow duckweed ponds, where dissolved nutrients are assimilated during rapid plant growth. The treated water is subsequently returned to the fish units.

Harvested duckweed is washed, dried, and milled for incorporation into feeds for catfish larvae and fingerlings. Its protein-rich biomass may also provide essential amino acids, vitamins, minerals, and carotenoids.

This approach aims to enhance water reuse, recover nutrients, and produce a local feed supplement, supporting circular and resource-efficient catfish production.

TAURINE SUPPLEMENTATION SUPPORTS IMMUNE AND METABOLIC RESILIENCE TO THERMAL STRESS IN SENEGALESE SOLE *Solea senegalensis* FED PLANT-BASED DIETS

Introduction

The reduction in the use of marine ingredients in aquafeeds raises concerns regarding the supply of key functional nutrients, such as taurine. This is particularly relevant as plant-derived ingredients, commonly used in fish diet formulations, are virtually devoid of taurine. Taurine plays key roles in osmoregulation, antioxidant defence and immune function, and its deficiency may compromise fish resilience to environmental stressors. Thermal stress is a relevant challenge under climate change scenarios, yet the interaction between taurine nutrition and stress response remains poorly understood. This study evaluated whether taurine supplementation modulates physiological, immune and metabolic responses to thermal stress in Senegalese sole (*Solea senegalensis*) fed plant-based diets.

Material and Methods

Three isonitrogenous and isolipidic diets (59% crude protein and 8% crude fat, dry matter basis) were formulated using practical ingredients. A control diet (CTRL) contained 69% marine ingredients, while in the PLANT diet marine ingredients were reduced to 11%. The PLANTTAU diet was the PLANT formulation supplemented with 1% taurine.

Senegalese sole juveniles (41 ± 1 g) were distributed into 18 tanks in a recirculating aquaculture system and maintained at 19.7 ± 0.5 °C during a four-week conditioning period. Fish were then sampled after 24 h fasting ($n = 3$ tanks per diet). The remaining fish were subjected to a thermal challenge by increasing water temperature by 5 °C for 12 days, followed by a second sampling.

Growth performance, hepatosomatic index (HSI), plasma stress indicators, innate immune parameters and hepatic free amino acids, including metabolites related to methionine metabolism, were analysed.

Results and Discussion

Growth performance and plasma cortisol and glucose were not affected by diet or thermal challenge. However, thermal stress modulated innate immunity, decreasing lysozyme and antiprotease activities while increasing nitric oxide levels.

A significant diet $\times$ stress interaction was observed for peroxidase activity. Post-stress peroxidase activity was highest in CTRL fish, while PLANTTAU reached comparable values, unlike the unsupplemented PLANT diet. This suggests that taurine supplementation supported the maintenance of innate oxidative immune response under thermal stress.

HSI decreased after thermal challenge, suggesting mobilisation of hepatic reserves. Hepatic free amino acid profiles showed marked diet- and stress-dependent changes. The PLANT diet strongly depleted hepatic taurine, whereas supplementation restored taurine levels close to CTRL before stress. Thermal challenge reduced hepatic taurine in CTRL and PLANTTAU fish, suggesting increased taurine utilisation under stress.

Beyond taurine, methionine-related metabolism was also modulated by diet and stress. Hepatic methionine decreased after thermal challenge in all dietary groups, suggesting increased utilisation under stress. CTRL fish showed the highest pre-stress methionine levels and, after stress, a marked increase in homocysteine, cystathionine and cysteine, indicating activation of the methionine–transsulfuration pathway. By contrast, PLANT fish showed lower methionine availability and consistently low homocysteine levels, while cystathionine and cysteine increased after stress. In PLANTTAU fish, methionine was also reduced after stress, but cystathionine and cysteine remained stable, suggesting that taurine supplementation altered the stress-induced adjustment of sulphur amino acid metabolism rather than restoring a CTRL-like profile.

(Continued on next page)

Diet-dependent responses were also observed for amino acids linked to nitrogen metabolism and redox balance. Glutamine decreased after stress in CTRL, increased in PLANT and remained stable in PLANTTAU. Glycine increased after stress in CTRL and PLANTTAU, whereas it decreased in PLANT. Together, these results suggest that taurine supplementation did not simply restore the overall hepatic amino acid profile of CTRL fish, but contributed to stabilising selected metabolic pools under thermal stress.

Conclusion

Taurine supplementation in plant-based diets for Senegalese sole did not affect growth but modulated selected immune and metabolic responses to thermal stress. While hepatic taurine levels were restored, broader sulphur amino acid metabolism was not fully normalised. Taurine supplementation stabilised specific metabolites and supported post-stress peroxidase activity, highlighting its role in promoting resilience under challenging conditions.

Background

Nature-based solutions (NbS) can be classified according to how much humans intervene and alter ecosystems. These classifications are useful for terrestrial, coastal, and marine environments and aim to balance biodiversity protection, climate change mitigation, and social-ecological advantages. Low trophic aquaculture, such as bivalve aquaculture, is considered a sustainable aquaculture practice that helps maintain biodiversity and supports ecosystem services like food security, may fall under Type-3 NbS (Ghaedi et al., 2026). However, the extent to which systems like bivalve aquaculture boost or sustain biodiversity is not well understood or quantified, and the trade-offs between risks and benefits are still uncertain.

Methodology and aims

The primary objective of this research conducted in EU-funded TRANSEATION project is to evaluate the beneficial impacts of low trophic bivalve aquaculture as NbS on biodiversity in mussel production operations utilizing longline and raft infrastructures, while also considering possible adverse effects on ecosystems. Forty ropes measuring six meters each, seeded with mussels of 4-5 cm shell length (at a density of 400-600 individuals per rope linear meter), were deployed within longline and raft setups located in offshore and port environments, respectively. The study investigates biodiversity changes linked to longline and raft aquaculture by incorporating multi-method observations at multiple stages: before, during, and after production cycles. This methodology integrates both water column and benthic habitat assessments through diverse and complementary techniques. Acoustic data were obtained via an innovative triple-frequency acoustic buoy installed on both the longline system and mussel raft, permitting ongoing monitoring of the water column throughout 1-year cultivation period. These acoustic findings are augmented by detailed image analysis and direct sampling of the benthic habitat, furnishing a holistic understanding of biodiversity dynamics within ecosystem compartments. A comprehensive rating system integrating these datasets was developed to appraise the ecological effectiveness of these infrastructures as NbS, taking into account the temporal and spatial dimensions of mussel production.

Figure 1. Fish abundance temporal and depth variations associated to mussel longline and raft culture areas. The study demonstrates a scalable methodology for assessing ecological impacts and benefits of aquaculture practices, supporting more sustainable management and improved evaluation of NbS performance in marine systems.

(Continued on next page)

This analysis aims to identify opportunities for expanding bivalve aquaculture by leveraging its environmental benefits—such as supporting biodiversity conservation—as NbS, while considering both the challenges and advantages involved in promoting sustainable aquaculture practices.

Results and conclusions

Preliminary findings indicate marked seasonal fluctuations in acoustic fish abundance at both aquaculture sites, with consistently greater values observed at the raft compared to the longline system (Figure 1). At the longline location, fish abundance reached its highest levels during autumn and spring and showed reductions in winter and summer. The shorter time series at the raft site similarly demonstrated seasonal variation, notably a distinct decline during the onset of cultivation and peak abundance in summer. Initiation of farming corresponded with significant alterations in vertical distribution: at the longline, maximum abundances transitioned from deeper strata prior to cultivation to surface layers during both daytime and nighttime post-cultivation; at the shallower raft site, changes were primarily apparent during daylight hours, with substantial decreases in bottom-layer abundances following the commencement of farming activities (Figure 1). Benthic surveys were undertaken within the culture areas, and benthos samples together with ROV imagery are currently being processed for taxonomic assessment of the benthic communities. Final results from this study are anticipated to be available in July 2026.

*corresponding/presenting joao.araujo@ipma.pt

Introduction and methods

Sea urchin aquaculture, particularly *Paracentrotus lividus*, is gaining increasing interest due to the high market value of its gonads and the need to reduce fishing pressure on wild populations. At the same time, the invasive seaweed *Rugulopteryx okamurae* has become an ecological and economic concern along the Portuguese coast, affecting biodiversity, fisheries and tourism (Boesiger, 2024). However, its high biomass availability may represent an opportunity for valorization within a circular blue economy framework. This study evaluated the use of *R. okamurae* as a feed source for *P. lividus*, either as a dried macroalgal diet or incorporated into formulated feeds. Four diets were tested: dried *Ulva* sp., dried *R. okamurae*, a formulated diet containing 20% *Ulva* sp., and a formulated diet containing 10% *Ulva* sp. + 10% *R. okamurae*. *Ulva* biomass was produced at IPMA facilities and solar-dried in greenhouse trays, while *R. okamurae* was harvested and dried by Easy Harvest Lda. Formulated diets were produced by Sparos I&D using a previously validated formulation for *P. lividus* (Araújo et al., 2023). The trial lasted 139 days and was conducted in open-circuit systems under natural environmental conditions, monitored on a daily basis. Diet effects were assessed in juveniles through survival, feed conversion ratio and growth performance, and in pre-commercial sea urchins through gonadosomatic index (GSI) and gonad proximate composition. Sea urchins were fed every two days, with uneaten feed recorded before each feeding. Weight and test diameter were measured monthly. Differences among treatments were analyzed using one-way ANOVA or Kruskal–Wallis tests, followed by post-hoc comparisons.

Results and discussion

The results of this study demonstrate that the invasive macroalga *R. okamurae* can be incorporated into the diet of sea urchins (*P. lividus*), although its effectiveness is highly dependent on the mode of inclusion. Sea urchins fed exclusively with dried *R. okamurae* exhibited poor zootechnical performance, including weight loss, minimal test growth and a markedly reduced gonadosomatic index (GSI), indicating limited nutritional suitability as a sole feed source (see table1). These findings are consistent with the presence of secondary metabolites, such as diterpenes, which are known to reduce palatability and digestibility (Casal-Porras, 2021). Nevertheless, continuous ingestion and high survival rates (>94%)

Table 1: *Paracentrotus lividus* production parameter: Total Diameter Gain (TDG), Total Specific Growth Rate for Diameter (TSGRD), Feed Conversion Rate (FCR) and gonads proximal analysis

sea urchins production parameters	Diet	TDG (%)	TSGRD (% day ⁻¹)	FCR
	Dry <i>Ulva</i> spp.	9.01 ± 6.33 ^{ab}	0.06 ± 0.04 ^{ab}	11.17 ± 1.87 ^a
	Dry <i>R. okamurae</i>	0.97 ± 1.08 ^b	0.01 ± 0.01 ^b	n.a.
	<i>Ulva</i> -based Feed	13.27 ± 2.72 ^a	0.09 ± 0.02 ^a	6.5 ± 0.96 ^a
	Mix Feed	11 ± 2.88 ^a	0.07 ± 0.02 ^a	7.58 ± 0.98 ^a
Sea urchins gonads proximal analysis	Diet	Protein (% DM)	Fat (% DM)	Energy (MJ/kg DM)
	Dry <i>Ulva</i>	60.10 ± 4.38	10.11 ± 1.28	20.19 ± 0.53
	Dry <i>R. okamurae</i>	55.54	10.13	20.77
	Mix Feed	54.77 ± 5.77	13.29 ± 0.95	21.38 ± 0.68

(Continued on next page)

suggest the absence of acute toxic effects, highlighting the trophic plasticity of the species and its capacity to adapt to novel food sources. In contrast, the inclusion of *R. okamurai* in a formulated diet resulted in significantly improved performance, yielding the highest somatic growth and GSI values among treatments, surpassing both macroalgal and control feed diets. This indicates that processing and dietary balancing can mitigate the limitations associated with raw biomass, enhancing nutrient availability and feed efficiency. Proximate analysis of the gonads revealed that dietary treatments influenced their biochemical composition, reflecting differences in nutrient assimilation and allocation. In particular, formulated diets promoted a more favourable nutritional profile, consistent with enhanced gonadal development and improved production performance. Overall, the results support the potential valorization of *R. okamurai* as a functional ingredient in aquafeeds, contributing to circular economy strategies by transforming an abundant invasive species into a valuable resource. However, further research is required to optimize inclusion levels, assess long-term effects and evaluate the sensory attributes and market acceptance of the produced gonads, which remain critical for commercial application.

*corresponding/presenting garcangeli@izsvenezie.it

Introduction and Methods

The European flat oyster (*Ostrea edulis*) is a key species for sustainable aquaculture and restoration programmes in the Adriatic Sea. However, information on emerging pathogens affecting this species remains scarce. Within the Interreg Italy–Croatia MARINET project, a cross-border health surveillance programme was carried out to investigate the occurrence of listed and emerging pathogens in farmed *O. edulis* from Italy and Croatia. Oysters were collected between 2024 and 2026 from seven farming areas located along the Italian (Duino, Cattolica, Mattinata and Gallipoli) and Croatian (Lim Bay, Budava and Mali Ston Bay) coasts. Samples were examined using histology, cytology and duplex real-time polymerase chain reaction (PCR) assays for listed diseases (IFREMER). Specimens showing histological features compatible with *Perkinsus* infection were further analysed by end-point PCR (Casas *et al.*, 2002), sequencing and phylogenetic analysis to confirm species identity.

Results and Discussion

No infections with *Marteilia refringens* or *Bonamia ostreae* were detected in both Italian and Croatian farms. In contrast, *B. exitiosa* was detected exclusively in Italian oyster farms, with 11 positive oysters in Duino, one positive oyster in Mattinata and two positive oysters in Gallipoli, whereas all Croatian farming sites (Lim Bay, Budava and Mali Ston Bay) and Cattolica tested negative.

Perkinsus-like organisms were detected in oysters from all investigated areas, although prevalence varied among sites. Positive oysters were recorded in Duino (52/330), Cattolica (5/30), Mattinata (1/20), Gallipoli (6/20, increasing to 12/30 during a mortality event), Lim Bay (8/120), Budava (7/123) and Mali Ston Bay (3/65). Histological examination revealed multiple developmental stages in connective tissues of the visceral mass, mantle, gills, labial palps and gonads, frequently associated with haemocytic infiltration. Molecular characterization confirmed all analysed isolates as *Perkinsus mediterraneus*. In Italian sites, parasite occurrence appeared to be influenced by temperature, with higher prevalence observed at intermediate water temperatures (approximately 17 °C). Overall, infections occurred at low to moderate prevalence, suggesting an endemic distribution.

This study represents the first confirmed report of *P. mediterraneus* in the Adriatic Sea, extending the known geographical distribution of the parasite and highlighting the value of integrated histological and molecular surveillance for detecting emerging pathogens in *O. edulis*.

EVIDENCE FOR IMMUNE PRIMING AND CROSS-PROTECTION IN *Magallana gigas* AGAINST *Vibrio splendidus*

Noushin Arfatahery*

Freie Universität Berlin

Berlin, Germany

*Presenting author: arfa3133@gmail.com

Introduction

Bacterial pathogens of the genus *Vibrio* represent a major challenge in oyster aquaculture and are associated with substantial mortality events worldwide. Immune priming has emerged as a potential mechanism by which invertebrates can enhance protection following prior pathogen exposure. However, the specificity and breadth of such responses remain incompletely understood in oysters.

Materials and Methods

Pacific oysters (*Magallana gigas*) were exposed to sublethal doses of *Vibrio splendidus* strains differing in origin and virulence characteristics. Humoral immune responses were evaluated using cell-free haemolymph plasma and bacterial growth assays under controlled conditions.

Results and Discussion

Exposure to sublethal bacterial concentrations resulted in inhibitory effects during subsequent challenge conditions. Stronger responses were observed against sympatric strains, while partial cross-protection against allopatric strains was also detected. Differences between in vitro and in vivo observations suggest that humoral immune components may contribute substantially to immune priming effects.

Conclusion

Understanding immune priming mechanisms in oysters may provide insights for disease mitigation and sustainable aquaculture practices. These findings highlight the importance of host–pathogen interactions and may contribute to improved management strategies for shellfish production.

EFFECT OF ALTERNATIVE DIETS ON CAROTENOID CONTENT, COLOUR PARAMETERS AND BIOACCESSIBILITY IN SEA URCHIN *Paracentrotus lividus* GONADS

* nicola.arriu@unica.it

Introduction

The sea urchin *Paracentrotus lividus* is an echinoderm widely distributed along the coasts of the Mediterranean Sea and the eastern Atlantic Ocean, extending northward to Ireland. This species is harvested for its gonads (roe), which are highly valued as a seafood delicacy in many European cuisines. However, increasing demand for roe, combined with overfishing, climate change, and pollution, has led to a progressive decline in natural stocks over recent decades. In response, several countries, including Italy, have implemented management measures for sea urchin fisheries at both national and regional levels. In this context, the development of echinoculture represents a promising strategy to mitigate overexploitation through restocking initiatives, while also providing a sustainable supply of biomass for the market. To advance knowledge on diet formulation and its suitability for echinoculture - currently the main constraint limiting the development of this practice, this study investigates the effects of experimental feeding regimes. Specifically, the green algae *Ulva* spp. (class Ulvophyceae) was selected as the primary substrate due to its sustainability, low cost, and wide availability in many coastal lagoons (Addis et al., 2023). In addition, meal derived from the black soldier fly, *Hermetia illucens*, was included as an alternative protein source; insect-based meals have recently been authorized in Europe as feed ingredients in aquaculture (EPRS, 2024).

The aim of this study is to evaluate the effects of two experimental diets on gonadal growth and quality, assessed in terms of color, carotenoid profile, and bioaccessibility.

Material and Methods

Trials were carried out at the research facility GillaLab (University of Cagliari, [Home - GillaLab](#)). Sea urchins (n= 240) were fed with two experimental pellet diets 1) the green seaweed *Ulva* spp. (UL) and 2) *Ulva* spp. supplemented with *Hermetia illucens* meal (IN). These treatments were compared with control groups: sea urchins reared in land-based tanks and fed with fresh biomass (CT), wild sea urchins (SI), and sea urchins reared in open-sea cages (SS). Gonadal growth was assessed using the gonadosomatic index (GSI), while gonad color was measured using a CIELAB colorimetric system L^* =lightness, a^* =red/green and b^* = yellow/blue (Chroma meter CR-410, Konica Minolta Sensing, Inc., Tokyo, Japan). Carotenoid profiles were determined by chromatographic analysis and *in vitro* digestion (INFOGEST 2.0 protocol) was applied to assess carotenoid bioaccessibility (Brodkorb et al. 2019). The experiment lasted 30 days.

Figure 1. Colour model of gonad samples from the different experimental groups (CT, UL, IN, SS and SI). L^* , a^* , b^* values, as well as RGB and HEX codes, are reported.

Figure 2. Gonad-somatic index (GSI, %) of (CT, UL, IN, SS and SI). Data are expressed as mean $\pm$ standard deviation.

(Continued on next page)

Results and Discussion

The highest GSI values were observed in SS (7.42 ± 1.97) and IN (4.77 ± 1.65), followed by CT (3.91 ± 1.03), UL (3.04 ± 0.81), and SI (2.79 ± 0.84). The ΔE^*ab index represents the comprehensive color difference between two samples in the CIELAB color space. Color variation among gonad samples were determined with SS as the reference. Gonads from UL and IN groups showed color parameters comparable to wild specimens, with low chromatic differences ($\Delta E^*ab = 6.70$ and 7.20 , respectively), indicating acceptable visual quality. Carotenoid analysis revealed lutein, echinenone, and amauroxanthin as the main compounds, with significant variability among treatments. Higher lutein concentrations were found in the CT ($10.93 \pm 0.65 \mu\text{g/g}$) and SS ($8.29 \pm 0.38 \mu\text{g/g}$), while UL and IN, showed the lower levels (4.44 ± 0.28 and $4.07 \pm 0.24 \mu\text{g/g}$, respectively).

The INFOGEST 2.0 protocol highlighted how the bioaccessibility values (%) of IN sea urchin for lutein and echinenone were generally higher compared to those observed in UL and CT.

Overall, although experimental diets resulted in lower carotenoid content, they produced gonads with colour characteristics similar to wild individuals, suggesting their potential suitability for echinoculture. The inclusion of insect meals improved gonadal growth, highlighting a promising strategy for sustainable feed formulation.

OPTIMIZING AQUACULTURE BREEDING PROGRAMS WITH EARLY-LIFE GENOTYPING

Adriana Artiles* Samuel A May, Alejandro P Gutierrez

Center for Aquaculture Technologies
8445 Camino Santa Fe, Suite 104
San Diego, CA, 92121, United States

aartiles@aquatechcenter.com

Aquaculture breeding programs continue to evolve as genetic tools become more accessible and integrated into routine practice. Greater availability of reliable genotyping tools has been crucial for enabling genetic progress in breeding programs.

This talk explores how genotyping candidate broodstock early in life within a genomic selection framework can improve breeding outcomes. This approach is widely used in terrestrial livestock breeding programs, such as cattle and swine, but is less commonly applied in aquaculture programs. Using insights from early-life genotyping provides a powerful framework for making earlier and more informed breeding decisions. This approach is particularly valuable in species with longer production cycles, where the cost of raising animals to maturity is high. In this framework, only a small number of high-value candidate broodstock need to be raised to maturity, resulting in greatly reduced costs for feed, facilities, and personnel.

Early-life genotyping enables breeders to assess genetic merit as soon as individuals are large enough to individually tag, improving selection accuracy and intensity while reducing infrastructure requirements and costs. Early genotyping also helps maintain genetic diversity by enabling balanced representation across families, avoiding the unintended loss of valuable genetic variation that can occur with traditional phenotype-based culling strategies. Selective reductions over the course of the life cycle allow for phenotypes to be assessed at multiple time points, decoupling early-life phenotypes from late-life phenotypes, and can result in genetic improvements to production traits that would not be possible from late-growth alone. Importantly, even when unfavourable genetic correlations exist between key traits, the added precision provided by the data allows breeders to make more balanced and informed decisions.

Case examples from commercial breeding programs demonstrate how integrating early-life genotyping into selection strategies can improve key production traits. This strategy not only improves the efficiency and speed of genetic gain but also changes how selection decisions are made across the breeding cycle for more cost-effective aquaculture breeding programs.

MASSIVE OPEN ONLINE COURSE (MOOC) IN SUSTAINABLE AQUACULTURE FOR LOW TROPHIC SPECIES

The expectations for sustainable food production in aquatic systems are high, especially of low trophic species products with a low carbon footprint. To enhance the knowledge among students, practitioners, and teachers, we developed a massive open online course (MOOC) in sustainable aquaculture for low trophic species (SALTS). The course was launched in April 2023 and contributes to the much-needed increased literacy in the field necessary for enhanced and diversified aquaculture production. The course is free, easily accessible and students may progress through the modules at own pace. By now more than 1000 individuals have signed in to the course and over 100 have completed the course and received the certificate. In this presentation, we describe the methodological approach for MOOC development, present the course content and structure, as well as student evaluations and recent updates of the course.

How to develop a MOOC

According to the constructive alignment theory, deciding on learning outcomes is the first and the most important step in developing a course. Learning outcomes will guide what material should go into the course and what type of assessments will be used. SALTS is a master level course, which means we expect the students to acquire higher levels of cognitive learning (Revised Bloom's Taxonomy – Apply, Analyse, Evaluate, and Create). Higher levels of learning expect students to have a good knowledge of the concepts. Therefore, some learning activities and assessments must occur at the lower levels of cognitive learning (Remember, Understand). The aim is to cover the value chain of several low trophic species through 10 modules. The AquaVitae Horizon 2020 project scientists provide the research-based content needed, and some of them have contributed to the course updates.

Course modules and the pilot

The modules are: 1) Sustainability of Low Trophic Aquaculture (LTA), 2) LTA Governance, 3) Food nutrition and safety, and consumer perspectives 4) Business, economics, and markets, 5) Production systems, 6) Macroalgae, 7) Echinoderms, 8) Molluscs, 9) Herbivorous finfish, and 10) Future of LTA. Each module consists of a short introduction video followed by an engagement activity. The module contains 2-3 sub-topics, including videos, quizzes, reading material, advanced assessment and additional material. This educational material has been provided for online students, and for teachers who can utilise the material in a flipped classroom format. The entire course is equivalent to 5 ECTS points (125-140 hours in total). Each module takes approximately 13 hours to complete. The course is available on the Open edEX platform: Sustainable Aquaculture for Low Trophic Species | UiT OpenedX.

ECONOMIC LOSSES FROM DISEASE IN GLOBAL AQUACULTURE

Frank Asche*, Taryn M. Garlock and James L. Anderson

School of Forestry, Fisheries and Geomatics Sciences
University of Florida
Gainesville, FL 32611
Frank.Asche@ufl.edu

Disease is a major challenge that limits aquaculture production and productivity globally. Intensification of aquaculture has led to enhanced risk of disease emergence, although the increased control with the production process enhances the ability to prevent or handle disease. While disease management requires significant investment in disease control, the largest cost associated with disease is most often foregone revenue even when extreme preventative and treatment costs are incurred. However, despite the significant challenges associated with disease, the losses associated with disease in aquaculture are poorly documented, and there are surprisingly few recent estimates despite the continued rapid increase in aquaculture production. The FAO estimated losses to the global aquaculture industry were \$6 billion per year over a decade ago, and more recent studies quantifying the economic costs typically focus on specific diseases, species, or regions, precluding a comprehensive understanding of the magnitude of disease at a global scale and how the challenges differ by species. Most published studies also document losses in wealthy countries despite these countries contributing a relatively small share of global aquaculture production.

In this paper we will provide estimates of disease cost in aquaculture globally, as well as by species and country. We estimate the global production losses to be \$16.0 billion per year or 5.1% of the global production value. The losses rates vary significantly by species, with shrimp having the highest loss rate with 29.6%. With its high production value it then makes up about one quarter of the total disease cost in aquaculture.

INTEGRATIVE OMICS ANALYSIS IDENTIFIES CANDIDATE CAUSATIVE MUTATION FOR RESISTANCE TO CARDIOMYOPATHY SYNDROME IN ATLANTIC SALMON

Introduction

Cardiomyopathy syndrome (CMS) is a severe viral cardiac disease of Atlantic salmon caused by piscine myocarditis virus (PMCV). The disease typically manifests several months after sea transfer, during the second year of production when fish reach approximately 3.6 kg. Clinical signs are often absent until mortality begins, resulting in compromised fish health and welfare as well as substantial economic losses for producers. CMS is characterized by a slow progression of pathology, and even minor stressors, such as treatment for sea lice infestation, may trigger mass mortality events [1]. Histopathological examination reveals severe inflammation and necrosis primarily affecting the endocardium and spongy myocardium of the atrium and ventricle [2], accompanied by extensive infiltration of mononuclear immune cells, including lymphocytes and macrophages [3]. Estimates of heritability for resistance to CMS vary widely depending on phenotypic definitions (e.g., survival, viral load, or histology), environmental conditions (field versus controlled challenge), and population structure. Previous studies have identified genomic regions on chromosomes 12, 23 and 27 associated with genetic variation in CMS resistance, with the major quantitative trait locus (QTL) on chromosome 27 explaining approximately 30% of the genetic variance [4]. In the present study, we aimed to fine-map these genomic regions, with primary focus on the QTL located on chromosome 27, and to identify causative genes and/or mutations underlying host resistance to CMS.

Materials and Methods

The study population originated from the MOWI ASA breeding nucleus and included four year classes (YC2016, YC2017, YC2019, YC2021). Individuals were selected for whole-genome resequencing (WGR) to fine-map previously identified QTL regions and for functional validation using transcriptomic (atrium) and proteomic (plasma) analyses. WGR was conducted on YC2016–YC2019, while YC2021 was used for expression analyses. All individuals had pedigree data, CMS phenotypes (challenge or field), and genotypes from the NOFSAL03 (~55K SNPs) array. Sampling was stratified by genomic breeding values (gEBV) and haplotype status, limiting relatedness (≤ 4 per sire, ≤ 2 per dam). Individuals were classified into three groups resistant (FUL; gEBV > 1.25 SD, two favorable haplotypes), intermediate (HET; > 0.625 SD, one copy), or susceptible (DEL; < 1.25 SD, no copies). A total of 157 individuals were selected for WGR and 30 ($n=10$ per group) from YC2021 for transcriptomic and proteomic analyses. Sequencing (150 bp paired-end) was performed on the BGISEQ platform. Reads were quality-filtered (using Trimmomatic), aligned to *ICSASG_v2* (using BWA-MEM), and variants called using SAMtools/bcftools, and variant annotations via Ensembl VEP. Transcriptomic data were generated on Illumina NovaSeq 6000, processed with STAR, and analysed with edgeR. Plasma proteomics was conducted using Q-Exactive Orbitrap, with analysis in MaxQuant and statistical evaluation in Perseus and Unscrambler. Genome-wide association analysis using sequence-derived variants was performed using linear mixed model in GCTA [5] with “--mlma-loco” function, including year class as a fixed effect and additive genetic effects based on a genomic relationship matrix: $y = \mu + \alpha + e$, where y is the vector of phenotypic records, μ is the overall mean, and α represents fixed effects with corresponding design matrix X . The vector α denotes additive genetic effects, with G as the genomic relationship matrix and design matrix X , while e represents residual effects.

Results and Discussion

Alignment of sequence reads within the target QTL region on chromosome 27 (10–12 Mbp) identified 8,813 variants, including five high-impact SNPs spanning approximately 13 genes. Among these, two immune-related genes, *MRI* and *HAI1F*, emerged as strong candidates. Genome-wide association analysis reinforced a robust signal in this region; however, inclusion of sequence-derived variants did not further increase statistical significance beyond that captured by the SNP array. Moreover, high-depth (~100×) resequencing comparing FUL and DEL groups revealed reduced or absent read alignments in specific segments of the susceptible DEL group relative to resistant FUL individuals, indicating the presence of a structural variant, most likely a deletion spanning exonic regions of the *HAI1F* gene. This putative deletion was experimentally validated at both genomic and transcriptomic levels using a targeted PCR assay on 30 individuals (10/group), which showed complete absence of amplification in DEL individuals. Additionally, differential expression analysis

(Continued on next page)

Figure 1: **A)** Copy number variation analysis identified a putative deletion within the QTL region on chromosome 27 in the DEL group. **B)** Integrative Genomics Viewer visualization shows near-complete loss of read coverage across the region in DEL compared to FUL. **C)** PCR validation confirms the deletion, with no amplification in DEL group. **D)** Transcriptome analysis revealed concordant differentially expressed genes with fine-mapping results, supporting the findings.

identified *MRI* and *HA1F* as the only significantly regulated genes between FUL and DEL groups. Specifically, *MRI* was strongly upregulated in susceptible fish, whereas *HA1F* exhibited markedly reduced expression. Proteomic analyses corroborated these findings, demonstrating significantly elevated levels of the *MRI* protein product (*A0A1S3PYN4*) in the DEL group. The concordant evidence from fine-mapping, structural variant detection, transcriptomics, and proteomics strongly supports a central role for *MRI* and *HA1F* in resistance to CMS. These results suggest that dysregulation of key immune pathways, potentially driven by structural variation, may impair host defence mechanisms, with reduced *HA1F* expression likely contributing to compromised immunity in susceptible individuals.

Acknowledgment

The results produced in current study are a part of “CMS-Edit” and the “Genomics4Robust” projects. CMS-Edit project was funded by The Research Council of Norway under grant agreement number 294504 while Genomics4Robust project is an internally funded project from Nofima AS under project number 13281.

INFLUENCE OF LATITUDE-SPECIFIC LIGHT REGIMES ON LETTUCE PRODUCTION IN DECOUPLED AQUAPONIC SYSTEMS UNDER CONTROLLED ENVIRONMENT AGRICULTURE

Faiqa Atique^{1*}, Oliver Körner¹

1. Leibniz-Institute of Vegetable and Ornamental Crops
Grossbeeren, Germany
atique@igzev.de

Introduction

Controlled environment agriculture (CEA) enables resource-efficient food production through precise regulation of environmental conditions. Decoupled aquaponic systems (DAPS) provide a flexible production approach by separating fish and plant components, allowing improved control over nutrient delivery and system optimisation. However, how such systems respond to location-specific environmental conditions, particularly light availability, remains insufficiently understood.

Materials and Methods

Lettuce (*Lactuca sativa*) was cultivated in an NFT-based decoupled aquaponic system using water from a tilapia (*Oreochromis niloticus*) recirculating aquaculture system under controlled light environments simulating latitude-dependent conditions of Oslo, Berlin, and Madrid. The experiment was conducted in four consecutive cultivation rounds, each lasting three weeks. Three photosynthetic photon flux density (PPFD) levels (approximately 491, 625, and 815 $\mu\text{mol m}^{-2} \text{s}^{-1}$) were applied under a 12-hour photoperiod using LED lighting. Three cultivation systems were compared: hydroponics (HP), conventional decoupled aquaponics (CAP), and nutrient-balanced decoupled aquaponics (DAP). Plant growth and water-use efficiency was evaluated across treatments.

Results

Plant growth was influenced by both light regime and cultivation system. DAP and HP systems showed comparable biomass production and water-use efficiency, while CAP consistently performed lower across all light conditions. Among the tested scenarios, moderate light conditions (Berlin simulation) resulted in the most balanced plant growth across systems.

Conclusion

The results show that incorporating location-specific light variability is important for optimizing aquaponic system performance. Nutrient-balanced decoupled aquaponic systems can achieve productivity comparable to hydroponics under controlled conditions. These findings support the development of predictive, location-adapted aquaponic designs to improve resource-use efficiency and system stability in controlled environment agriculture.

COMMUNICATING SCIENCE FROM INDUSTRY: BUILDING TRUST, AVOIDING BIAS, AND CREATING GENUINE ENGAGEMENT

N. Audiffren^{1*}, Bézagu, M.¹, Boersma R.¹, Guo, A.¹

¹Innovafeed, Nesle, France

*Presenting author : nadege.audiffren@innovafeed.com

Introduction

In a context where science communication is increasingly scrutinised for conflicts of interest, industry actors are facing a particular challenge: how to share rigorous, evidence-based findings while maintaining credibility and fostering real engagement with the scientific community. This tension is particularly acute in animal nutrition and aquaculture, where commercial stakes are high and the line between scientific communication and marketing can appear blurred. However, industry generates a significant volume of applied research that, if communicated responsibly, can make a genuine contribution to the collective knowledge base. This perspective abstract draws on our experience as an insect ingredient company to reflect on the formats, principles and pitfalls of industry science communication.

A growing toolkit for industry-led science

Industry has progressively developed a range of approaches to generate credible, communicable evidence. Collaborative PhD programmes allow companies to engage with academic institutions on questions that require expertise, equipment, infrastructures or methodological experience beyond internal capacity. These partnerships are mutually beneficial: industry gains access to independent scientific validation, while academic teams engage with real-world research questions and datasets. Research consortia represent a further step, bringing together actors from across the value chain under the scientific oversight of dedicated research institutions. Projects of this kind, where feed manufacturers, producers, ingredient suppliers and scientists work on shared challenges with agreed methodologies, offer a model for generating evidence that is both industrially relevant and scientifically robust. For more targeted questions, partnerships with contract research organisations (CROs) provide controlled, reproducible trial conditions to generate new results and build product-specific claims.

The credibility challenge: trust, bias and transparency

Each collaboration format carries its own credibility profile and its own risks. Funding source, study design, choice of comparators, and the selective reporting of favourable results are all legitimate concerns that the scientific community raises when evaluating industry-generated evidence. These concerns are not unfounded, and industry communicators must engage with them directly rather than defensively. In practice, this means being transparent about methodologies used, trial conditions and their limitations, and clearly distinguishing between findings that are statistically robust and those that are preliminary or observational.

As white papers have emerged as a valuable communication format, enabling companies to share structured, evidence-based content with professional and scientific audiences outside the traditional peer-reviewed publication route, we must also make sure to comply with the above guidelines.

Conferences such as this one play a central role in connecting actors, providing a space where industry and academic scientists can exchange on equal footing.

Submitting work to peer review, even when the timeline is challenging, remains the gold standard. Where that is not possible, applying the same standards of transparency and rigour to other formats is both achievable and necessary.

Reaching beyond the scientific community

Engaging peer scientists is only part of the communication challenge. Industry actors are also well positioned to act as translators of science, bringing evidence-based knowledge to broader audiences including farmers, feed manufacturers, policymakers and the general public. This requires a different set of skills and formats than those used in academic communication, and one that industry, with its commercial communication experience, can genuinely contribute to.

(Continued on next page)

Social media and short-form video have opened new channels for science communication that the aquaculture and animal nutrition sectors are only beginning to explore. A well-crafted post explaining a key result, or a short video clip from a trial site or processing facility, or even an impactful infographic or simplified visual can reach audiences that a conference presentation or peer-reviewed journal article never will. These formats should come with clarity, visual storytelling and a personal voice, all of which sit more naturally with industry communicators than with many academic researchers. Used responsibly, they can build genuine public engagement.

Conclusion

Industry has a legitimate and important role to play in science communication, provided it is exercised with honesty and methodological discipline. Today's range of formats, from peer-reviewed publications and white papers to social media, creates real opportunities to contribute meaningfully to scientific debate and make results more widely accessible.

The credibility of these contributions depends not on the absence of commercial interest, which is neither realistic nor required, but on the transparency with which that interest is declared and the rigour with which the science is conducted and reported. Building that trustworthy science-backed communication is a long-term investment, but one that benefits the entire field.

Industry is not a passive beneficiary of scientific progress. It is increasingly an active participant in generating, communicating and contextualising it. Embracing this role across all available channels, from academic journals to digital platforms, is both an opportunity and a responsibility.

HISTOPATHOLOGY OF THREE ECONOMICALLY IMPORTANT MARINE FISH SPECIES FROM SELECTED ESTUARIES OF THE GULF OF GUINEA FOR SUSTAINABLE FISHERIES MANAGEMENT

Introduction

The health of fish populations is closely linked to the quality of their environment, particularly in estuarine ecosystems where natural and human-induced changes can influence aquatic life. Histopathological examination of fish tissues provides valuable information on the effects of environmental stressors and serves as an important tool for monitoring ecosystem health. This study assessed the liver and gonadal tissues of three commercially important marine fish species, *Ilisha africana*, *Cynoglossus senegalensis*, and *Scomberomorus tritor*, collected from the Benin, Brass, and Escravos estuaries of the Gulf of Guinea, Nigeria. Selected water quality parameters were also evaluated to provide baseline information for environmental monitoring and sustainable fisheries management.

Materials and Methods

Fish samples were collected from the three estuaries, and a total of eighteen liver and gonad tissue samples were examined using standard histological procedures. Tissues were fixed in 10% neutral buffered formalin, processed using paraffin embedding techniques, sectioned, and stained with haematoxylin and eosin for microscopic examination. Histopathological alterations were assessed using Histopathological Alteration Index (HAI) and Gonadal Alteration Index (GAI) values. Water quality parameters including temperature, dissolved oxygen, pH, salinity, turbidity, total suspended solids, and nitrate concentration were measured using standard laboratory and field methods.

Results and Discussion

Microscopic examination showed that *Ilisha africana* and *Scomberomorus tritor* maintained normal liver and gonadal structures across all sampled estuaries. Their tissues displayed well-organized cellular arrangements with no visible lesions, resulting in HAI and GAI values of zero.

In contrast, *Cynoglossus senegalensis* showed mild histopathological alterations in both liver and gonad tissues. The observed changes included slight sinusoidal congestion, cytoplasmic vacuolation, and mild germ-cell degeneration. These lesions occurred at a frequency of 33.3%, with mean lesion scores of 1.33 ± 1.15 and HAI and GAI values of 4. Although these findings indicate exposure to low levels of environmental stress, the alterations were minor and unlikely to have significantly affected organ function.

Water quality conditions across the estuaries were generally suitable for fish survival and growth. Temperature ranged from 26.83–27.42 °C, dissolved oxygen from 6.08–6.13 mg L⁻¹, pH from 7.32–7.88, salinity from 21.75–24.92 ppt, turbidity from 12.67–17.50 NTU, total suspended solids from 35.67–46.67 mg L⁻¹, and nitrate concentrations from 1.60–1.85 mg L⁻¹. Most parameters showed no significant spatial variation, although pH differed significantly among locations ($p < 0.05$). Correlation analysis further revealed that salinity played a major role in influencing other environmental variables within the estuarine ecosystem.

Overall, the absence of severe tissue damage suggests that the Benin, Brass, and Escravos estuaries currently provide favourable environmental conditions for fish health. However, the recurring mild alterations observed in *Cynoglossus senegalensis* indicate that this species may be more sensitive to environmental changes and could serve as a useful bioindicator for future monitoring programmes.

Table 1. Summary of Histopathological Findings

Species	Liver Condition	Gonad Condition	HAI	GAI
<i>Ilisha africana</i>	Normal	Normal	0	0
<i>Cynoglossus senegalensis</i>	Mild congestion and vacuolation	Mild germ-cell degeneration	4	4
<i>Scomberomorus tritor</i>	Normal	Normal	0	0

(Continued on next page)

Conclusion

The study demonstrated that fish populations inhabiting the Benin, Brass, and Escravos estuaries are generally healthy, with normal liver and gonadal structures observed in most species examined. The mild tissue alterations detected in *Cynoglossus senegalensis* suggest the presence of low-level environmental stress, but not to an extent that threatens fish health or reproductive performance. These findings provide important baseline information for environmental assessment, fisheries conservation, and the sustainable management of estuarine resources in the Gulf of Guinea.

Acknowledgment

The authors acknowledge the support of Delta State University, Abraka, Nigeria, and Eliezer Analytical Laboratory, Asaba, for assistance during sample processing and analysis.

Interests in carbon markets worldwide across the globe have increased significantly due to the growing urgency of climate change been heightened by climate change mitigation, prompting a reassessment of nature-based solutions needed for the reducing tion of greenhouse gases (GHG) emissions. Wetland environments and forests have long been recognized as carbon sinks, but little is known about how aquaculture helps sequester carbon and how it may be included into carbon credit markets. With a focus on shellfish, seaweed and integrated multi-trophic aquaculture (IMTA), this study examines the potential of aquaculture systems to sequester carbon. This study also examines how prepared various aquaculture systems are to take part in compliance and voluntary carbon markets. Through biological processes including carbonate shell formation, photosynthetic CO² uptake and sedimentary carbon burial, aquaculture can function as a blue carbon sink. The study outlined crucial conditions for inclusion in carbon credit schemes, including additionality, permanence and measurability. It also provided insight into new methodologies and technological developments, including Life Cycle Assessment, AI-based monitoring and blockchain for transparent carbon accounting. Notwithstanding these benefits, a number of barriers still stand in the way of progress, including the high costs of verification for small-scale producers, the restrictive regulatory frameworks, and the lack of scientific clarity surrounding carbon measurement. Policymakers' heightened interest in aquaculture and its potential to significantly impact national climate policies are demonstrated by case studies of blue carbon projects and pilot programs.

To realize this potential fully, the study suggests increased investment in research, capacity building, and policy integration. The aquaculture sector can play an important role in the production of climate-smart food, ensuring environmental restoration and sustainable development by bridging gaps between aquaculture and carbon finance.

ALTERNATIVE PEPTIDE SOURCES AS A DIETARY STRATEGY TO ATTENUATE STRESS SIDE-EFFECTS: AN IMMUNOLOGICAL APPROACH IN EUROPEAN SEABASS LARVAE *Dicentrarchus labrax*

Introduction

Developing stress-reducing strategies has been a priority for aquaculture experts, from engineers to nutritionists. The inclusion of functional ingredients, both as supplements or even in replacement of others, has been thoroughly investigated in the quest for feed formulations that enhance fish welfare and promote health. Protein hydrolyzates from various raw materials renders the most promising bioactive compounds, which incorporation in feeds for fish larval stages has been reported to reduce the impact of stress factors (Aragão et al. 2022). By replacing both fish protein hydrolysate and fish meal with poultry, feather, yeast, wheat and whey peptide fractions, this study aims at exploring the potential of these ingredients to enhance European seabass post-larvae, *Dicentrarchus labrax*, resilience to stress. In particular, it targets the immune response following exposure to an acute stress.

Material and methods

European seabass larvae (73 DAH, initial weight ≈ 0.3 g) were distributed in fifteen 50 L tanks of a recirculating seawater system to which 5 dietary treatments were randomly assigned in triplicates: a commercial diet serving as the control diet (CTRL), and four CTRL-based diets in which fish protein hydrolysate was replaced with poultry (PH), feather (FH), wheat+whey (WWH) hydrolysates and yeast (Y). After acclimatization, seabass larvae were fed the experimental diets for one week, 5 times a day. At the end of the feeding period, the water column was lowered and fish were kept confined for 30 minutes after which the tank was slowly refilled to the top. The feeding period was extended for one more week following the acute stress. Fish were sampled at the end of the feeding period (0h), 48 hours post-stress (48h) and one week post stress (1w), at which points a triangular portion of the peritoneal cavity containing the digestive tract was dissected and snap frozen for the analysis of lysozyme, peroxidase and bactericidal activities and nitric oxide concentration.

Results and discussion

Both nitric oxide concentration and peroxidase activity were higher in fish sampled one week post stress than in fish sampled before the acute stress for all the dietary treatments except WWH. This transversal time effect points to a natural stress-induced response. Moreover, at one week post stress the response was still not stabilized, and was not attenuated by the dietary treatments. Peroxidase activity of fish fed WWH was the exception, as levels before the acute stress were already higher than those of CTRL-fed fish (Fig. 1). An augmented peroxidase activity is usually associated to cell activation and degranulation. However, and since such pre-stress stimulatory potential was not similarly detected in other immune parameters, complementary approaches are required to ascertain the extent of WWH immune-stimulatory role.

Conclusion

The replacement of fish protein fraction with the selected alternative peptide sources did not significantly modulate (attenuated nor intensified) European seabass larvae immune response to an acute stress. Moreover, the majority of the dietary treatments did not affect the immune status prior to stress, with the exception of WWH. This might be regarded as an indication of the tested diets safety regarding a putative inflammatory potential. Additional investigation with more functional endpoints is nevertheless required for a more complete assessment of these alternative protein fractions' stress-counteracting potential.

(Continued on next page)

Figure 1. Peroxidase activity in the viscera of European seabass larvae fed experimental diets and sampled at the end of the feeding period (0h ■), 48h following a 30-minutes acute stress (48h ■) and one week post stress (1w ■) (means $\pm$ SD). a and b stand for significant differences attributed to dietary treatment; x,y,z stand for significant differences attributed to sampling time. Two-way ANOVA followed by Tukey post-hoc test ($p \leq 0.05$).

Introduction

Vaccination is a common and necessary practice in aquaculture, since it is one of the most effective tools to prevent infectious disease outbreaks. However, vaccination practices can be fastidious and time consuming, where fish have to be netted and handled by different operators, causing stress to the animals and disrupting normal daily operations. Amongst different vaccination approaches, dip vaccination is minimally invasive, avoids the use of anaesthetics and requires a lesser amount of human intervention and handling than intraperitoneal vaccines. Nonetheless, both the vaccine itself, normally consisting in highly concentrated viscous substances immiscible in water which reduce the efficacy of oxygen capture and exchange, the netting and crowding required for fish immunization, create stressful conditions that can impact fish health. The present work summarizes the main results from three studies aimed to evaluate the physiologic and metabolic effects of acute stress induced by dip vaccination in three juvenile fish species: European seabass (*Dicentrarchus labrax*), rainbow trout (*Oncorhynchus mykiss*) and Atlantic salmon (*Salmo salar*) pre-smolts.

Material and Methods

Briefly, European seabass (32 g IBW), Atlantic salmon (6-7 g IBW) and rainbow trout (4-5 g IBW) were randomly distributed between tanks and acclimated for one week, all fish were fed commercial diets. Environmental conditions were kept constant, with a temperature of 20°C and salinity of 35 ppt for seabass, whereas salmonid species were maintained at 16°C (rainbow trout) and 14°C (Atlantic salmon) in freshwater. Sampling procedures were transversal to all trials. Before vaccination, samples were collected constituting the time 0 (pre-challenge). Afterwards, fish were netted and transferred into a smaller tank containing the vaccine solution in the case of the vaccine group (VAC) or only water in the case of sham group (SHAM). European seabass were vaccinated with an experimental vaccine containing *Tenacibaculum maritimum* antigens, whereas trout and salmon fingerlings were vaccinated with a commercial one (Aquavac ERM) against *Yersinia ruckeri*. Both groups remained in the tank with aeration for 30 seconds (European seabass) or 1 min (salmonid species). Fish were returned to their initial tanks and samples were collected at 1-, 6-, and 24-hours post-vaccination. At every sampling point, blood, plasma and liver were sampled for the analysis of humoral parameters, metabolites and hepatic oxidative stress response. Brain, hypophysis and head-kidney were collected to assess neuroendocrine and immune responses according to previously defined molecular markers. Skin mucus and water were sampled both for proteomic and transcriptomic (miRNA) analysis, while skin tissue was collected solely for transcriptomics (RNAseq).

Results and discussion

European seabass plasma cortisol levels increased in both vaccinated and sham groups 1-hour after stress and gradually decreased reaching basal levels after 24h. Plasma glucose showed a similar pattern to cortisol, however, glucose levels remained higher in the VAC group compared to SHAM, returning to baseline after 24 hours. Finally, after 1 hour of vaccination plasma lactate levels increased in both groups, but the increase was significantly higher in vaccinated fish. However, this effect disappeared after 6 hours, with lactate levels returning to their baseline. In trout juveniles, following the vaccination procedure, cortisol levels increased in VAC group at 6 hours post-vaccination returning to basal levels after 24h, SHAM group levels remained unchanged. In addition to that, lactate and glucose followed a similar pattern, showing an increase at 6 hours post-vaccination in VAC group. Regarding, those same parameters in SHAM group, glucose increased after 1 hour and 24 hours post-vaccination, while lactate remained unaffected when compared to CTRL group.

(Continued on next page)

Monocyte counts and plasma nitric oxide (NO) levels in European seabass progressively decreased over time in stressed groups (VAC and SHAM). High glucocorticoid levels can trigger monocyte migration from blood to peripheral tissues. Contrarily, in rainbow trout there is an increase in monocytes 24h post-vaccination in SHAM group, which coincided with a concomitant increase in NO production. Monocytes are NO producing cells and higher or lower NO levels are directly related to cell activation and migration, possibly mediated by cortisol.

Seabass hepatic GSH/GSSG ratio showed a significant drop at 24h in both SHAM and VAC groups, with significantly lower values when compared to earlier time points and to CTRL. The decrease of hepatic GSH/GSSG ratio at 24 h, indicates oxidative stress in the liver. Lower GSH/GSSG ratio values could point to excess ROS production. The decline was higher in vaccinated fish than in SHAM group, suggesting that the immune activation triggered by the antigen increased oxidative demands beyond handling stress alone. On the other hand, trout hepatic GSH/GSSG ratio remained unaffected throughout the experiment for both groups (SHAM and VAC).

These findings indicate an acute stress response immediately after the vaccination procedure in European seabass with a subsequent recovery overtime and a delayed and milder stress response in rainbow trout. The integration of all generated data, is expected to provide better understanding of stress and health related mechanisms involved in vaccination induced stress, namely the relation between the HPI axis and the immune mechanisms. Atlantic salmon samples are currently under evaluation.

Introduction

Juvenile Asian seabass (*Lates calcarifer*) in intensive hatcheries is highly susceptible to bacterial infections, and there is growing interest in non-antibiotic approaches such as non-lethal heat shock (NLHS) to improve fish robustness. This study presents preliminary findings evaluating whether repeated NLHS can enhance survival and modulate stress and immune responses in seabass juveniles exposed to commercial hatchery water containing natural environmental microbiome (**Fig. 1**).

Materials and Methods

Fish (2.90 ± 0.11 g) were reared for 5 weeks in 12 tanks of the BSL2 facility at the National University of Singapore. The experiment followed a 2×2 factorial design, with or without weekly NLHS (10 °C increase for 1 h) and with or without weekly additions of hatchery water as a mock infection. Growth performance and feed utilisation were recorded, and tissue (head kidney) were sampled for quantitative PCR analysis of heat-shock, antioxidant and immune genes. In parallel, tank water, asymptomatic and symptomatic fish were screened by PCR for key bacterial and viral pathogens. NLHS had a significant positive effect on fish survival ($p = 0.002$).

Results and Discussion

NLHS had a significant positive effect on fish survival ($p = 0.002$). In absence of NLHS, the mock infection with hatchery water, had a negative effect on fish survival ($p = 0.864$). NLHS did not significantly alter final body weight, feed conversion ratio or thermal-unit growth coefficient, demonstrating good tolerability of the conditioning protocol. Preliminary head-kidney gene expression results indicate NLHS-associated up-regulation of heat-shock proteins and selected immune markers. Collectively, these findings show that appropriately managed NLHS can improve time-dependent survival of juvenile seabass during realistic hatchery-water exposure, supporting its application as a practical, non-chemical tool for health management in marine finfish hatcheries.

Introduction

Infaunal organisms inhabiting marine sediments serve as valuable ecological indicators, offering insights for the influence of key environmental factors in such habitats. Ecosystem health for these habitats subjected to wave storm events with different magnitude in frequency or intensity is reflected in several aspects like species composition, biodiversity, pollution tolerance, or resilience to physical disturbance among others. High-energy environments like wave storms may compromise survival and ecophysiology of inhabitants with potential to disrupt trophic interactions within the benthic food web. Here, we proposed to investigate the impact of high-energy environments on infaunal organisms, monitoring mortality events but also the importance of sublethal effects that may threaten or imbalance metabolism, energetics and surviving bivalve's health. The clam *Polititapes rhomboides* was the target species, creating different physical disturbance environments (short- and long-term scenarios) followed by an additive abiotic stressor (seawater warming, +3°C). Altogether, behavioral, ecophysiological, and stress-related immune responses were monitored, resembling natural drivers impact on historic mortality events of this infaunal population.

Results and Discussion

Mortality events of the clam's populations subjected to sediment mobilization was noted for 16 and 24 days of perturbation (but not for 8 days), representing 14% and 24% of the population, respectively. In all cases, mortality was accelerated with temperature increase reaching 41% for the worst scenario, temperature increase after 24 days of sediment disturbance. In any case, mortality was not linked to rickettsias proliferation or abundance as experimental colony densities remained extremely low and far below the >160 colonies/mm² recorded during natural peak mortality episodes (Darriba et al., 2012; Villaceros-Robineau et al. 2022). As a general pattern, valve opening behaviour declined significantly (15-25%) during sediment mobilization with minor differences among perturbation exposure time (8, 16 and 24 days). Temperature increase at the end of these high-energy exposure periods did not suppose any significant detrimental effect for clam's valve behaviour. Interestingly, primary valve opening behaviour which precedes the rest of the vital functions showed a significant correlation with feeding patterns that have not been observed in other bivalves (Comeau et al. 2018). It is plausible to speculate on such biological correlation for another trophic niche (e.g. infaunal disposition with siphons fully extended along sediment surface).

Figure 1. Cumulative mortality (%;A) and Scope For Growth (SFG; B) of the clams subjected to short- and long-term physical disturbance and seawater warming.

(Continued on next page)

Physical perturbation of individuals caused a significant decrease in feeding and metabolic rates (approximately half of calm scenario) although posterior seawater warming activated also time-specific responses (increase) in both physiological parameters based on optimal food availability set-up selected. Projected energetic status showed a significant degree of vulnerability for disturbed populations based on scope for growth decreased (SFG index; Figure 1B). The cessation of such physical disturbance, together with seawater warming, led to a relatively short-term increase in feeding rates—supported by the availability of optimal food resources—to restore energetic status, although still far from the undisturbed scenario. Combined sediment mobilization and seawater warming significantly increased nitric oxide production after each perturbation cycle (8, 16, or 24 days), with stronger effects following the longest disturbance. Clams under calm conditions did not show nitric oxide increase, even at high temperature, indicating disturbance as the main stressor. A comprehensive scheme of behavioural, physiological and immune-system shifts that infaunal populations experience when subjected to key abiotic stressors responsible of mortality events in the natural environment is discussed. Such knowledge is necessary not only for maintaining biodiversity in our coastlines but also relevant for the socioeconomic sector associated as well as understanding the set of ecosystem services being supported by this and other infaunal species.

Introduction

The Precision Fish Farming (PFF) approach integrates sensors, predictive models and decision support systems in four-phase-cycle which include: 1) Observe: real time data from the sensors; 2) Interpret: predictive models to retrieve information from the system; 3) Decide: artificial intelligence (AI) & decision support system; 4) Act: automation & output correction. According to (Fore&al., 2024), the Digital Twin (DT) concept represents a suitable framework for implementing the PFF in cage culture. In this paper, we extend the approach to Recirculation Aquaculture Systems (RAS) and propose a web-based application for allowing end users to test the Knowledge Based Model component of the DT. This study was developed in the framework of the Italy Slovenia INTERREG project “Circular Rainbow”, aimed at promoting the transition from Flow Through System to Hybrid Flow Systems and RAS in trout farming. The latter would lead to enhanced circularity, better control of water quality and hence fish welfare, higher resilience to the effect of climate change on water quantity and quality.

Materials and methods

A DT can be defined as “a virtual representation of a physical asset enabled through data and simulators for visualising, predicting, monitoring, optimising and controlling system states, and improved [decision making](#)”. It includes three main components: i) an observation system; ii) Knowledge Based Models (KBM); iii) data driven models. Taking into account the typical structure and functionality of a RAS, the KBM component included a Mass Budget (MB) and an Energy Budget (EB) module. The data driven component, thus far, has been implemented only for improving the water temperature prediction of the EB module using the Extended Kalman Filter. The MB module includes biotic and abiotic variables, namely “Mean weight of the fish”, “Number of fish”, “Total ammonia nitrogen”, “Nitrate”, “Dissolved oxygen”, “Dissolved inorganic carbon”, “Alkalinity” and “Total suspended solids”. The MB module simulates the evolution of the fish biomass, water circulation, chemical and biochemical processes, deposition of suspended solids. Most processes are affected by water temperature, which is the output of the EB module. The main forcings/controls are: i) feed ration; ii) oxygen supply; iii) air temperature and humidity; iv) quantity and quality of make-up water; v) addition of a base, e.g. NaHCO₃, to control pH. The DT was tested on a pilot RAS located in Pagnacco (Udine, Italy). The observation system included automatic sensors for detecting water temperature, dissolved oxygen, pH, CO₂ and energy use of the most relevant devices, e.g. heat pump, every 15 minutes. This data set was complemented by the weekly sampling of TAN, nitrate, Reactive Phosphorus, Alkalinity. The KBM was coded using R: from the mathematical point of view, the code solved a system of Dynamyc Algebraic Equations including 8 * 16 state variables, where 16 is the number of components of the pilot RAS, as pH and the speciation of DIC and DIN are simulated assuming chemical equilibrium. A demo version of the KBM is freely available at the web interface DiGiTrout: <https://bluefarm.shinyapps.io/DiGiTrout/>, which includes also KBM of FTS and HFS virtual farms. This interface was developed in R (v4.5.1) using the Shiny package (v1.11.1).

Results & discussion

The output of the KBM component of the DT compared well with the data collected in the pilot RAS from October 2025 to February 2026. The growth of rainbow trout was correctly simulated within the weight range 150-500 grams, as shown in Figure 1-a, which compares the model output (line) with the mean weight, averaged over the 12 tanks included in the pilot. The processes affecting the water quality are quite complex: the KBM correctly simulated the trend in nitrate, not shown, related to the increase in fish biomass and, therefore, TAN excretion, thus suggesting the biofilter activity was well reproduced. One of the most relevant model output is pH, which is affected by fish metabolism but depends also on the buffer capacity of the solution: as one can see from Fig. 1b, the trend in pH is correctly simulate both in fish tanks and biofilter: however, the comparison also indicates a slight bias, which should be further investigated. The concentrations of Dissolved oxygen and CO₂ depends also on the efficiency of air blower and degassing units, which were tuned to fit the data.

(Continued on next page)

Figure 1: a) Mean weight in all tanks: comparison between model output (line) and manual samples (point).
b) pH in a fish tank and biofilter: comparison between model output (blue and red lines) and data from sensors (violet and green lines)

Concerning the EB module, water temperature and air temperature inside the building were correctly simulated. The Kalman Filter adjusts a parameter used to describe the building transmittance with high precision, with small fluctuations, indicating that the pre-simulation calibration was accurate. Reversing these calculations, the heat provided by the heat pump can be retrieved. This information allows the operator to estimate energy costs related to water cooling/heating.

Overall, the comparison between the KBM component of the DT and the data observed in the Circular Rainbow project indicated that the complex physical, biochemical and chemical processes occurring in a RAS were satisfactorily modelled. On this basis, a prototype of a general KBM for a RAS system was designed, coded and made available through the DiGiTrout web interface, an application which allows one to simulate two RAS management scenarios: 1) daily management (7-day ahead simulation); 2) long term planning (6-month ahead simulation). The web application provides a list of Key Performance Indicators (KPIs), e.g. feed demand, Specific Growth Rate (SGR), fresh water used as input, Feed Conversion Ratio (FCR), total suspended solids collected, dissolved oxygen provided by the air blowers. This information can be used by farmers to improve management. In conclusion, a DT can not only provide a virtual RAS with results comparable to the real systems, but also provide actionable information regarding costs and use of key resources such as feed, fresh water and energy. DT can open new scenarios in the aquaculture sector, optimizing productivity and also allowing farmers to upscale their plant, since forecasts of trends and costs can be generated with high confidence.

Introduction

Worldwide arising challenges from antibiotic-resistant bacteria require new decontamination strategies. In this regard, the microbial inactivation via reactive oxygen and nitrogen species, provided by the technology of cold atmospheric plasma (CAP) can be applied in recirculating aquaculture systems (RAS) to prevent future disease outbreaks. The decontamination properties of CAP in RAS showed promising results in the past (Balazinski, Hahn et al. 2025). In addition, toxicity tests performed in-vitro on fish cells confirmed a safe application (Balazinski, Hahn et al. 2026). For the consideration of this technology in real environment, an animal testing setup was performed to obtain in-depth results on fish welfare and impact on the water microbiome.

Materials and Methods

The experimental trial was carried out with two equally equipped RAS setups (Figure 1). Each consisted of two tanks with 90 L each, followed by a drum filter, a biofilter and a decontamination unit which was either ultraviolet radiation (UV) or CAP. Each setup had a total capacity of 580 L. In each tank approximately 70 rainbow trout were transferred. The experiment ran for three weeks. For the UV setup two UV lamps each of 55 W were operated continuously. In contrast, CAP was applied daily for 8 h in cycles of 10 min on and 30 min off, corresponding to 2.03 hours of treatment per day. During the experimental trial, water samples were taken at least once a week to determine the microbial load and microbiome in the water, the ionic composition of the water and also the stress of the fish. Standard water parameters, such as oxygen, conductivity, pH and temperature were recorded by a data logger every 15 minutes.

Figure 1: RAS setup with (A) CAP and (B) UV as decontamination unit

Table 1: Comparison of CAP and UV (Average energy consumption [W], Daily device runtime [h], Average microbial load [cfu/mL]), n= 20

	Average energy consumption [W]	Daily device runtime [h]	Average microbial load [cfu/mL]
CAP setup	500	2.03	2.16E+04 (±2.66E+04)
UV setup	110	24.00	3.27E+04 (±5.03E+04)

(Continued on next page)

Results

The evaluation of the water samples revealed only negligible deviations between the two setups, resulting in an average microbial load of four orders of magnitude (Table 1). For the microbiome analyses the highest abundance in CAP and UV was given by the phylum Pseudomonadota, with a mean abundance of $32\% \pm 15\%$ for CAP and $57\% \pm 2\%$ for UV. Regarding the water composition it is noteworthy, that the pH, conductivity and oxygen values remained stable. Cortisol measurements showed no differences between the two groups.

Discussion

The implementation of CAP in RAS showed, that a sufficient microbial inactivation can be achieved with far shorter treatment periods in contrast to the UV application. In this regards, CAP provides a powerful tool for future RAS decontamination, without affecting major water parameters, such as oxygen, conductivity, pH and temperature. In addition, the composition of the water microbiome was constant, indicating optimal cultivation conditions. However, the experiments were successfully performed with rainbow trout, further testing must be carried out to obtain optimal settings for other species and setups.

Introduction

Microalgae have attracted growing attention as functional feed ingredients in aquaculture, as a result of their favourable nutritional composition and richness in bioactive compounds. *Spirulina platensis* is well known for its high protein content, essential amino acid profile, and antioxidant pigments such as phycocyanin and carotenoids (Bortolini *et al.*, 2022). The chemical composition of *Spirulina platensis* includes approximately 53% crude protein, 6.6% crude lipids, and 15.3% soluble carbohydrates, along with significant levels of B-complex vitamins, vitamin E, and minerals such as potassium and iron (Michael *et al.*, 2019; Alagawany *et al.*, 2021). Previous studies have reported beneficial effects of powdered *Spirulina platensis* at 3–10% dietary inclusion on growth and health of various fish species, including salmon (Roohani *et al.*, 2019), koi carp (Napolitano *et al.*, 2022), and common carp (Ahmed, 2023), but these have exclusively used dried biomass. Most studies to date have relied on dried or powdered spirulina biomass, which requires energy-intensive harvesting, centrifugation, and drying steps. Using the liquid culture directly, algal biomass together with its growth medium, could substantially reduce processing costs while preserving heat-sensitive bioactive molecules. Cultivating *S. platensis* on recirculating aquaculture system (RAS) wastewater integrates nutrient recycling into the production chain. As an important freshwater aquaculture species in Romania, common carp (*Cyprinus carpio*) provides a suitable model for evaluating such novel feed strategies. This study investigated if dietary inclusion of unprocessed liquid *S. platensis* culture at 5%, 10%, and 15% can register comparable growth, health, and antioxidant benefits to those reported for conventional spirulina powder.

Materials and Methods

Spirulina platensis was cultivated in 1000 L tanks filled with 90% RAS wastewater and 10% Zarouk medium, illuminated with a 300 W LED lamp, and harvested at the stationary phase two weeks after inoculation (biomass: 1.04 ± 0.02 g L⁻¹ absolute dry weight). Juvenile carp (initial weight 11.01 ± 0.9 g) were randomly assigned to 12 tanks in a RAS facility (30 fish per tank, three replicates per treatment) and fed one of four isonitrogenous diets for 12 weeks: a control diet (15% water top-dressing), V1 (10% water + 5% liquid spirulina), V2 (5% water + 10% liquid spirulina), or V3 (15% liquid spirulina). Fish were fed at 3% body weight day⁻¹ in three daily meals. At the end of the trial, growth performance, feed utilisation, somatic indices, flesh proximate composition (NIR analysis), haematological profile (automated haematology analyser), and tissue-level antioxidant enzyme activities (SOD, CAT, GPx) and lipid peroxidation (MDA) were assessed.

Results and Discussion

All spirulina-supplemented groups showed significantly higher weight gain than the control in weight gain ($p \leq 0.001$), feed conversion ratio, specific growth rate, and relative growth rate, with V2 (10% inclusion) achieving the best overall performance. Polynomial contrast analysis confirmed an initially near-linear improvement followed by a plateau at 15% inclusion, meaning that 15% did not improve results beyond 10%. CF, HSI, and VSI did not differ significantly between groups, which eliminates negative effects on fish condition. Flesh protein content increased progressively from 13.68% (control) to 14.72% (V3), while lipid content declined from 14.48% to 10.22%, which means leaner fillets with higher protein value. Collagen content also rose with increasing spirulina levels. Hematological responses were dose-dependent: white blood cell counts peaked in V1 and decreased at 15% inclusion, while hemoglobin concentrations were higher in supplemented groups, consistent with the known erythropoietic effects of spirulina's iron and phycocyanin content (Ahmed, 2023). Antioxidant enzyme activities increased across muscle, liver, and intestinal tissues in a dose-dependent manner, with significant elevations in SOD, CAT, and GPx in V2 and V3 groups. MDA levels decreased progressively, indicating reduced oxidative damage. The observed reduction in MDA is consistent with findings in cyprinids supplemented with

(Continued on next page)

micro- and macroalgae (Abdel-Tawwab *et al.*, 2021; Ahmadifar *et al.*, 2023). Al-Deriny *et al.* (2020) attributed the SOD upregulation in *Nile tilapia* to the polyphenol and carotenoid content of *Spirulina platensis*, which is likely to explain the tissue-level responses observed in the present study. The parallel improvement in growth and antioxidant status suggests that the upregulation of enzymatic defenses represents a beneficial adaptive response rather than a marker of oxidative stress.

Conclusion

Unprocessed liquid *S. platensis* culture grown on RAS wastewater proved to be an effective functional feed ingredient for common carp, delivering growth and health benefits comparable to those reported for dried spirulina. The 10% dietary inclusion registered the optimal balance between growth enhancement, improved flesh composition, and strengthened antioxidant defence. This finding supports the potential of the low-cost, circular approach for practical carp aquaculture.

CIRCULAR BIOECONOMY IN AQUACULTURE: GROWTH PERFORMANCE, MEAT QUALITY AND HEMATOLOGICAL RESPONSES IN *Cyprinus carpio* FED WITH LIQUID *Chlorella vulgaris*, CULTIVATED ON WASTEWATER FROM A RECIRCULATING SYSTEM

M. N. Nicoară¹, G.-I. Plavan¹, D. A. Șerban², M. Burducea², C.-A. Barbacariu^{2*}

Circular Bioeconomy and Ecological Rationale

Recirculating aquaculture systems (RAS) generate nutrient-rich wastewater containing elevated concentrations of nitrogen, phosphorus and organic matter, compounds that represent both an environmental burden and an underutilized biological resource. Microalgae, particularly *Chlorella vulgaris*, are efficient biological filters capable of assimilating these compounds while simultaneously producing protein-dense, bioactive biomass. When algae are cultivated on RAS effluent, two objectives are achieved within a single closed loop: the wastewater is biologically depolluted and the resulting biomass is valorized as a functional fish feed ingredient, exemplifying circular bioeconomy principles at the farm scale.

The liquid culture of *C. vulgaris* (LCV) used in this experiment was produced in a 1000 L photobioreactor supplied with 90% RAS wastewater and 10% Tamia-type nutrient medium. Chemical analysis of the RAS effluent confirmed substantial concentrations of ammonium (NH_4^+), nitrite (NO_2^-), phosphate (PO_4^{3-}), calcium (Ca^{2+}) and magnesium (Mg^{2+}), alongside microelements including copper (Cu), nickel (Ni) and manganese (Mn). Following two weeks of cultivation under a 300 W Lumatek LED lamp, the algal culture reached the stationary growth phase (dry biomass $1.05 \pm 0.03 \text{ g L}^{-1}$; crude protein 48%, lipids 14.5%, carbohydrates 19.2%; lysine-rich essential amino acid profile), with concomitant depletion of nutrient loads in the culture medium, confirming the depollution function of the algal culture. By delivering the biomass directly as a liquid suspension sprayed onto commercial pellets, the approach eliminates the energy-intensive steps of centrifugation, drying and storage, further reducing the ecological and economic footprint of the process.

Four isonitrogenous and isolipidic diets were formulated: Control (15% water) and three LCV diets at 5% (V1), 10% (V2) and 15% (V3) inclusion. Juvenile *C. carpio* ($11.39 \pm 0.84 \text{ g}$; $n = 360$; 30 tank⁻¹, triplicate) were reared for 12 weeks in a RAS comprising 12 fiberglass tanks (0.5 m³), fed three times daily at 3% body weight day⁻¹. Growth indices, flesh proximate composition (NIR; DA 7250) and hematological parameters (Abacus Vet 5) were assessed and analyzed by one-way ANOVA with Tukey post-hoc test (SPSS v.21; $p < 0.05$).

Results and Discussion

Growth performance improved in a positive linear fashion with increasing LCV inclusion. Weight gain (WG) and relative growth rate (RGR) were significantly higher in V2 and V3 than Control ($p \leq 0.01$), specific growth rate (SGR) was significantly elevated in V2 ($p \leq 0.05$), and feed conversion ratio (FCR) declined from 3.00 ± 0.05 (Control) to $2.52 \pm 0.06 \text{ g g}^{-1}$ (V3). Somatic indices (condition factor, hepatosomatic index, viscerosomatic index) were unaffected, confirming physiological safety across all inclusion levels.

Flesh quality responded positively: protein content increased from 67.66% (Control) to 70.60% (V2; $p < 0.001$), moisture decreased markedly ($p < 0.001$), and ash content rose with inclusion level ($p < 0.001$), reflecting enhanced mineral deposition consistent with the mineral-rich biochemical profile of *C. vulgaris* biomass produced on RAS wastewater.

Haematological assessment revealed elevated white blood cell (WBC) counts across all LCV groups ($p = 0.001$), haemoglobin concentrations increasing from 115 to 138–140 g L⁻¹ ($p = 0.001$), and dose-dependent increases in erythrocytes and thrombocytes (V3: $0.74 \times 10^{12} \text{ L}^{-1}$ and $27 \times 10^9 \text{ L}^{-1}$, respectively), collectively indicative of immunostimulatory activity consistent with β -glucan and polysaccharide-mediated macrophage activation.

Conclusion

Cultivating *C. vulgaris* on RAS wastewater simultaneously depollutes aquaculture effluents and generates a functional, cost-effective feed ingredient that improves growth, flesh quality and immunohematological status of common carp. By closing the nutrient loop between fish waste and fish feed, the approach offers a scalable, ecologically grounded model for sustainable RAS-based aquaculture aligned with circular bioeconomy principles. Future work should assess metal accumulation dynamics in algal biomass across successive cultivation cycles and evaluate the long-term productive and ecological outcomes at semi-industrial scale.

Introduction

Aquaculture has been seeking more effective and safer alternatives for parasite control in fish. In this context, the present study evaluates the use of chitosan and modified alginate nanoparticles containing praziquantel for oral administration in juvenile *Colossoma macropomum*, aiming to control monogenean infections and assess potential hematological and histological changes associated with the treatment.

Material and Methods

Chitosan and modified alginate nanoparticles loaded with praziquantel were produced by complex coacervation and administered orally to juvenile *Colossoma macropomum*. Hematological analyses were performed using blood samples collected at 7, 14, and 21 days after treatment, with a control group for comparison. Histological analyses of the intestine and gills were conducted using hematoxylin and eosin (H&E) and periodic acid–Schiff (PAS) staining to evaluate tissue morphology.

Table 1. Hematological profile of *Colossoma macropomum* during the experimental period at 7, 14, and 21 days after treatment. Values are expressed as mean $\pm$ standard deviation (SD).

Parâmetro	7 dias	14 dias	21 dias
Eritrócitos ($10^6/\mu\text{L}$)	$0,14 \pm 0,11$	$0,19 \pm 0,17$	$0,19 \pm 0,17$
Leucócitos ($10^3/\mu\text{L}$)	$137,30 \pm 112,48$	$133,35 \pm 130,26$	$133,35 \pm 130,26$

(Continued on next page)

Discussion and Results

Hematological and histological analyses were performed to evaluate the physiological response and tissue morphology of fish throughout the experimental period, following the methodologies described by Ranzani-Paiva et al. (2013). Hematological analysis revealed slight variations in blood parameters over the sampling period (Table 1). Erythrocyte counts averaged $0.14 \pm 0.11 \times 10^6/\mu\text{L}$, $0.19 \pm 0.17 \times 10^6/\mu\text{L}$, and $0.18 \pm 0.14 \times 10^6/\mu\text{L}$ at 7, 14, and 21 days, respectively. Hematocrit and estimated hemoglobin showed a gradual decrease throughout the experimental period, whereas total leukocyte counts remained similar at 7 and 14 days, with an increase observed at 21 days. Differential leukocyte counts were characterized by a predominance of lymphocytes during all sampling periods, consistent with the hematological evaluation methods proposed for teleost fish by Ranzani-Paiva et al. (2013).

Histological evaluation of the intestine and gills performed at 7 and 21 days after treatment showed preservation of the overall tissue architecture (Figure 1). Intestinal folds and villi remained organized, while the gills maintained the structural organization of the filaments and secondary lamellae, with no marked morphological alterations observed between the evaluated periods. Similar histological approaches have been employed to assess tissue responses in *Colossoma macropomum* exposed to different experimental conditions (Vieira et al., 2019). Overall, the results suggest that the hematological variations observed throughout the experiment were not accompanied by evident histological alterations under the experimental conditions evaluated.

SUPPORTING METABOLIC HEALTH AND PERFORMANCE IN FISH THROUGH BILE SALT SUPPLEMENTATION

G. Bardera¹, M. Dehasque¹, W. G. Nuez-Ortín¹

¹Adisseo, France

*Presenting author e-mail: guillermo.bardera@adisseo.com

Introduction

Fish synthesize primary bile acids (BAs) from cholesterol via classical (CYP7A1) and alternative (CYP27A1) pathways, after which they are conjugated and stored in the gallbladder as bile salts (BS). Upon feeding, BS are released to emulsify dietary lipids, enabling efficient hydrolysis and absorption. Most BA are recycled through enterohepatic circulation; although a physiologically relevant fraction is lost in faeces and must be resynthesized (Zhou *et al.*, 2024). In fish, the magnitude of this loss varies with diet and species. Additionally, intensive aquaculture conditions—including handling, high stocking densities, variable water quality, and plantproteinrich feeds—can impair hepatic BA synthesis, gallbladder emptying and recycling efficiency. Soy-derived ingredients may further reduce digestive capacity by diluting taurine and introducing antinutritional factors (Staessen *et al.*, 2021). A diminished BS pool compromises lipid digestion, nutrient utilization, energy balance and growth. This study evaluated whether supplementing diets with bovinederived BS (200 mg/kg) could support BA homeostasis, lipid digestion and production performance in red seabream (*Pagrus major*) and Nile tilapia (*Oreochromis niloticus*) reared under commercial conditions.

Material and Methods

Two independent feeding trials were performed. In Trial 1, juvenile red seabream (initial body weight 151 g) were stocked at 12.8 kg/m³ (12 fish per 140L tank) in a recirculating aquaculture system (RAS) operated at 24 °C. Four replicate tanks per treatment received either a control feed (42% crude protein, 13% fat) or the same feed supplemented with 200 mg/kg bile salts (BS; Lipogest, Adisseo) for 18 weeks. The basal diet included 26% fishmeal, 25% soy protein concentrate, and 10% soybean meal, reflecting a moderate plantprotein inclusion level consistent with commercial formulations. Plasma bile acid (BA) and cholesterol concentrations, growth performance, and feed conversion ratio (FCR) were measured. Because only two treatments were compared, independent twosample ttests were used to evaluate differences ($p < 0.05$).

In Trial 2, Nile tilapia (initial weight 44.8 g) were stocked into ten hapas (2 m × 1 m × 1 m) placed in a reservoir, with five hapas per treatment. Each hapa held 70 fish (1.6 kg/m³). The basal diet contained 28% crude protein and 4% fat, with 33.8% soybean meal and 11.2% poultry meal as the primary proteins and no fishmeal. Fish were fed three meals daily for 10 weeks at 31–35 °C and 5 ppt salinity, reaching ~500 g at harvest. Growth performance, FCR and fillet yield were assessed. Due to potential variance heterogeneity in field conditions, Welch's ttest was applied ($p < 0.05$).

Results

In red seabream, BS supplementation significantly increased plasma BA concentrations by 17% and plasma cholesterol by 44% relative to the control. Elevated plasma cholesterol indicates improved nutrient utilization and a more favourable energy balance. Increased circulating cholesterol also enhances hepatic BA synthesis, expanding the gallbladder BS reservoir. These metabolic improvements translated into superior performance, with BSsupplemented fish exhibiting a significant 7% increase in specific growth rate (SGR) and a numerical 2% decrease in FCR compared to control. In tilapia, BS supplementation resulted in a numerical 2.4% increase in fillet yield and a 4.5% reduction in FCR at harvest. These benefits occurred despite fluctuating temperatures and moderate salinity in the reservoir, demonstrating improved nutrient retention efficiency and physiological robustness.

Discussion

Across species and production systems, dietary supplementation with 200 mg/kg bovine BS (Lipogest, Adisseo) effectively supported BA homeostasis, digestive function and performance. In seabream fed a soyrich diet, increased plasma cholesterol and BA levels indicate enhanced enterohepatic circulation, better gallbladder filling and improved bile availability for lipid emulsification. This resulted in higher feed efficiency and growth. In tilapia reared under warm and moderatesalinity conditions, BS supplementation improved nutrient utilization and fillet yield, suggesting stronger metabolic resilience. The lack of fishmeal and high soybean meal inclusion in the tilapia diet underscores the value of BS supplementation in plantproteinbased formulations, where endogenous BA synthesis and taurine status may be limiting. As aquaculture continues to adopt sustainable, lowfishmeal feeds, BS supplementation represents an effective nutritional tool to maintain bile acid pool adequacy, support hepatic health and optimize production outcomes.

ENHANCING THE COST EFFICIENCY OF EUROPEAN SEABASS (*Dicentrarchus labrax*) FEEDS THROUGH MARINE PEPTIDE-BASED FORMULATION STRATEGIES

Bardera G^{1*}, Dehasque M¹, Robles-Arozarena R², Nuez-Ortín WG¹

¹ Adisseo, France

² Testing Blue S.L., Puerto Real, Spain

*Presenting author e-mail: guillermo.bardera@adisseo.com

Introduction

The expansion of aquaculture production is driving the development of feed formulation strategies that improve sustainability, increase resilience to fluctuations of raw material prices, and enhance economic efficiency. Fish meal (FM) remains a key ingredient in marine fish diets due to its nutritional value and palatability; however, sustainability targets and formulation economics are encouraging a progressive reduction in FM inclusion. Consequently, cost-saving strategies increasingly focus on reducing FM levels or utilising alternative FM qualities, provided that growth performance and feed efficiency are maintained. Marine peptide concentrates (MPCs), characterised by high digestibility and functional bioactive properties, offer effective support for these approaches by enhancing nutrient utilisation and growth efficiency. This study evaluated the efficacy of a marine peptide concentrate (Pepsea F) as a functional additive in European seabass (*Dicentrarchus labrax*), assessing its ability to support FM inclusion reduction and FM quality substitution strategies while enhancing biological and economic performance.

Material and Methods

An 11-week feeding trial was conducted using European seabass with an initial mean body weight of 18 g. Fish were reared in a recirculating aquaculture system (RAS) using 150-L tanks stocked with 25 fish per tank under controlled conditions (water temperature 22.7 ± 1.2 °C). Feed was supplied twenty times per day using automatic feeders. Experimental feeds included the marine peptide concentrate, Pepsea F (liquid, 40% crude protein (CP40); Adisseo), at inclusion levels of 0.75%, 1.5% or 2.25% under two cost-reduction strategies: (i) partial replacement of high-quality FM (CP68), reducing inclusion from 20% to 10%, and (ii) substitution of FM quality from CP68 to CP60 at a constant 20% inclusion level. Each treatment was tested in triplicate. All experimental feeds were formulated to be isoproteic, isolipidic and isoenergetic. Growth performance parameters, including feed intake, specific growth rate (SGR), and feed conversion ratio (FCR), were measured. Data were analysed using one-way ANOVA followed by Tukey's post-hoc test ($p < 0.05$). An economic assessment based on feed cost, feed efficiency, biomass output, and return on investment (ROI) was conducted using Turkish raw material prices as reference (September 2025).

Results

Reduction of FM inclusion from 20% to 10% (CP68) negatively affected SGR and FCR when no functional additive was applied. However, supplementation with Pepsea F significantly restored and improved performance. Inclusion of 1.5% Pepsea F in the 10% FM diet resulted in a numerical 4% increase in feed intake, 5% in SGR and a 4% improvement in FCR compared to the 20% FM control diet, while simultaneously reducing feed formulation cost by 32 €/t. Improved feed efficiency corresponded to approximately 40 kg of feed saved per metric ton of feed, equivalent to 60 €/t in on-farm savings. Combined with feed formulation savings, total economic benefit reached 92 €/t of feed. In addition, increased growth performance resulted in a 5% increase in final biomass, corresponding to an additional 50 kg of fish per metric ton, equivalent to 325 € of extra income (farm-gate price: 6.5 €/kg). This scenario yielded an ROI of the additive of 8.

In the second strategy, replacement of FM quality from CP68 to CP60 negatively impacted growth and feed efficiency. Supplementation with 0.75% Pepsea F not only mitigated these effects but exceeded the performance of the 20% CP68 control diet, numerically improving feed intake by 1%, SGR by 4% and FCR by 2%. Feed reformulation reduced feed cost by 19 €/t, while improved FCR generated an additional 30 €/t in feed savings for producers (49 €/t combined). Biomass gains generated approximately 260 € of additional income per metric ton of fish produced. This scenario resulted in an ROI of 12.

Discussion

The results demonstrate that Pepsea F effectively compensates for both reduced FM inclusion and downgraded FM quality in European seabass feeds, maintaining or improving growth performance and feed efficiency relative to high-FM control diets. The observed improvements in SGR and FCR highlight the functional role of marine peptides beyond their nutritional contribution, linked to enhanced palatability and nutrient utilisation. Importantly, the substantial ROI values obtained across both formulation strategies confirm the economic relevance of Pepsea F inclusion, delivering benefits at both feed mill and farm levels. Overall, these findings support the use of marine peptide concentrates as sustainable, functional tools to optimise seabass feed formulations, reduce dependence on high-quality fish meal, and enhance profitability in marine aquaculture.

DIETARY LYSOPHOSPHOLIPIDS ENHANCE GROWTH PERFORMANCE AND ASTAXANTHIN DEPOSITION IN ATLANTIC SALMON (*Salmo salar*) AND RAINBOW TROUT (*Oncorhynchus mykiss*)

Bardera G^{1*}, Dehasque M¹, Nuez-Ortín WG¹

¹ Adisseo, France

*Presenting author e-mail: guillermo.bardera@adisseo.com

Introduction

Astaxanthin is an essential carotenoid in salmonid nutrition and a major determinant of flesh pigmentation, directly influencing consumer acceptance and market value. As salmonids are unable to synthesize astaxanthin *de novo*, dietary supplementation is mandatory. Beyond pigmentation, astaxanthin contributes to antioxidant protection, immune modulation, and stress resistance. However, its bioavailability is often limited by its lipophilic nature, low solubility in the intestinal environment, and reliance on passive absorption mechanisms. Nutritional strategies that enhance lipid digestion, emulsification, micelle formation, and postabsorptive transport may therefore improve astaxanthin utilization and retention. Lysophospholipids exhibit superior emulsifying properties compared to conventional phospholipids and are involved in lipoprotein metabolism. This study evaluated the effects of a lysophospholipid-based additive (Aqualyso, Adisseo) on growth performance and fillet pigmentation in Atlantic salmon (*Salmo salar*) and rainbow trout (*Oncorhynchus mykiss*).

Material and Methods

Two feeding trials were conducted. In the first trial, Atlantic salmon post-smolts (initial body weight 160 g) were reared for 12 weeks in 1.2 m³ tanks (35 fish per tank; three replicates per treatment) under controlled salinity (33 ppt) and temperature (12 ± 2 °C). A basal diet (45% crude protein, 28% lipid) containing 60 ppm astaxanthin and no lecithin was supplemented with graded inclusion levels of liquid Aqualyso (0, 0.05, 0.1, and 0.2%). Fish were fed to apparent satiation. Growth performance parameters were assessed at weeks 6 and 12, and fillet samples were analysed for astaxanthin and total carotenoid concentration to determine pigment retention efficiency.

In the second trial, rainbow trout sub-adults (initial body weight 300 g) were fed for 10 weeks in a flow-through system (1,600 L tanks; 18 fish per tank; two replicates per treatment) at natural water temperatures (13–14 °C). A basal diet (44% crude protein, 25% lipid; 60 ppm astaxanthin) was compared with the same diet supplemented with 0.1% powdered Aqualyso. Growth performance was monitored, and fillet pigmentation was evaluated at weeks 5 and 10 using colourimetric analysis (CIE Lab* system; n=12 fillets per treatment at each sampling point). Statistical analyses were performed using one-way ANOVA or Students T-test, with significance set at $p < 0.05$.

Results

In Atlantic salmon, Aqualyso supplementation improved growth performance in a dose-responsive manner. The 0.1% inclusion level produced the strongest growth response, with numerically higher feed intake (+10%) and specific growth rate (+6%) compared to the control, observable from week 6 onwards, while feed conversion ratio was unaffected. All supplementation levels increased fillet astaxanthin concentration. The greatest improvement in pigment utilization was observed at 0.05% inclusion, resulting in a numerical increase of 32% in fillet astaxanthin concentration and a 29% increase in astaxanthin retention efficiency. Total carotenoid concentration and retention were numerically increased by 24% and 23%, respectively.

In rainbow trout, dietary inclusion of 0.1% Aqualyso numerically increased final body weight by 5% and improved feed conversion ratio by 3%. Colourimetric analysis indicated higher redness (a*) and yellowness (b*) values at week 5, and a significant improvement in hue angle (h) at week 10, indicating enhanced pigmentation efficiency compared to the control.

Discussion

Lysophospholipid supplementation improved growth performance and astaxanthin utilization in both salmonid species. These effects are likely linked to enhanced emulsification, more efficient micelle formation, improved lipid digestion, and increased intestinal absorption of lipophilic compounds such as astaxanthin. This pigmentation benefits were consistently demonstrated through complementary evaluation approaches: biochemical quantification of astaxanthin and carotenoid retention in Atlantic salmon, and objective colourimetric measurements in rainbow trout. Overall, the results support the use of lysophospholipids as an effective nutritional strategy to improve growth and optimize pigment efficiency in salmonid aquaculture.

TRANSCRIPTOMIC INSIGHTS INTO THE ONSET AND MATURATION OF THE CIRCADIAN CLOCK IN EURASIAN PERCH

Introduction

The circadian clock coordinates multiple aspects of physiology, including digestion (Pal and Maitra, 2018), cell proliferation (Tamai et al., 2012), stress responses (Sánchez-Vázquez et al., 2019), spawning, and behavior (Marchesan et al., 2005). While the molecular architecture of the circadian system is well characterized in adult vertebrates, its developmental onset and early functional organization remain poorly understood, particularly in fish. In teleosts, circadian rhythms have been described at both behavioral and molecular levels (Cuesta et al., 2014); however, studies addressing their ontogeny are still limited. As a result, the timing of initial rhythmicity and the processes underlying the establishment of a functional circadian system during early development remain largely unresolved.

The aim of this study was to determine the onset and progression of circadian rhythmicity in Eurasian perch by combining high-resolution temporal sampling of core clock gene expression with transcriptomic profiling to identify rhythmically expressed genes and associated molecular pathways across key developmental stages.

Results and discussion

Using high-resolution temporal sampling, we demonstrated that core circadian clock genes in Eurasian perch begin to oscillate at 3 days post-hatching (DPH) and exhibit robust rhythmicity by 28 DPH under a controlled photoperiod (14L:10D). These two developmental stages were therefore selected for transcriptomic profiling using 24-hour round-the-clock sampling at 4-hour intervals to capture diel gene expression dynamics and identify molecular pathways involved in the emergence and consolidation of circadian regulation. Using MetaCycle, we identified 1,466 rhythmically expressed genes at 3 DPH and 478 at 28 DPH, of which 206 were shared between both stages, indicating a combination of conserved and stage-specific rhythmic processes.

Temporal clustering with TCseq revealed seven distinct expression clusters at each developmental stage, reflecting diverse rhythmic patterns across the diel cycle. Functional annotation and gene ontology analyses further indicated that these clusters were associated with a range of biological processes, suggesting a progressive organization of circadian-regulated pathways during development. This approach uncovered both shared and stage-specific rhythmic transcripts, including several genes not previously described as circadian biomarkers in fish. Among these were, for example, *ciart* and *cipc*, which are known components of the negative regulatory arm of the circadian clock in other vertebrates but have not yet been characterized in fish.

To further investigate candidate genes associated with early circadian development, we implemented two complementary validation strategies. First, a cross-species approach targeted genes previously reported in mammals or other model organisms but not in fish, including *ciart* and *cipc*, to assess their evolutionary conservation and potential functional relevance in teleost circadian systems. Second, we selected a set of ten putative novel circadian rhythm-associated genes identified from our transcriptomic dataset, representing candidates with no prior links to circadian regulation. Collectively, these findings expand current knowledge of the genetic architecture underlying early circadian development and lay the groundwork for further mechanistic exploration.

TOWARDS STANDARDISED FISH WELFARE ASSESSMENT: DEVELOPMENT OF A DIGITAL MULTI-INDICATOR PLATFORM

Introduction

Fish welfare assessment is increasingly recognized as a key component of modern aquaculture, but its routine implementation remains challenging. Frameworks such as the Salmon Welfare Index Model and FISHWELL have shown the value of formal assessment using operational welfare indicators (Stien et al., 2013; Noble et al., 2018). However, welfare information is often fragmented across production records, health monitoring and isolated observations. Production key performance indicators are relevant to welfare, but they do not fully capture behavioural expression, environmental suitability or management practices (Martins et al., 2012; Saraiva et al., 2019). This work describes the development and preliminary applicability testing of WAAVE - Welfare Assessment of Aquatic Vertebrates, as a digital multi-indicator workflow for structured fish welfare assessment across aquaculture, research laboratories and public aquaria.

Methodological development

WAAVE was developed by FishEthoGroup as a mobile and web-based workflow grounded in scientific literature and applied welfare research. The indicator catalog integrates animal-based, environmental-based and management-based indicators, including external appearance, feeding behaviour, swimming patterns, respiratory rate, aggression, water quality, light conditions, disturbance, staff training, handling protocols, records and traceability. The workflow was designed to assign indicators according to the selected production or rearing context, allowing aquaculture, laboratory and public aquarium assessments to use a consistent structure while retaining setting- and species-specific relevance.

Indicators are evaluated through a traffic-light scoring system and are manually scored by trained users. The workflow then summarizes the assessment into structured outputs, including an overall welfare score, priority concerns and a report intended to support interpretation and follow-up actions (Figure 1). The aim is not to automate welfare judgement, but to standardize indicator selection, scoring and reporting in a transparent format that can be reviewed and improved through validation.

Figure 1. WAAVE workflow from indicator selection to structured welfare output.

(Continued on next page)

Scientific basis and preliminary application

WAAVE reflects work highlighting the importance of species-specific welfare knowledge (Saraiva et al., 2019), behavioural indicators (Martins et al., 2012), environmental enrichment (Arechavala-Lopez et al., 2022), and context-dependent management decisions such as stocking density (Saraiva et al., 2022). The platform has undergone internal applicability testing in FishEthoGroup facilities and preliminary use with Odysseo Oceanarium, Mauritius. These early applications suggest that a structured digital workflow can help identify welfare aspects not routinely captured through production or health monitoring alone. WAAVE is now entering a closed testing phase with selected partners to evaluate usability, indicator relevance, reporting usefulness and setting-specific applicability under operational conditions.

Discussion

WAAVE is intended to complement, not replace, existing farm management and health monitoring systems. Its contribution lies in translating welfare science into a practical, human-scored workflow that integrates behavioural, environmental and management observations. By standardizing data collection and summarizing outputs, WAAVE may support routine welfare monitoring, staff communication and continuous improvement across facilities working with fish. Future work will focus on validation and refinement of setting-specific and species-specific indicator sets.

Introduction

Successful aquaculture production depends on healthy and reproductively competent broodstock capable of producing high-quality gametes. Nutrition is a key determinant of reproductive performance, and increasing attention has been directed toward the use of sustainable alternative protein sources in aquafeeds. In this context, insect-derived meals have emerged as promising alternatives to conventional fishmeal. Although their effects on growth performance and fillet quality have been extensively investigated (Alfiko et al., 2022), comparatively little is known about their potential impacts on broodstock reproductive performance, gonadal development, and gamete quality. The limited studies conducted in species such as zebrafish and brown trout have reported inconsistent outcomes (Chemello et al., 2022). Consequently, the long-term implications of insect-based diets for fish reproductive health and performance remain poorly understood.

Materials and methods

Freshly hatched African catfish (*Clarias gariepinus* BURCHELL, 1822) larvae were fed *Artemia* nauplii for the first five days post-hatch. Following this initial period, experimental diets were introduced. The Control group received only commercial feeds, while in the BSF33 group, 33% of the feed was replaced with Black Soldier Fly (*Hermetia illucens* L.) (BSF) meal. In the BSF50 group, 50% of the feed was substituted with BSF meal. Fish were maintained in a continuous recirculating aquaculture system (RAS) at a constant temperature of 25 ± 1 °C.

To ensure optimal broodstock selection, continuous growth measurements and phenotypic selection were carried out throughout the rearing period. After 18 months of culture, 5 females from each group were selected and used for indicated propagation. After propagation fish were dissected and residual ovaries were fixed in 10% formaldehyde solution until further processing.

Sample processing was done according the protocol of Egezza et al., 2024. The prepared histological sections were examined using a Nikon Eclipse E600 research microscope. In the ovarian tissue sections, oocytes were classified according to their developmental stage, and the cells belonging to each developmental category were subsequently counted. The developmental stages of the oocytes were determined based on the classification applied by Lefler et al. (2008), according to which oocytes can be categorized into protoplasmic (prot%), cortical alveoli stage (cort%), and vitellogenic (vit%) stages.

Results

Analysis of the histological sections revealed no statistically significant differences in the distribution of ovarian oocytes across developmental stages among the dietary treatment groups. Approximately 72–74% of the oocytes were in the protoplasmic stage, while 6–7% showed the onset of cortical alveoli stage, and 19–21% were in the vitellogenic stage.

Table 1. Maturity stages of oocytes observed in the residual ovaries of individuals from the different dietary treatment groups

	prot%	cort%	vit%
Control Group	73,6%±6,6 ^a	6,9%±2,1 ^a	19,4%±7,4 ^a
BSF33 Group	72,5%±19,6 ^a	6,0%±2,1 ^a	21,5%±18,5 ^a
BSF50 Group	73,6%±5,8 ^a	6,7%±1,7 ^a	19,7%±4,1 ^a

(Continued on next page)

Discussion

The predominance of protoplasmic-stage oocytes (72,5–73,6%) and the presence of vacuolizing (6,0–6,9%) and vitellogenic oocytes (19,4–21,5%) indicate ongoing ovarian development and reproductive activity. The presence of a considerable proportion of vitellogenic oocytes suggests active yolk deposition and progression towards advanced oocyte maturation. As no significant differences were detected among dietary treatments in the distribution of oocyte developmental stages, the tested diets did not appear to adversely affect ovarian development or the progression of oocyte maturation. However, oocyte developmental stage alone does not provide a direct measure of oocyte quality or reproductive readiness and should therefore be interpreted together with reproductive performance parameters.

Conclusion

Replacing 33% and 50% of the complete feed with black soldier fly larvae meal has no negative effect on the oocyte developmental stages in the brooder age African catfish.

NEUROFEED - LINKING SUSTAINABLE NUTRITION TO NEUROENDOCRINE MECHANISMS IN STRESS RESILIENCE ON EUROPEAN SEABASS: THE ROLE OF BLACK SOLDIER FLY LARVAE OIL

Ana Basto^{1*}, Diogo Peixoto¹, Diana Marques¹, Rita Azeredo¹, Luisa M.P. Valente^{1,2}

*Presenting author: anafbasto@gmail.com

Background and objective

Aquaculture intensification exposes fish to recurrent stressors, including handling, transport, vaccination and overcrowding. When stress responses are prolonged, recurrent, or severe, activation of the hypothalamus-pituitary-interrenal axis can disrupt metabolism, suppress immune competence, reduce growth and compromise welfare. There is therefore a need for affordable and sustainable feed ingredients that provide nutritional value while improving the capacity of farmed fish to cope with acute challenges. Black soldier fly (BSF) larvae oil, a co-product of *Hermetia illucens* processing, is a circular lipid source with potential functional properties. Preliminary observations in European seabass (*Dicentrarchus labrax*) indicate that dietary inclusion of this oil may attenuate the cortisol peak and improve metabolic and oxidative responses after acute stress (Basto et al., 2025). However, the neuroendocrine mechanisms underlying these effects remain unknown. This project aims to determine whether BSF larvae oil modulates central and peripheral pathways controlling stress resilience in European seabass.

Conceptual approach

The project builds on samples collected at the end of a 12-week feeding trial in which juvenile European seabass (initial body weight: 12 ± 1 g) were fed on one of two isonitrogenous, isolipidic, and isoenergetic diets: a control diet or an experimental diet containing 5.2% BSFLO, which completely replaced poultry oil. At the end of the trial, fish were sampled under basal conditions or after an acute challenge combining one minute of air exposure, 14 minutes of overcrowding at 100 kg m⁻³, and 60 minutes of recovery. The hypothalamus, pituitary gland and head kidney were collected to assess the central and peripheral coordination of the stress response. RNA sequencing of the hypothalamus and head kidney will identify diet-dependent transcriptional programmes and enriched biological pathways. Candidate genes emerging from this analysis will then be integrated with classical neuroendocrine markers and analysed by real-time quantitative polymerase chain reaction (RT-qPCR) across the three target tissues. This combined strategy will link transcriptome responses with targeted regulation of the hypothalamus-pituitary-interrenal axis.

Figure 1. Conceptual overview of NEUROFEED project.

(Continued on next page)

Expected outcomes and significance

The project is expected to reveal whether BSF-derived oil reshapes the molecular response to acute stress and to identify biomarkers associated with improved resilience. By moving beyond conventional performance indicators towards a mechanistic understanding of nutrition-neuroendocrine interactions, the study will establish a biological basis for the use of BSF larvae oil as both an energy source and a functional aquafeed ingredient. The resulting knowledge may support the design of more sustainable, welfare-oriented diets while strengthening circularity through the valorisation of an insect-processing co-product.

ALFUNFEED - FUNGAL SINGLE-CELL PROTEIN FROM MACROALGAL WASTE FERMENTATION: IMPROVING SUSTAINABILITY AND REDUCING THE CARBON FOOTPRINT OF FISH AQUAFEEDS

Cristina Velasco¹, Ana Basto^{1*}, Carlota Freiría¹, José Luis Soengas¹

¹CIM, Centro de Investigación Mariña

Laboratorio de Fisioloxía Animal

Departamento de Bioloxía Funcional e Ciencias da Saúde

Facultade de Bioloxía

Universidade de Vigo, Spain

*Presenting author: anafbasto@gmail.com

Background and objective

The continued expansion of aquaculture requires sustainable, nutritionally adequate and economically viable alternatives to conventional fish- and plant-derived proteins. At the same time, macroalgal processing industries generate substantial quantities of residual biomass that remain underutilised despite containing valuable nutrients and fermentable compounds. AlFunFeed proposes an integrated circular approach in which macroalgal by-products are converted through scalable fermentation into fungal single-cell protein (SCP). By linking marine biomass valorisation with aquafeed production, the project aims to reduce waste, alleviate pressure on conventional protein resources and support the development of local circular bioeconomy value chains. The overall objective is to validate macroalgae-derived fungal SCP as a safe, functional and eco-efficient protein source for carnivorous fish species.

Conceptual approach

AlFunFeed integrates biotechnology, aquaculture nutrition and environmental assessment throughout the ingredient-development process. Selected fungal strains and fermentation conditions will be optimised to efficiently convert macroalgal residues into nutritionally valuable microbial biomass. The resulting SCP will be characterised for its proximate composition, amino acid profile, digestibility-related properties and potential safety constraints before its incorporation into nutritionally balanced experimental diets. The biological performance of the new ingredient will be evaluated in juvenile European seabass (*Dicentrarchus labrax*) through feeding trials designed to assess feed acceptance and feeding regulation, nutrient digestibility, growth performance and feed utilisation. Its potential functional effects will also be examined by evaluating immune competence, physiological condition, welfare-related indicators and gut microbial communities. This multidisciplinary assessment will determine whether fungal SCP can provide benefits beyond its role as a dietary protein source. The nutritional evaluation will be complemented by life-cycle assessment (LCA) and cost analyses comparing SCP-based feeds with conventional aquafeed formulations. These analyses will quantify potential changes in carbon and nutrient footprints, resource use and production costs, while identifying the main environmental and economic factors affecting future industrial implementation.

Expected outcomes

AlFunFeed is expected to establish a technological and biological foundation for the conversion of macroalgal by-products into high-quality aquafeed ingredients. The project will generate knowledge on production scalability, nutritional suitability, safety, functional performance and environmental competitiveness. By combining waste valorisation with the development of stable alternative protein sources, AlFunFeed may contribute to reducing aquaculture's dependence on resource-intensive ingredients and strengthening the resilience and competitiveness of European aquaculture. Engagement with researchers, industry stakeholders and policymakers will further support knowledge transfer, responsible resource use and the future adoption of circular feed-production strategies.

Acknowledgment

AlFunFeed project (SBEP2024-794) is co-funded by the European Union under the Horizon Europe Programme through the Sustainable Blue Economy Partnership and by the respective national funding organisations.

Introduction

Aquaculture production of bivalves relies heavily on the continuous supply of high-quality live microalgae¹, particularly during early juvenile stages characterized by high feeding rates and elevated nutritional demands. However, large-scale microalgae production remains technically demanding, costly, and subject to variability in both nutritional quality and availability, posing significant operational constraints for hatcheries². These limitations have driven growing interest in alternative or complementary feeding strategies capable of reducing dependence on live feeds without compromising biological performance. Among these, powdered or inert diets have emerged as promising options, offering advantages in terms of storage, handling, and consistency³. Despite these benefits, their effectiveness as partial or total substitutes for live microalgae remains insufficiently understood, particularly during juvenile development. This knowledge gap is especially relevant for high-value species such as *Ruditapes decussatus*, in which early-stage nutrition strongly influences growth performance and overall physiological condition⁴. Therefore, this study aimed to evaluate the effects of partial and total replacement of live microalgae with a formulated powdered diet (PearlDiet) on the growth and physiological condition of juvenile *R. decussatus*.

Materials and Methods

Juvenile *R. decussatus* (~1 mm initial shell length) were reared for 28 days in 8 L closed systems using ultrafiltered seawater. Clams were distributed as pooled samples (~0.5 g wet weight, WW) across five dietary treatments in triplicate: 1) live microalgae (LM) Dose 1; 2) LM, Dose 2; 3) 50% LM + 50% PearlDiet (PD); 4) 25% LM + 75% PD; and 5) 100% PD. LM consisted of *Tisochrysis lutea*, *Chaetoceros calcitrans*, and *Skeletonema costatum* (1:1:1, v/v), while PD comprised a microalgal blend fortified with docosahexaenoic acid (DHA) and supplemented with carbohydrates, probiotics, and yeast. Diets were administered daily in two feeding events at fixed rations: LM at 10% (Dose 1) and 5% (Dose 2) and PD at 15% (g dry weight g⁻¹ WW of juveniles). Water was renewed every two days and continuous aeration was provided. Environmental conditions were monitored daily. Sampling was performed weekly, with biomass standardized at each time point to maintain comparable system density. Growth was assessed based on changes in WW and shell morphometrics (shell length, SL; shell height, SH; shell area, SA), while physiological condition was evaluated through organic matter content (OMC).

Figure 1.

(Continued on next page)

Results

At the end of the experiment, there were no significant differences in WW, SL, or SA among juveniles fed all LM-containing diets, except for those fed LM Dose 1, which showed the lowest growth (WW, SL, and SA) among these treatments. The growth of juveniles fed 25% LM + 75% PD (WW: 2.09 ± 0.13 g, SL: 3.51 ± 0.82 mm, SA: 7.17 ± 2.9 mm²) did not differ significantly from that of juveniles fed LM Dose 2 (WW: 2.26 ± 0.16 g, SL: 3.68 ± 0.94 mm, SA: 7.33 ± 3.11 mm²). Juveniles fed 100% PD showed the lowest WW, SL, SA, and OMC values, which were significantly lower than those observed in most dietary treatments. No significant differences in OMC were observed between juveniles fed 25% LM + 75% PD and those fed LM Dose 2 or any other LM-containing diets. Juveniles fed 100% PD showed significantly lower OMC values ($10.55 \pm 0.25\%$) compared to all other treatments.

Growth performance and physiological condition of juvenile *Ruditapes decussatus* over a 28-day feeding trial under different dietary treatments. (A) pooled wet weight (g); (B) organic matter content (OMC, %). Values are presented as mean $\pm$ SD ($n = 3$). Different lowercase letters indicate significant differences among treatments at day 28 (one-way ANOVA, Tukey post-hoc test, $p < 0.05$). LM: live microalgae; PD: PearlDiet

Discussion

The present study demonstrates that a substantial reduction in live microalgae supply is possible without compromising the growth and physiological condition of juvenile *R. decussatus*. Comparable growth and OMC between the 25% LM + 75% PD and LM treatments, particularly relative to LM Dose 2 (the best-performing LM treatment), indicate that a substantial proportion of live microalgae can be replaced by a formulated powdered diet while maintaining juvenile clam performance. This finding is especially relevant, as live microalgae constitute the natural diet of bivalves and their production remains a major technical and economic constraint for bivalve seed production¹. Similar approaches have been reported in bivalve spat, where non-live or concentrated microalgal diets have been shown to support growth when used as complementary feeds rather than as complete substitutes³. The lower performance observed in the 100% PD treatment suggests that further improvements in formulation are needed to fully match the nutritional and functional properties of live microalgae. However, the strong performance observed at high inclusion levels of inert diet highlights the potential of partial replacement strategies to improve hatchery efficiency. Overall, these findings support the use of PearlDiet as a complementary feed to reduce reliance on live microalgae, thereby enhancing production sustainability and reducing operational costs.

Introduction

Common carp (*Cyprinus carpio*) is one of the most widely cultured and consumed fish species in Central Europe. Ensuring humane slaughter is essential not only for fish welfare but also for maintaining fillet quality. However, many conventional slaughter methods do not consistently meet fish welfare standards. Electrical stunning (ES) has emerged as a promising humane slaughter technique, as species-specific studies indicate that it can induce an irreversible stun or a reversible state of unconsciousness. Nevertheless, if ES is applied improperly, it may compromise both fish welfare and product quality. In common carp, the effectiveness of ES depends strongly on the optimization of electrical parameters. Therefore, precise control and validation of these parameters are critical to ensure reliable induction of unconsciousness while preserving fillet quality. This study is designed to optimize electrical stunning conditions at an industrial scale, with the aim of improving both welfare outcomes and product quality in common carp processing.

Materials and Methods

The in-water electrical stunning (ES) protocol was evaluated in common carp (3–4 kg) at a commercial fish processing plant (Rybářství Chlumec nad Cidlinou, Czech Republic). Two stunning systems were used: an existing plant-operated stunner (AC, 230 V, 50 Hz, 5 A) and a newly developed ES unit capable of both AC and DC application (50 Hz, adjustable 0–320 V and 0–15 A). A total of 80 fish were randomly assigned to four treatment groups (n = 20 per group): percussion stunning as the control (T0), T1 (commercial stunner; AC, 220 V, 5 A, 7 min), T2 (AC, 320 V, 6 A, 5 min), and T3 (DC, 320 V, 6 A, 5 min).

To assess the effectiveness of stunning, immediately after stunning, 10 fish per treatment were transferred to a recovery tank to monitor the return of consciousness at 0, 2.5, 5, 7.5, and 10 minutes post-stunning. Physiological stress responses were evaluated using blood indicators (cortisol, lactate dehydrogenase, glucose, potassium). For the product quality assessment, rigor mortis progression and muscle pH were monitored over 72 hours (0, 6, 12, 24, 36, 48, 60, and 72 h). Additionally, key fillet quality parameters such as drip loss, ATP, glycogen, glucose, lactate, haemoglobin content, color, and texture were analyzed using standard protocols.

Results

Fish subjected to percussion and the newly developed DC stunning (T3) did not regain consciousness during the 10-minute post-stunning observation period, indicating a prolonged unconsciousness and effective stunning. In contrast, 50% of the fish treated with the plant stunner (T1: AC) regained consciousness within 10 minutes, while an even higher recovery rate (70%) was observed in the T2 (AC) group, suggesting less effective stunning. Cortisol and other blood parameters did not differ significantly ($p > 0.05$) among treatments compared to percussion, indicating a comparable acute stress response across groups. However, clear differences were observed in post-mortem muscle dynamics and fillet quality. The onset of rigor mortis occurred significantly earlier ($p < 0.05$) in T1 (at 12 h), followed by T2, T3, and finally T0 (percussion), suggesting accelerated metabolic exhaustion in AC-treated fish. The pH of fish muscle is also consistent with rigor progression. Drip loss was slightly higher ($p > 0.05$) in all electrically stunned groups compared to percussion, indicating reduced water-holding capacity. Muscle glycogen content was significantly lower in T1 and T2, but higher in T0 and T3 ($p < 0.05$), reflecting greater pre-mortem energy depletion in AC treatments. In contrast, glucose levels were highest in T1, consistent with increased glycogen breakdown. Additionally, muscle haemoglobin content was significantly elevated in T1 compared to other treatments ($p < 0.001$), suggesting greater tissue damage or blood retention. Overall, these results indicate that DC (T3) stunning provides effective induction of prolonged unconsciousness comparable to percussion, while preserving better fillet quality than AC (T1 & T2) treatments.

SUBMERGED FARMING AS PREVENTIVE MEASURE AGAINST *Lepeophtheirus salmonis*: THE IMPORTANCE OF PARASITE BIOLOGY AND BEHAVIOUR KNOWLEDGE

AS Båtnes^{1*}, Hatlebakk M¹, Fledsberg EG¹, Solem OM¹, Antonsen E¹, Pambudi MR¹, Høvik CA¹, Miljeteig C¹

Lepeophtheirus salmonis infestation is a major challenge for the Atlantic salmon (*Salmo salar*) aquaculture industry. Submerged farming (sea cages below 20 m depth) has emerged as a promising preventive measure against the parasite, being based on that there is a higher abundance of infective stages of *L. salmonis* in upper water layers. Although infestation levels seem reduced, some infestation still occur in submerged cages, and infestation mechanisms are poorly known. The current study summarises several investigations of *L. salmonis* biology and behaviour related to submerged farming.

Production data from submerged farms were collected and analysed. Different life stages of *L. salmonis*, including egg strings, were collected from submerged cages and brought to the laboratory. Survival was investigated, and hatching and development of larvae from the egg strings was monitored. Behavioural responses of nauplii, copepodites, pre-adult and adult stages to stimuli such as light, pressure, and different salinities were quantified.

In the current data set, there was a 90% reduction in delousing treatments in submerged cages compared to conventional surface cages, highlighting the positive effect of submerged farms but showing that infestations still happen. Survival of *L. salmonis* collected at submerged farms did not differ from that of lice from surface farms, neither did hatching and development of larval stages. This indicates that the depth of submerged cages does not represent a challenge to the basic biology of the parasite. Behavioural experiments with larvae originating from submerged and surface farms show that the larvae are positively phototactic and negatively barotactic, and avoid certain salinities. However, light, pressure, and salinity mediated behaviour differently depending on *L. salmonis* origin. The results highlight the need for detailed knowledge on biology and behaviour of the parasite to predict the effects of preventive measures, and that this knowledge is needed to optimise the measures.

LINKING GENOMICS AND SHELL MORPHOLOGY IN MANILA CLAM (*Ruditapes philippinarum*): INSIGHTS FROM SNP ARRAYS AND CT IMAGING

Background

The Manila clam (*Ruditapes philippinarum*) is one of the most widely cultivated bivalve species globally, valued for its rapid growth, environmental tolerance, and economic importance in coastal aquaculture. Its production is increasingly challenged by disease outbreaks, rising temperatures, and other environmental stressors linked to climate change. Selective breeding, supported by genomic tools, offers a powerful approach to enhance resilience, productivity, and key commercial traits in this species.

Previously, we have developed and validated a high-density SNP array for the Manila clam to enable large-scale genomic analyses supporting selective breeding. SNP discovery was conducted using low-coverage whole-genome sequencing across multiple European populations, followed by the design and validation of a 49K Axiom® SNP array. The platform demonstrated high call rates and robustness across diverse experimental cohorts, providing a comprehensive resource for downstream analyses of heritable traits, including growth, disease resistance, and thermal tolerance.

Methods

To complement genomic data, a large-scale phenotyping effort was undertaken using computed tomography (CT) scanning of 1000 clam shells. A purpose-built holder was designed and iteratively refined to ensure consistent positioning and optimal scan quality. High-resolution scans were used to extract detailed morphometric parameters, including shell width, depth, thickness, and density, enabling precise quantitative characterization of shell structure.

Results

The CT-derived data provides a novel, high-resolution characterization of shell morphology and allows deeper investigation into which morphological traits are most strongly influenced by genetic variation, strengthening the integration of phenotypic and genomic datasets for selective breeding applications.

INTEGRATED MULTI-OMICS OF MICROBIAL COMMUNITY STRUCTURE OF RAINBOW TROUT GUT AND CULTURE SYSTEM

Introduction

The assembly of the gut microbiome in fish is a dynamic and tightly regulated process influenced by host genetics, early-life environmental exposure, diet, and aquaculture practices. Although, the host-focused RNA-seq datasets are routinely generated in aquaculture research and breeding programs yet the microbial information contained in unmapped reads is typically overlooked. Advances in high-throughput sequencing technologies, along with the multi-omics approaches has enabled integration of microbial community structure with the functional characterization. This combined approach provides insights into microbial roles and will improve understanding host-microbiome-environment interactions and aquaculture sustainability. This study aims to comprehensively characterize the intestinal meta-transcriptome of *Oncorhynchus mykiss* using different rearing systems, with particular emphasis on the influence of early-life rearing environments.

Materials and Methods

Eyed eggs (200 degree-days post fertilization) of specific pathogen-free (SPF) rainbow trout (*Oncorhynchus mykiss*) were reared in two contrasting systems flow through system (FTS: low organic matter) and Recirculatory Aquaculture System (RAS: high organic matter), each in triplicates. At late fry stage (35 days post hatching, dph) the gut samples were collected along with corresponding water microbiome samples via vacuum filtration using membrane filters (0.22 µm nitrocellulose membrane filter, 47 mm diameter, Millipore™). Total DNA and RNA was extracted from both the sample types. Microbial community composition will be characterized using 16S rRNA gene amplicon sequencing to study the influence of rearing conditions on the microbiome assembly. Furthermore, meta-transcriptomic analysis of gut-associated microbial communities and water samples was conducted by RNA-seq datasets. These poly(A)-selected RNA-seq enriched for eukaryotic mRNA, enable retrospective investigation of microbial functional dynamics under various baseline conditions. Relevant datasets will be identified using targeted keywords including “rainbow trout” and “*Oncorhynchus mykiss*”, “fish gut microbiota”, “microbial dysbiosis fish” along with the study type “gut meta-transcriptome”. Paired-end reads will be processed using standardized bioinformatics pipelines incorporating automatic library type detection, quality control, and validation of read mappings.

Expected Results

It is expected that microbial community in the two rearing systems vary significantly in both water and gut. The RAS with more stable water microbiota will support a more stable microbiota with higher alpha diversities. In contrast, the FTS with continuous water exchange harbor less stable microbial community often dominated by potentially pathogenic r-strategists indicating, including opportunistic or pathogenic taxa. These differences in environmental microbial composition are expected to directly influence initial gut colonization and subsequent microbiome assembly in rainbow trout.

Discussion

Early-life rearing conditions are known to significantly influence the microbial community assembly in both water and gut environments of fish. FTS and RAS previously showed differences in the water microbial community due to the differences in water exchange. In addition, the bacterial density in water entering the rearing tanks of RAS was shown to be more than 10 times higher than in the FTS. It is expected that early environmental microbial conditions will have lasting impacts on both microbial functional potential and host intestinal health.

Overall, it is anticipated that aquaculture system design plays a central role in shaping microbiome- development and resilience in fish, supporting the concept that early microbial environments have long-term implications for aquaculture and productivity.

IDENTIFICATION AND MAPPING OF SUITABLE SITES FOR GILTHEAD SEABREAM FARMING IN THE MEDITERRANEAN: INTEGRATION OF OCEANOGRAPHIC PARAMETERS, DIETARY REGIMES, FUNCTIONAL FEED FORMULATION, INTEGRATED MULTI-TROPHIC AQUACULTURE, AND PARASITIC PRESSURE

*corresponding/presenting author redaislembennoui@gmail.com

Mediterranean coastlines face escalating pressures from urbanization, anthropogenic pollution, and climate change impacts, making the identification of viable sites for marine aquaculture a major scientific and decision-making priority. Gilthead seabream (*sparus aurata*) is an ecologically and economically important species for Mediterranean regions, but it presents strict environmental requirements regarding temperature, salinity, hydrological dynamics, water quality, trophic availability, and parasitic exposure. These parameters vary across coastal sectors, necessitating an integrated spatial approach to optimize farm site selection and adapt nutritional formulations and sustainable production strategies accordingly.

This study evaluates the suitability of Mediterranean coastlines for gilthead seabream farming by leveraging oceanographic and biogeochemical variables from the Copernicus program (Copernicus, 2023), particularly sea surface temperature, salinity, marine currents, and chlorophyll-a concentration. The analysis aims to identify coastal zones offering optimal conditions for marine farm establishment, while accounting for major ecological constraints including coastal pollution, ecosystem fragility, and seasonal environmental variability. Copernicus data will be systematically validated and corrected through advanced quality control procedures. Python will serve as the primary analysis tool with specialized libraries for geospatial and statistical processing.

Beyond physicochemical parameters, this study integrates critical biological factors: the natural dietary regime of *sparus aurata*, its physiological adaptation to seasonal variations in trophic resources, and its susceptibility to parasitic pressures (Koven, 2002). These elements directly influence farming performance and guide the formulation of functional feeds tailored to each geographic zone. To enhance sustainability and production resilience, this research explores a multi-trophic aquaculture approach (Chopin, 2013) combining gilthead seabream and European sea bass farming with the culture of mussels (*mytilus edulis*) and oysters (*crassostrea gigas*). This strategy leverages ecological relationships based on mutualism and commensalism, where fish waste becomes nutritional resources for filter-feeding mollusks, which simultaneously provide biological purification and naturally regulate dissolved oxygen, pH, and ammonia accumulation.

The integration of all these factors (oceanographic parameters, biological characteristics, nutritional requirements, multi-trophic systems, and parasitic pressure assessments) will produce comprehensive spatial suitability mapping and deliver an evidence-based framework for sustainable aquaculture planning adapted to Mediterranean coastal realities. This holistic approach reconciles aquaculture development with coastal ecosystem preservation, optimizes production performance through location-specific functional feed formulations, and enhances environmental stability through integrated multi-trophic aquaculture systems.

Introduction

Microalgae cultivation on wastewater and anaerobic digestate enables simultaneous biomass production and nutrient recovery while reducing the need for mineral fertilisers. The resulting biomass can be valorised as biostimulants, biofertilisers, feed ingredients, bio-based materials, or energy products (Berden-Zrimec *et al.*, 2024). However, biomass productivity in digestate-fed systems is often lower than expected from nutrient availability alone. Previous studies have shown that additional CO₂ supplementation can significantly improve algal growth, indicating that inorganic carbon availability may become limiting under cultivation conditions (Berden-Zrimec *et al.*, 2026). While effective, continuous CO₂ injection increases operational costs.

Recent laboratory studies demonstrated that crude algal extracts prepared from *Scenedesmus*-dominated biomass stimulate growth in digestate-based cultures, suggesting improved utilisation of inorganic carbon already present in the medium (Berden-Zrimec *et al.*, 2026). The present study evaluated whether a similar effect could be achieved in pilot-scale digestate-fed raceway ponds.

Figure 1. Raceway pond culture fed with anaerobic digestate and dominated by *Scenedesmus dimorphus* and *S. quadricauda*.

Figure 2. Experiments results: (left) First study, (right) Second study.

(Continued on next page)

Materials and methods

Experiments were conducted in identical raceway ponds (7.5 m², approximately 1250 L) cultivated on biochar-filtered anaerobic digestate from a food-waste biogas plant (Ljubljana, Slovenia). The ponds (Figure 1) were operated under the same conditions with digestate addition of approximately 10 L da⁻¹ and automatic pH control through CO₂ injection. The dominant species were *Scenedesmus dimorphus* and *S. quadricauda* (Figure 1).

Crude algal extract (CAE) was prepared from harvested pond biomass by drying and mechanical disruption and was directly added to the selected pond (100 g). Biomass growth was monitored by optical density (OD₆₈₀) and dry weight measurements. Two approaches for lipid stimulation were applied after the growth phase to explore the possibility of digestate-grown biomass valorisation for fuels.

Results and discussion

CAE supplementation increased biomass accumulation in both pilot-scale experiments (Figure 2). After 11 days of the first trial, the CAE-treated pond reached more than twice the biomass concentration of the untreated control. The first experiment was affected by intermittent power outages and interrupted digestate feeding between days 4 and 6. Despite these disturbances, the CAE-treated pond maintained substantially higher biomass accumulation than the control, suggesting improved culture robustness under suboptimal cultivation conditions. The second experiment was performed later in the season (Figure 2b) in stable operation conditions, exhibiting difference between treatments only in the first days after supplementation.

The lipids production was not stimulated by lowering the digestate addition and adding phosphate. On the other hand, removing 75% of the medium and replacing it with water with phosphate, resulted in alteration of the composition of total lipids content. Although the total lipids were rather constant, their composition in phospholipids was decreased suggesting an enrichment of total lipids with glycerides. The free fatty acids produced by the degradation of phospholipids can be utilized for the synthesis of glycerides.

The findings indicate that the stimulatory effect of CAE is reproducible and pronounced shortly after addition. While CAE initially stimulated biomass accumulation in both experiments, the effect was stronger and more persistent under interrupted feeding and other suboptimal cultivation conditions. CAE supplementation may represent a practical tool for improving biomass productivity in digestate-fed cultures by enhancing the utilisation of nutrients and inorganic carbon already available in the cultivation medium.

OLAMUR – LARGE SCALE REALISATIONS OF MULTI-USE SCENARIOS WITH LOW-TROPHIC AQUACULTURE

Ø. Bergh *

Institute of Marine Research

Norway

*corresponding/presenting oeivind.bergh@hi.no

Introduction

OLAMUR Offshore Low Trophic Aquaculture in large Scale Realisation is a large EU Flagship project in the Baltic/North Sea region (2023-2026) of the Mission Ocean and Waters. The project comprises 25 partners in 8 countries, with three major case studies (Figure 1). Since 2025, five Associated Regions have been attached to the project, in Ireland, Spain, Portugal, Türkiye, and Bulgaria, expanding the project's activity to the Atlantic, the Mediterranean and the Black Sea. The overall aim is to explore and enhance concepts of multi-use of marine space. The purpose of this presentation is to provide a brief overview of the project's activities many of which will be presented in the session on "offshore and multi-use" at the Aquaculture Europe 2026.

Results and tentative conclusions

LTA cultivation experiments with seaweeds and mussels have been carried out in all three case studies, and results are being analysed. In addition to growth yield, analyses of contaminants are being processed. Both the Baltic and the North Sea are characterized by extensive human activities, shipping, fisheries, and surrounded by populated shores. Especially the Baltic are receiving excess nutrients from waterways draining into the basin. The Baltic, which is only connected to the North Sea through the narrow and shallow Danish straits, is also characterized by low salinity, particularly in the inner parts.

Growth yield of seaweeds were strongly related to local conditions, of which salinity plays a major role. This is in accordance with estimates models published early in the project (Maar et al. 2023). In the Estonian case, the seaweed that was cultivated was *Ulva* sp, which tolerates low salinity much better than the *Saccharina* sp cultivated at site A and B. With blue mussels, good yields were obtained at all sites.

Stakeholder interviews were carried out involving LTA farmers, wind farmer industry and legislators in the different countries. Legislation is highly variable among European nations, and even among German Länder. Whereas some countries (Estonia) have developed legislation taking into account that LTA may neutralize excess nutrients from other activities, most countries practice the sector principle, which *de facto* counteracts multi-use concepts.

LTA farming is at different stages of development. In general shellfish have better developed markets than farmed seaweeds. Upscaling is a prerequisite to obtain sustainable industries. Synergies were obtained between the different industries, in particular with vessel operation and with surveillance of the utilized area. The five associated regions are at different stages with respect to development of the multi-use concepts. LTA is carried out in most countries, whereas the Portuguese case includes a floating offshore wind farm.

The main conclusion is that large-scale multi-use of area is possible and is an attractive pathway to obtain more area-efficient utilization of European marine area. We have also found it advisable to include the different industries in such a way that multi-use is beneficial for all partners.

Introduction

Aquaculture is one of the world's most dynamically developing agricultural sectors (Cai & Leung, 2024; Mair et al., 2023; Verdegem et al., 2023). Methodological advancements, the development of new technologies, product development, digitalization, and the preservation of biodiversity are all cornerstones of the European Green Deal formulated by the European Union. Innovation and research and development are the driving forces behind these processes (COM, 2020; FFS, 2021).

In our study, we sought to assess the grant application activities of the Hungarian aquaculture sector within the framework of three main themes (innovation, resource utilization, and project management).

Materials and Methods

In compiling the questionnaire, we formulated 17 strategic questions covering several major themes that addressed the core issues of the research. In the first group, we examined the general characteristics of the businesses, such as their nature, duration of active operation, and size. In the next thematic area, we examined the companies' history of grant applications, their current status, their objectives (e.g., energy investments, innovation, digitalization, research and development of ecosystem services, etc.), and their opinions regarding the difficulties encountered in connection with grant applications. In the final topic group, the questions focused on companies' opportunities for obtaining information related to projects, as well as their experiences with project management.

Results and Discussion

Based on our survey, the Hungarian aquaculture sector is open to implementing research, development, and innovative investments, and has recognized the importance of collaborating with universities and research institutes (Mankins, 1995). However, the importance of digitalization, organizational development, and human resource development must be emphasized. The main constraints in terms of grant application activity are the administrative burden and the high proportion of own contribution required under the criteria (EC, 2021; R, 1380/2013). The European Union's new guidelines (initiatives) and public consultations may offer solutions to these current problems. Innovation in the accessibility of grant calls is unavoidable; the involvement of new platforms is crucial (HUNATiP, 2018). The sector possesses both empirical and theoretical project management experience. Applications are managed both within companies and with the involvement of external experts (companies).

The topics covered by the exploratory questionnaire can be expanded to facilitate more in-depth and comprehensive research. It is also important to engage additional segments of the aquaculture sector (fishmongers, feed manufacturers).

(Continued on next page)

Acknowledgment

We would like to thank all representatives of the Hungarian aquaculture sector for contributing their insights to these results.

Introduction

Baltic salmon (*Salmo salar*) and pikeperch (*Sander lucioperca*) hold paramount economic and ecological importance to the Baltic region. Despite their value, these fish exhibit significant sensitivity to environmental stressors, including pollution and fluctuating water quality parameters. Currently, their biological fitness and long-term resilience are increasingly threatened by anthropogenic pressures, climate change, and the prevalence of diseases in hatchery environments (Veedu & Thomas, 2026). This vulnerability often leads to an unsustainable reliance on antimicrobial agents, which compromises the quality of fish rearing and contributes to the growth of antimicrobial resistance (Merrifield *et al.*, 2010). To address these challenges, the present study investigated the efficacy of probiotic supplementation, aiming to evaluate its impact on fish growth, survival, and health across various developmental stages (Imentai *et al.*, 2020).

Materials and methods

Experimental trials on juveniles were conducted within two different rearing environments, specifically, flow-through system (FTS) and recirculating aquaculture systems (RAS) (Table 1). This approach aligns with prevailing regional cultivation practices and ensures the evaluation of results under varying conditions. Additionally, trials with Baltic salmon compared two distinct probiotic administration routes: dietary supplementation via feed and immersion baths. Tested commercially produced probiotics consisted of a synergistic blend of active ingredients: lactic acid bacteria (*Lactobacillus* spp., *Sporolactobacillus* spp., and *Weizmannia* spp.), yeast cultures, fermented plant and herb extracts, phyto-ferments, sugar cane molasses, natural minerals and sea salt.

Results and discussion

Research outcomes demonstrate that the effectiveness of probiotic treatment is highly dependent on both the developmental stage of the fish and the delivery method.

1. Early-stage Baltic salmon (fry and early parr): bath immersion showed more favourable outcomes than dietary supplementation. Key benefits included enhanced survival rates, stabilized feeding behaviour, and a marked reduction in physiological stress symptoms.
2. Pathology mitigation: in Baltic salmon parr specifically, bath applications resulted in a 20% average reduction in the incidence of gill cover necrosis.
3. Late-stage salmon (presmolts): for fish at the presmolt stage, the dietary route became the most effective, leading to significant improvements in measurable growth metrics.
4. Pikeperch fry: long-term dietary intervention proved most impactful. A three-month probiotic feeding regimen administered during the peak growth period resulted in a substantial increase in both body weight and condition factor.

Table 1. Experimental trials conducted on salmon and pikeperch juveniles.

System type/fish species	Baltic salmon			Pikeperch	
Flow-through system	Fry	Parr	Presmolts	-	-
RAS	-	Parr	Presmolts	Fry (4-6 months)	Older fingerlings (6+ months)

(Continued on next page)

These findings confirm that the efficacy of probiotic application is highly stage- and species-specific. Consequently, optimizing delivery strategies — transitioning from immersion baths in early life stages to targeted dietary supplementation during peak growth periods — represents a promising approach to improving fish health and resilience across aquaculture operations.

By providing a targeted means to support fish health and development, probiotics may represent a sustainable preventive strategy that could help reduce the need for antimicrobial treatments. Such an approach may contribute to addressing the growing challenge of antibacterial resistance. Ultimately, the integration of species-specific probiotic protocols may contribute to the long-term viability and ecological fitness of Baltic salmon and pikeperch resources, while supporting more robust and sustainable hatchery production. This strategy not only enhances immediate growth outcomes but may also contribute to improved fish health and resilience, supporting a more sustainable approach to modern aquaculture.

IMPROVEMENT OF NON-INVASIVE PREDICTION OF CARCASS YIELD IN FISH USING AN AI-DRIVEN PHENOTYPING PIPELINE COMBINING ULTRASOUND AND 2D/3D IMAGING

M Besson^{1*}, C Ermacora¹, E Segret², N Picchi³, A Desgranges³, B Imarazene⁴, J Doerflinger⁴, N Pinte⁵, A Bajek⁵, F Chenier⁶, M Gautier-Villa⁶, P Haffray¹

Introduction

Improving carcass yield through breeding program is essential to improve the economic and environmental sustainability of fish farming, particularly for species marketed as processed fillets, such as rainbow trout or salmon. Hence, predicting carcass yield accurately on breeding candidates is key to maximize the genetic gain achievable for this trait. The method currently used to predict carcass yield on candidates is to measure, using ultrasound, the thickness of the fillet below the ribs (E8) and the total depth of the belly cavity (E23) (Haffray *et al.*, 2013). With those metrics, breeders are able to predict viscero-somatic index and thus carcass yield. The R^2 between the ratio E8/E23 and carcass yield is about 0.3. The aim of the present study was to improve this prediction and to facilitate the phenotyping of carcass yield on candidates by developing a phenotyping machine combining ultrasound with 2D and 3D images analysed by an AI pipeline.

Materials and Methods

We developed an integrated phenotyping machine combining a 2D camera (Keyence VS Series), a 3D camera (Zivid 2+ MR60) and an ultrasound (IMV Exapad). In parallel, we developed an AI framework (FishFusionNet) capable to analyse the different information provided by these devices.

Prior to being processed by the FishFusionNet, the data from each device underwent specific preprocessing steps. For the 2D images, we developed two YOLO-based models: one to automatically detect 15 anatomical keypoints at strategic locations on the fish (FishKpt), and another to segment the different body parts (FishSeg). These segmentations were then used in combination with the 3D data to estimate volumes of the respective body parts. The 3D acquisitions also enabled the generation of a surface heat map of the fish.

Figure 1. Pipeline of the FishFusionNet AI model.

(Continued on next page)

Finally, we developed YOLO-based models (EchoSeg) to segment E8 and E23 features on ultrasound images. To calibrate and validate the different models for rainbow trout, we phenotyped two different populations of fish derived respectively from Viviers de Sarrance (960 fish) and Bretagne Truite (1230 fish) nucleus.

Results and Discussion

The initial results of the FishFusionNet, trained on data from Viviers de Sarrance, show a substantial improvement of the prediction accuracy compared to the traditional ultrasound method, with an R^2 of 0.62 between the carcass yield measured and the carcass yield predicted. However, these results do not yet include ultrasound data, as the EchoSeg model is currently under development. We therefore expect further gains in predictive performance with the integration of ultrasound features via EchoSeg, as well as through the inclusion of the data from the fish of Bretagne Truite. Then, since fish from both populations were genotyped, we will estimate the genomic correlation between the measured carcass yield and the predicted carcass yield. This is to verify whether predicted carcass yield represents the same genetic trait as the measured carcass yield.

Context and Methodology

The blue shrimp was introduced in the 70s in Hawaiï, New-Caledonia and French Polynesia leading currently to some breeding programs (Haffray et al., 2025). The long-term cryopreservation of the male genetic resource would be an interesting backup. Thus, this study aimed at testing the methodology used to cryopreserve the banana shrimp (*F. merguiensis*) spermatophores (Nimrat et al., 2022).

To do so, 118 mature males were sampled either in cryovials (the whole spermatophore ; n=140) or in straws (a suspension of the sperm mass). The fresh control consisted of the 20 males used for straw cryopreservation. The extender was the same calcium-free saline solution as in Nimrat et al. (2022), adding antibiotics (streptomycin-penicilin) and DMSO (dimethylsulfoxide) as cryoprotectant. There were 20 min of equilibration prior to freezing on a floating rack 3 cm above liquid nitrogen for 10 min before storing in the liquid nitrogen tank. Viability controls (eosine staining under light microscopy) happened just after freezing, then one, two, three, five and seven months later. Thawing lasted 20 s for straws and 160 s for spermatophores at 30°C.

Figure 1: Assessment of sperm viability during cryopreservation either in cryovials (spermatophore) or in straws (sperm mass)

(Continued on next page)

Results and Disucssion

The Viability in the fresh controls was 100%. The viability of the cryopreserved samples lowered over the eight-month storage in liquid nitrogen from 80% to 27%. The decrease was slower in straws than in cryovials (Figure 1). However, the fertilization success is the ultimate test to ensure that cryopreservation can work as a backup for the genetic resources of the species. A pre-test was conducted with 6 mature females that were manually fertilized with 15 thawed spermatophores and several hundreds of larvae were obtained.

These preliminary results are the first mentioned in blue shrimp. It was a proof-of-concept but there is still room for methodology improvements so that the viability remains higher for a longer time. The most important being to ensure good storage conditions and regular supply in liquid nitrogen (a rise in temperature inside the tank is the strongest hypothesis to explain any decline in viability). The next step would be to apply a dedicated design for manual fertilization from thawed material to truly validate the whole process.

Acknowledgements

We feel very indebted towards the DRM who owns the shrimp line and VAIA hatchery in Tahiti financing 100% of the blue shrimp production through a public market with the CAPF: they let us use part of their broodstock in order to conduct the experiment. We warmly thank IsBlue for the mobility grant, the UPF for the training grant, OSO farming, Blue Genetics, Aquapesca and UPRA-NC Crevette for their financial support. We also thank also Ifremer (Vairao) for the place allocated to achieve the sampling of the animals.

PALATABILITY OF BLACK SOLDIER FLY LARVAL MEAL IN *Penaeus vannamei*: A BIOCHEMICAL AND IN VIVO COMPARISON WITH SQUID MEAL

M. Bézagu^{1*}, Donati L.¹, Walraven M.¹, Dias J.², Barreto A.³

¹Innovafeed, Nesle, France

²SPAROS Lda, Olhão, Portugal

*Presenting author marine.bezagu@innovafeed.com

Introduction

Squid meal is widely used as a reference palatant in *Penaeus vannamei* diets, but its reliance on wild fisheries raises concerns over price volatility, supply instability, and ecological impact. Black soldier fly larvae (BSFL, *Hermetia illucens*) offer a promising alternative through their rich profile of short-chain peptides, free amino acids (fAA) and nucleotides, but their functional efficacy as shrimp palatants remains undercharacterised. This study compared the biochemical composition of a BSFL-derived ingredient with commercial palatants, and assessed if this BSFL-based ingredient could replace squid meal while maintaining or improving feed attractiveness and efficiency in *P. vannamei*.

Materials and Methods

A 17-day feeding trial was conducted at the RIASEARCH R&D facility (Portugal) using juvenile *Penaeus vannamei* (initial weight: 7.4 g; 25 shrimp/tank, n=4). Three isonitrogenous and isolipidic extruded diets were tested: a negative control (Control), a 3% squid meal diet (Squid), and a diet in which squid meal was fully replaced by 3% BSFL meal (BSF). Feed intake (%ABW/day) and FCR were calculated at trial end and analysed by one-way ANOVA with Tukey's post-hoc test ($p < 0.05$).

Selected commercial palatants, including squid meal, were sourced and submitted to physico-chemical characterisation. Nucleotide content was determined by HPLC-UV (ISO 20638:2015, Eurofins, Nantes, France), and protein solubility, molecular weight profile and fAA content (CE 152/2009) were analysed at Upscience (Saint-Nolff, France).

Results

Both the BSF and Squid diets significantly increased relative daily feed intake compared to the Control diet ($p < 0.05$), with no significant difference detected between BSF and Squid. Numerically, the feed intake of BSF diet was increased by +7.56% relatively to Control (Figure 1). The trial duration (17 days) allowed shrimps to approximately double their weight across all groups. No statistically significant differences in FCR were observed among treatments.

Figure 1. Average daily feed intake of *P. vannamei* fed either the control diet (Control), the BSFL-based diet (BSF), or the squid meal diet (Squid). Different letters indicate statistically significant differences between groups ($p < 0.05$).

(Continued on next page)

A separate benchmarking of Hilucia™ meal against marine-derived palatants shows that BSFL meal contains markedly higher nucleotide levels (223 mg/100g vs. 27 mg/100g for squid meal), a higher proportion of small peptides (% <1,000 Da; 58.3% vs. 34.1% for squid meal), and comparable soluble protein content (26.9% vs. 25.6% CP). Free amino acid content was also noticeably higher than that of squid meal (1.6% vs. 0.6% DM).

Discussion

These results confirm that BSFL meal included at 3% exerts a phago-stimulatory effect in *P. vannamei* comparable to squid meal, while maintaining feed efficiency. This is consistent with its biochemical composition, as nucleotides, short-chain peptides and fAA are recognised feeding stimulants in crustaceans (Suresh et al., 2011; Lee & Myer, 1997). Although the 17-day duration limits conclusions on long-term growth, it was sufficient to double animal weight and calculate FCR, and the absence of differences between BSF and Control groups suggests that increased intake would translate into faster growth at farm scale. Beyond palatability, BSFL ingredients offer meaningful advantages over marine-sourced palatants in terms of supply security, price stability and environmental footprint (Van Phi et al., 2020), complementing a growing body of evidence for beneficial effects of BSFL inclusion on shrimp feed intake, growth and disease resistance (Richardson et al., 2021; Novriadi et al., 2023; Keetanon et al., 2024). Further trials with longer durations and varying inclusion levels should be conducted to confirm dose-response relationships and validate the palatant effect of BSFL meal at commercial scale.

ilaria.biasato@unito.it

Brewing by-products are recognized as suitable rearing substrates for black soldier fly (BSF), but the potential of using brewer's spent grains (BSG) and brewer's spent yeast (BSY) at different dietary ratios has rarely been investigated. This study evaluated the effects of BSG-BSY-based diets on BSF larval growth, survival, and conversion efficiency. A total of 3000 6-day-old BSF larvae were allotted to 5 dietary treatments (6 replicate boxes/diet, 100 larvae/box, 0.9g/larva): i) BSY2.5 (97.5% of BSG + 2.5% of BSY), ii) BSY5 (95% of BSG + 5% of BSY), iii) BSY7.5 (92.5% of BSG + 7.5% of BSY), iv) BSY10 (90% of BSG + 10% of BSY), and v) control (GA, Gainesville diet). Larvae were individually weighed (at least 30/replicate) every 4 days (10 and 14 days of age) and at the end of their growth (5% of prepupae), and their survival calculated. Bioconversion efficiency corrected for residue (BER), reduction rate (RR), and waste reduction index (WRI) were also calculated. Data were analysed by GLMM (IBM SPSS software, $P < 0.05$). The BSY10 larvae overall showed the highest weight among the BSG-BSY-based diets, but lower than GA ($P < 0.05$). At 10 days of age, BSY7.5 and BSY10 larvae displayed higher weight than BSY2.5 and BSY5 ($P < 0.05$), with BSY10 and GA being similar ($P > 0.05$). The 14-day-old larvae were also heavier when fed BSY7.5 and BSY10 diets than the other BSG-BSY-based diets ($P < 0.01$), but lighter than GA ($P > 0.05$). At the end of growth, the BSY10 larvae showed the highest weight among the BSG-BSY-based diets ($P < 0.05$), being analogous to GA ($P > 0.05$). Survival rates were similar among the diets ($P > 0.05$). All the BSG-BSY-based diets were characterized by higher BER than GA, with BSY7.5 and BSY10 larvae also displaying a better BER than BSY2.5 and BSY5 ($P < 0.01$). Similar RR and WRI were observed among the BSG-BSY-based diets ($P > 0.05$), but lower than GA ($P < 0.05$). In conclusion, including 7.5 and 10% of BSY in BSG-based diets led to the best BSF larval growth and conversion efficiency.

FEEDING RAINBOW TROUT WITH DIETS BASED ON *Hermetia illucens* AND *Spirulina* MEALS: IMPLICATIONS FOR GUT MICROBIOTA

Ilaria Biasato^{1*}, Davide Buzzanca¹, Katerina Loufi¹, Sara Bellezza Oddon¹, Zaira Loiotine¹, Jorge Dias², Tatiana Poletto², Laura Gasco¹, Ilario Ferrocino¹

*corresponding/presenting ilaria.biasato@unito.it

Introduction

In the last decades, the aquaculture industry has mainly directed its efforts towards the replacement of fishmeal with alternative protein sources, as a consequence of its sustainability and economic issues. Vegetable proteins have already been successfully included into commercial diets for rainbow trout, but novel feed ingredients – such as insects and microalgae – have also gained increasing attention (Sheikhzadeh et al., 2019; Biasato et al., 2022). In particular, *Hermetia illucens* (HI) meal has been reported to positively modulate the gut microbiota of rainbow trout in terms of selection of short-chain fatty acids (SCFAs)-producing bacteria and reduction of foodborne disease-causing pathogens (Biasato et al., 2022), while *Spirulina* (SP) seems to be able to promote gut microbiota diversity and increase beneficial bacteria in different fish species (Ren et al., 2022; Zhang et al., 2024). However, these two alternative protein sources have always been tested individually. Therefore, the present study aims to evaluate the impact of HI and SP meals – both individually and in different mixture percentages – on the gut microbiota of rainbow trout.

Materials and Methods

Seven isonitrogenous, isolipidic, and isoenergetic diets were formulated: a control diet (CTRL) containing 20% of fishmeal, and six diets where the fish meal was 100% replaced with HI meal (HI100), 100% SP meal (SP100), 75% HI and 25% SP (MIX1), 66.6% HI and 33.3% SP (MIX2), 33.3% HI and 66.6% SP (MIX3), and 25% HI and 75% SP (MIX4). A total of 441 fish (initial body weight of 200.5 ± 2.6 g) were randomly allotted to 21 400L-tanks (3 replicates/diet, 21 fish/tank). At the end of the trial (88 days), 6 fish per tank were slaughtered and the posterior content was collected for the characterization of the gut microbiota by means of 16S rRNA sequencing analysis. The bioinformatics analysis was performed using QIIME 2 v2.2022.2.0 (<https://docs.qiime2.org/>) importing the raw reads for quality and chimera filtering step by dada2 denoise-paired script (sampling depth 7,500). The amplicon-sequence variants (ASVs) were used for taxonomic assignment by comparison with the Greengenes2 v2022.10 databases obtaining taxa abundances. The R package microeco (v1.16.0) was used in RStudio (R v4.4.2; RStudio 2024-10-31 ucrt) to perform statistical analysis ($P < 0.05$).

Results

The 16S rDNA amplicon sequencing analysis allowed the detection of 329 bacterial genera. Observed, Fisher and Chao1 alpha diversity indices were lower in the CTRL, HI and MIX4 diets when compared to MIX3, while the latter also was also characterized by a higher Simpson and Shannon indices than the CTRL, and CTRL, HI, MIX1 and MIX4 groups, respectively (One-way ANOVA, $P < 0.05$). Inverted Simpson and Pielou indexes also resulted higher in the MIX3-fed fish in comparison with the CTRL, MIX1 and MIX4 diets (One-way ANOVA, $P < 0.05$). Differently, the beta-diversity analysis did not show a clear separation among the diets (Bray-Curtis's distances; Principal Coordinates Analysis [PCoA], $P > 0.05$). However, Permutational Multivariate Analysis of Variance (PERMANOVA) demonstrated differences in gut microbiota composition between the CTRL and HI100 diet ($F = 4.06$, $R^2 = 0.30$, $P < 0.05$). Part of the taxa resulted differentially abundant among the groups, with *Weissella* spp. resulting less abundant in the CTRL and SP100 groups when compared to HI100-fed fish, and *Streptococcus* spp. being lower in the SP100 diet than the HI100 group (Dunn's Test of Multiple Comparisons, $P_{adj} < 0.05$). Lastly, each dietary treatment displayed a distinct set of unique bacterial genera, thus indicating a strong selective pressure on the gut microbiota of the fish. In particular, the SP100 diet showed the highest number of diet-exclusive taxa (including *Holdemanella*, *Paraeggerthella* and *Gallalistipes*), followed by MIX3 and MIX4 groups (mainly characterized by *Cellulomonas*, *Trichococcus* and *Nocardioides*).

(Continued on next page)

Discussion

The results herein obtained suggest that the diets containing the highest percentages of inclusion of SP meal (SP100, MIX3 and MIX4) were able to exert a most pronounced effect on the gut microbiota of the rainbow trout, as a consequence of its highly degradable polysaccharides and fermentable oligosaccharides (which led to the selection of unique bacterial genera associated with carbohydrate degradation and fiber fermentation) (ibrahim et al., 2026). However, the highest alpha diversity overall identified for the MIX3 diet interestingly suggests a potential synergy between SP and HI. Indeed, the concomitant presence of chitin (cellulose-like, insoluble fiber) – which reasonably explains the selection of cellulose-degrading (*Weissella*) (Biasato et al., 2022) and degraded chitin-using (*Streptococcus*) (Yildirim-Aksoy et al., 2019) ASVs in the HI100 group – and fermentable oligosaccharides (soluble fibers) may offer more diversified nutrients for the gut microbiota.

OYSTER STOCKING DENSITY MODULATES PRODUCTIVE OUTPUT IN A LAND-BASED MULTI-TROPHIC SYSTEM

Introduction

Recirculating multi-trophic aquaponic systems integrate fed aquatic species with organic and inorganic extractive organisms to reuse water and convert residual outputs into additional products (Granada et al., 2016; Spradlin & Saha, 2022). However, saltwater applications remain underdeveloped, and the biomass ratio among trophic compartments requires optimization. Within the SuInAp project, this study evaluated whether Pacific oyster (*Crassostrea gigas*) stocking density affected water quality, gilthead seabream (*Sparus aurata*) performance and product quality, and feed-normalized output in a system also producing edible salicornia.

Materials and Methods

Nine independent systems were allocated to 0, 30 or 60 oysters per system (F-O0, F-O30 and F-O60; three replicate systems per treatment) for 134 d. Each system included a fish tank, a 5-L settling tube, an oyster tank, a biofilter, cartridge filtration and ultraviolet treatment, plus an independent four-level nutrient film technique unit for salicornia. Twice weekly, 100 L were transferred from the biofilter to the plant reservoir and 100 L from the plant reservoir to the oyster tank. Water quality was monitored throughout the trial. Fish growth, feed conversion and survival were evaluated from day 0 to 134. Four fish per system were sampled for somatic indices, processing yields, muscle pH and scale cortisol (ng g⁻¹ matrix). Apparent system biomass productivity was calculated as fish biomass gain plus whole-oyster biomass gain plus harvested edible salicornia biomass per unit feed; extractive productivity included oyster gain and salicornia only. The system was the experimental unit. Preliminary treatment comparisons used exact randomization tests on system-level values and time-weighted water means.

Results

Time-weighted temperature, dissolved oxygen, pH, turbidity, chlorophyll, ammonium, nitrate and phosphate did not differ among treatments. Initial fish weight averaged 78.3-81.2 g and final weight 153.1-169.5 g. Specific growth rate (0.497-0.548% d⁻¹), feed conversion ratio (1.41-1.47) and survival (86.7-93.3%) were unaffected by oyster density. Apparent system biomass productivity was 2.60 ± 0.62, 3.86 ± 0.70 and 2.65 ± 0.46 kg fresh product kg⁻¹ feed in F-O0, F-O30 and F-O60, respectively (P = 0.079). Extractive productivity was highest in F-O30 (1.90 ± 0.48, 3.13 ± 0.69 and 1.94 ± 0.28 kg fresh extractive biomass kg⁻¹ feed; P = 0.046). Oyster density did not affect viscerosomatic or hepatosomatic indices, carcass yield (93.7-94.3%), fillet yield (46.4-47.1%), edible meat yield (37.0-38.5%), muscle pH or scale cortisol (1080-1350 ng g⁻¹ scales).

Discussion

The intermediate oyster density increased feed-normalized extractive output by approximately 65% relative to F-O0 and 61% relative to F-O60, without detectable impairment of water quality, fish growth, feed utilization, processing yields or scale cortisol. The non-linear response indicates that increasing the number of extractive organisms does not necessarily maximize whole-system production, emphasizing the need to balance trophic biomass and system design (Nederlof et al., 2022). These preliminary findings support the concept that integrated production of fed and extractive species can diversify fresh-food output while maintaining seabream performance and physiological status. Direct nutrient-retention measurements will be required to distinguish productive output from nutrient-use efficiency.

*corresponding/presenting author@email.eu

The SMARTTANG project (2022–2025) aimed to develop, test, and document scalable cultivation strategies for sugar kelp (*Saccharina latissima*) using tube and net-based systems adapted from existing nearshore mussel aquaculture infrastructure.

Through systematic hatchery trials, testing different seeding techniques and net materials (nylon, polyester, polypropylene) a final seeding was made, seeding five 50 m nets with a depth of 1.2 m with *S. latissima*. The nets were deployed in a commercial mussel farm in Limfjorden, Denmark. The field trials documented, that the biomass yields were controlled by depth and vertical/horizontal deployment orientation: Nets deployed horizontally near the surface achieved the highest yields, with up to 13.2 ± 2.4 kg fresh weight m^{-2} , compared to 7.2 ± 0.7 - 8.4 ± 0.3 kg m^{-2} on vertically oriented nets and 4.9 ± 0.5 kg m^{-1} on a horizontal line. The biomass quality was suitable for food, feed, and biorefining applications, though iodine concentrations and biofouling increased markedly toward harvest in late April, underscoring the need for early harvest.

Trials were conducted for harvesting kelp of the nets testing existing mussel harvesting equipment, but it was apparent that technology development was needed to effectively harvest the nets. The harvested biomass was processed at a large scale facility using a screw press and a microcutter to obtain a biomass slurry, which was readily fermentable with addition of a lactic acid bacteria inoculum. The fermented biomass stored well, and was still useable and pH stable after 1 years of storage, after which it was tested in a commercial scale setting as feed for pigs. The raw biomass was also used for development of a new snack for kids, which was evaluated within the project.

Finally, a complementary sustainability assessment integrating Life Cycle Assessment and Techno-Economic Analysis compared net-based systems with conventional longline cultivation. While net systems achieved high area-specific yields, longline systems showed substantially lower material intensity, greenhouse gas emissions and higher economic performance.

Overall, the SMART TANG project demonstrated that *S. latissima*, can be produced on tube-net systems, and used for food and feed, but longline systems currently remain superior in terms of environmental footprint and economic viability. The results provide concrete guidance for seaweed producers, technology developers, and policymakers seeking to scale-up nearshore kelp cultivation in European waters.

ASSESSMENT OF BIOACTIVE PEPTIDE ENRICHED DIETS ON GROWTH AND ROBUSTNESS OF EUROPEAN SEABASS (*Dicentrarchus labrax*) POST-LARVAE

Introduction

Fish in aquaculture are frequently exposed to inherent stressors that can impair growth performance and survival. Nutritional strategies based on the use of functional ingredients have appeared as a promising approach to enhance fish robustness and improve resilience to stress. Bioactive peptides obtained from alternative protein sources have shown potential to enhance growth, modulate immune and antioxidant responses, and improve stress resilience in fish. The present study evaluated the effects of diets supplemented with alternative peptide fractions on the growth performance, stress response, antioxidant status, and immune function of European seabass (*Dicentrarchus labrax*) post-larvae.

Materials and Methods

Five experimental diets were evaluated: a commercial control diet (D1), two poultry-based diets in which fish-derived protein ingredients were partially replaced by chicken protein hydrolysate and poultry meal (D2) or feather meal hydrolysate and poultry meal (D3), a yeast-based diet (D4), and a diet containing wheat hydrolysate and whey protein isolate (D5). European seabass post-larvae were reared under controlled conditions in a closed system from 84 to 112 days after hatching (DAH). Fish were assessed for growth performance, antioxidant and immune responses, and stress resilience before and after an acute stress challenge, consisting of confinement of fish at the bottom of the tanks for 30 min. Analysed humoral and oxidative stress parameters, from digestive tract tissue, included lysozyme activity, nitric oxide levels, peroxidase activity, bactericidal activity, catalase activity, superoxide dismutase (SOD) activity, glutathione peroxidase activity, and thiobarbituric acid reactive substances (TBARS). In addition, the expression of molecular biomarkers associated with stress, antioxidant defence, and immune regulation (*hsp90*, *hsp70*, *gr1*, *gr2*, *il10*, and *sod1*) was analysed.

Results and Discussion

An overall analysis of the growth indicators reveals that, in this case, the performance of diets D2 and D3 were similar to the commercial control (D1). Indicating that a partial replacement of the traditional fish protein hydrolysate and fish meal by chicken protein hydrolysate and poultry meal (D2), and by feather meal hydrolysate and poultry meal (D3), did not impact, positively or negatively, the growth performance of European seabass post-larvae. However, fish fed the diet supplemented with wheat hydrolysate and whey protein isolate (D5) showed the lowest weight, length and relative growth rate. Survival rates were statistically similar throughout all the diets at the end of the trial (112 DAH).

Regarding antioxidant and humoral responses, the D2 diet significantly increased *sod1* gene expression and nitric oxide levels at the end of the feeding period, while significantly reducing peroxidase activity immediately following the stress challenge. No significant differences in bactericidal activity were observed among groups prior to the stress challenge. D1 fed fish showed an increase in bactericidal activity following the challenge, whereas fish fed D3 presented a reduction. Most supplemented groups showed a similar reduction trend, although their values remained at intermediate levels and did not differ significantly from those of either D1 or D3. Lysozyme activity remained stable before and after stress, but an increase was observed during the recovery period, in D5 fed fish. These molecular responses were not accompanied by changes in oxidative damage biomarkers, indicating that the effect was not sufficient to alter the oxidative status of the fish under the conditions tested. This discrepancy is consistent with the relatively low mortality of the stress challenge, which likely did not produce the physiological impact necessary.

Results suggest a dietary induced modulation of redox-responsive pathways, that may have resulted in an improved antioxidant preparedness prior to stress exposure, in fish fed the chicken protein hydrolysate and poultry meal diet (D2). In addition, the experimental treatments influenced innate immune responses to the stress challenge, particularly in fish fed D3 (feather meal hydrolysate and poultry meal diet), by affecting the activation of immune defence mechanisms.

(Continued on next page)

Overall, the present study demonstrated that alternative peptide fractions can influence the robustness and resistance of European seabass post-larvae, while maintaining a growth performance comparable to that of a commercial-like diet. The most promising responses were observed in fish fed a diet containing chicken protein hydrolysate and poultry meal. However, further studies using a more suitable stress challenge are needed to confirm these effects and validate their biological relevance.

Introduction

Bivalve aquaculture plays a key role in global seafood production, with many species reared in coastal areas that are highly exposed to anthropogenic contamination, including marine litter (Van Der Schatte Olivier et al., 2020). As sessile and filter-feeding organisms, bivalves are particularly prone to accumulate contaminants and suspended particles, e.g. microplastics, which may pose risks from ecotoxicological and seafood safety standpoints (Tanaviyutpakdee & Karnpanit, 2023). To counteract this pervasive problem, the plastic industry has invested in the development of “eco-friendly” alternative materials made from natural and renewable sources and/or with the capacity to biodegrade (Rosenboom et al., 2022). However, and, in case of bio-degradable polymers this tendency is higher than for conventional plastics, as bio-fragmentation occurs simultaneously to typical fragmentation from natural drivers (UV-radiation, temperature, oxygen and mechanical stress). In addition, literature regarding the ecotoxicological aspects of bio-based plastics is scarce, thus, failing to support the sustainability and “eco-friendliness” claims these materials hold. Hence, this study aimed to investigate the ecotoxicological responses of two bivalve species (*Mytilus edulis* and *Ruditapes philippinarum*) extensively farmed in Europe, upon exposure to microplastics derived from commercially relevant petroleum-based (polyethylene terephthalate, PET), partially bio-based (polybutylene succinate, PBS) and bio-based plastics (poly[propylene] 2,5-furandicarboxylate, PPF).

Materials and Methods

M. edulis (~ 20g) and *R. philippinarum* (~13 g) were kept in glass beakers with ~5 L seawater under optimal rearing conditions (18.0 ± 0.5 °C, 8.0 ± 0.2 pH, > 7 mg/L O₂). During 21 days of trial, bivalves were daily fed with a *Tetraselmis* spp. solution once a day and exposed via water to 1 mg/mL of three types of microplastics: i) PET; ii) PBS; or iii) PPF. Bivalves were sampled from each treatment after 72 hours (T₇₂) and 14 days (T₁₄) of microplastic exposure and after 7 days (day 21, T₂₁) of depuration period. The digestive glands and gills were collected to evaluate different physiological endpoints: oxidative stress (catalase activity [CAT], superoxide dismutase [SOD], glutathione S-transferases [GST], and lipid peroxidation [LPO]), metabolic enzymes activity (lactate dehydrogenase [LDH] and citrate synthase [CS]), digestive enzymes activity (α -amylase, pepsin, and trypsin), and animal condition indexes.

Results and Discussion

In mussels digestive gland, significant differences were found in CAT (T₇₂), SOD (T₇₂, T₁₄, and T₂₁), and GST (T₇₂, T₁₄, and T₂₁). CAT was upregulated by the exposure to PBS (T₇₂). SOD was upregulated by the exposure to both PPF and PBS at T₇₂ and T₁₄, and downregulated after 7 days of the depuration period (T₂₁) in PET treatment. GST was upregulated by PET in both T₇₂ and T₂₁, while a downregulation was observed in PBS at both T₇₂ and T₂₁, and in PPF at T₂₁. These patterns suggest that the antioxidant defense system of the mussels gland was differently activated depending on the polymer type and trial phase. The upregulation observed at T₇₂ indicated an early response to oxidative stress in mussels exposed to PBS and PPF exposure. However, the persistence of altered SOD and GST activities at T₁₄, and the downregulation observed after the depuration period (T₂₁), may reflect a prolonged physiological effect or an inability of the antioxidant system to fully recover even after 7 days of ceasing microplastics exposure.

(Continued on next page)

These preliminary results highlight that the exposure to bio-microplastics may not be as environmentally harmless as it is often claimed. Despite being produced in more sustainable ways, alternative polymers such as PBS and PPF, may induce oxidative stress and disrupt key physiological processes in wild and/or extensively farmed marine species. This raises concerns for the aquaculture sector, because if a shift towards more sustainable and supposedly eco-friendlier alternatives occur, it is important to ensure that these materials will not negatively impact animal health, productivity, and ultimately result in microplastic accumulation in the edible fraction of seafood. Therefore, ensuring that novel materials are not only bio-derived but fully biodegradable, as well as non-toxic to marine organisms is important to assure a sustainable aquaculture practices and seafood safety.

PHYSIOLOGICAL RESPONSES OF EUROPEAN SEABASS (*Dicentrarchus labrax*) TO CHRONIC VESSEL NOISE IN OFFSHORE CAGE FARMING

Introduction

Anthropogenic underwater noise is an increasing stressor in marine environments, largely driven by maritime activities. Vessel traffic represents the dominant source of low-frequency noise in coastal areas, overlapping with the hearing range of many fish species, including European seabass (*Dicentrarchus labrax*) (Popper and Hawkins, 2019). As seabass rely on acoustic cues for communication and environmental perception, vessel noise may disrupt these processes and induce physiological stress. Previous studies have shown that boat noise can activate the stress response in fish, increasing cortisol levels and altering metabolic activity (Širović et al., 2026). While these effects may be adaptive in the short term, repeated exposure could impair welfare and performance. This is particularly relevant in aquaculture, where seabass is often reared in coastal areas with frequent vessel traffic. However, the long-term effects of noise exposure under real farming conditions remain poorly understood. This study aims to investigate the physiological responses of European seabass to chronic vessel noise in offshore sea cage systems.

Materials and methods

Adult European seabass (n=144; mean weight±SD: 336.3±78.6g) were chronically exposed to daily 1-hour playbacks of sudden unfamiliar boat noise in three offshore sea cages at the fish farm Valle Ca' Zuliani srl (Monfalcone, Italy). Sampling was conducted at predefined time points to assess physiological responses over time. A representative number of fish (n = 12 per cage at each sampling point; three cages in total) were collected after the first sound exposure (T1), after 1 month of daily exposure (T2), and after 2 months of daily exposure (T3). A baseline sampling (control, T0) was performed 30 days prior to the onset of experimental noise exposure. Fish sampling was carried out after the sound exposure and, immediately after capture, fish were euthanized and blood and scales collected. Cortisol concentrations were quantified by radioimmunoassay (RIA) in plasma and scales to assess the primary stress response (Meloni et al., 2025). Secondary stress indicators, including plasma glucose, lactate, and heat shock protein 70 (HSP70) levels, were measured using an automated analyser (BIONSEN, EKF Diagnostics) and a commercial ELISA kit (Cusabio), respectively. Total proteins (TP) as additional stress indicator and Advanced Oxidation Protein Products (AOPP) as oxidative stress marker were assessed using a BCA kit (ThermoFisher) and the protocol outlined by Witko-Sarsat et al. (1998), respectively. Blood smears were prepared from heparinized entire blood and the differential leucocyte was performed to check for the fish health. Data were analyzed using a linear mixed model with condition and sex as fixed factors, weight as covariate and tank as random factor.

Results and discussion

Chronic vessel noise influenced physiological responses in European seabass, with different results according to the explored stress indicators. Plasma cortisol increased at all exposure times compared to the baseline period (T0), with the highest levels at T3 (after two months of exposure) (147 ng/ml; p<0.001). In contrast, scale cortisol showed a different pattern, with a significant increase only at T2 (after 1 month of exposure) (0.92 ng/g vs. 0.14 ng/g; p<0.05) and remained stable up to T3. Plasma glucose decreased at T2 compared to T0 (210 mg/dL vs. 103 mg/dL; p<0.05), followed by a marked increase from T2 to T3 (103 mg/dL vs. 224 mg/dL; p<0.05), which may indicate a shift in energy allocation along exposure. Lactate increased significantly from T0 to T2 (9.09 mmol/L vs. 13.7 mmol/L; p<0.05), suggesting potential elevated metabolic demand during exposure. Cellular stress response (HSP70) showed a significant increase only at T2, while the AOPP/TP ratio increased after the first exposure. Neutrophil-to-lymphocyte ratio (NLR), an indicator of chronic stress, was not significantly affected (0.11). Overall, these results indicate that chronic vessel noise exposure may influence endocrine and metabolic homeostasis. However, no clear evidence was found to indicate a chronic stress.

(Continued on next page)

Conclusions

The data indicate an initial physiological stress response, reflected by early changes in oxidative stress markers, immune parameters, glucose, and lactate, which partially attenuate over time. Low scale cortisol levels in the 2-month exposure groups, along with the absence of an elevated neutrophil-to-leukocyte ratio, do not support the development of chronic stress. Some variations in acute indicators (plasma cortisol, glucose, and lactate) may instead reflect transient disturbances from cage farming and handling rather than noise exposure per se. Overall, chronic vessel noise, under the tested conditions, induces measurable early physiological responses in farmed European sea bass without clear evidence of chronic stress. Future studies are needed to investigate whether different types of vessel noise, as well as varying modes and timing of exposure, may produce different effects in fish.

Introduction

In recirculating aquaculture systems (RAS), water quality depends on the continuous removal and transformation of feed residues and fish waste. System stability is highly sensitive to waste accumulation, making effective mechanical and biological filtration essential to control suspended solids, nitrogen compounds, and chemical oxygen demand. Faecal integrity strongly affects removal efficiency: well-formed faeces are easily captured, whereas fragmented faeces break into fine particles that are harder to remove. These increase turbidity and organic load, leading to higher oxygen demand, reduced biofilter performance, and overall deterioration of water quality. This may lead to a decrease in fish performance.

Lignocellulose, derived from soft wood, is known to take positive influence on faecal integrity in companion animals and livestock. This study aims to investigate the effect of lignocellulose on fish performance, faecal integrity and water quality parameters in rainbow trout (*Oncorhynchus mykiss*) reared in RAS.

Materials and Methods

Rainbow trout with an average weight of 57 g were used for this trial. The animals were acclimatized to rearing conditions (2 weeks) and subsequently homogeneously allocated (240 - 250 animals) to one of 12 identical Ecotrons (RAS units) with 2.000 L tanks. Each group was fed with one of 3 iso-nitrogenous, iso-lipidic and iso-energetic diets containing graded inclusion levels of lignocellulose at 0, 1.0 and 2.0 %. In total 2920 animals were initially stocked and four ecotron replicates were used per diet.

After six weeks zootechnical performance data and faeces (striping 6 fish per unit) were collected. Water oxygen concentration and pH were continuously monitored and standard quality parameters (NO₂- and NH₄+) including chemical oxygen demand (with small scale tube method; ST-COD) were measured once a week. The faecal score was conducted using a 3-level scoring scale with observational faecal consistency: 1: no structure (diarrhea), 2: some structure/firmness and 3: solid faecal structure.

Results

The inclusion of lignocellulose in the diets of rainbow trout did not significantly influence zootechnical parameters. The evaluation of faecal integrity and water quality showed significant influence of lignocellulose compared to the control group (see table).

Table

Results of ST-COD and Faecal Scoring

Group / Parameter	ST-COD average (mg O ₂ /L)	SD	Faecal Score average	SD
Control	12.2 ^a	1.72	1.9 ^a	0.39
1 % Lignocellulose	8.0 ^b	2.96	2.8 ^b	0.08
2 % Lignocellulose	6.1 ^b	0.89	2.6 ^{ab}	0.25

a,b: Different superscripts in a column indicate significant differences. COD: (p<0.01); Faecal Score (p<0.05); 1: no structure (diarrhea), 2: some structure/firmness, 3: solid faecal structure. SD: Standard deviation.

(Continued on next page)

Discussion

Lignocellulose, an insoluble dietary fiber composed of cellulose, hemicellulose, and lignin, plays an important role to manage faecal consistency in companion animals i.e. dogs (Abd El-Wahab et al. 2022) and livestock animals i.e. broiler chicken (Farran et al. 2013). Lignocellulose supports gut functionality by stimulating peristalsis and improving intestinal transit. Due to its high water binding capacity, it absorbs and retains free water in the gut, increasing digesta bulk and promoting the formation of firmer, more cohesive faeces.

This feeding trial in rainbow trout (*Oncorhynchus mykiss*) with inclusion of 1 % and 2 % lignocellulose in the diet compared to a control group shows the efficiency to promote faecal integrity in a new species and environment. In RAS faecal consistency strongly affects waste removal efficiency. The stability of the system is highly dependent on effective removal of faeces from the fish tanks and culture water to control water quality. The significant improvement of the faecal score in this trial between control and 1% lignocellulose inclusion is accompanied by the decrease of ST-COD, a water quality parameter, for lignocellulose enriched diets up to 2%. ST-COD is considered a parameter directly linked to waste removal efficiency.

Further investigations are needed (other fish species, other breeding systems, other sources of lignocellulose) to understand the mode of action and confirm the interest of dietary lignocellulose supplementation in aquaculture.

Introduction and objectives

It is a long-standing critique of private enterprise that management is incentivized to optimize financial return to shareholders over other objectives such as resource use efficiency or avoidance of environmental and social harms. This has been countered through many initiatives including the World Economic Forum Stakeholder Capitalism initiative (World Economic Forum, 2020) and the EU Green Deal strategy (European Commission (2019)). The concept of the circular economy has emerged as a practical strategy to improve sustainability whilst supporting continued economic growth (Tuladhar, A. et. al., 2022). The SmartAqua4FuturE (SAFE) project is one of many that is exploring technical innovations that support a more circular bioeconomy especially in the context of European freshwater aquaculture. As one component of the project, the authors examined the financial viability of candidate technologies from a business perspective to help identify opportunities and constraints that might be relevant for sector stakeholders and governance organisations.

Approach and methods

The main approach taken was that of a marginal analysis, calculating the additional costs of implementing a technology and comparing it with the additional income that could be generated, or savings that might be made through avoiding previous costs. Spreadsheet models were used to conduct a sensitivity analysis to help identify the most critical elements contributing to net benefits and determine potential financial incentives for adoption. The main challenge was access to industry cost data, making it necessary to use a mixture of actual data, information from academic literature and estimated costs from other financial models. The other main issue to consider was the likely impact of operational scale on costs and returns. Data generated within the project was at experimental or pilot scale and potentially unrepresentative of costs and returns at commercial scale.

Results

The main example highlighted concerns the collection of sediment from carp ponds in Poland using straw bales which can subsequently be incorporated into substrate for oyster mushroom cultivation. Oyster stem byproducts can then be incorporated into carp diets, especially those used to prepare juvenile fish for over-wintering. Experimental work showed this to be technically feasible and economically interesting in terms of scale as Poland is both a major producer of farmed carp and oyster mushrooms. Financial analysis suggested that even as a byproduct, oyster mushroom stems would be an expensive feed ingredient, but at low inclusions rates it acts as a functional feed and improves over-wintering survival rates sufficiently to justify the additional costs involved. The collection of pond sediment for incorporation in mushroom substrate appears uncompetitive with current alternatives. However, a second example provides an interesting counterpoint. Analysis of the marginal costs of using a high-efficiency drier to produce biofertilizer from recirculated salmon system sludge in Norway appeared financially attractive. However, the sensitivity analysis showed the most important factors to be the high cost of electricity in the test location and the disposal fees avoided by treating and selling rather than dumping the waste sediment. Where electricity prices are lower, a less efficient drier at lower capital cost would be more cost effective, and where sediment disposal fees are low or non-existent, biofertilizer production is uneconomic. This is broadly the case in Poland where there is no cost for releasing suspended solids from pond aquaculture where carp production is below 1.5 t/ha/yr. If an appropriate solids discharge fee were introduced in Poland, the collection and utilisation of pond sludge would become more financially attractive as a means of reducing total costs rather than increasing farm income.

Discussion

The results suggest that there will be some circular economy innovations that provide financial advantage and are likely to be adopted by aquaculture enterprises providing the technology is robust and there are no significant regulatory barriers. Other innovations are unlikely to be adopted if they impose additional cost on the producer unless they become essential due to regulatory or market drivers. Encouraging enterprises to increasingly internalize their externalities almost inevitably leads to higher prices for consumers, but could lead to lower costs for society as a whole. There is therefore a need for both technical and policy innovation to support the emergence of more circular businesses.

Introduction

It has already been established through research that fish larvae have high nutritional needs in phospholipids. Phospholipids (PLs) have a prominent role as structural components of cellular membranes, and at the larval stage the formation of tissues and organs is still underway (Sargent et al. 2002; Saleh et al. 2012). At the same time, not much is known about the PL needs of fish in the juvenile stage or later. This may be because there is some evidence, albeit limited, of the existence of a PL biosynthesis mechanism in fish (Sargent et al. 2002). Currently in Mediterranean aquaculture improved growth rates in fish have been achieved through the application of certain genetic selection programs (Ferosekhan et al. 2022). Knowing that faster weight gain also means faster tissue development, questions are raised about whether the needs of fish in structural nutrients, such as PL, are covered only by their biosynthetic ability. The aim of the present study is to investigate if the increased nutritional intake of PLs will affect production and physiological characteristics of gilthead seabream (*Sparus aurata*) of commercial size. Simultaneously, the efficiency of PL sources of marine and plant origin is explored.

Methodology

Five different diets were formulated and produced, of which one was used as a Control diet (typical composition of commercial diets, PL 0.45%). The rest of the diets contained, in pairs, krill oil (K) and soybean oil (S) in two levels (PL 0.7% and PL 1.0%). This was to achieve a 50% and 100% increase in PL content compared to the Control diet. Going forward the diets will be referenced as K50, K100, S50 and S100. Fifteen homogeneous groups of 10 juvenile gilthead seabream with initial body weight (BW) 28.0 ± 0.13 g (triplicated groups for each treatment) were used. Fish were fed according to water temperature and BW. Mean water temperature was 21.1 ± 0.2 °C. When the fish reached commercial size, the trial ended (total duration: 8 ½ months), weight and length were measured and blood samples, as well as liver, intestine and fillet tissues were taken. The growth parameters that were investigated include: fish weight (W) and its coefficient of variation (CV_w), specific growth rate (SGR), feed conversion ratio (FCR), thermal growth coefficient (TGC) and organosomatic indices. Additionally, the physiological condition of the fish was evaluated by analyzing blood samples (cholesterol, glucose, albumin, triglycerides, total protein, total antioxidant capacity, catalase). Sample analysis is still ongoing, so presented below are the results that have been gathered up until now.

Results

Fish weight was significantly lower in the Control treatment. The K100 diet resulted in higher final weight, followed by K50. The S50 and S100 diets showed no significant differences from the Control diet. Similar results were obtained for SGR and TGC. CV_w and FCR did not show significant differences among treatments. Serum biochemical parameters weren't significantly different from control except for cholesterol, which was higher in fish that consumed K100. Organosomatic indices (Hepatosomatic index, spleenosomatic index, viscerosomatic index, perivisceral fat somatic index) didn't show significant differences among treatments.

Table 1: Results of selected parameters analyzed for the experiment.

(Continued on next page)

Discussion

Present results suggest that the genetically improved gilthead seabream that are currently used in intensive aquaculture have higher PL needs. Also, there is an indication that krill oil is a more efficient source of PLs than soybean oil. At the same time, the physiological state of the fish is not affected, as indicated by the analysis of the samples. To our knowledge, there is a limited number of studies regarding PL needs in Mediterranean aquaculture fish species, while there is little to no research on adult fish. Despite this, Kokou et al. (2021) reported similar results for gilthead seabream rearing from 12 to 50 g. Conclusions regarding growth, in addition to the physiological condition of the fish, will be clearer after further analysis of the samples. Nonetheless, there seems to be potential in increasing the phospholipid level of gilthead seabream growout diets.

EMBRYONIC THERMAL HISTORY AND ITS PERSISTENT EFFECTS ON CARDIAC MOLECULAR RESPONSES IN ATLANTIC SALMON

Introduction

In Atlantic salmon aquaculture, the application of specific thermal regimes, particularly the use of higher temperatures to accelerate embryonic development, is a widely used strategy to optimise production efficiency. However, accumulating evidence indicates that promoting rapid growth through higher temperatures during early development may entail substantial physiological costs, with potential long-term consequences for fish health, robustness, and the structural integrity of vital organs. Recent evidence further suggests that lower embryonic temperatures may represent a more favourable approach, conferring lasting beneficial effects on the fish. The heart, which exhibits pronounced plasticity during early ontogeny, is especially susceptible to thermally induced developmental perturbations. In this study, we investigate how different embryonic temperature conditions influence cardiac molecular responses to challenge, both *in vitro* and *in vivo*, in Atlantic salmon, with a particular focus on genes involved in cellular stress responses and tissue structural organisation.

Materials and Methods

Fertilised eggs were exposed to three distinct thermal regimes from fertilisation until the eyed stage. These included a constant-temperature group maintained at 8 °C, a cold-exposure group maintained at 4 °C, and a fluctuating-temperature group following an 8, 4, and 8 °C profile. After this period, all groups were transferred to a standardised temperature of 8 °C for the remainder of embryonic development and hatching, and were maintained at this temperature until the onset of exogenous feeding. Fish were subsequently reared at 12 °C until the end of the trial. Cardiomyocytes were isolated at the parr and smolt stages and subjected to experimental stressors, including oxidative stress and induced hypoxia. Cellular responses were assessed 24 hours after exposure. For the *in vivo* stress trial, Atlantic salmon smolts were subjected to a stress challenge involving 10 seconds of air exposure followed by 30 minutes of confinement. Heart samples were collected before stress, immediately after stress, and at 4 and 8 hours post-stress. From each heart, the ventricle, atrium, and bulbus arteriosus were dissected and analysed separately for gene expression.

Results

Preliminary data reveal pronounced heterogeneity in gene expression across cardiac tissues and embryonic thermal regimes. In the *in vitro* challenge experiments, cardiomyocytes exhibited distinct expression profiles linked to their thermal history. Exposure to hypoxia resulted in significant interaction effects between embryonic temperature and treatment, characterised by a strong induction of heat shock protein genes alongside a concurrent downregulation of the marker *cyp11a1*. Similarly, oxidative stress elicited significant interaction effects in several key biomarkers, with the induction of *hsp70* and antioxidant defence enzymes, including *gstt*, *mnsod*, and *gpx*, being clearly modulated by embryonic temperature. While expression levels of these markers remained stable or declined in the constant 8 °C group, they showed modest upregulation in the 4 °C and 8, 4, and 8 °C groups. Samples from the *in vivo* stress trial are currently being processed, and the results will be presented at the conference.

Conclusion

Embryonic thermal history clearly shapes cardiac molecular responses to later life stress in Atlantic salmon, with lower or fluctuating temperatures conferring distinct regulatory effects on key stress and antioxidant pathways. The differential induction of heat shock proteins and antioxidant defence genes suggests that cooler embryonic conditions may promote enhanced cardiac stress resilience. These findings highlight the heart as a sensitive target of early thermal programming and underscore the need to balance short term production gains with long term physiological robustness in aquaculture. Ongoing *in vivo* analyses will further clarify the functional relevance of these molecular patterns at the whole organism level.

Introduction

French algaculture is diverse but remains limited in terms of production, with 283 T of macroalgae, 430 T of spirulina and 9.3 T of microalgae produced in 2024 (Agreste, 2024). To date, the management of genetic resources and the implementation of genetic improvement practices in algae are poorly documented. In micro-algae and spirulina, genetic selection is limited by current cultivation practices, which rely on asexual reproduction. In macro-algae, diverse cultivation practices have been described, either related to sexual reproduction of introduced *Undaria pinnatifida* (Guzinski et al., 2018) or to the use of wild, locally-collected strains to produce F1 progeny, generally without any selective breeding approaches (Goecke et al., 2020). International guidelines recommend that genetic improvement of macro-algae follows the principles established for terrestrial crops, including the development of homogenous, distinct and stable varieties or cultivars as certified commercial products (FAO, 2019). The arguments for adopting such breeding strategies are however questionable, regarding the size and the stage of development of the French algal production.

Advances in international research have reported proof of concept studies aimed at developing new selective breeding practices in micro- and macro-algae, similar to those used in terrestrial and aquaculture species in populations with large genetic variability and established pedigree-based selective breeding practices (Bråtelund et al., 2026; Mauger et al., 2026; Nehr et al., 2025). Successful industrial implementation of such innovations will require 1) improved characterisation of current genetic practices, socio-economical and technical contexts and 2) establishment of selective breeding models and the necessary technical and administrative ecosystem, including regulations.

To capitalize on these opportunities, a French national and collective initiative was launched in 2026 through the TEHASIS project. The project aims to bring together algal producers, scientific and technical stakeholders, including Ultra-Peripheral Regions (UPR) and Overseas Countries and Territories (OCT), with the objective of fostering innovation transfer and establishing the foundations for future algal breeding programs.

Objectives

TEHASIS (2026-2028) aims to develop a strategic framework for the domestication and the genetic improvement of French algal aquaculture through an integrated approach combining stakeholder mapping, assessment of genetic management practices and knowledge transfer. The main objective is to co-design, for each species, a genetic roadmap for domestication and genetic improvement to strengthen the resilience of production facilities and culture collections, improve production quality and enhance adaptation to future challenges. In parallel, technical workshops and training sessions will be organized for professionals. Public outreach activities, including conferences, trade fairs and social media communication, will also be organised to improve societal awareness and perception of domestication and genetic improvement approaches in algaculture.

(Continued on next page)

Action plan

The first phase consists of an exhaustive inventory of algal production facilities and culture collections operating in France.

Two working groups “macroalgae” and “microalgae, including spirulina” were created to gather together scientific, technical and industry stakeholders. These working groups will provide shared and comprehensive summaries of current knowledge on genetic improvement for the most important species, and for specific issues related to individual species. In parallel, a mapping of the stakeholders, and associated value chains will be conducted, to identify opportunities and weaknesses of these emerging new sectors, to design scenarios, and to qualify potential environmental, societal and socio-economic risks for the future roadmap of these value chains.

Expertise in reproductive biology and genetics in algae and quantitative genetics in animals will be combined with companies’ know-how to design selective breeding programs according to species.

Based on those findings, each working group will produce an operational roadmap identifying technological bottlenecks, research and innovation priorities, and the most appropriate genetic improvement strategies according to the biological, economic, organizational and regulatory characteristics of each sector.

Expected outcomes

By the end of the project, TEHASIS will deliver a roadmap to initiate domestication and genetic improvement within French algal production facilities and culture collections while increasing awareness among professionals of the benefits of genetic management and selective breeding. By promoting the adoption of genetic tools and concepts, the project aims to make these approaches more accessible, thereby enhancing the competitiveness, innovation capacity and resilience of the sectors, including social acceptance.

TEHASIS also seeks to strengthen collaboration among algal farmers, scientists and technical stakeholders by establishing a national network dedicated to algaculture genetics and promoting knowledge exchanges and innovations.

In the longer term, the project will support the establishment of sustainable private and public technical and scientific support. The knowledge generated, operational roadmaps and collaborative network developed through TEHASIS will help identify sector-specific research priorities and stimulate future applied research and innovation projects. Beyond its national scope, TEHASIS may serve as a model for the development of coordinated breeding strategies across Europe, fostering collaboration between research institutions, industry stakeholders and policymakers to strengthen the sustainability, competitiveness and resilience of the European algae sector.

ASSESSING COASTAL SUSTAINABILITY THROUGH MACROALGAL COMMUNITIES ON MOROCCO'S CENTRAL ATLANTIC COAST

Bouzzammit Nadia ^{1,2}

1. Laboratory of Aquatic Systems: Marine and Continental Environments, P.O. Box 8106, Faculty of Sciences, Ibn Zohr University Dakhla Avenue, Agadir, Morocco

2. Laboratory of Oceanography, Marine Biology and Aquaculture, Higher Institute of Marine Fisheries presenting Author email: nadia.bouzzammit@edu.uiz.ac.ma

Introduction:

Marine macroalgae are major primary producers in shallow coastal ecosystems and are widely recognized as sensitive indicators of environmental quality, ecological status, and habitat change. Because macroalgal assemblages respond rapidly to variations in nutrient availability, hydrodynamics, light, substrate stability, and pollution, they are increasingly used in coastal monitoring frameworks to assess ecosystem condition and sustainability (Harley et al., 2012; Mancuso et al., 2021). Seaweeds are not only important for the environment, but they also have increasing socio-economic value. They help support fisheries, contribute to the blue bioeconomy, and are used in the food and industries. They also play an important role in supporting the livelihoods of coastal communities. For this reason, conserving and monitoring seaweeds is important for both biodiversity management and sustainable development. (FAO, 2021; UNCTAD, 2024; Valero et al., 2017). On the central Atlantic coast of Morocco, these issues are especially important because coastal productivity is strongly shaped by upwelling dynamics, hydrodynamic forcing, and local geomorphology (Belmajdoub et al., 2023; Makaoui, et al., 2023). Recent work on the Moroccan Atlantic margin shows that upwelling intensity varies markedly in space and time and plays a central role in nutrient enrichment, phytoplankton productivity, and the distribution of marine organisms. In the Agadir–Cap Ghir sector, coastal circulation is further influenced by semidiurnal tides and dominant westerly to northwesterly winds, creating a physically dynamic environment where benthic communities can provide valuable ecological signals.

On the central Atlantic coast of Morocco, coastal productivity is strongly influenced by upwelling dynamics, hydrodynamic forcing, and local geomorphology. Studies conducted along the Moroccan Atlantic coast have shown that upwelling intensity varies markedly across space and time and plays a central role in nutrient enrichment, phytoplankton productivity, and the distribution of marine organisms (Belmajdoub et al., 2023; Makaoui, et al., 2023). In the Cap Ghir area, coastal circulation is further influenced by semidiurnal tides and dominant westerly to northwesterly winds, creating a physically dynamic environment in which benthic communities can provide valuable ecological signals (Rhomad et al., 2022). Although ecological importance of this coastline, the knowledge of Atlantic Moroccan macroalgae is still limited at the local level. Recent studies from El Jadida and the southern Atlantic coast have shown that Moroccan shores contain a high diversity of macroalgae (Benhniya et al., 2024; Boutafda et al., 2025). However, the presence and distribution of these species are still not well documented in several areas. This lack of information is particularly important for Cap Ghir, where intense hydrodynamics movement and permanent upwelling create favorable conditions for the development of diverse macroalgal communities, but where local baseline data are still scarce. The study aims to assess macroalgal biodiversity, evaluate their role as indicators of coastal ecosystem health and sustainability on the central Atlantic coast of Morocco.

Material and methods

Study area

The study focused on the intertidal zone of the Cap Ghir site, located on the central Atlantic coast of Morocco.

Sampling and Identification

Macroalgae samples were collected across different seasons. Species were identified based on standard morphological and anatomical criteria using existing taxonomic keys for the region.

Data Analysis

The community structure was analyzed by calculating:

The Qualitative Dominance Index (DQi), which assesses the relative species richness of the major taxonomic groups.

The Rhodophyceae/Phaeophyceae (R/P) ratio, used to infer the thermal affinity of the flora according to Feldmann (1937).

(Continued on next page)

Figure 1: Study area

Figure 2: Qualitative dominance of different systematic groups

Results & Discussion

The floristic inventory of the Cap Ghir region identified 76 species, distributed into three classes:

Qualitative Dominance: The floristic composition shows a strong dominance of red algae (63.6 %), confirming that Cap Ghir hosts a highly diverse and stable macroalgal community. This dominance is often linked to stable and favorable local environmental conditions (Hassoun et al., 2018).

Thermal Affinity (R/P Ratio): The calculated R/P ratio is an indicator of the flora's thermal affinity (Boudouresque & Verlaque, 2013).

$$R/P = 48 \text{ (Rhodophyceae)} \div 15 \text{ (Phaeophyceae)} = 3.2$$

A value of $R/P = 3.2$ indicates a flora of warm-temperate affinity (Feldmann, 1937). This finding is consistent with the known hydrodynamics and seasonal variability of the central Moroccan Atlantic coast (Bessa et al., 2021). Overall, this study provides a crucial baseline for future environmental monitoring.

EPIGENETIC DIFFERENCES BETWEEN LACUSTRINE AND RIVERINE BROWN TROUT FINGERLINGS REVEALED BY NANOPORE SEQUENCING

Jernej Bravničar ^{1*}

¹ Department of Animal Science
Biotechnical faculty
University of Ljubljana
Slovenia

*corresponding/presenting jernej.bravnicar@bf.uni-lj.si

Introduction

Brown trout (*Salmo trutta*) exhibit striking life-history polymorphism with lacustrine (lake-dwelling) forms typically growing faster and reaching larger sizes, while maturing later, when compared to riverine residents. Neutral genetic differences between these ecotypes are minor, suggesting that epigenetic regulation could underpin their divergent phenotypes. DNA methylation mediates phenotypic plasticity and may transmit parental environmental information to offspring. Epigenome-wide studies in salmonids show that maternal life history has a stronger influence on offspring methylation patterns than early-life temperature, with differentially methylated regions (DMRs) enriched for genes involved in metabolism, neurobiology and digestion [1]. Genome scans of migratory versus resident brown trout highlight outlier loci near genes such as FAM70A, GRID1, CDH20 and EZH2 [2], while rainbow-trout smolts show DMRs in genes controlling neuronal differentiation (NEUROD4, GRM1), muscle development (MYOM3) and immune function (RSAD2) [3]. These findings provide a framework for investigating epigenetic differences between lacustrine and riverine fingerlings.

Materials and methods

Ripe brown trout were collected from Lake Bled and the Sava Bohinjka River during the 2018 spawning season, and their progeny reared at same conditions, forming novel broodstock of both ecotypes. In spawning season 2024, broodstock were striped and milked, producing F2 lacustrine and riverine progeny. At six months of common garden conditions, five fingerlings from each ecotype were sampled. High-molecular-weight DNA was extracted from brain and liver tissues using a modified CTAB protocol and sequenced on MinION Mk1c devices (R10.4 flow cells). Base-calling and methylation detection used Guppy and Megalodon. Methylation frequencies were mapped to the *S. trutta* genome, and DMRs between ecotypes were identified with MEDIPS and methylartist. Genes overlapping significant DMRs were annotated and analysed for functional enrichment.

Expected outcomes

Because lacustrine trout grow faster, we anticipate DMRs in promoters of metabolic and muscle-development genes, leading to enhanced energy assimilation and growth. Differences may also occur in neurodevelopmental and immune-related genes, reflecting adaptations for adfluvial movement and stress responses. Candidate targets include FAM70A, GRID1, CDH20, EZH2, NEUROD4, GRM1, PCDHGC5, CLDN10, MYOM3 and RSAD2 [2][3]. These epigenetic signatures will be validated through targeted resequencing and gene expression analyses in subsequent work.

Discussion

This study will be among the first to apply long-read nanopore sequencing to examine genome-wide methylation differences in brown trout. Comparing lacustrine and riverine fingerlings raised in a common garden will help disentangle inherited epigenetic marks from environmental effects. Identifying DMRs in growth- and migration-related genes may explain the fast growth of lacustrine forms and aid development of markers for selective breeding for producers to select or induce beneficial epigenetic states. Understanding epigenetic contributions to life-history variation also informs conservation by highlighting the importance of maintaining epigenetic diversity.

Introduction and approach

Striped bass (*Morone saxatilis*) is a high-value finfish species with expanding potential in North American aquaculture, including pond-based and recirculating aquaculture systems. However, year-round production remains constrained by a narrow spring spawning window, seasonal availability of fry and fingerlings, and temperature-dependent growth. This synthesis compares two complementary strategies for stabilizing supply: staggered broodstock conditioning for out-of-season spawning and cold banking with feed restriction for temporary storage of fingerlings. The comparison evaluates biological control points, infrastructure needs, operational complexity, economic implications, animal welfare considerations, and suitability for hatchery, grow-out, and vertically integrated production systems. It also frames ongoing techno-economic assessment as a necessary next step for comparing these approaches across production scales and infrastructure pathways.

Results and implications

Staggered broodstock conditioning. Broodstock manipulation acts at the reproductive control point by using photoperiod, temperature, and, when needed, hormonal induction to phase-shift maturation and spawning. Reproductive timing is governed by the brain–pituitary–gonad axis, and by exposing multiple broodstock cohorts to phase-shifted photothermal regimes, hatcheries can induce spawning outside the natural spring window to provide predictable egg and larval supply (Andersen et al., 2021). However, this approach requires controlled indoor facilities, skilled technical labor, and substantial energy inputs for temperature regulation. It also carries risks of variable gamete quality, spawning failure, and additional juvenile-rearing challenges when larvae are produced outside the season when earthen pond nursery systems are biologically feasible.

Cold banking and feed restriction. Fingerling cold banking acts later in the production cycle by reducing temperature and ration to slow metabolism and preserve juveniles for delayed stocking. For striped bass, a practical cold-banking range is approximately 10–15°C, with careful rewarming and refeeding to support compensatory growth—a well-described response mediated by growth hormone and insulin-like growth factor signaling (Borski et al., 1998; Picha et al., 2006; Turano et al., 2007). Sorting fingerlings into groups undergoing one to four weeks of feed restriction can extend availability by several weeks. This strategy is less capital-intensive and more accessible to grow-out operations, but extended or poorly managed storage may compromise growth recovery, immune function, welfare, and overall production efficiency.

Integration and economic assessment. The two strategies should be viewed as complementary rather than mutually exclusive. Hatcheries can use staggered spawning to expand the availability window for larvae and fingerlings, while producers can selectively cold bank cohorts for several weeks to align stocking with tank availability, seasonal conditions, and market timing. A hybrid approach offers a resilient framework for improving domestic striped bass supply chains. A critical gap identified in this review is the absence of detailed economic analyses comparing these strategies across production scales and system types. Ongoing techno-economic modeling work (Brawley, in preparation) is directly addressing this need, estimating capital and operating costs, energy sensitivity, scale effects, and market-aligned stocking scenarios so that biological feasibility can be translated into practical decision tools for hatcheries, growers, and vertically integrated operations.

THE ROLE OF MARITIME SPATIAL PLANNING IN SUPPORTING EGD-DRIVEN AQUACULTURE DEVELOPMENT IN THE MEDITERRANEAN

D. Brigolin^{1*}, M. Mazzotta¹, E. Cahís I Reixach¹, A. Fudoli¹, F. Carella¹

*dbrigolin@iuav.it

The European Green Deal (EGD) establishes a cross-sectoral agenda directly impacting on the marine environment, with a momentum which has been recently reinforced by the Ocean Pact (European Commission, 2025). Maritime Spatial Planning Directive (MSPD, 2014/89/EC) can directly contribute to the achievement of EGD sectoral goals, and methodologies assessing the relevance of this contribution are currently of interest (Bocci et al., 2026).

The present work explores the relationship between MSPD implementation and aquaculture spatial planning, through Allocated Zones for Aquaculture - AZA - definition and management (Macias et al., 2019). The work was carried out within the project MEDIGREEN “Mediterranean approach towards a maritime European Green Deal in MSP” funded by EMFAF (EMFAF-2023-PIA-MSP). We investigated the role of MSP in supporting sustainable aquaculture development by performing two parallel analyses:

1. collecting information from aquaculture experts and management bodies on the current stage of development of AZA and MSP planning in the Mediterranean, on the level of integration between AZA sectorial plans and MSP plans, and on the availability/interoperability of support tools used in aquaculture planning. Prioritized areas and areas with high potential for aquaculture currently identified in the different countries were also mapped;
2. performing a desk-based analysis on three aspects which are influencing aquaculture spatial planning and management: i) multi-level governance alignment; ii) interaction of aquaculture with other maritime uses and with marine conservation; iii) environmental interactions and climate resilience of aquaculture zones. This second step was performed by reviewing aquaculture strategic documents at the national level, technical documents from European Commission and General Fisheries Commission for the Mediterranean, and by collecting examples from existing AZA experiences.

Results of the two analyses are discussed, in order to define more clearly the role of MSP in contributing to the EGD objective of sustainable sea-food production; the discussion benefits from the feedback received within two recent meetings of the Community of Practice on Maritime Spatial Planning in the Mediterranean (MED-MSP COP), in which the preliminary results of the work were presented.

ADVANCED OXIDATION PROCESSES FOR REMOVAL OF OFF-FLAVOUR COMPOUNDS IN RECIRCULATING AQUACULTURE SYSTEMS (RAS)

Marko Brkic

ULTRAAQUA

Email: mbr@ultraaqua.com

Recirculating aquaculture systems (RAS) often experience accumulation of off-flavour compounds, notably geosmin and 2-methylisoborneol (MIB). The complexity and variability of both the RAS system and its water matrix, including organic matter and salinity, challenge the effective design and application of treatment technologies for off-flavour control.

This research demonstrates advanced oxidation processes (AOPs) for the removal of geosmin and MIB in RAS. A laboratory-scale comparative study was conducted using water from a commercial salmon RAS growout system to assess the degradation of geosmin and MIB using UV/H₂O₂, O₃/H₂O₂, vacuum-UV, and ozone pre-treatment followed by vacuum UV. The laboratory results were used to derive degradation kinetics and compare treatment performance under realistic RAS matrix conditions. Selected AOP configurations were subsequently tested at pilot scale to verify the laboratory findings.

A mechanistic mass-balance model was developed to describe geosmin and MIB dynamics in RAS growout and purge tanks and to enable application across different system designs. The model represents compound production, distribution between fish and water, and hydraulic exchange, and incorporates water-treatment from the laboratory- and pilot-scale experiments.

The model allows sizing and operational assessment of AOP water treatment to reduce geosmin and MIB in water and fish. Depending on the case, treatment can be applied in growout to prevent offflavour and avoid depuration, increasing capacity and avoiding weight loss. Alternatively, treatment during depuration can reduce purge time and thereby minimize weight loss.

Figure 1 Comparative test of four advanced oxidation process (AOP) for degradation of geosmin and 2-methylisoborneol (MIB) in commercial salmon RAS water: UV/H₂O₂, O₃/H₂O₂, vacuum-UV (VUV), and ozone pre-treatment followed by vacuum-UV (VUV). Water concentrations are shown as a function of increasing dose.

SEASONAL VARIATION IN FATTY ACID COMPOSITION OF EUROPEAN SEA BASS (*Dicentrarchus labrax* L.) FILLETS AND FEED

Mia Brkljača^{1*}, Silvia Križanac¹, Renata Barić¹

¹Cromaris dd., Zadar, Croatia

**Presenting author: e-mail: mia.brkljaca@cromaris.hr

Introduction

Dietary lipids provide energy and essential nutrients, including essential fatty acids. Long-chain polyunsaturated fatty acids (LC-PUFA), particularly eicosapentaenoic acid (EPA) and docosahexaenoic acid (DHA), support fish growth, development and regulation of inflammatory processes. Marine fish have a limited capacity to synthesize LC-PUFA from alpha-linolenic acid (ALA) and linoleic acid (LA); consequently, tissue fatty acid composition is strongly influenced by dietary supply, in addition to species, age and rearing conditions (Carr et al., 2023). Seasonal changes in feed raw-material availability may alter dietary fatty acid profiles and potentially affect fillet composition. This study compared total fat and selected fatty acid indicators in feed and European sea bass (*Dicentrarchus labrax*) fillets collected during winter and summer 2025.

Materials and methods

European sea bass (400-600 g) were sampled from commercial cages during the first (Q1, winter) and third (Q3, summer) quarters of 2025. Fish were fed at approximately 80% of apparent satiation with diets containing 43% crude protein and 16-20% crude fat. Fillet samples were prepared as 12 pooled samples, each comprising five fish, and fatty acid composition was determined. Twelve feed samples were collected in each quarter. Fatty acid composition was expressed as a percentage of total fatty acids (%TFA).

Two-way analysis of variance (ANOVA) was performed using quarter (Q1 and Q3) and sample type (feed and fillet) as factors.

Results

Total fat was lower in fillets than in feed in both Q1 (9.12 vs 16.92 g/100 g sample) and Q3 (10.20 vs 18.28 g /100 g sample). In Q3, ALA was lower in fillets than in feed (4.06 vs 6.96 %TFA), whereas the Q1 values were 4.13 and 5.57 %TFA, respectively. In Q1, EPA was lower in fillets than in feed (3.35 vs 4.14 %TFA); Q3 values were 3.30 and 3.71 %TFA. The EPA/DHA ratio was also lower in Q1 fillets than in Q1 feed (0.56 vs 0.70), while Q3 values were 0.55 and 0.65. The n-3/n-6 ratio was numerically lowest in Q1 fillets (0.71), compared with 0.91 in Q1 feed, 0.78 in Q3 fillets and 0.83 in Q3 feed. No significant differences in LA or DHA proportions between fillets and feed were detected in either season. Within fillets, total fat and the evaluated fatty acid indicators remained stable between Q1 and Q3.

Discussion

The seasonal stability of fillet fat content and the evaluated essential fatty acid profile suggest that the feeding strategy maintained a consistent nutritional composition of European sea bass fillets across winter and summer. The lower ALA proportion in Q3 fillets relative to feed may reflect increased metabolic utilization during the warmer period. Lower EPA and EPA/DHA values in Q1 fillets relative to feed, together with the comparatively low n-3/n-6 ratio in winter fillets, may indicate greater utilization or lower retention of n-3 fatty acids during colder conditions. These findings suggest that increasing the winter dietary supply of n-3 fatty acids, particularly EPA, could be considered. The feed fatty acid profile remained comparatively stable between sampling periods, indicating that seasonal variation in raw materials did not substantially affect the evaluated feed composition.

Introduction

Brazilian marine fish farming still has low production, despite the high market value of this sector. In this context, native species with aquaculture potential, such as *Pogonias courbina*, require further investigation. Biofloc technology (BFT) has become established as a more sustainable production system capable of contributing to water quality maintenance and providing microbial biomass as a supplementary nutrient source. Supplementation of BFT with microalgae, such as *Nannochloropsis oculata*, may enhance its potential nutritional and immunological benefits for cultured organisms. Therefore, this study evaluated, for the first time, the effects of biofloc technology, with and without *N. oculata* supplementation, on the growth performance, hematological parameters, and immune responses of juvenile *P. courbina*, using a clear-water system as the control.

Materials and Methods

The experiment was conducted over 42 days at the Federal University of Santa Catarina, using a completely randomized design with four treatments: clear water in continuous flow (CW), bioflocs (BFT), BFT supplemented with 5 mg L⁻¹ of *N. oculata* (BFT+5), and BFT supplemented with 10 mg L⁻¹ of *N. oculata* (BFT+10). Each treatment was evaluated in quadruplicate in 400 L tanks containing seawater at 33 ppt, and tanks assigned to the biofloc treatments were inoculated with mature biofloc at 20% of the total water volume. Twenty juveniles were stocked per tank and fed a commercial diet containing 40% crude protein and 7% ether extract three times daily (08:00, 12:00, and 16:00 h) to apparent satiation. The microalgae, obtained from a live culture, were added twice weekly. Water quality was monitored throughout the experiment; sucrose was added when ammonia levels exceeded 1 mg L⁻¹, and solids were removed by settling when total suspended solids reached 400 mg L⁻¹. Water temperature was maintained between 27 and 28 °C, and dissolved oxygen remained above 5 mg L⁻¹. At the end of the experiment, *Vibrio alginolyticus* was used to assess plasma antimicrobial and agglutination activities through twofold serial dilution assays.

Results and discussion

Juvenile *P. courbina* adapted well to the BFT conditions, with survival rates approaching 100% across all treatments. Fish reared in the CW system exhibited significantly higher final body weight and weight gain than those reared in the biofloc treatments ($p < 0.05$), while BFT+5 showed intermediate responses for some production parameters. No significant differences were detected among treatments for the hematological or immunological parameters evaluated, although the BFT+10 treatment showed a tendency toward lower erythrocyte and leukocyte counts.

Similar findings were reported by Silva et al. (2023), who observed increased final biomass in *Oreochromis niloticus* when the biofloc system was supplemented with 5 mg L⁻¹ of *Scenedesmus obliquus*. The authors likewise found no overall differences in hematological parameters. However, unlike the findings of the present study, microalgal supplementation increased monocyte counts and antimicrobial titers. Although *N. oculata* contains bioactive compounds with potential antimicrobial and immunostimulatory properties (Zahran et al. 2023), the contrasting responses may be related to interspecific differences in biofloc utilization, since *O. niloticus* is recognized as an active consumer of particles in the system, whereas this ability is not yet well established for *P. courbina*. Furthermore, the lower values observed for some hematological parameters in the BFT+10 treatment suggest that increasing the microalgal concentration may not result in a dose-dependent immunostimulatory response.

Introduction

Biofloc Technology (BFT) is an alternative to conventional aquaculture systems that converts nitrogenous waste into microbial biomass, thereby improving nutrient recycling within the culture environment. The flathead grey mullet, *Mugil cephalus*, is an important member of the family Mugilidae and is widely distributed in saline and euryhaline waters, including the Mediterranean region. Its omnivorous and detritivorous feeding behavior allows the direct utilization of biota present in the culture environment, making this species a suitable candidate for rearing under BFT conditions. Given the rich microbial community characteristic of biofloc systems, different nutritional and environmental strategies may be applied to further optimize fish performance and physiological responses. Based on this premise, three experiments were conducted to investigate different nutritional approaches and management in *M. cephalus* reared under BFT. Specifically, the objectives were to: (1) evaluate the early intestinal physiological response to dietary fishmeal replacement; (2) assess the effects of continuous darkness, probiotic supplementation, and their interaction on zootechnical performance; and (3) evaluate the effects of microalgae and probiotic supplementation on stress responses under oxygen and density challenges.

Materials and Methods

Three independent experiments were conducted with juvenile *Mugil cephalus* reared under BFT conditions. In Experiment 1, three diets containing 15%, 5%, or 0% fishmeal (**FM15**, **FM5**, and **FM0**, respectively) were tested in triplicate for 27 days, followed by evaluation of growth performance, body composition, intestinal enzyme activity, gut microbiota, and transcriptomic responses. In Experiment 2, fish were exposed for 72 days to a 2 × 2 factorial combination of photoperiod (12 h light:12 h dark vs. continuous darkness) and probiotic supplementation, resulting in four treatments: **Light**, **Dark**, **Light+Prob**, and **Dark+Prob**. Zootechnical performance was evaluated, together with changes in the bacterial community of the biofloc between the beginning and end of the trial. In Experiment 3, four treatments were tested in triplicate for six weeks: **Dark**, **Dark+Prob**, **Microalgae**, and **Micro+Prob**. The Dark groups were maintained under continuous darkness, whereas the Microalgae groups received *Chlorella vulgaris* under a 12 h light:12 h dark photoperiod. Probiotic supplementation was applied to the Prob treatments, and stress responses were subsequently assessed under oxygen and density challenges. The microalgae, obtained from a live culture, were added once a week, at 18×10^6 cells ml⁻¹. In experiments 2 and 3, a commercial feed (DIBAQ - 3.5 mm) with 30% crude protein and 7% crude fat was provided three times daily at a 2 %/d feeding rate, and the probiotic (Sanolife PRO-W *Bacillus subtilis* and *B. licheniformis*) was added once a week, at 1g m⁻³. Water quality was monitored throughout the three experiments.

Results and discussion

Across all three experiments, survival was close to 100% in all treatments, and fish maintained satisfactory growth, supporting the suitability of biofloc technology for rearing juvenile *M. cephalus*. In experiment 1, complete fishmeal replacement maintained growth and feed efficiency but was associated with reduced intestinal enzyme activity, lower lipid reserves, and transcriptomic changes related to lipid metabolism. Regarding the intestinal microbiota, beta diversity showed significant differences between the initial and final samples (FM15: $p = 0.009$; FM0: $p = 0.007$), while no differences were detected between the dietary treatments ($p = 0.798$), suggesting a temporal shift potentially influenced by the biofloc microbial community. Biofloc nutritional composition was not significantly affected by the different diets. In Experiment 2, continuous darkness and probiotic supplementation significantly improved SGR and relative weight gain, while probiotic supplementation also increased protein efficiency ratio, and no significant interaction between the two factors was detected. Biofloc maintained under continuous darkness, and therefore under more heterotrophic conditions, showed a significantly higher crude protein content than biofloc exposed to light. The microbial community in the water was mainly influenced by time. Beta-diversity analysis revealed a clear temporal shift in community composition ($p = 0.001$), whereas

(Continued on next page)

photoperiod, probiotic supplementation, and their interaction had no significant effect. In the third trial, weekly microalgae supplementation improved zootechnical performance under light conditions compared with Experiment 2, resulting in values comparable to those observed in the Dark and Dark+Prob treatments. Microalgae supplementation was associated with a more favorable stress response, as CAT activity was maintained during the challenge, GPx activity returned to basal levels after 24 h of recovery, and the cortisol increase was lower than in the Dark group. Compared with the previous experiment, crude protein content increased in the Microalgae treatment to values comparable to those observed under the Dark condition, whereas the Micro+Prob treatment remained lower than the Dark. Overall, Experiments 1 and 2 confirmed that the microbial community changed over time as the biofloc system matured, consistent with previous reports by Kim et al. (2022). The higher biofloc protein content observed under continuous darkness is consistent with Martinez-Porchas et al. (2020), who reported markedly higher protein levels under heterotrophic than photoautotrophic conditions. The inclusion of microalgae in the biofloc system in Experiment 3 did not improve growth performance, however, its potential functional role was evident, which is consistent with Jung et al. (2017) in tilapia. These results suggest that even under BFT conditions, *M. cephalus* showed limited tolerance to complete fishmeal replacement, whereas it adapted well to different environmental and management strategies within BFT without compromising productive performance.

Seaweed cultivation can serve as an innovative solution to recycle nutrients in effluent from land-based aquaculture systems, and here, the green algae genus *Ulva* is a promising candidate due to its high phenotypic plasticity, high growth rates, and biochemical composition. The qualities of *Ulva* have been described worldwide; however little research and development has been conducted in the Nordic countries. This study presents an extensive screening and characterisation of Danish *Ulva* strains and their performance in a range of temperatures, nutrient regimes and salinities. Ten Danish/German *Ulva* strains were documented to grow 6-22% day⁻¹ in free floating cultures, of these, several strains of *U. compressa*, showcased the most stable growth performances (11-32% day⁻¹). Additionally, the optimal temperature for nitrogen uptake in *U. compressa* was repeatably identified to be around 14-16 °C (30-40 mg L⁻¹ week⁻¹) while tissue concentrations of high value compounds such as ulvan were higher at colder temperatures (150-180 mg g⁻¹). The salinity tolerance of *Ulva* strongly depended on the nutrient availability, and the growth rate at low salinities decreased 10-fold for *U. fenestrata*, while salinity (5-25 ppt) did not affect growth of neither *U. fenestrata* nor *U. compressa* when nutrient concentrations were high. These results are currently being applied at a land-based salmon production site where the growth of *U. compressa* is grown in effluent water. Hence, this extensive research and development approach will showcase the potential to integrate *Ulva* cultivation in a range of aquaculture facilities and hereby diversify the product portfolio, while increasing both profit of the production.

Sharing the space at sea

Pressure on the coastal zone and offshore waters in Europe is increasing, in particular as a consequence of the expansion of offshore wind farms (OWF) [1]. At the same time we look to the sea for future food production to reduce pressure on land. With the recent UN Biodiversity Beyond National Jurisdiction Treaty and the EU Ocean Pact, the international focus on protection and restoration of the sea calls for responsible governance and management structures. Marine Multi-Use (MU), where space, infrastructure and services are shared between several actors [2] is suggested for 1) Optimising use of ocean space, 2) Boosting efficiency, reducing footprints and increasing safety of operations, and 3) Enabling the circular blue economy with the potential to increase global low trophic aquaculture (LTA) production by 132% using 10% of existing and planned OWF area for production of seaweed and mussels [3]. Realising this potential, however, requires adaptive governance frameworks that recognise both engineered ecosystem services and disservices across ecosystems, marine activities and value chains [4].

Figure 1. Concept figure of the Multi-Use prototype installed and run over 3 years in the Danish Krieger Flak Windfarm [3]. In the windfarm, production of mussels and seaweed take up nutrients and carbon, and the blue biomass is used for food, feed or biomaterials. The removal of nutrients mitigates eutrophication.

(Continued on next page)

Outcomes of the WIN@sea project

Since 2023, a pilot scale lowtrophic aquaculture (LTA) site in the OWF at Danish Kriegers Flak (DKF) in the Baltic Sea has been established, operated and decommissioned as part of the the WIN@sea and OLAMUR projects. Here, joint MU procedures between OWF operator and LTA producer was demonstrated: site selection, risk assessments, shared wind and wave forecasts, joint maintenance operations and Crew Transfer Vessel (CTV) undertaking regular monitoring of site status, environmental parameters and biodiversity. Low salinity limited the seaweed productivity at DKF, but mussel settling and growth showed potential for production of marine protein. Dynamic 3D ecological models were used for predicting yields and ecosystem services and further taken into a site selection tool for identifying optimal sites for LTA within OWF, considering also local carrying capacity. Based on project data, LifeCycle Analysis is in progress for documenting the environmental and economic viability of the MU concept in the Danish Baltic and North Sea basins. The concept and dilemmas of sharing the space at sea has been developed into a board game for communicating Marine MU and ocean literacy in the Danish education system.

Introduction

Arginine is a functional amino acid involved in protein synthesis, nitrogen metabolism and growth regulation in fish (Li et al., 2021). Different color phenotypes of rainbow trout (*Oncorhynchus mykiss*) may be associated with distinct metabolic responses due to their genetic background (Hattori et al., 2020). Therefore, this study evaluated postprandial changes in free arginine concentration in the dorsal muscle of four rainbow trout strains subjected to fasting and refeeding.

Materials and Methods

Four rainbow trout strains (wild-type, cobalt blue, yellow-albino and white-albino) were reared under identical conditions and fed a commercial diet containing 45% crude protein. After 48 h of fasting, fish were sampled at 0, 15, 180 and 360 min after refeeding. Free arginine concentrations in dorsal muscle were determined by HPLC-UV, reverse-phase column at 35°C, using 10 mM sodium acetate buffer and acetonitrile in gradient mode, with a flow rate of 1 mL min⁻¹, according to Badawy and Morgan (2010) and Matheus et al. (2017). Data were analyzed using a generalized linear mixed model with Gamma distribution and log link function, considering the interaction between time and strain.

Results and Discussion

Under fasting conditions, the cobalt blue strain showed the highest arginine concentration (Figure). After feeding, arginine levels changed differently among strains, with the white-albino strain presenting the highest concentration at 15 min postprandially. However, this strain showed the most pronounced decline over time and the lowest concentration at 360 min. In contrast, wild-type and cobalt blue trout maintained higher arginine concentrations throughout the experimental period ($p < 0.05$). These results indicate that genetic background influences arginine metabolism in rainbow trout. Previous studies have shown that pigmentation traits are associated with differences in stress responsiveness, endocrine regulation and growth performance (Khan et al., 2016; Rodríguez et al., 2019). The higher arginine availability observed in the more pigmented strains may reflect differences in amino acid utilization, whereas the marked reduction observed in the white-albino strain suggests a greater allocation of arginine to physiological maintenance processes, potentially reducing its availability for muscle growth.

Figure. Free arginine concentration (µM) in the dorsal muscle of rainbow trout strains after refeeding. Values represent means $\pm$ SD. Different lowercase letters indicate significant differences among strains within each sampling time ($p < 0.05$).

Introduction

Aquaculture expansion is increasingly required to meet rising demand for aquatic foods, but continued growth depends on reducing environmental pressures, particularly nutrient emissions in sensitive coastal systems (Crona et al., 2023). Integrated multi-trophic aquaculture (IMTA) has been proposed as a strategy to mitigate aquaculture-derived nitrogen (N) and phosphorus (P) emissions by co-cultivating extractive species such as mussels and seaweed alongside fed finfish (Chopin et al., 2012; Buck et al., 2018). However, the biomass scale required to achieve nutrient-balanced production remains poorly quantified, particularly under environmentally constrained Baltic Sea conditions (Sickander and Filgueira, 2022). This study evaluates the environmental feasibility of nutrient-neutral offshore aquaculture using a rainbow trout (*Oncorhynchus mykiss*) system integrated with blue mussels (*Mytilus edulis*) and seaweed (*Ulva* spp.), combining attributional life cycle assessment (LCA) with farm-gate nutrient mass-balance modelling.

Materials and Methods

Primary foreground data were collected from a multi-use offshore aquaculture site in Tagalaht Bay, Estonia, hosting adjacent trout, blue mussel, and seaweed cultivation systems. The assessment followed ISO 14040/14044 and applied a cradle-to-farm-gate system boundary. Nutrient emissions from trout farming were quantified using a farm-gate mass-balance approach based on feed inputs, biomass retention, and residual emissions, consistent with established aquaculture nutrient budgeting methods (Cho and Bureau, 1997). Environmental impacts were assessed in SimaPro using the ReCiPe 2016 Midpoint (H) method. Scenario analysis was used to estimate the mussel and seaweed biomass required to offset trout-derived N and P emissions under different IMTA configurations, and coefficients were further scaled to European aquaculture production levels.

Results

Per ton of harvested trout, offshore production emitted 63.7 kg N and 6.9 kg P to the marine environment, while feed production dominated climate change impacts, contributing approximately 2,880 kg CO₂-eq t⁻¹ trout. Scenario analysis indicated that achieving full nutrient neutrality would require 10.37 t of extractive biomass per ton of trout, comprising 6.76 t of mussels and 3.61 t of seaweed. In contrast, the current pilot IMTA configuration offset only about 0.42 % of N and 0.45 % of P emissions. Scaling these requirements to current European trout production suggests that nutrient-neutral production would require extractive biomass volumes far beyond present seaweed production capacity.

Discussion

The results show that IMTA can reduce eutrophication impacts by converting nutrient losses into harvestable biomass, but nutrient-neutral aquaculture is strongly constrained by the scale at which extractive species must be deployed. Under Baltic Sea conditions, current pilot-scale IMTA systems fall far short of delivering ecologically meaningful nutrient compensation (Buck et al., 2018; Sickander and Filgueira, 2022). At the same time, the analysis reveals a structural divergence between nutrient and climate mitigation pathways: while IMTA can reduce farm-level eutrophication, feed production remains the dominant driver of climate and resource-related impacts, consistent with previous aquaculture LCA studies (Henriksson et al., 2012). Overall, the study provides system-level evidence that nutrient-neutral aquaculture will likely require a dual strategy combining ecologically significant extractive biomass deployment with upstream feed optimization.

Introduction

Aquaculture disease surveillance requires continuous and non-invasive tools capable of detecting changes in fish welfare before mortality becomes evident. European seabass (*Dicentrarchus labrax*) is a high-value species in Mediterranean aquaculture, and bacterial outbreaks such as vibriosis can cause both behavioural deterioration and visible body changes. In this study, it is investigated whether monocular underwater video provides early disease-related evidence without requiring fish handling, invasive sampling, or a disease-specific visual model.

A zero-shot approach is adopted, in which potential disease-related anomalies are identified by comparison with the behavioural and visual patterns observed in the remaining healthy fish population. It is hypothesised that disease pressure alters two complementary signal families: how fish move and use the available space, and how individual fish appear in segmented image crops. By combining these complementary signals, this study demonstrates that disease-related changes are detected up to two days before mortality becomes evident.

Materials and Methods

The experimental setup consisted of 154 healthy European seabass monitored in a controlled tank measuring $1.33 \times 1.03 \times 0.58$ m. Two underwater cameras with a resolution of 1280×864 pixels and a frame rate of 30 fps were used. The experimental protocol combined progressive thermal stress, in which the water temperature was increased from 23°C to 30°C, over eight weeks and rapidly returned to 23 °C during week nine. The pathogen was exposed at this final week to induce vibriosis-related stress.

Videos were recorded 24h/day and subsequently trimmed at specific times, including four feeding periods of 8 minutes each, and 1 minute videos in intervals of one hour between feedings. The most relevant footage for this study was the period immediately after feed delivery (at 07:30, 12:00, 15:00, and 16:45).

Fish instances were isolated from the tank background, and masks, bounding boxes, and cropped images were obtained on a frame-by-frame basis using SAM 3 video segmentation (Carion et al., 2025). Two separate methods were then applied, and their outputs combined to generate the final warning signal.

For Method A, instance masks were converted into trajectories by extracting mask centroids and linking detections across consecutive frames. A Hungarian assignment step based on centroid distance and mask overlap was applied (Kuhn, 1955; Bewley et al., 2016). Short, low-confidence, or physically implausible tracklets were discarded before the remaining trajectories were aggregated into descriptors of spatial occupancy, residence time, transition frequency, movement persistence, and swimming activity (Anas et al., 2020).

For Method B, segmented crops were used to compare two alternative physical-evidence representations. The first representation consisted of DINOv3 embeddings (Siméoni et al., 2025) classified using a gradient-boosting model (Friedman, 2001). The second consisted of handcrafted descriptors based on colour, texture, morphology, deformation, and posture-related cues.

Finally, the outputs of both Method A and B were combined to identify relevant indicators, reduce potential false positives, and increase confidence in the final warning signal.

(Continued on next page)

Results

Method A reveals disease-related changes in how fish move through the tank, including alterations in spatial use, movement persistence, residence patterns, and overall swimming activity, especially evident during feeding periods. Healthy fish display vigorous swimming and rapidly approach the surface with fast and explosive movements in search of food. In contrast, diseased fish tend to remain near the bottom, separated from the rest of the shoal, and exhibit slow and subdued swimming.

Method B shows strong internal discrimination between healthy and vibriosis-labelled fish crops. The first approach combines frozen DINOv3 embeddings with a gradient-boosting classifier, achieves an ROC AUC of 0.9454 for crops extracted from videos in which the anomaly is known to be present. As a second approach, an interpretable model based on handcrafted colour and texture features achieves a comparable ROC AUC of 0.9447 under the same internal test conditions. The selected alternative for Method B is the DINOv3 representation, while the handcrafted features were used as an interpretable baseline (Ahmed et al., 2022). The most relevant physical indicators include reduced chromatic variation, altered texture, and deviation from the compact appearance manifold associated with healthy fish.

The aggregation of crop-level predictions at the video level makes the physical signal easier to interpret. For each video, the proportion of fish crops classified as suspicious is calculated for each video. This proportion is consistently lower for the healthy videos. The difference in proportions observed reaches 0.660, indicating a clear separation between the two groups in the current test set. In pre-mortality videos, abnormal visual patterns are detected up to two days before mortality. Overall, the trajectory-based and crop-based methods provide complementary evidence: the former captures changes in fish behaviour and spatial use, while the latter detects changes in physical appearance from the same monocular video recordings.

Discussion

The main contribution of this study is a dual-evidence, zero-shot early-warning framework for detecting disease-related signals in aquaculture. The proposed system combines behavioural anomalies derived from fish trajectories with physical anomalies extracted from segmented fish images.

Trajectory analysis (Method A) captures changes in movement, activity, and use of space (Arechavala López et al., 2025, Yang et al., 2021). This source of evidence is particularly valuable because behavioural deterioration may emerge before severe external signs or mortality become apparent. Crop-level analysis (Method B) complements this information by identifying visible changes in the bodies of individual fish, including alterations in colour, texture, morphology, and posture.

The combination of Method A and Method B increases confidence that an alert reflects genuine biological deterioration. Agreement between the two methods is particularly important because individual image features may be affected by factors such as temperature, camera angle, tank appearance, or illumination, while trajectory estimates may be influenced by occlusions, missed detections, or non-fish artefacts.

In all videos in which an anomaly is indicated by Method A, typically one or two days before mortality, the same anomaly is also successfully detected by Method B, and vice versa. A high level of consistency is therefore observed across all tested videos containing diseased fish. More than two days before mortality, abnormalities may be detected independently by either method, depending on the position and visibility of the diseased fish.

The current performance metrics should be interpreted as preliminary internal evidence. Further validation should include balanced temperature conditions, open-sea cages, variable turbidity and illumination, greater levels of occlusion, and larger fish populations. Future work should also investigate the advantages of using multiple cameras. A multi-camera configuration may improve detection performance and reduce false alarms caused by tracking errors, occlusions, or non-fish artefacts.

Introduction

Fish transport is an essential yet stressful practice in aquaculture. Acute transport-induced stress can compromise both specific and non-specific immunity, disrupt osmoregulation, and increase disease susceptibility, potentially leading to delayed mortality. Monitoring fish welfare physiologically remains challenging, as current methods rely on invasive procedures such as blood sampling, tissue collection, or surgical implantation of biosensors. Moreover, the established indicators are often detected too late for timely intervention. The skin and mucus of teleost fish are central to innate and adaptive immunity and homeostasis. Given the feasibility of minimally invasive or non-invasive sampling, they represent promising matrices for biomarker discovery enabling earlier and less intrusive health monitoring in farmed species.

Materials and methods

To investigate the molecular signatures following acute stress, three key European aquaculture species: Atlantic salmon (*Salmo salar*), European seabass (*Dicentrarchus labrax*), and rainbow trout (*Oncorhynchus mykiss*) were subjected to a transport challenge. The transportation trials were designed to simulate current transport conditions specific to each species. Skin tissue and mucus samples were collected at three time points: before transport, immediately after stress exposure, and following a 24-hour recovery period. Bulk polyA RNA sequencing was conducted on skin samples, while small RNA sequencing and proteomics were performed on skin mucus. Sequencing data were processed using nf-core pipelines for RNA-seq (nf-core/rnaseq) and small RNA-seq (nf-core/smrnaseq), while proteomic data were analysed using the FragPipe pipeline. Differential expression analysis (DEA) was performed using edgeR (transcriptomic) and FragPipeAnalystR (proteomic) R packages. Additionally, unsupervised machine learning based on Multi-Omics Factor Analysis (MOFA+) was performed. The results of DEA and MOFA were compared and similarities highlighted.

Results and Discussion

Differential expression analysis, complemented by MOFA multiomics integration, revealed species-specific stress responses differing in both timing and magnitude. Enrichment analyses and shared element comparisons further highlighted the negative physiological impact of transportation stress across species. The acute transcriptomic response, based on the number of differentially expressed genes immediately following stress, was markedly stronger in Atlantic salmon (3,134 DEGs) and rainbow trout (1,241 DEGs) compared to European seabass (309 DEGs). Conversely, European seabass exhibited a stronger and more rapid skin mucus proteomic response, being the only species with differentially abundant proteins detected at the post-stress timepoint. Cross-species comparison identified a conserved set of 42 genes and 3 miRNAs while no protein was found to be commonly differentially abundant across all three species. To filter out candidate biomarkers, elements consistently identified across at least four subgroups defined by species, pairwise comparisons, and omic layers, were highlighted. The 17 highlighted biomarker candidates are primarily associated with coagulation, extracellular matrix remodelling, wound healing, and immune response which was also reflected in the observed commonly activated pathways, while pathways associated with biosynthesis and metabolism were inhibited. Among the candidates, arginase (ARG2), ferroxidase (F5), and papilin a (PAPLNA) were the most consistently represented across subgroups. Independently, MOFA integration identified factors that separated samples by condition in all three species. While several candidate biomarkers were recovered across species and omic layers, none were consistently top-weighted across all three species in the factors relevant to stress, emphasising the complexity of the stress response and the need for multiple complementary discovery approaches. Future analyses incorporating supervised machine learning and expanded datasets will further refine biomarker prioritisation and improve fish welfare assessment.

Universidade de Santiago de Compostela, Spain
*corresponding/presenting noemi.bujan@usc.es

Introduction

Edwardsiella piscicida is a major bacterial pathogen affecting aquaculture worldwide. Although comparative genomics has revealed substantial diversity within the species, the functional significance of lineage-specific accessory genes remains largely unexplored. As the accessory genome represents a major source of genomic diversity, its characterization may provide valuable insights into the evolutionary processes underlying bacterial adaptation. Here, we investigated the functional repertoires encoded by lineage-specific accessory genes across *E. piscicida* lineages.

Material and Methods

Ten *E. piscicida* isolates representing different geographical origins and fish hosts were subjected to whole-genome sequencing using Illumina technology by EgoGenomics. Raw sequencing reads were quality assessed before de novo genome assembly. The resulting assemblies showed genome completeness ranging from 91% to 97%. Genomes were structurally and functionally annotated prior to comparative pangenome analysis. A core-genome phylogeny was reconstructed from the core gene alignment to define the major evolutionary lineages. Lineage-specific hypothetical proteins identified within the accessory genome were functionally characterized using eggNOG-mapper to infer their putative biological roles.

Figure 1. Core-genome phylogeny of the ten *E. piscicida* isolates included in this study and summary of the predominant lineage-specific accessory functional repertoires inferred from eggNOG annotation. Comparative analysis identified distinct functional repertoires associated with each major phylogenetic lineage, suggesting that diversification of the accessory genome may contribute to adaptive success of *E. piscicida*.

(Continued on next page)

Results and Discussion

The pangenome comprised 4,372 gene clusters, including 2,946 core genes and 1,426 accessory genes. Whereas the core genome was highly conserved, the accessory genome contained numerous lineage-specific proteins, many of which lacked previous functional characterization. The annotation revealed that the major phylogenetic lineages differ in the composition of their accessory genomes with biological processes including horizontal gene transfer, host interaction, defense mechanisms and regulatory functions. Clade I was characterized by proteins associated with mobile genetic elements, Type VI secretion systems and restriction-modification systems, whereas the E98 lineage, KGE7090 lineage and Clade II displayed representative functions related to bacteriophages and defense systems, conjugative elements, and adhesion, replication and metabolism, respectively (Figure 1). These findings suggest that the evolutionary diversification of *E. piscicida* is accompanied by functional specialization of its accessory genome, consistent with the hypothesis that lineage-specific accessory functional repertoires may contribute to the adaptive success of this pathogen in aquaculture environments.

Introduction

Aquaculture is expected to play an important role in addressing global challenges such as climate change, limited resources, and the growing demand for sustainable food and bio-based products. In this context, algae cultivation is becoming increasingly relevant, as it can provide biomass for food, feed, pharmaceuticals, cosmetics, and other applications, while also contributing to circular bioeconomy models.

At the same time, working with algae is not straightforward. Information about species, cultivation conditions, processing technologies, and market applications is scattered across many different sources, including scientific papers, databases, and industry reports. This makes it difficult for stakeholders to get a clear overview and to make informed decisions, for example when selecting suitable species, identifying cultivation locations, or evaluating production strategies.

In the [AlgaeProBANOS](#) project, we address this problem by developing a set of digital tools that bring these different types of information together and support more data-driven decision-making across the algae value chain.

A Digital Ecosystem for the Algae Value Chain

The tools developed in Work Package 4 are designed to work together as a small ecosystem, following a simple pipeline from data collection to analysis and decision support.

At the base, we developed automated data collection and integration tools that gather information from different sources, including open-access scientific publications, Wikipedia, biodiversity databases, marine observation systems, and project-specific datasets. The goal here is not just to collect data, but to clean, structure, and connect it in a way that makes it usable across the other tools.

On top of this data layer, we built the [Algae Knowledge Base](#), which allows users to explore algae-related knowledge through a simple question–answer interface. The system uses a retrieval-based approach, meaning that it looks up relevant scientific sources before generating an answer. This makes the output more reliable and traceable compared to general AI tools, and better suited for domain-specific questions such as cultivation conditions or application areas.

The interactive [Algae Farming and Products dashboard](#) provides a more visual way of exploring the data. Users can browse species, look at their geographic distribution, identify producers, and explore possible product applications. In practice, this makes it much faster to answer questions that would otherwise require searching across multiple databases and sources.

Finally, the [Algae Economist](#) focuses on the economic side. It allows users to define simple production scenarios and get an estimate of costs and key indicators such as LCOP, ROI, and IRR. This helps in getting a first idea of whether a certain production pathway is economically interesting or not.

All tools described here are publicly available and can be accessed online at <https://algaeprobanos.eu/digital-tools/>.

(Continued on next page)

Results and Impact

When used together, these tools support a simple but practical workflow. Users can start by exploring species and regions in the dashboard, then use the Knowledge Base to better understand the biological and technical aspects, and finally use the Economist to check whether a given scenario could make economic sense. This allows stakeholders to:

- identify promising species and locations
- access relevant knowledge more quickly
- connect biological data with industrial applications
- and perform basic economic assessments

Based on initial use within the project, the main benefit is a clear reduction in the time needed to gather and connect information, together with better transparency in how decisions are made.

Conclusions

The tools developed in AlgaeProBANOS show how digitalisation and AI can support more informed and structured decision-making in algae aquaculture. Instead of relying only on fragmented data and experience, stakeholders can use integrated tools that combine data collection, knowledge access, visual exploration, and economic analysis.

This becomes particularly important in the context of global change, where faster and more reliable decisions are needed to develop sustainable and scalable aquaculture solutions.

Chlorella vulgaris is a protein-dense green microalga with functional properties relevant to aquaculture nutrition. This study evaluated the influence of graded dietary inclusion of *C. vulgaris* dried powder on growth performance, feed efficiency, and flesh proximate composition of juvenile sterlet (*Acipenser ruthenus*) under recirculating aquaculture system (RAS) conditions. A 36-day feeding trial was conducted with four dietary groups: Control (standard commercial diet) and three *C. vulgaris* inclusion levels — V1 (1.5%), V2 (3.0%), and V3 (4.5%) — with 100 fish per tank (initial mean weight 1.59 ± 0.52 g). Specific growth rate (SGR) ranged from 7.39 to 7.58%/day in supplemented groups versus 6.71%/day in Control, and feed conversion ratio (FCR) improved with inclusion, with V2 achieving the best value (0.382 vs. 0.483 in Control). Differences in final body weight and length were not statistically significant ($p > 0.05$). Flesh composition differed significantly among groups for all measured parameters: crude protein increased with inclusion level, fat content peaked in V2, and ash content increased progressively with *C. vulgaris* dose. *C. vulgaris* powder at 1.5–4.5% inclusion significantly modified sterlet flesh proximate composition and numerically improved growth performance and feed efficiency, with the 3% inclusion level identified as the most feed-efficient under the conditions of this study.

Introduction

Processed animal proteins, such as poultry by-product meal (PBM), combine high nutritional quality with a low environmental footprint, aligning with circular bioeconomy principles (Galkanda-Arachchige et al., 2020). Meagre (*Argyrosomus regius*), a high-value whitefish species native to the Adriatic Sea, has gained renewed interest in Mediterranean aquaculture due to its quality, rapid growth, and adaptability to farming conditions (Kružić et al., 2016). Beyond growth and economic performance, evaluating how alternative protein sources shape the gut microbial ecosystem is essential, since intestinal bacteria and fungi play key roles in digestion, nutrient absorption, and immune homeostasis, and can serve as sensitive early indicators of dietary impact on fish health. This study presents the first combined assessment of the bacterial (16S rRNA) and fungal (ITS2) intestinal communities of meagre fed increasing dietary inclusion levels of PBM as a fishmeal substitute.

Material and methods

Three experimental diets incorporating PBM as a partial fishmeal replacement at two inclusion levels (T1, T2), plus a fishmeal-based control diet (T3/CF), were formulated to meet the nutritional requirements of meagre. The feeding trial was conducted in an open-circuit, outdoor water system at the Laboratory of Aquaculture, Institute of Oceanography and Fisheries (Split, Croatia). A total of 110 meagre (initial mean body weight: 1220 ± 154 g) were acclimated for four weeks on a commercial diet before being randomly distributed into six concrete tanks (600 L; 18 fish per tank, two replicate tanks per treatment). At the conclusion of the trial after one year, digesta content was sampled from the proximal (PI) and distal (DI) intestine of fish from each dietary group for gut microbial community characterization (12 replicates per treatment for each intestinal segment). Fungal (ITS2) and bacterial (16S rRNA V3-V4 region) community composition were characterized in parallel by amplicon sequencing on the Illumina platform. Sequences were denoised into amplicon sequence variants (ASVs) using DADA2 and taxonomically classified against the SILVA 138.2 (16S) and UNITE (ITS2) reference databases. Alpha and beta diversity were calculated for both datasets, and group differences were tested using ANOSIM and PERMANOVA (Bray-Curtis).

Results and discussion

The fungal (ITS2) community was diverse and highly individually variable, dominated by Malasseziomycetes, Dothideomycetes, Sordariomycetes, Eurotiomycetes and Saccharomycetes. Alpha diversity was consistently higher in the proximal than distal intestine, and the fishmeal control showed the lowest fungal diversity and evenness in both segments, while beta diversity and ANOSIM/PERMANOVA confirmed that dietary effects on the mycobiome were strongest distally, with T2 showing an intermediate community structure between T1 and the control.

The bacterial (16S) community was overwhelmingly dominated by Gammaproteobacteria across nearly all samples and diets, indicating a comparatively stable core bacterial assemblage relative to the fungal community. In contrast to the mycobiome, bacterial alpha diversity was highest, not lowest, in the fishmeal control, particularly in the distal intestine. Beta diversity, ANOSIM and PERMANOVA converged on a single, striking pattern: the distal intestinal bacterial community of the control group was markedly and significantly distinct from all other diet-by-segment combinations, whereas proximal communities and both PBM-fed groups (T1, T2) remained largely indistinguishable from one another regardless of gut segment.

(Continued on next page)

Taken together, both microbial kingdoms indicate that PBM inclusion reshapes the meagre intestinal microbial ecosystem primarily in the distal intestine, but with contrasting directionality: PBM diets increased fungal diversity and evenness relative to the control, while the bacterial community of PBM-fed fish appeared more homogeneous than the compositionally distinct, more diverse distal bacterial community observed under the fishmeal-based diet. These complementary bacterial and fungal signatures underscore the value of a dual-kingdom amplicon approach for capturing diet-driven shifts in fish gut microbial ecology, and support poultry by-product meal as a viable, sustainable fishmeal alternative without inducing a uniformly destabilizing effect on the meagre gut microbiota.

Introduction

Marine aquaculture is increasingly challenged by rising water temperatures, particularly in the Mediterranean, where temperatures close to 30 °C may induce chronic thermal stress in European sea bass (*Dicentrarchus labrax*). Temperature-dependent growth responses in fish have been widely described (Fonds et al., 1992). In parallel, functional ingredients such as inulin may contribute to intestinal homeostasis, microbiota stability and innate immune modulation under intensive farming and heat stress conditions (Srirengaraj et al., 2023; Zhou et al., 2022). The present study evaluated the effects of three diets differing in protein and lipid levels, dietary energy content, and inulin inclusion on growth performance, immunology, histopathology, welfare, and fillet proximal composition of *D. labrax* reared under chronic thermal stress.

Materials and Methods

A 12-week nutritional trial was conducted in a recirculating aquaculture system using 450 *D. labrax* specimens with an initial body weight of 113.24 ± 15.82 g. Fish were randomly distributed into 9 tanks (50 fish tank⁻¹) in triplicate groups. Water temperature was progressively increased from 22 to 30 °C during the first week and then maintained at 30.0 ± 1.0 °C. Three diets were tested: i) diet CD, commercial diet (46.5 % protein, 20 % lipid); ii) diet HE, high-energy diet (44 % protein, 24 % lipid); and iii) diet FD, functional diet (46.5 % protein, 18 % lipid) supplemented with 0.5 % inulin. Productive performance was assessed through final body weight, specific growth rate, feed intake, feed conversion ratio and survival. Immunological analyses included reactive oxygen species in plasma, lysozyme activity in plasma and mucus, protease/anti-protease activity and total proteins in mucus, and phagocytic activity in anterior kidney. Histopathology was evaluated in liver and intestine. Welfare assessment included plasma glucose, triglycerides, cholesterol and cortisol, together with hepatic triglycerides, cholesterol, superoxide dismutase, catalase, glutathione peroxidase and malondialdehyde. Final fillet proximal composition was also determined.

Results

Initial body weight was similar among treatments. At the end of the trial, fish fed diet FD showed the highest final body weight (209.23 ± 6.23 g fish⁻¹) and specific growth rate (0.75 ± 0.04 % day⁻¹), significantly higher than fish fed diet HE (191.84 ± 1.93 g fish⁻¹; 0.64 ± 0.01 % day⁻¹; $P < 0.05$), while diet CD presented intermediate values (204.07 ± 6.46 g fish⁻¹; 0.72 ± 0.04 % day⁻¹). Feed conversion ratio did not differ among treatments (1.82–1.83), and survival was 100 % in all groups. Most immune indicators followed similar trends among diets and did not show significant differences at the final sampling, except for phagocytic activity, which was higher in fish fed diet HE. Welfare assessment revealed significantly higher plasma glucose and triglyceride levels in fish fed diet HE, whereas fish receiving diets FD and CD displayed a more favourable metabolic profile under prolonged exposure to 30 °C. Histopathological evaluation revealed normal lipid vacuolization in liver and preserved intestinal integrity, with no relevant lesions associated with any diet. Final fillet proximal composition was not significantly affected by dietary treatment.

Discussion

The results indicate that increasing dietary lipid to 24 % was not advantageous under chronic heat stress, as the high-energy diet was associated with poorer growth performance and a less favourable metabolic response. In contrast, the functional diet supplemented with inulin provided the best overall response, combining the highest growth with lower plasma glucose and triglycerides levels and maintaining histological safety and final fillet quality. The tendency towards greater antioxidant enzyme activation in fish fed diet HE also suggests higher oxidative pressure in this group. Overall, moderate lipid levels combined with functional ingredients, such as inulin, appear to improve physiological adaptation of *D. labrax* specimens to prolonged exposure to high water temperature.

Introduction

Integrating aquaponics into recirculating aquaculture systems (RAS) leverages the interactions among fish, plants, and the microbiome, supporting optimized growth and a sustainable production model (Joyce et al., 2019). Within the AWARE project, the use of treated wastewater in aquaponic systems has been shown to produce safe food in accordance with European regulations (Cabo et al., 2025). Although microbial communities are recognized as key ecosystem stabilizers, their role within aquaponics systems remain insufficiently understood (Kushwaha et al., 2025). The aim of this study is to compare the temporal evolution of bacterial surface communities at three locations within RAS units operated with treated wastewater and with dechlorinated water. Through a metataxonomic approach, the study pretend to generate insights into the composition, diversity, and potential functional roles of these communities within the aquaponic system.

Methodology

Experimental system: Experiment was conducted in a small-scale, Recirculatory Aquaculture System (RAS) installed in Castellana Grotte coupled with a municipal wastewater plant. The experimental system comprised three different RAS modules, RAS1, 2 and 3. RAS1 operated using dechlorinated tap water (CONTROL), while RAS2 and RAS3 were supplied with reclaimed water. RAS were stocked with Nile tilapia (*Oreochromis niloticus*) and a 5 m² of crop planting surface with capacity for 90 lettuce plants (*Lactuca sativa* Batavian Red).

Surface sampling: was conducted at the beginning of the experiment and subsequently after two months period in accordance with the procedures outlined in ISO 18593 for the assessment of both wet and dry surfaces on the vegetable growing tables (GTs), tanks (TKs) and sumps (Ss).

Microbiome characterization: bacteriome was characterised using next-generation sequencing (NGS) techniques. Following DNA extraction (PureLink™ Microbiome DNA Purification Kit, Invitrogen) and purification (OneStep™ PCR Inhibitor Removal Kit, Zymo Research), amplification and library preparation were performed using the 16S Barcoding Kit 24 V14, from Oxford Nanopore Technologies (ONT), following the standard protocol. Finally, 16S rRNA amplicon sequencing was carried out using the ONT's MinION platform, which enables real-time, long-read sequencing. The sequences generated were analyzed in the cloud served EPI2ME, from ONT, with the 16s workflow. Sequences below 800 bp and longer than 2000 bp were discarded. Finally, filtered reads were classified with minimap2 using SILVA as reference database.

Results and Discussion

The evolution of the bacterial communities in the growing tables (GTs), sump (S) and tanks (TKs) of RAS1, RAS2 and RAS3 was characterized through metataxonomic analyses. The composition of the bacterial communities was analyzed though a non-metric multidimensional scaling (NMDS) analysis based on Bray-Curtis dissimilarity distance and subsequent clusterization.

Overall, the analysis of the microbiota present on RAS surfaces clearly revealed locationdependent differences in the temporal evolution of bacterial communities throughout the experiment. At the beginning of the trial (t0), the bacterial composition detected in the GTs clustered with that found on the Ss, both characterized by a high relative abundance of *Rhizobiales Incertae Sedis*, *Rhodobacteraceae*, *Reyranellaceae*, *Hyphomicrobiaceae*, *Chitinophagaceae*, *Legionellaceae*, and *Burkholderiaceae*. Notably, members of the order *Rhizobiales* are known to participate in nutrient cycling in aquatic systems (Jia et al., 2019).

(Continued on next page)

By the end of the experiment (t2), however, the bacterial communities in the GTs were dominated by members of the family *Aeromonadaceae* across all three RAS units, together with *Enterobacteriaceae*, which reached its highest relative abundance in the GT of RAS1 (GT1). Importantly, the absence of *Aeromonas hydrophila* in the food produced within the RAS ensured product safety.

In the case of the Tks, the initial surface-associated communities formed a distinct cluster. Nevertheless, after two months (t2), the microbial communities in the RAS units operating with reclaimed water (RAS2 and RAS3) became similar to those of the Ss, showing a predominant relative abundance of *Exiguobacteriaceae*. The order *Rhizobiales* remained detectable, particularly in the Tk and S of RAS2. This pattern suggests that microbial composition at these locations is likely shaped by the extreme environmental conditions typical of the Castellana region during summer, as members of *Exiguobacterium* are known to withstand stressors such as high temperature, salinity, and heavy metal exposure.

By the end of the trial, the microbiota on Ss and Tks in systems using reclaimed water converged, being dominated by *Exiguobacteriaceae*. In contrast, the plant GTs of all three RAS units exhibited a distinct microbial trajectory, with *Aeromonas* becoming dominant (up to 91% relative abundance). This indicates that, while reclaimed water strongly influences the bacterial communities of Ss and Tks, it has a more limited impact on those of the GTs.

Conclusion: Bacteriome evolution on Ss and Tks surfaces is influenced by the use of reclaimed water, whereas its impact on GT surfaces appears to be more limited. Differences in microbial dynamics across RAS locations may arise from systemspecific factors such as water circulation configuration, as well as the influence of biofilter, plant, and fish microbiota. Finally, considering the spatial context of each surface within the RAS, it can be inferred that submerged S and Tk surfaces more closely reflect the systemwide microbiome, whereas the exposed GT surfaces likely mirror the microbiota associated with lettuce roots.

Background

Aquaculture is increasingly driven by the need to better understand fish behaviour as a fundamental feature of health, welfare, and production performance. In cultured systems, behavioural responses emerge from the dynamic interplay between physiological state, environment and social interactions, giving rise to complex collective patterns that remain poorly resolved by conventional monitoring strategies. Current approaches to behavioural monitoring in aquaculture rely largely on population-level observations or aggregate indicators such as bulk activity, spatial distribution or group movement metrics. These methods are suitable for detecting general trends, but they provide limited insight into individual variability and may fail to resolve subtle or heterogeneous behavioural responses. This limitation is particularly relevant in experimental and pilot-scale contexts, where understanding individual responses is essential for assessing the effects of genetics, nutrition, environmental conditions or management strategies. Individual-level behaviour monitoring addresses these limitations by enabling the direct acquisition of behavioural and physiological signals from single fish. By operating at the individual scale, such approaches allow variability, heterogeneity and response dynamics to be captured, rather than averaged out at the population level. This is especially relevant in aquaculture research, where experimental questions often target differential responses to controlled changes in genetics, feeds, environmental conditions or husbandry practices. The availability of miniaturised sensing technologies has facilitated the practical implementation of individual behaviour monitoring in experimental and pilot-scale aquaculture research.

Sensor-based individual behaviour monitoring

One way to address these monitoring needs at the individual level is through sensor-based approaches. FishBIT is a miniaturized individual monitoring device designed for behavioural and welfare assessment in aquaculture research. The device is externally attached to the operculum using a minimally invasive fixation system, allowing stable placement without impairing respiration, feeding, or normal swimming behaviour. Its small size (15 x 6 x 6 mm) and low weight (below 1.8 g in air) allow fish to rapidly recover normal activity, making the device suitable for behavioural studies under experimental and controlled conditions. FishBIT integrates a triaxial accelerometer that captures opercular and body movements with high temporal resolution, enabling simultaneous recording of physical activity and respiratory responses. Opercular movements provide a reliable indicator of respiratory frequency, while body-related acceleration signals reflect locomotor activity. Both signals are acquired continuously at the individual level, without reliance on visual observation. It has been successfully applied in major European aquaculture species, including gilthead sea bream, European sea bass, rainbow trout and Atlantic salmon. Previous studies have demonstrated the robustness of the device for monitoring behavioural responses to nutritional, environmental, and physiological challenges (Calduch-Giner et al., 2022). The updated version of FishBIT (Figure 1) incorporates advances in sensor design and system integration aimed at improving usability and performance.

Battery capacity has been increased (3 V, 30 mAh), enabling extended recording periods of up to 200 hours. The hardware configuration also includes additional inertial sensing components, such as a gyroscope, expanding the range of motion-related signals available at the individual level. Connectivity has been enhanced through the integration of Near Field Communication (NFC), allowing wireless device programming and data retrieval without physical connectors. In parallel, the use of a new ultra-low-power microcontroller and updates to the internal electronics architecture have increased computational capacity and data handling efficiency, supporting more flexible signal acquisition and on-board data management.

(Continued on next page)

Future Perspectives and Development

FishBIT has been established as a reliable individual monitoring tool for assessing activity, respiratory responses and behavioural changes in aquaculture, supporting applications in welfare assessment and experimental research. Building on these capabilities, the advances presented here enhance device autonomy, connectivity and computational capacity, and extend its applicability in experimental and pilot-scale aquaculture studies. The incorporation of enhanced on-board processing capacity facilitates a more effective use of the inertial sensing hardware of the device. In this context, current research is exploring the use of gyroscopic information to support the inference of individual movement trajectories. Such trajectory-based descriptors could provide additional insight into spatial behaviour and relative positioning of fish within a group, opening new possibilities for the study of collective organisation under controlled conditions. In parallel, ongoing developments in data analysis software aim to facilitate the interpretation of complex behavioural datasets. Machine-learning-based approaches are being investigated as tools to assist in pattern recognition, data integration and decision support, facilitating the scalable use of individual behaviour monitoring in aquaculture research and precision management scenarios.

³WMR - Wageningen Marine Research, P.O. Box 77, 4400 AB Yerseke, The Netherlands

In the Netherlands, mussel farming has traditionally been concentrated in sheltered waters such as bottom plots in the Wadden Sea and the Eastern Scheldt. However, these areas are facing spatial pressures that limit further expansion. As part of the Dutch Mussel Covenant, efforts are initiated to explore the potential for alternative farming locations outside these conventional areas, including coastal areas such as the Voordelta and offshore wind farms.

These new locations offer promising opportunities to reduce pressure on the space and to enhance mussel production. On the other hand, they also present significant challenges related to environmental dynamics, technical feasibility, regulatory complexity, and financial viability. This pilot study aimed to explore the feasibility of offshore mussel farming under highly dynamic conditions.

A pilot study was conducted from 2022 to 2024, approximately 2 km offshore in the North Sea. see Figure 1. This pilot study aimed to evaluate the technical and ecological feasibility of offshore mussel farming using two different types of suspended mussel rope systems: 1) a floating double longline and 2) a submerged longline. Both systems were equipped with various rope types and sock materials to test grow-out success and mussel seed collecting during reproduction season. During the pilot phase, the system was stocked with different sizes and offspring mussels.

Figure 1 Pilot location in the Voordelta, the Netherlands

Given the highly dynamic water conditions at the pilot site, a broad range of parameters were monitored throughout the pilot period.

Both systems were equipped with accelerometers and load cells to track the movement of the ropes and the entire system. At the site, flow velocity profiles and wave height were measured at intervals.

Chlorophyll-a concentrations were continuously measured using sensors, both near the pilot location and at a reference site approximately 2 km away.

(Continued on next page)

Mussel growth was also monitored using a standardized method for tracking growth over time.

During the pilot period, we encountered several challenges and gained valuable insights:

Securing necessary permits was a major bottleneck.

Robust technical performance of the system, although over-dimensioned relative to actual forces.

Local seed outperformed translocated seed; growth and survival depended on depth and exposure to movement.

Operational constraints at sea limited timely management, which adversely influenced the results.

This presentation will highlight the “lessons learned” and implications for mussel farming under high dynamic conditions.

IS CO-FARMING OF AQUATIC SPECIES MORE SUSTAINABLE THAN MONOCULTURE?

Introduction

Integrated Multitrophic Aquaculture (IMTA) has been assumed to be more sustainable than monoculture of aquatic species, but wider adoption by the industry has not yet taken off. The BLUEBOOST project investigates the extent to which adding species to monoculture systems is technically feasible, scalable and economically and environmentally more sustainable in six case studies. Here we present preliminary results of three of these case studies. The first case (Poland) is a freshwater IMTA system combining commercial carp pond farming (*Cyprinus carpio*) with crayfish (*Pontastacus leptodactylus*) and watercress (*Nasturtium officinale*) cultivation. The second case (Italy) is commercial offshore mariculture (*Sparus aurata*, *Dicentrarchus labrax*, and *Argyrosomus regius*) with the integration of flat oyster (*Ostrea edulis*) lantern farming. The third case (Brazil) is a RAS-IMTA system integrating biofloc shrimp monoculture (*Penaeus vannamei*) with oysters (*Crassostrea gazar*), sea cucumbers (*Holothuria grisea*), mullets (*Mugil liza*), and *Salicornia nei*.

Methods

Data on production and use of energy and materials, generation of waste and emissions was collected from the three case studies through site visits, and through online meetings and communication before and after the visits. Life Cycle Assessment methodology was used following a pre-defined scheme (Ziegler et al. 2024), e.g. using the functional unit 1 tonne of (mixed) biomass with an economic value and applying mass-based allocation between co-products where needed. Nutrient retention potential was assessed by quantifying the fraction of N and P retained in biomass harvested from the system relative to those released by fed species and carbon deposited and released. Basic discounted cash flow analysis was used to assess the private profitability of the proposed IMTA systems compared to the established monoculture equivalents.

Results and discussion

Important drivers of Polish carp farming were the amount of feed used per tonne of fish, which was more important than feed composition. In some years, fish were fed only grains, in others, a combination of grains and compound feed. The incremental IMTA investment is financially worthwhile due to the additional income from crayfish and watercress that can be achieved with moderate additional inputs in the form of infrastructure (crayfish cages) and labour. Still, emissions were not affected due to the small volume of additional species (a few kilos) in relation to the volume of carp harvested (25 tonnes). Also in farming of marine finfish (European seabass, gilthead seabream, and meagre) off Sardinia, environmental impacts are driven by feed use. In the IMTA setup, with the addition of European flat oyster farming, emissions remain almost unchanged, again due to the low volume of oysters farmed (96 kg liveweight oysters vs 376 tonnes of finfish). The IMTA investment is profitable, since oysters can be farmed without the use of extra feed and using relatively low-cost gear and the species added has a high economic and cultural value for which consumers may be willing to pay a premium compared to established non-native oyster species (*Magallana gigas*, Pacific cupped oyster). In the Brazilian case, emissions from shrimp monoculture were mainly driven by energy use of the recirculating system which was only moderately lowered by the addition of mullet, oysters, sea cucumbers and edible salt marsh plants (*Salicornia* sp.), again due to the low volumes of these species farmed. Although they did not require any additional feed or energy inputs, only some farming infrastructure, containers for keeping them and tubing to pump the water, the extra outputs were too small to affect the environmental assessment of the system. Whether the sales of outputs from an up-scaled IMTA operation are enough to justify the IMTA investment is still subject to inquiry.

(Continued on next page)

Conclusions

Preliminary results from the case studies confirm findings from the literature about IMTA, that the environmental benefits are small and that the main improvement potential is financial. For IMTA to deliver larger environmental benefits, the systems need to be scaled up so that volumes of co-farmed species match. As a next step of BLUEBOOST, theoretically scaled up production will be modelled, both from an environmental and economic perspective, and three more case studies will follow- in Spain, Portugal and Brazil.

Introduction

Integrated Multi-Trophic Aquaculture (IMTA) is a key strategy for enhancing resource-use efficiency and mitigating the environmental impacts of intensive monoculture by promoting nutrient (N, P, C) recirculation. The BLUEBOOST project evaluates the technical feasibility, scalability, and sustainability of integrating low-trophic species (LTS) into fed aquaculture systems across six distinct case studies. However, accurately quantifying the “retention potential” of LTS remains a methodological challenge. Existing models often rely on generalized literature-derived averages, failing to account for local and seasonal variability in farm management and species biochemical composition. This frequently leads to imprecise estimates when applied to operational, real-world systems. To address these limitations, this study presents preliminary nutrient retention results from two [BLUEBOOST project](#) case studies: a freshwater pond system (F-IMTA) in Poland (common carp, crayfish, and watercress) and a marine cage system (M-IMTA) in Italy (seabream, seabass, meagre, and flat oyster).

Methods

This study employs a stoichiometry-driven approach to quantify and retention in harvested LTS biomass (Nederlof et al., 2022), integrating laboratory diagnostics with mass-balance modeling over 7-month (F-IMTA) and 24-month (M-IMTA) cycles. and were determined via CHNS analysis, while was quantified via ICP-MS. In the freshwater IMTA daily biomass dynamics were reconstructed for crayfish and watercress. In marine oysters' daily growth was modeled via Gompertz curve fitted to weight-at-age data samplings. Fed fish species growth and metabolic outputs were simulated using TGC models and deterministic mass-balance equations (Cho & Kaushik, 1990; Wang et al., 2012). The bioremediation potential was defined as the ratio of nutrients removed by extractive components to those emitted by fed species (Checa et al., 2024).

Results

Mass balance of C, N and P values for both F- and M-IMTA inputs (feed, stocked spat/juveniles, etc.) and outputs (harvested biomasses, released emissions, etc.) were reported in table 1. Results refer to a complete production cycle: May-November 2025 for F-IMTA and May 2024-June 2026 for M-IMTA.

Discussion

Based on site-specific laboratory data across seasonal growth stages, this study provides a high-resolution, empirical snapshot of two BLUEBOOST project case studies, establishing a functional baseline for real-world IMTA bioremediation potential. Although open-system interactions, such as natural food inputs and ambient nutrient uptake, cannot be fully decoupled, these findings reflect the actual operational efficiency of the system. Ultimately, these results provide the empirical foundation required to develop commercial-scale upscaling scenarios and optimize nutrient recovery across temperate freshwater and marine multitrophic aquaculture systems.

Introduction

Mediterranean aquaculture, composed of family-owned enterprises farming gilthead seabream (*Sparus aurata*) and European seabass (*Dicentrarchus labrax*), largely relies on periodic manual sampling for biomass estimation. This labor-intensive process involves crowding, anesthesia, and handling, which induces stress, scale loss, increased cortisol levels and potential impaired growth. While non-invasive AI-based machine vision is established in salmon farming, its application in the Mediterranean remains experimental and at a pilot scale. Non-invasive AI-based methods for biomass estimation are based on the use of underwater stereo-cameras that provide biomass data essential for optimizing feeding regimes, while eliminating fish handling (Anwary et al., 2023). This study models the potential environmental and economic implications of implementing high-rate image acquisition and low-error Artificial Intelligence Weight Estimation (AiWE). The system can optimize feeding protocols and reduce nutrient discharge. The goal was to investigate the extent to which AiWE reduces environmental impacts and operational costs through optimized management, while indirectly supporting animal welfare in sea-cage farming via non-intrusive monitoring and reduced acute stress.

Materials and Methods

A Life Cycle Assessment (LCA) was conducted (ISO 14040/14044) using SimaPro 10.2.0.2 and the ReCiPe 2016 Midpoint (H) and Cumulative Energy Demand v. 1.12 methods. The functional unit was 1 kg of harvested fish (seabream/seabass). Primary data (2024) were collected from a medium-scale and a small-scale Italian farm. The system boundaries (gate-to-gate) focused on activities affected by the technology shift: feed input, manual sampling days, fuel consumption, handling-related mortality, and service boat use. Three scenarios were modeled assuming feed loss reductions of 3% (S1), 5% (S2), and 10% (S3) due to improved feeding precision (i.e., reduced overfeeding), according to Chamberlain and Stucchi (2007) and Piedecausa et al. (2009). Nutrient emissions (%N, %P, and %C) were modelled accordingly. Key parameters like cage infrastructure and baseline emissions were kept constant to ensure comparability. Feed and fuel prices and labor rates were sourced from peer-reviewed literature and sectoral reports to ensure model scalability across Mediterranean aquaculture.

Table 1. LCIA baseline (per kg/fish) and scenario reductions (%). Data limited to feed and monitoring inputs; not representative of overall production impacts. BS: baseline, S1: Scenario 1, S2: Scenario 2, S3: Scenario 3. Only the impact categories of climate change (CC) and marine eutrophication (ME) are shown as an example.

	Medium-scale Farm								Small-scale Farm							
	Seabream				Seabass				Seabream				Seabass			
	BS	S1	S2	S3	BS	S1	S2	S3	BS	S1	S2	S3	BS	S1	S2	S3
CC (kg CO ₂ -Eq)	1.7	-	-	-	2.2	-	-9%	-	2.5	-	-	-	622	-	-	-
	7	4%	6%	11%	1	6%		13%	0	4%	5%	10%	7	3%	5%	10%
ME (kg N-Eq)	0.0	-	-	-	0.0	-	-	-	3.2	-	-	-		-	-	-
	4	5%	7%	13%	5	8%	10%	16%	1	3%	6%	11%	259	4%	6%	11%

(Continued on next page)

Results

Seabream production exhibited lower baseline environmental impacts than seabass across all categories (Table 1). Implementation of AiWE led to consistent impact reductions, peaking in S3 (10–15% for seabream, 10–17% for seabass). These improvements were primarily driven by reduced feed losses and avoided handling-related mortality. Under an economic perspective, AiWE would save significant labor time (27 days/year in large-scale; 15 days/year in small-scale), allowing staff to focus on higher-value tasks such as maintenance and health monitoring. At a feed price of 1.75 €/kg, AiWE scenarios yielded significant seasonal savings: for the medium-scale farm, reductions reached €241,500 (3%, for S1), €390,250 (6%, for S2), and €736,750 (11%, for S3). Small-scale savings totaled €51,647 (4%, for S1), €64,975 (5%, for S2), and €128,507 (10%, for S3).

Discussion and conclusion

This study provides the first quantitative evidence of the environmental and economic implications of implementing AI-based growth monitoring. By optimizing the Feed Conversion Ratio (FCR) through real-time weight estimation, AiWE could reduce uneaten feed waste and nutrient discharge. The transition from invasive manual sampling to non-intrusive AI monitoring enhances operational efficiency by eliminating handling-related mortality and reclaiming significant labor time. By reducing sampling labor, AiWE allows redirecting staff toward critical maintenance and inspection tasks, increasing operational efficiency. These results demonstrate that reducing physical fish handling is not only key for improving animal welfare, but also a key driver for both economic and environmental performance. AI-driven approaches should be promoted as a best practice to improve the resilience and sustainability of the Mediterranean aquaculture industry.

Introduction

Ocean warming is a major driver of change in marine ecosystems, particularly in the Mediterranean Sea, where temperature increases exceed global averages. These changes are associated with more frequent marine heatwaves and can significantly alter host–pathogen interactions (Okon et al., 2024). Betanodaviruses (NNV) represent a key threat to both wild and farmed fish species. Their replication is temperature-dependent, with higher temperatures enhancing viral proliferation and disease severity. Climate change is therefore expected to increase the frequency and intensity of outbreaks mainly caused by the RGNNV genotype and the reassortant strain RGNNV/SJNNV. Recent mortality events in dusky grouper (*Epinephelus marginatus*) provide a valuable case study to investigate environmental indicators such as SST anomalies and cumulative heat stress, with implications for aquaculture monitoring and forecasting.

Materials and Methods

Mortality events were recorded in Portofino (Italy) and Larvotto (Monaco) Marine Protected Areas (MPAs) during 2018–2019. Virological analyses confirmed RGNNV infection. Environmental analysis was based on daily sea surface temperature (SST) data obtained from the CMEMS Mediterranean Sea Physics Reanalysis (2000–2020). SST values were spatially averaged over each MPA using all available grid cells. Two temporal windows were considered: October, corresponding to the mortality period, and the July–August–September–October (JASO) period, representing the warm season preceding outbreaks. A climatological baseline (2000–2018) was defined. For each day, climatological SST values were calculated as the mean across baseline years. Daily anomalies were obtained by subtracting climatological values from observed SST. Annual mean anomalies were calculated for both October and JASO and ranked using empirical cumulative distribution functions (ECDF) to assess their extremeness. To quantify thermal stress, a cumulative heat stress index (CHI) was calculated using the 90th percentile of climatological SST as a dynamic threshold. The index integrates both intensity and duration of threshold exceedance (°C·days), providing a robust measure of prolonged heat exposure.

Results

All analysed fish tested positive for RGNNV, with high genetic similarity among strains, suggesting regional viral connectivity. SST anomaly analysis showed heterogeneous results for October, with values close to climatological means. In contrast, the JASO period exhibited consistently elevated anomalies across sites and years. At Portofino, JASO 2019 showed an anomaly of approximately +0.9 °C (90th percentile). At Larvotto, JASO 2019 reached +1.1 °C (95th percentile), while 2018 recorded the most extreme anomaly (+1.53 °C, 100th percentile), representing the warmest season on record. The cumulative heat stress index revealed that 2018 experienced the highest thermal stress values at both sites (Larvotto: 37.3; Portofino: 36.2), corresponding to extreme percentile ranks. In 2019, CHI values remained elevated, although lower, indicating persistent but less extreme thermal stress conditions.

(Continued on next page)

Figure 1. Cumulative heat index distribution based on the climatology in each site. The gray bar represents the range between the 10th and 90th percentiles for each site and year. Black dots and red triangles represent the median and target year’s value, respectively.

Discussion

Our results demonstrate that prolonged and cumulative warming, rather than short-term temperature increases, characterized the periods preceding mortality events. Thus, prolonged thermal stress appears to be a key factor in triggering NNV outbreaks. SST anomalies and CHI are effective environmental indicators for monitoring and forecasting disease risk. The high similarity between viral strains in wild and farmed fish suggests a shared epidemiological network, with potential bidirectional transmission. Climate change is expected to exacerbate these risks, increasing frequency of outbreak and duration. Integrating environmental indicators into aquaculture monitoring systems could improve risk assessment and management strategies.

Conclusions

Thermal anomalies and cumulative heat stress are key drivers of betanodavirus outbreaks. Integrated environmental monitoring systems are essential to support sustainable aquaculture under climate change.

Introduction

Global warming is rapidly reshaping marine ecosystems by increasing the frequency and intensity of thermal anomalies, thereby posing a major challenge to both wild and farmed fish in the Mediterranean basin, a recognised climate-change hotspot where warming rates exceed the global average (Atalah et al., 2024). Because temperature is a key driver of growth, metabolism, welfare, and disease resistance, Mediterranean aquaculture species such as gilthead sea bream (*Sparus aurata*) are particularly vulnerable to both seasonal variability and extreme thermal events. However, despite its importance, thermal tolerance remains a complex and multifactorial trait whose molecular basis is still poorly understood in most farmed fish (McCaw et al., 2020), especially with regard to the interplay between transcriptional and epigenetic regulation. In this context, integrative omics approaches have proven valuable for identifying robust welfare-related markers in gilthead sea bream (Belenguer et al., 2024), but their potential to elucidate the molecular mechanisms underlying seasonal thermal acclimation remains largely unexplored. To bridge this gap, we investigated a gilthead sea bream population that endured record marine heatwaves during the summer of 2022 while maintaining normal growth and production performance. Building on this, we integrated long-read epigenomic profiling with short-read transcriptomics across contrasting seasonal temperatures in metabolically active tissues. This approach enabled the identification of key molecular markers and regulatory mechanisms underlying thermal acclimation, which were subsequently validated in independent populations with the same genetic background under different warming and cooling scenarios.

Materials and methods

Gilthead sea bream from three production batches (2021, 2023, 2024) originating from the same Mediterranean hatchery (Avramar, Burriana, Spain) were reared from early life stages (~5 g) at the IATS experimental facilities. The first batch was assigned to the SEASON experiment, in which fish were maintained in 3000 L tanks from May 2022 to February 2023, with tissue sampling conducted in summer (July 2022; 28 °C; ~70 g) and winter (February 2023; 12.4 °C; ~340 g). Total DNA and RNA from white skeletal muscle (WSM) and liver were extracted and sequenced using Oxford Nanopore Technologies (PromethION 24) and Illumina NovaSeq 6000 platforms, respectively. DNA reads were basecalled with a modification-aware model, 5mC methylation (CG context) was identified using Modkit, and differentially methylated sites (DM5mC) were detected with MethylKit. RNA reads were mapped to the CSIC reference genome, and differentially expressed transcripts (DETs) were identified (FDR < 0.05). Integration of DETs with differentially methylated genes, combined with negative correlation analyses, regulatory-region filtering, and gene enrichment, enabled the identification of key molecular markers in both tissues. Additional filtering in WSM resulted in 23 candidate thermal-responsive genes (cTRGs), which were functionally validated as thermal responsive genes in separate trials, using fish from the 2023 and 2024 batches. In the WARMING-WINTER trial (February 2025), fish of ~360 g body weight were acclimated at 14 °C and then gradually exposed to 20 °C and 26 °C (~3 °C/day), with and intermediate sampling point. In the WARMING-SUMMER trial (June 2025), juvenile fish (~18 g) were exposed to either progressive warming (20–26 °C) or constant temperature (20 °C), followed by a common increase to 30 °C. In the COOLING-SUMMER trial (September 2025), fish (~184 g) acclimated at 28 °C were subjected to rapid cooling (~3 °C/day) to 22 °C and 16 °C, with sampling at each temperature step. Oxygen saturation remained above 75% in all trials.

Results and Discussion

Long-read ONT sequencing generated 825 Gb of data (avg. 29x genome coverage), detecting methylation at 78% of CG sites, with a prominent fraction found in gene bodies and promoter regions, confirming the suitability of the platform. Parallel RNA-seq identified 33,807 active transcripts. Seasonal comparisons revealed 6,356 DETs and 195k DM5mC in liver and 7,651 DETs and 302k DM5mC in the WSM. Omics integration and robust filtering highlighted 148 differentially expressed and methylated genes (DEMGs), as a reason of 51 in Liver and 101 in WSM (Fig. 1). Indeed, muscular responses

(Continued on next page)

Fig. 1. Graphical abstract of the main results in this study.

were higher at all layers and a diverse spectrum of functions, such as response to light, oxygen, and metabolic cues, were found as enriched. The 36 WSM cTRGs (23 from multi-omics and 13 extra genes) were further validated in the thermal-only trials. Of note, 31 out of 33 responded at least in one of the trials, becoming TRGs. PERMANOVA and PLSDA approaches showed a major temporal dynamic where the CTRL/initial sampling times were, regardless the trial, separated the most from the final points where temperature is maximum/minimum or has persisted. Once responsiveness and temporal dynamics were accredited for TRGs, our work further disclosed the major opposite expression change between WARMING and COOLING trials, mainly driven by up to 12 TRGs (*cs, ghr1, ghr2, grp170, igf1r, pcna, slc27a4, sod2, spread2, stk11, usp4, usp7*). These genes, involved in energetic, oxidative stress, cell proliferation and protein turnover cues, form an integrated molecular network that adjusts muscle physiology to thermal challenges. Altogether, this work opens novel perspectives to inform the effects of marine heatwaves in Mediterranean species and provides a mechanistic framework for understanding thermal resilience, supporting the development of genomic tools for climate-resilient aquaculture.

Introduction

Mugil cephalus is a cosmopolitan species valued for its cured roes (*bottarga*). Its high market value drives the development of aquaculture practices, with the establishment of all-female populations being a key objective.

M. cephalus is gonochoristic species, lacking sexual dimorphism. Dor et al. (2016) identified a sex-determining locus suggesting an XY sex-determination system. Ferraresso et al. (2021) linked this to variants in the follicle-stimulating hormone receptor (*fshr*) gene, with females being homozygous (wt/wt) and males heterozygous (wt/m1 or wt/m2). However, homozygous (wt/wt) males occur in wild populations. Selecting such genotypes for breeding was proposed as strategy to produce female F1 progeny. Andree et al. (2024) validated a rapid, non-lethal, PCR-RFLP assay for genotyping, enabling early sex identification and broodstock selection. Authors used these tools to genotype male individuals in a captive F1 population showing skewed sex ratios (91.4% female), confirming that all tested males in that population were also homozygous wt/wt.

This study aimed to confirm if 1) wt/wt males can produce viable offspring and 2) the resulting progeny expresses the wt/wt genotype associated with a predominantly female phenotype.

Methods

In August 2025, a wild-caught wt/wt male identified by PCR-RFLP and confirmed by sequencing was selected based on sperm fluency and mated with a female (FAO Fisheries and Aquaculture Technical Papers No. 699). Fertilized eggs were transported to IMC laboratories, where rearing is ongoing. At 80dph animals were genotyped by both PCR-RFLP and sequencing. In October 2026 phenotypic sex of the offspring will be evaluated by histology to associate genotype with phenotype.

Results & Discussion

Progeny genotyping revealed 100% wt/wt genotype. Results of the genotype/phenotype association will be reported. This outcome contributes to a growing body of evidence that an XX/XY sex determination system in *Mugil cephalus* exists and demonstrates that wt/wt males can successfully be used to produce viable offspring with all female genotype.

The Atlantic blue crab (*Callinectes sapidus*) is one of the most rapidly expanding invaders in the Mediterranean Sea, where it has established populations across all coastal and estuarine habitats. While its impacts in these environments are well documented, little is known about its occurrence and ecological role in inland waters. This study provides the first evidence of significant upstream migration of blue crabs along the Po River and nearby branches (Northern Italy), beyond typical coastal habitat distributions. Blue crab occurrences were based on 50 validated geo-referenced records collected between 2022 and 2025 through fishermen reports. Environmental variables and blue crab upstream distance were analyzed to explore possible drivers of this migration. The potential trophic interactions between blue crab and riverine fish species were also examined through a systematic literature review. The findings revealed that upstream dispersal reached distances of more than 160 km from the sea, primarily driven by adult males. No clear correlation was found between upstream distance reached by blue crab and water temperature, conductivity, dissolved oxygen, or river discharge, suggesting that ecological dynamics, rather than abiotic filtering, likely drive inland expansion. The literature review highlighted only a few documented trophic interactions in European freshwaters, although potential predation by invasive fish species and competition with native fauna may occur. These results underscore the urgent need for targeted monitoring and research to evaluate the ecological consequences of blue crab invasion in freshwater systems, particularly regarding its potential impacts on biodiversity, food web dynamics, and ecosystem functioning.

Introduction

Global aquaculture is currently facing unprecedented challenges due to climate change, which threatens the stability of traditional aquatic ecosystems through rising temperatures, droughts, and extreme weather events (Ahmed et al. 2021). In this scenario of environmental vulnerability, recirculating aquaculture systems (RAS) emerge as a strategic and highly resilient solution (Badiola et al. 2018). However, this technological solution is accompanied by high energy requirements, mainly due to the use of water circulation pumps, aeration, filtration, temperature control using heat pumps, and indoor climate management (Martins et al. 2010). As a result, the environmental sustainability of RAS strongly depends on their energy performance and associated greenhouse gas emissions, making energy-efficient design and operation a key challenge for the sector (Dalsgaard et al. 2013). This study was developed in the framework of the Interreg Italy-Slovenia project “Circular Rainbow,” and the aim of this work is to develop and apply an integrated simulation model of a recirculating aquaculture system and its hosting building using TRNSYS (dynamic system simulation software used for building energy simulation) with the objective of quantifying energy consumption and evaluating the potential for emission reduction through energy efficiency measures and on-site renewable energy systems.

Materials and methods

The study evaluates the energy performance of an indoor pilot recirculating aquaculture system (RAS) through a dynamic simulation framework implemented in TRNSYS. The modeled system is a 900 m² facility with 5 hatchery tanks, 6 nursery tanks, 3 pre-growth tanks and 4 grow-out tanks, located in Udine, Italy. The estimated total production of the plant is 25000 kg of rainbow trout for a total water volume of 1000 m³ in the tanks. The system includes two sump loops, an equalization tank and two biofilter vessel loops. The TRNSYS simulation couples the model of the multizone building envelope and the water tanks model at an hourly time step, resolving transient heat and moisture exchanges (including water surface evaporation) driven by external weather data. Electrical loads for pumps, filtration and lighting are treated deterministically, while thermal demands are dynamically simulated. To evaluate efficiency and emission reduction strategies, three scenarios are compared against a baseline representing a reference system with conventional natural ventilation and building integrated photovoltaic (PV) panels:

Scenario 1: Integration of a photovoltaic (PV) system.

Scenario 2: Addition of battery storage for increased PV self-consumption.

Scenario 3: Implementation of optimized mechanical ventilation strategies.

Figure 1: Daily energy demands by subsystem, total and net (Grid import (with PV)).

(Continued on next page)

Results & Discussion

The annual energy analysis of scenario 1 reveals that electricity demand to the grid can be reduced by the 44% with the building integrated photovoltaic on the roof surface reducing the energy demand from 14 kWh/kg of fish to 8 kWh/kg. These results are shown in Figure 1. The “total energy demand” is the sum of all the demands of the subsystems, while the “grid import (with PV)” indicates the net demand of energy including the energy produced by the photovoltaic panels. The “heat pump tanks” indicates the energy required to control the temperature of the water in the tanks, “devices” is the energy required by the circulating pumps and all the other devices, while the “building heating” and “building cooling” indicate the energy required to control the temperature and the humidity inside the building.

Scenario 2, including the battery storage system, allows to reduce the net energy demand to 1 kWh/kg of fish including a 100 kWh storage and an extension of 1000 m² of PV panels. The energy demand is used to estimate the carbon emissions and then are minimized by reducing the electricity demand from the grid with other combinations of PV and battery. Overall, the combined implementation of PV generation, battery storage, and ventilation strategies result in a significant reduction of annual carbon emissions compared to the baseline scenario. This study demonstrates the potential of integrated building and process simulation to support the design and operation of energy-efficient recirculating aquaculture systems. By coupling RAS tanks and building models in TRNSYS, it is possible to capture key interactions between water, air, and energy systems that strongly influence overall performance.

Funding

This research was funded by the European Union in the framework of the Interreg VI-A Italy-Slovenia 2021-2027 programme project “Circular Rainbow” cod. ITA-SI0600132 (G33C23000620007)

GENETIC IMPROVEMENT OF POST-WINTER CONDITION INDEX IN YELLOWTAIL KINGFISH (*seriola lalandi*)

A Carrasquillo ^{1*}, Garcia-Ballesteros S¹, Rousseau L², Maguire F², Luinstra M², Looseley M¹, Smedley M¹

1 Xelect Ltd, United Kingdom

2 Yumbah Aquaculture, Australia

*corresponding/presenting angel.carrasquillo@xelect.co.uk

Yellowtail Kingfish cultured in net pens can experience growth cessation and even weight loss during the winter period when temperatures fall below optimum. As an emerging, group spawning species, knowledge of genetic improvement strategies in this species is limited. Genetic improvement for winter resilience present an opportunity to improve productivity with shorter production cycles and increased eFCRs. This requires repeated individual weight measurements across a production cycle, which is impractical to evaluate on large net pens. Post winter condition index was evaluated across two generations of a yellowtail kingfish breeding programme representing six year classes. A moderate heritability of 0.28 was observed with an increase of post-winter condition index Breeding Values from 14.26 (± 0.03) to 14.43 (± 0.04) across generations. Genetic correlations of 0.47 are also shown between post-winter condition index and tank-based fasting daily growth coefficients (DGCs) corroborating supporting that post-winter assessment will enable selection for improved ability to maintain weight through winter. These results demonstrate the potential of selectively breeding for winter performance in yellowtail kingfish. In addition, it is one of the first examples of realized genetic gains from selective breeding in this species.

FUNCTIONAL FEED ADDITIVES REDUCE BACTERIAL-RELATED MORTALITY IN *Dicentrarchus labrax* ACROSS CONTROLLED AND FARM CONDITIONS

Carril G¹*, Tinsley J¹, Forberg T¹, Planas E¹, Noguerra B¹, Gonzalez Vecino JL¹

¹ BioMar Group
Kalkværksvej 16
15, 8000 Aarhus, Denmark

*corresponding/presenting author: gable@biomar.com

Introduction

Bacterial infections remain a major constraint in Mediterranean farming of European sea bass (*Dicentrarchus labrax*), particularly during warm periods when disease pressure is highest. Pathogens such as *Photobacterium damsela* subsp. *piscicida* continue to cause significant mortality despite the use of vaccination and improved management strategies. In line with the sector's transition toward reduced use of antibiotics, functional feeds that support the fish's natural defence mechanisms are increasingly considered as preventive health tools.

Materials and Methods

The efficacy of a functional package composed of additives and microingredients was evaluated through two complementary experiments: a controlled bacterial challenge trial and a large-scale farm validation trial. The challenge trial consisted of a seven-week feeding period followed by a bath challenge with *Photobacterium damsela* subsp. *piscicida* under controlled conditions in juvenile sea bass (initial body weight 21.8 g) at 22°C. The field trial was conducted at a commercial sea bass grow-out site, with over 1.6 million fish (initial body weight 185 g), covering a natural high-risk period for bacterial outbreaks (August-November). Mortality was continuously monitored and relative percent survival (RPS) was calculated to compare fish fed a control diet with those receiving the functional additive package.

Results and Discussion

Under controlled conditions, fish fed the functional diet showed significantly improved survival following bacterial challenge, with mortality reduced by 11.9 % compared to the control group, corresponding to an approximate 32% improvement in RPS. Statistical analysis indicated a strong treatment effect, with a 98% probability of direction and an odds ratio of 1.75 whose uncertainty interval excludes 1.0, indicating a statistically significant association. These survival benefits were consistently confirmed under commercial farming conditions, where the functional diet reduced overall mortality during periods of elevated disease pressure. In the field trial, mortality was reduced by 1.69 %, resulting in a 47% improvement in RPS and a 97% probability of direction with an odds ratio of 1.91, corresponding to a 91% higher risk of mortality in the control group compared with the test group.

Conclusions

The combined evidence from controlled challenge and commercial field trials shows that functional feed additives can significantly reduce bacterial-related mortality in European sea bass. Such nutritional strategies represent a robust and sustainable complement to existing health management practices, supporting fish survival during predictable high-risk periods.

Introduction

Tilapia aquaculture worldwide is increasingly challenged by bacterial disease outbreaks, with streptococcosis representing one of the most relevant threats to production, especially under intensive farming conditions and elevated water temperatures. Streptococcal infections severely impair growth, feed efficiency, immune competence and survival, finally generating substantial economic losses and raising concerns about the sustainability of tilapia production. Among the nutritional strategies explored to support fish health and reduce disease susceptibility, dietary antimicrobial compounds, including botanical extracts, organic acids, and other bioactive feed additives, have shown potential to modulate gut microbiota, enhance innate immunity, and improve resilience against pathogenic bacteria (Kuebutornye e Abarike 2020; Radwan et al. 2022; de Aguiar et al. 2023; Liliana et al. 2024) and production globally was about 4.5 million tons in 2013 and is predicted to exceed 6.6 million tons by 2030. The emergence of diseases has led to significant loss to tilapia aquaculture over the years. Medicinal plants have been known for use in treating some human diseases and studied in aquaculture to find safe and eco-friendly compounds that are suitable alternatives to the use of antibiotics and chemical compounds. Several parts including seeds, roots, flowers, leaves, and their extracts have been applied in tilapia aquaculture, administered to fish through injection, immersion, and oral. The biological activities of medicinal plants include enhancement of growth and feed utilization, stimulation of the cellular and humoral immune response, gene expression, and increased disease resistance in tilapia. Despite the potential contribution of medicinal plants, there are some drawbacks including few commercially available medicinal products, no precise data on optimal dose requirements, lack of toxicity studies, and inadequate data on the effects of medicinal plants at the molecular level. This article describes the role of medicinal plants and their forms used to improve growth, feed utilization, immune response, and disease resistance as well as the prospects of medicinal plants in tilapia aquaculture.”,”container-title”:”Aquaculture International”,”DOI”:”10.1007/s10499-020-00506-3”,”ISSN”:”0967-6120, 1573-143X”,”issue”:”3”,”journalAbbreviation”:”Aquacult Int”,”language”:”en”,”page”:”965-983”,”source”:”DOI.org (Crossref. This study evaluated the impact of different doses of a microencapsulated phytogenic blend (PHYTO) on Nile tilapia (*Oreochromis niloticus*) subjected to a cohabitation challenge with *Streptococcus agalactiae*.

Materials and Methods

A total of 675 Nile tilapia (average weight 16.85 ± 0.2 g) were stocked into 9 tanks (670 L) within a freshwater recirculating aquaculture system and allocated randomly to 3 experimental groups (3 tanks/treatment, 75 fish/tank). Treated groups received dietary supplementation of PHYTO at 0.5 or 1 kg/MT of feed via top-coating (PHYTO 0.5 and PHYTO 1.0, respectively), while the control group (CTR) received unsupplemented feed. Growth phase lasted 28 days, then a 31 days cohabitation challenge was performed by transferring 20 fish from each experimental tank into a challenge unit with 8 fish inoculated with *S. agalactiae*. Fish were bulk-weighed on day 28 of growth phase and on day 31 post-challenge (dpc) to assess performance parameters while survival was monitored daily. Additionally, 5 fish per tank ($n = 15$ /treatment) were sacrificed to evaluate condition factor (K), hepatosomatic index (HSI) viscerosomatic index (VSI) and intestinal histopathological signs. Data were analyzed using one-way ANOVA with Tukey’s *post-hoc* test or Kruskal–Wallis test for non-parametric data, survival data were analysed using Kaplan–Meier analysis. Significance was set at $p \leq 0.05$, tendency was set at $0.05 \leq p \leq 0.1$ (GraphPad Prism v.11.0.1; GraphPad Software, Inc., Massachusetts, USA).

Results

Statistical analysis of performance did not reveal any significant difference in growth and challenge phase for any treatment. Survival analysis of the challenge phase highlighted a tendency for relative percent survival improvement of PHYTO 1.0 group compared to both PHYTO 0.5 and CTR groups (+29% RPS) with the last mortality event in the treated group recorded 9 days prior to CTR. Regarding body composition all the diets experienced similar K-index in both growth and challenge phase, however regarding VSI and HSI, only PHYTO 1.0 was able to maintain pre-challenge body composition indexes. Other groups instead experienced an increase compared to pre-challenge levels suggesting an ongoing hepatomegaly process during the cohabitation trial although with different degrees of severity (PHYTO 0.5 +20% HSI; CTR +51% HSI). From a histological perspective, treated groups showed numerical decrease in all pathological alterations evaluated after challenge compared to CTR with a significant decrease of erythrocyte extravasation in the intestinal lining and a statistical trend for the mitigation of cellular inflammatory infiltration for all supplemented groups.

(Continued on next page)

Conclusions

In conclusion, dietary supplementation with microencapsulated phytogetic compounds demonstrated potential as nutritional strategy to support Nile tilapia survival, resolve infection in shorter timing and finally mitigate clinical alterations during *S. agalactiae* challenge. These findings therefore support the integration of this phytogetic additive in tilapia feeds to promote innovative and sustainable intensive aquaculture nutrition practices. Moreover, further studies are necessary to optimize phytogetic dosages, application timing and finally confirm effectiveness against other aquatic pathogenic *Streptococcus* spp. strains.

Introduction

The limited preventive and therapeutic interventions permitted under organic aquaculture regulations increase the importance of timely disease diagnosis and effective health monitoring, not only to limit pathogen spread, reduce antibiotic use, and mitigate production losses, but also to establish humane intervention endpoints and reduce fish suffering (Beg et al., 2024; Lembo et al., 2019).

Yersiniosis, caused by *Yersinia ruckeri*, is one of the most important bacterial diseases affecting salmonids worldwide. However, the early host immune response to naturally transmitted infection remains poorly characterized, as experimental infection models commonly bypass the natural route of pathogen exposure, hindering the identification of reliable indicators of disease onset. To address this gap, a cohabitation challenge was established using gavage-inoculated shedder fish to characterize the early systemic response of recipient rainbow trout (*Oncorhynchus mykiss*).

Materials and Methods

Juvenile rainbow trout (~12 g) were randomly assigned to 120-L tanks (40 fish tank⁻¹). Following acclimation, 12 fish were sampled as uninfected controls (CTRL). Thereafter, 10 fish per tank were anesthetized and inoculated via oral gavage with *Y. ruckeri* strain QSP57.1 (3.5×10^{10} CFU mL⁻¹). The upper lobe of the caudal fin was clipped to identify orally inoculated fish, which were returned to their tanks as shedders, while the remaining 30 fish per tank served as naïve cohabitants (1:3 shedder-to-cohabitant ratio).

Nine shedder fish were sampled at 3, 6, 9, 24, 48, 72, 96 and 120 hours following oral gavage to quantify splenic bacterial load. Twelve cohabitant fish were sampled after 24 h of cohabitation (T0h), and subsequently at 3, 6, 24, 48, 72 and 96 hours (one tank per time point). In cohabitants, spleen samples were collected for bacterial load quantification, blood was collected for total red blood cell (RBC) and white blood cell (WBC) counts, hemoglobin concentration, mean corpuscular hemoglobin (MCH), and plasma humoral immune parameters. Head-kidney tissue was also collected at the indicated times for gene expression analysis. Three additional replicate tanks were used exclusively for daily mortality monitoring over 15 days.

Results and Discussion

Mortality was first observed in shedder fish at four days after oral gavage, while in cohabitant fish appeared one day later. After 15 days, cumulative mortality reached 53.3% and 34.4%, respectively (Figure 1). Probe-based qPCR confirmed that gavage-inoculated shedders successfully transmitted the pathogen to naïve cohabitants, with the prevalence of infected fish and splenic bacterial burden increasing over time in both groups.

Preliminary hematological analyses indicated that RBC counts remained stable throughout the study, whereas hemoglobin concentration, MCH and total WBC counts progressively declined, with significant reductions detected at 96 h. Ongoing analyses of plasma humoral immune parameters and gene expression will provide additional insight into the early systemic response to infection.

Conclusions

This study establishes oral-gavage-mediated cohabitation as a biologically relevant model for investigating the natural horizontal transmission of *Y. ruckeri* in rainbow trout, enabling the characterization of the early host responses and the future identification of early diagnostic biomarkers of infection.

Introduction

The production of the macroalga *Macrocystis pyrifera* is mainly associated with the demand for alginate extraction (Vásquez et al., 2014), driving advances in cultivation techniques to improve its growth. The availability of nitrogen is essential for tissue formation, energy conversion, and storage in vacuoles and chloroplasts (Harrison and Hurd, 2001) productivity, epiphytes and the amount of certain products formed. Carbon, nitrogen and phosphorus are the main three nutrient elements added to large scale aquaculture systems. This review focuses mainly on nitrogen and the nitrogen physiology of seaweeds. Important concepts such as nutrient uptake, assimilation, storage, response to nutrient additions, nutrient ratios, and critical tissue nitrogen levels are discussed in terms of their application to aquaculture. For a particular species grown in an aquaculture system, it is important to know the C:N:P ratio of the seaweed under nutrient saturating conditions. This information will make the delivery of C, N, and P more economical. Nutrient uptake rates vary considerably with various physical, chemical and biological factors. In particular, light and temperature influence nutrient uptake rates, but we require further research to fully understand their effects. Nitrate uptake by some seaweeds is light dependent (i.e. diel periodicity). Rapid growth during early stages of production is essential for the viability and productivity of the culture. Consequently, the addition of commercial fertilizers to culture media can influence production costs. As an alternative to external inputs, Integrated Multitrophic Aquaculture (IMTA) recycles nutrients from the main species cultured into biomass of low-trophic-level organisms, such as macroalgae (Neori et al., 2004). Therefore, this study evaluated whether increasing nitrogen availability in a continuous-flow system with turbot (*Scophthalmus maximus*) affects the growth of two *M. pyrifera* morphotypes (few- and multiple-frond seedlings) in outdoor tanks and whether these effects persist after transfer to suspended longline culture at sea.

Materials and methods

In the winter of 2026, a two-part experiment was set. The first part lasted 21 days and consisted of two treatments with four replicates each: natural water (NW) and integrated aquaculture (F). The NW treatment used 1,000-L tanks with constant aeration and seawater recirculation, whereas the F treatment integrated 1,000-L macroalgae tanks with 1,500-L turbot tanks, with continuous water flow from the fish to the macroalgae tanks. Sixty juvenile *M. pyrifera* sporophytes per replicate, representing two morphotypes (few- and many-frond) (Buschmann et al., 2020), were used. Ten sporophytes of each morphotype were tagged for weekly weight monitoring. In the second-part experiment, the 20 tagged sporophytes from each tank were transferred to a longline at 1.5 m depth, and cultivated for 30 days. Forty sporophytes were collected and weighed after 15 days, and the remaining individuals after 30 days. Average weight gain (g) and SGR (% day⁻¹) were calculated. Water quality (ammonia, nitrite, nitrate, and phosphate) was monitored weekly during the experiment. Statistical analyses were performed using PAST v4.03. Data normality and homoscedasticity were assessed using the Shapiro–Wilk and Levene tests, respectively. One- or two-way ANOVA followed by Tukey's test was used when assumptions were met, with $p \leq 0.05$.

Table 1. Performance of *Macrocystis* juveniles in natural seawater (NW) and fish tank water (F) during the 21 days they were cultivated in land tanks and 30 days on a longline at sea.

	Land-based tanks (21 days)		Longline (30 days)	
	Seawater - NW	Fish tank - F	Seawater - NW	Fish tank - F
Few fronds				
Average weight gain (g)	3.81 ± 1.64	3.61 ± 1.24 B	11.26 ± 5.08 B ^b	26.76 ± 10.61 ^a
SGR (% day ⁻¹)	2.19 ± 1.26	2.49 ± 0.94	2.35 ± 1.05 ^b	4.43 ± 0.49 ^a
Many fronds				
Average weight gain (g)	5.21 ± 2.05	6.14 ± 2.13 A	37.00 ± 17.96 A	35.13 ± 7.34
SGR (% day ⁻¹)	1.86 ± 0.61	2.19 ± 1.08	3.92 ± 1.60	3.62 ± 0.72

(Continued on next page)

Results

Ammonia concentrations differed significantly between treatments on days 14 (NW 26.6 ± 1.7 b; F 34.0 ± 1.3 a $\mu\text{mol L}^{-1}$) and day 21 (NW 25.3 ± 1.7 b; F 31.8 ± 1.8 a $\mu\text{mol L}^{-1}$) in the tank culture. Nitrate concentrations differed significantly between treatments at the beginning of the cultivation (NW 13.2 ± 2.8 b; F 18.9 ± 1.8 a $\mu\text{mol L}^{-1}$). For phosphorus, significant differences were found on Day 0 (NW 2.4 ± 0.0 a; F 1.0 ± 0.5 b $\mu\text{mol L}^{-1}$) and on Day 21 (NW 2.3 ± 0.8 b; F 3.1 ± 0.1 a $\mu\text{mol L}^{-1}$). Weight gain did not differ significantly between treatments during the 21-day tank culture (Table 1). In contrast, during longline culture, the few-frond morphotype showed higher weight gain and specific growth rate in the F treatment than in the NW treatment (Table 1).

SGR specific growth rate. Different letters in the same line indicate a significant difference between treatments. Capital letters in the same column indicate a significant difference within the same treatment between groups of fronds.

Discussion

The higher ammonia and nitrate concentrations in treatment F resulted from animal excretion and feed leaching (Silva et al., 2013), compared to with seawater. During land-based cultivation, the higher growth of the “many fronds” morphotype in treatment F may indicate a competitive advantage resulting from enhanced light interception due to its higher number of fronds, potentially increasing shading and limiting light availability to the “few fronds” morphotype. The insignificant difference between treatments can be explained by space limitations as macroalgal biomass increased (Xiao et al., 2019). In contrast, under longline cultivation, the higher weight gain in treatment F may be associated with the higher nitrogen retention achieved during the tank cultivation phase, which may have promoted subsequent macroalgal growth (Harrison and Hurd, 2001). With the increased space available, the “few fronds” morphotype showed growth similar to that of the “many fronds” morphotype in the treatment F.

THE GLASS-EEL-RESCUE PROJECT: AN INTEGRATED APPROACH TO SAFEGUARDING THE EUROPEAN EEL (*Anguilla anguilla*) THROUGH A RESTOCKING PROGRAM USING THE PCCR METHOD (POST-LARVAL CAPTURE, CULTURE AND RELEASE)

Introduction

The European eel *Anguilla anguilla* is currently classified as critically endangered (Pike et al., 2020), mainly due to habitat loss, overfishing, migration barriers, environmental degradation and increasing predation pressure. The severe decline of both adult and juvenile stages has made the development of innovative conservation strategies a priority at European and regional levels (Dekker, 2003). Restocking with juvenile eels is considered one of the available tools to support stock recovery, although its effectiveness can be limited by high mortality during the early life stages after release (European Council, 2007). In this context, the Post-Larval Capture, Culture and Release approach may represent a useful strategy to improve survival by rearing glass eels under controlled conditions until they reach a more robust juvenile stage before restocking (Cortés-Useche et al., 2021). At the same time, the invasive blue crab *Callinectes sapidus* is rapidly expanding in Mediterranean coastal ecosystems, causing ecological and economic impacts (Marchessaux et al., 2023). The use of eggs from ovigerous blue crab females as a natural feed source for glass eels may provide a dual benefit: supporting eel growth and contributing to the management of an invasive species.

Materials and Methods

The project will be carried out at the aquaculture facilities of the University of Bologna, Cesenatico, Italy. Glass eels will be collected during their natural migration in transitional waters and river mouths of Emilia-Romagna, or, if necessary, obtained from certified suppliers. After transport to the research facility, animals will be acclimated to controlled rearing conditions and a representative sample will be measured for body weight, total length and Fulton's condition factor. Eels will be maintained in recirculating aquaculture systems equipped with mechanical and biological filtration, temperature and oxygen control, UV and ozone water treatment. During the rearing phase, different feeding protocols based on eggs of *C. sapidus* will be tested and compared in terms of growth performance, survival, health status and welfare indicators. Water quality parameters, including temperature, dissolved oxygen, salinity, pH and nitrogen compounds, will be monitored daily. At the end of the culture period, juveniles will undergo biometric and health assessment and will be gradually acclimated to the environmental conditions of selected release sites.

Results

The expected outcome of the project is the development of a sustainable rearing protocol for glass eels aimed at improving survival and growth before release. Preliminary observations conducted by the research group suggest that diets including blue crab eggs may be suitable for the nutritional requirements of glass eels and may support very high survival rates under controlled conditions. The controlled rearing phase is expected to reduce early mortality by limiting predation, environmental stress and feeding difficulties, allowing the release of larger and more robust juveniles. The project will also generate data on the suitability of *C. sapidus* eggs as a natural feed ingredient, with particular attention to growth response, animal condition and practical applicability in conservation-oriented aquaculture.

Discussion

This approach integrates eel conservation, sustainable aquaculture and invasive species management within a single applied framework. Rearing glass eels to a more resistant juvenile stage before release could improve the effectiveness of restocking programmes, especially in areas where natural recruitment is low and early-stage mortality is high (Richardson et al., 2023). The use of blue crab eggs as feed may reduce reliance on commercial inert diets and provide a more natural and sensory-stimulating food source for juvenile eels. In addition, the removal of ovigerous blue crab females could contribute, although locally and partially, to reducing the reproductive pressure of this invasive species (Marchessaux et al., 2023). If successful, this pilot protocol could be replicated at regional and national levels, supporting conservation actions for *A. anguilla* while promoting circular and ecosystem-based solutions in aquaculture.

MONITORING OF *Photobacterium damsela* subsp. *piscicida* INFECTION IN SEA BASS (*Dicentrarchus labrax*) USING THREE FUNCTIONAL DETECTION METHODS

T. Castaño^{1,2*}, S. Mogas¹, C. Piquer¹

¹ KOA Biotech, Barcelona, Spain

² Department of Cell Biology, Physiology and Immunology, Universitat Autònoma de Barcelona, Spain

*corresponding/presenting teresa.castanyo@koabiotech.com

Introduction

Fish pasteurellosis or photobacteriosis caused by *Photobacterium damsela* subsp. *piscicida* (*Pdp*) is one of the most significant bacterial diseases affecting marine aquaculture in Europe, particularly in European sea bass (*Dicentrarchus labrax*) and gilthead sea bream (*Sparus aurata*) (EU Reference Laboratory for Fish and Crustacean Diseases, 2021). Despite its significant economic impact, the detection and diagnosis of this pathogen remain challenging. Conventional microbiological isolation is hindered by its inability to grow on selective media such as TCBS agar, its slow growth rate, and its lack of distinctive colony morphology. Molecular detection is also limited by the absence of subspecies-specific PCR primers, as currently available assays generally target the species level and cannot reliably discriminate *P. damsela* subsp. *piscicida* from the closely related *P. damsela* subsp. *damsela* (Andreoni & Magnani, 2014). Multiplex PCR assays based on 16S rRNA gene detection and the absence of *ureC* amplification have been developed as an improved approach for discriminating the pathogen at the subspecies level (Osorio et al., 2000). However, PCR-based methods have certain limitations when assessing bacterial pathogenicity, as they primarily provide information on bacterial abundance rather than direct evidence of virulence or pathogenic potential within the detected population.

To address these limitations and improve our understanding of the pathogen's infection dynamics, an in vivo challenge was conducted at CTAQUA (Centro Tecnológico de la Acuicultura, Cádiz, Spain) in which European sea bass (*Dicentrarchus labrax*) were experimentally infected with *Pdp*. The study aimed to monitor disease progression and evaluate pathogen detection in the aquatic environment throughout the course of an infection using microbiological techniques, phenotypic virulence assays, and a set of experimental biosensors developed by KOA Biotech.

Materials and Methods

Two experimental groups of European sea bass, were challenged by immersion with *Pdp* at final concentrations of 1.65×10^7 CFU/mL and 1.65×10^4 CFU/mL, respectively. Each experimental batch included three control tanks and three infected tanks. Water quality parameters were monitored daily, and fish mortalities were recorded throughout the challenge.

Figure 1. Comparison of microbiological and phenotypic Virulence Assessment methods for both fish groups. The x-axis shows the days post-challenge, while the y-axis displays bacterial load in CFU/mL (a) and functional assay activity (b).

(Continued on next page)

Water samples were collected daily for pathogen growth assessment. Samples were cultured on TCBS, TSA supplemented with 2% NaCl, and blood agar, with bacterial colonies quantified using an automated detection algorithm. Phenotypic virulence was assessed using four functional media targeting chondroitin sulfate, egg yolk, casein, and blood degradation. Pathogen levels were also monitored using KOA Biotech's experimental biosensors.

To verify the infection caused by *Pdp*, all deceased fish underwent external and internal necropsy, followed by bacteriological isolation from the head kidney. Pure cultures obtained on TSA supplemented with 2% NaCl were subsequently streaked onto TCBS agar to confirm the absence of bacterial growth on this selective medium.

Results

At the microbiological level, three bacterial populations were monitored: *Photobacterium damsela* subsp. *piscicida*., *Vibrio* spp., and “Other” bacteria, the latter classified as potentially protective bacteria identified within the water microbiome. The results showed peaks in *Photobacterium* CFU/mL at time points coinciding with increases in fish mortality. An antagonistic dynamic was also observed between the *Photobacterium* and *Vibrio* populations, together with an overall decline in the “Other” bacterial population.

At the functional level, the observed peaks correlated with the first mortalities, supporting the high pathogenic activity of the pathogen and the high mortality rates reached during the challenge.

Finally, at the biosensor level, an increase in the biosensor response was detected several days before the onset of the first mortalities.

Conclusions

Collectively, these results demonstrate that a multimethodological approach provides a more comprehensive understanding of the infection dynamics of *Photobacterium damsela* subsp. *piscicida*, and may contribute to improving its diagnosis in aquaculture facilities. The methodologies employed focus primarily on the functional characterization of pathogen presence rather than on genomic detection alone, potentially providing a more comprehensive understanding of the virulence dynamics that may develop during infection, as well as of the microbiological status of the surrounding water.

Summary

The aim of the MARINET project (italy-croatia.eu/web/marinet) is to investigate the potential for cultivating the European flat oyster (*Ostrea edulis*) at new potential sites in the Adriatic Sea and to expand its cultivation. The assessment of cultivation potential is based on the environmental conditions under which the European flat oyster can grow and the potential for spat settlement. For this purpose, a comparative analysis was conducted of sites characterised by naturally elevated phytoplankton abundance and the presence of a natural oyster population in the vicinity. Based on these criteria, nine sites were selected: four in Istria (Raša Bay, Budava Bay, Lim Bay and Savudrija) and five along the Italian Adriatic coast (Muggia, Duino, Cattolica, Mattinata and Gallipoli).

At each site, European flat oyster specimens were deployed to monitor their growth and mortality, as well as the environmental conditions under which they developed. In addition, collectors for oyster spat settlement were deployed at the sites in Istria and at Muggia, Duino and Cattolica. At sites where depths exceeded 10 metres, additional oyster specimens and collectors were deployed at greater depths to investigate the effects of depth and temperature on growth, spat settlement and the degree of fouling. To ensure that the results were as representative as possible of future production conditions, oyster sampling was conducted every two months, following a maintenance regime similar to that which would be applied under actual production conditions.

Growth rates were generally similar among the sites, except at Gallipoli and Mattinata, where the lowest growth rates were recorded. In contrast, the highest growth rates were observed at the northern Adriatic sites, namely Muggia, Lim, Savudrija, Duino, Raša, Budava and Cattolica. Regarding mortality, the European flat oyster showed a similar pattern across the sites, with higher mortality observed during periods of summer heat and lower mortality during the remainder of the year. Differences among the sites indicated that the lowest mortality rates were again observed at Muggia, Savudrija, Lim, Raša and Budava. Furthermore, with regard to spat recruitment potential, only Muggia and Savudrija showed higher recruitment levels, followed by moderate recruitment at Lim and Budava. This may be explained by the proximity of these sites to local oyster populations and the transport of sufficient numbers of larvae by marine currents to the collectors.

At the sites of Budava, Duino, Mattinata and Gallipoli, an additional analysis was conducted to determine whether the application of Integrated Multitrophic Aquaculture (IMTA) provided any benefits. The results indicated that the flat oysters at all sites ingested and utilised by-products of fish aquaculture; however, no noticeable increase in growth rates was observed compared with control samples at the same sites.

We conclude that each site has its own specific characteristics, strengths and weaknesses, and that all these aspects should be taken into consideration when planning future flat oyster aquaculture production sites. Overall, the most promising sites appear to be Muggia, Savudrija, Budava and Lim. However, coordinated production across all sites could maximise the aquaculture potential of the European flat oyster in the Adriatic Sea. A key aspect will be to adapt future aquaculture practices to local environmental and climatic conditions. It is therefore also recommended that environmental conditions continue to be monitored and that forecasting tools be developed to assess future risks and serve as early warning systems for aquaculture.

EVALUATION OF THE EFFECTS OF DIFFERENT CONCENTRATIONS OF TWO GRAPE-DERIVED POLYPHENOL-RICH ADDITIVES ON RAINBOW TROUT (*Oncorhynchus mykiss*) UNDER THERMAL STRESS CONDITIONS

Introduction

The rapid expansion of the aquaculture industry, combined with the ongoing effects of climate change, has increased the exposure of farmed fish to environmental stressors, among which temperature fluctuations represent one of the most critical challenges. Elevated water temperatures can disrupt metabolic balance, impair immune function, and promote the overproduction of reactive oxygen species (ROS), leading to oxidative stress and cellular damage.

In this context, dietary strategies based on natural compounds have gained increasing attention. Polyphenols, a diverse class of plant-derived bioactive molecules, are known for their strong antioxidant and anti-inflammatory properties and their ability to modulate immune responses. Grape by-products from the wine industry represent an important and sustainable source of such polyphenols, offering a valuable opportunity for the valorisation of agro-industrial waste through their conversion into functional feed ingredients for aquaculture (Quagliardi et al. 2024).

The inclusion of polyphenol-rich additives in aquafeeds has been associated with improved growth performance, enhanced antioxidant capacity, and increased resistance to stress in several fish species (Mansoori et al. 2024; Ahmadifar et al. 2012; Torricelli et al. 2024). However, the efficacy of different polyphenol sources and their optimal dietary concentrations, particularly under thermal stress conditions, remains to be fully elucidated.

Therefore, the present study aimed to evaluate the effects of different concentrations of two grape-derived polyphenol-based additives on growth performance, oxidative status, and selected biochemical parameters in rainbow trout under thermal stress conditions.

Materials and Methods

Five experimental diets were formulated: four supplemented with two polyphenol-based additives at two inclusion levels, and a control diet without additives.

A total of 450 rainbow trout (*Oncorhynchus mykiss*) (initial weight: 30 g) were randomly distributed into experimental groups and fed for 60 days. Fish were hand-fed to apparent satiation twice daily, and water temperature (13.0 ± 1 °C) and oxygen levels were continuously monitored.

At the end of the trial, growth performance (FBW, SGR, FI, FCR, survival) and morphometric and nutrient efficiency indices (CF, VSI, HSI, MFI, PER, GPR, LER, GLE) were evaluated. Samples were collected to assess carcass composition, liver histology, gene expression of inflammatory markers, plasma biochemistry, liver metabolomics and oxidative stress biomarkers (total antioxidant capacity (TAC), glutathione (GSH), antioxidant enzyme activity (CAT), lipid peroxidation (TBARS), protein carbonylation (PC), and mitochondrial ROS production (mtROS)).

Fish were then subjected to a thermal stress challenge, with temperature increased to 20 °C (2°C day⁻¹) and maintained for 15 days. At the end of the stress period, survival and growth parameters were recorded, and sampling was repeated to assess physiological and biochemical responses.

(Continued on next page)

Results and Discussion

Fish fed diets supplemented with polyphenol-based additives are expected to show growth performance, FI, and FCR comparable to or slightly improved compared to the control group, particularly at moderate inclusion levels. Recent studies have reported enhanced growth and feed utilization in rainbow trout fed polyphenol-rich diets, likely due to improved metabolic efficiency and antioxidant status (Mansoori et al. 2024).

Oxidative stress biomarkers are expected to be significantly affected by dietary treatments. Fish receiving polyphenol-supplemented diets are likely to exhibit higher TAC, increased GSH, and enhanced CAT activity, along with reduced lipid peroxidation, protein carbonylation, and mitochondrial ROS production. These responses are consistent with findings highlighting the antioxidant role of polyphenols in fish (Ahmadifar et al. 2012).

Gene expression analyses are expected to show modulation of immune and inflammatory markers, with a potential reduction of pro-inflammatory cytokines and improved immune status, as recently observed in fish fed plant-derived bioactive compounds (Torricelli et al. 2024).

Histological observations are likely to reveal generally preserved intestinal and hepatic structures, with possible improvements at moderate inclusion levels and mild alterations at higher doses, reflecting metabolic adaptation.

Following the thermal stress challenge, fish are expected to show increased oxidative stress and physiological disturbance due to elevated temperature, as widely reported for rainbow trout (Hosseinpour et al. 2024; Yousefi et al. 2024). However, fish fed polyphenol-enriched diets are likely to exhibit improved resilience, with higher survival rates and better maintenance of antioxidant defences.

Overall, polyphenol supplementation is expected to enhance antioxidant capacity and improve the resilience of rainbow trout under thermal stress conditions.

Conclusion

Overall, the trial is expected to show that moderate inclusion levels of polyphenol-based additives can enhance antioxidant status and support immune responses in rainbow trout without negatively affecting growth performance. These effects are likely to be more evident under thermal stress, improving fish resilience and reducing oxidative damage.

Given the impact of climate change on aquaculture, particularly rising water temperatures, polyphenols represent a promising strategy to improve fish robustness and support more sustainable production systems.

Introduction

European flat oyster (*Ostrea edulis*) is a bivalve mollusc belonging to the family *Ostreidae*, a native European species that has inhabited the Mediterranean basin since prehistoric times. Although this organism has been a commercially important resource in Europe for centuries, its population has undergone a substantial decline in most European countries as a consequence of disease emergence, environmental pollution, and climate-change-related stressors (Brundu et al. 2025). Given the importance of promoting biodiversity and preserving the European flat oyster, this species is included as a focus of the 'Marinet' Interreg project (italy-croatia.eu/web/marinet). The project is promoting and developing a sustainable aquaculture in the Adriatic context, especially by empowering small and medium-sized enterprises (SMEs). One of the project's goals is the development of useful decisional support tools, such as bioeconomic models, mathematical tools capable of estimating the profitability of an organism production process (Garza, 2024). Based on these premises, this study proposes a bioeconomic model to assess the economic feasibility of European flat oyster production in several case study sites in the Adriatic Sea.

Bioeconomic Model Framework

Bioeconomic model approaches consist in a composition of interacting mathematical sub-models, developed using adapted procedures according to Chary et al. (2022). In aquaculture context, a framework of three interconnected sub-models (biological, technological, and economic) is used (Garza, 2024). The biological sub-model predicts the growth and survival rate of the farmed organism, determining the final product biomass and consequently the possible revenues. The biological sub-model comprises three sections: spat collection, growth, and population dynamics. Growth and population models estimate individual monthly growth and biomass dynamics based on initial stock size and survival rates (Kamiyama et al., 2021). The technological sub-model estimates the farm's technological operations energy requirements. Considering the off-shore aquaculture context, the energy requirements are represented by fuel consumption needed to carry on working operations, such as maintenance of long line and oyster husbandry activities and by the electrical energy required to operate the side activities in the oyster farm. Finally, the last sub-model is the economical one, where results from biological and technological sub-models are combined with external economic data to key economic performance indicators of the farm (KPI). This sub-model is divided in yearly fixed and variable cost estimation, revenue estimation and final KPI indicators calculation, focusing in particular on break-even quantity (*BEP Q*) which represents the requested quantity of production to cover all the production costs (Jolly e Clonts, 1993).

Data Implementation and Results

To generate projections the model needs to be fed with environmental and in situ specific observed biological measurement data, in order to mimic possible local practices and growth conditions. The model is used to generate KPI taking in consideration a hypothetical offshore long line farm of flat oysters situated in the Adriatic Sea. Biological data were recorded in nine different farms involved in the project, located in Croatia and Italy, and were used to produce weight growth and survival models. To estimate fuel consumption in the technological submodel we use as raw data monthly operational hours of the boats and hourly fuel consumption ratio, obtaining the fuel volume of fuel utilized. However, they were selected to ensure that overall fuel consumption remained consistent with the values reported in oyster farm life cycle assessment studies (Summa et al., 2023). Regarding the economic sub-model, fixed costs were estimated using a rough comprehensive approach. Variable costs, on the other hand, were calculated by multiplying the monthly fuel consumption by an assumed fuel price. Among variable costs we find also monthly staff and utility costs. Revenues are estimated monthly, considering that the farmer will sell a certain percentage of the available product, which can vary on the basis of market demand and proposed price. Selling prices were estimated BMTI monthly market sale data (bmti.it/analisi-ittico/). The final output of the model are KPI, such as BEP, cumulative cost and revenues graphs or yearly profits evaluations. These support decision tools consent to evaluate different farm management strategic decisions. In fact, the results of this study provide an assessment of the differences in economic opportunities among the various production sites, and comparison among different scenarios obtained by varying systematically different parameters, such as selling prices or technological parameters.

(Continued on next page)

Conclusion

The outputs of the bio-economic model provide useful indicators to support farm managers in strategy decisions. At the same time, the model offers a structured framework for collecting, organizing, and analyzing farm data, thereby facilitating the monitoring of farm performance and operations. As this bio-economic model represents a first approach, its current structure should be considered flexible and adaptable. The proposed sub-models can be refined and modified according to site-specific conditions, data availability, and farmers' needs.

Introduction

Over the past decades, plastic pollution is a growing environmental concern, particularly in coastal and estuarine ecosystems where aquaculture production often takes place. Farmed species, especially those raised in extensive and semi-intensive systems, face increasing exposure to environmental contaminants, including plastic debris, discarded fishing gear, and other forms of marine litter. This exposure can pose risks to aquaculture industry through ingestion and the release of harmful chemicals into the surrounding water.

These concerns have intensified efforts to find alternatives to conventional plastics derived from fossil fuels. Among current alternatives, bioplastics have gained attention as more sustainable materials. The plastic industry often presents these polymers as environmentally friendly due to origin from renewable biological sources and, in some cases, greater biodegradation potential. Yet this same biodegradation potential raises ecological concerns, since bio-based polymers might fragment into microplastics more quickly than conventional petroleum-based plastics and release additives.

Current knowledge about the ecotoxicological effects of bioplastics remains limited, especially for recently developed polymers. This lack of information restricts an accurate assessment of the real environmental safety of bio-based plastics. Given the vulnerability of aquaculture species to marine litter and emerging plastic alternatives, further research is needed to assess biological impacts of these materials.

The present study aimed to investigate the ecotoxicological responses of farmed juvenile gilthead seabream (*Sparus aurata*) exposed to microparticles from three bio-based polymers: PLA (polylactic acid microplastics), PPF (polypropylene 2,5-furandicarboxylate microplastics), or a mix of PLA/PPF microplastics. Animal condition, metabolism, digestive and antioxidant activity, and cell damage to evaluate potential physiological effects associated with chronic exposure to these emerging materials were assessed.

Materials and Methods

Farmed *S. aurata* juveniles (18.78 ± 0.51 cm total length, 103.46 ± 5.52 g weight) were kept in recirculating aquaculture systems (RAS) under optimal rearing conditions: 24.0 ± 0.5 °C; (ii) dissolved oxygen: 7.2 ± 0.2 mg L⁻¹; (iii) salinity: 35.0 ± 0.5 ‰; (iv) pH: 8.0 ± 0.1 ; and (v) photoperiod: 12 h light/12 h dark.. During the 28-day exposure trial, specimens were fed 1% body weight of either a commercial-based diet (CTR) or one of three microplastic-contaminated diet, containing either i) PLA; ii) PPF, or iii) mixed polymers PLA/PPF microplastics. The three contaminated feeds contained ~60 particles g⁻¹ feed, each ranging between 500 and 1000 µm.

After 28 days of exposure trial, fish (n = 7 per treatment) were randomly collected and euthanized for dissection and collection of samples. To evaluate the ecotoxicological effects elicited by biobased microplastics, the following endpoints were assessed: animal condition, plasma metabolites, gut and liver biomarker responses indicative of oxidative stress (catalase, glutathione S-transferase, and superoxide dismutase activities), cell damage (ubiquitin content and lipid peroxidation), and digestive enzymes (trypsin, pepsins and amylase). Statistical differences between treatments were analyzed through one-way ANOVA.

Results and Discussion

Preliminary results show no significant alterations in fish condition between treatments, but significant differences in plasma metabolite profiles were registered. The most notable changes were found in glucose levels (+118%) of fish from the PLA+PPF treatment, and the total protein content (-16.7%) in fish from the PLA treatment.

(Continued on next page)

Regarding oxidative stress responses, in comparison with the control treatment, exposure to all biopolymers led to a reduction in the activity of antioxidant and detoxification enzymes present in fish gut. Still, there was no significant lipid damage observed in these fish.

Although data analysis is still ongoing, the results gathered so far suggest that while the tested materials did not affect fish condition, they may induce distinct metabolic responses, highlighting biological significance and potential long-term implications of biopolymers exposure in farmed juvenile fish. Hence, further research should be carried on bio-based polymers' ecotoxicological attributes, as to better support the “green” claims intended by these materials.

Introduction

Freshwater ecosystems possess high biodiversity supporting approximately 10% of all the species while occupying less than 1% of earth surface. In India freshwater ecosystem faces multiple anthropogenic pressures, including habitat degradation, pollution, flow modification, overexploitation, with climate change emerging as a widespread driver of ecological change. These stressors initiate conditions that favour the establishment and spread of invasive species while simultaneously affecting the resilience of native fish communities. Freshwater fish species are highly sensitive to temperature and especially vulnerable to climate-driven environmental changes. The impacts of climate change on fish distributions are projected to be severe, with studies predicting significant range contractions and shifts in freshwater communities.

Material and Methods

This current research aims to assess the habitat suitability of invasive-native under various environmental factors and highlight the implications for conservation strategies. Understanding water quality impacts and MaxEnt modelling, we evaluated the influence of spatial and environmental factors on native-invasive assemblages to determine invasion and environmental factors contributed to major alterations in native distribution pattern and predicting potential habitat suitability of invasive-native under climatic scenarios SSP1-2.6, SSP2-4.5, and SSP5-8.5 for the years 2050 and 2070. The species occurrence was documented in the Arkavathy River watershed, situated in a peninsular region was chosen for the study due to damming sites and angling reserve locations such as the Cauvery Wildlife Sanctuary. A total of 50 sampling points were chosen along the streams, covering the stretch from confluence to origin, with elevation ranging from 891 to 396 m above sea level.

Results

Redundancy analysis showed 82.24% explained variance, therefore, this model can help in future prediction of the effects of invasive alien species on native species assemblages. The MaxEnt model demonstrated high predictive accuracy, identifying 123.06 km² out of 4135 km² of highly suitable native species habitat, with future projections indicating a significant decline in suitable habitats by the year 2050 and 2070. Key environmental variables influencing habitat suitability included maximum temperature of warmest month, temperature seasonality, and isothermality.

Discussion

This study indicates that water quality monitoring is a good indicator of understanding shifts in the invasive-native distributional patterns. These findings underscore the urgent need for targeted conservation strategies to mitigate the impacts of climate change and anthropogenic pressures on endemic species, providing critical insights for the initial stages of developing policies for environmental restoration and fishery management.

INTEGRATING LOW-TROPHIC AQUACULTURE WITH OFFSHORE WIND FARMS: ENVIRONMENTAL AND ECONOMIC PERFORMANCE OF MULTI-USE SYSTEMS

M. Chakraborty¹, T. Boderskov², A. Bruhn^{2,3}, M. Thomsen^{1*}

Introduction

The continued expansion of offshore renewable energy infrastructure creates new opportunities for multi-use marine systems, in which low-trophic aquaculture can be co-located with offshore wind farms and potentially share spatial, infrastructural, and operational resources. Such integration may increase the efficiency of marine space use, reduce resource requirements and environmental burdens, and improve the economic feasibility of offshore aquaculture. This study evaluated the environmental and economic performance of offshore cultivation of sugar kelp (*Saccharina latissima*) and blue mussel (*Mytilus edulis*) as mono- and co-cultivation systems integrated with offshore wind farm operations under Danish offshore conditions. The analysis considered a commercial-scale cultivation area of 18.75 ha and investigated whether operational synergies associated with multi-use offshore systems could improve performance relative to standalone aquaculture.

Methodology

An integrated life cycle assessment (LCA) and techno-economic analysis (TEA) framework was applied to mussel mono-cultivation, seaweed mono-cultivation, and seaweed–mussel co-cultivation. Wind farm integration was modelled through shared offshore operations, including vessel use, diesel consumption, and monitoring activities. Environmental performance was evaluated using the Environmental Footprint (EF) 3.1 method. A separate scenario accounting for nutrient assimilation was evaluated to distinguish production-related impacts from potential ecosystem services benefits associated with nutrient removal. Economic feasibility was assessed over a 10-year project lifetime using Net Present Value (NPV), considering alternative market pathways for food- and feed-grade biomass.

Results and Discussion

Integration with offshore wind farm operations improved environmental performance across the cultivation systems. At farm scale, shared resource use reduced the environmental footprint of the co-cultivation system by approximately 17% relative to standalone cultivation. The carbon footprint decreased by approximately 4% for mussel mono-cultivation and 12% for seaweed mono-cultivation following wind farm integration, demonstrating that sharing infrastructure and offshore operations can reduce burdens associated with offshore logistics and farm management.

Economic viability was strongly influenced by both wind farm integration and the targeted biomass market. The highest economic benefit was obtained for co-cultivation combining high-value seaweed products with food-grade mussels, for which the 10-year NPV increased from approximately €10.8 million for standalone cultivation to €12.5 million following wind farm integration. In contrast, systems dependent on wholesale seaweed and feed-grade mussel markets remained economically constrained, indicating that operational synergies alone may not compensate for low biomass market values.

Conclusion

The combined environmental and economic assessment demonstrates that integrating low-trophic aquaculture with offshore wind farms can improve environmental and economic performance, particularly when shared infrastructure and operations are coupled with higher-value biomass applications. Co-cultivation showed the strongest overall benefit, supporting multi-use offshore systems as a pathway towards more resource-efficient and economically resilient marine production. However, market positioning remains a critical determinant of economic viability, highlighting the importance of integrating production-system design with biomass valorisation strategies.

Presenting author email: michael.chambers@unh.edu

The new Cooperative Institute Fostering Aquaculture Research and Marketing (**CIFARM**) was recently established in the US to expand seafood production and markets throughout the U.S. by developing aquaculture in territorial seas and the Exclusive Economic Zone, thereby enhancing coastal economies and supporting American maritime communities. The University of New Hampshire (UNH) was chosen as the lead institution by the National Oceanic Atmospheric Administration (NOAA) Office of Aquaculture (OAQ), along with Consortium members the University of Miami, University of Southern Mississippi, Hubbs SeaWorld Research Institute, and the University of Hawai'i, with regional Sea Grant Programs. CIFARM will work closely with state, federal and industry partners to foster sustainable aquaculture across diverse U.S. regions by establishing a coordinated framework that leverages regional expertise, streamlines permitting processes, and promotes innovation and workforce development.

This initiative aligns with the NOAA Aquaculture Strategic Plan goals, which include managing sustainability and efficiency, leading with science, educating and exchanging information, and supporting economic viability and growth.

Each CIFARM Consortium member, strategically located across the Northeast, Southeast and Caribbean, Gulf of America, West Coast, and the Pacific Islands, is designed to embody excellence in state-of-the-art infrastructure, aquaculture science and commercial expertise, active partnerships with diverse stakeholders, and a proven record of innovation. These Consortium members will facilitate local yet cross-cutting projects that involve educational institutions, Sea Grant, NOAA assets, industry partners, non-governmental organizations, and local seafood businesses and communities, ensuring that region-specific plans for seafood product development, test bed facilities, and educational programs are consistent across the nation.

BLUE MUSSEL HAEMOCYTE FUNCTION UNDER ENVIRONMENTAL STRESS

AF Chapuis ^{1*}, R Gibb ¹, T Regan ¹

¹ The Roslin Institute, University of Edinburgh, Scotland, UK.

*corresponding/presenting achapuis@ed.ac.uk

Blue mussels (*Mytilus* spp.) are economically and ecologically significant, they are the most farmed bivalves in Europe representing 35% of total aquaculture production. Climate change is increasing the frequency of extreme rainfall events, causing hyposalinity stress in sea loch aquaculture sites. Mussel immunity depends on haemocyte phagocytosis, but the effects of salinity stress on this critical immune function remain poorly understood. Haemocytes were extracted from Scottish rope-grown *Mytilus* spp. and exposed to salinities of 33, 20 and 13 parts per thousand (ppt) representing standard marine conditions, moderate hyposalinity and severe hyposalinity. Phagocytic activity was quantified using pHrodo™ fluorescent beads conjugated with *Staphylococcus aureus*, *Escherichia coli*, and Zymosan particles over 3-hour live imaging sessions. Additional experiments examined combined salinity and heat shock effects. Cells incubated at marine salinity (33 ppt) sustained stronger long-term phagocytic responses than those at 20 ppt or 13 ppt; severe hyposalinity uniformly suppressed phagocytosis. While mild hyposalinity produced a transient increase in phagocytic activity, likely representing a change between immune function and osmotic stress tolerance. Optimal survival conditions were modelled at 28.4 ppt and 10.4°C. Severe hyposalinity combined with heat stress severely compromised haemocyte function. These findings highlight the vulnerability of mussel aquaculture to climate driven multi-stressor events and suggest that extended observation periods are essential for accurate assessment of phagocytic capacity.

The intensification of aquaculture has largely simplified ecological structures, leading to the dominance of monoculture systems, truncated trophic pathways, and limited contributions of natural food webs to production. However, there is growing interest in more complex systems, such as integrated and multi-species aquaculture, due to their potential benefits in nutrient recycling and resource-use efficiency. Optimizing stocking densities, species assemblages, and feeding strategies in such systems requires a detailed understanding of predator–prey interactions, energy and nutrient flows among functional groups, and overall ecosystem functioning. These challenges highlight the need for analytical frameworks capable of representing multi-species aquaculture systems as ecological networks rather than isolated production units.

Among ecosystem modelling tools, the Ecopath with Ecosim (EwE) framework has become one of the most widely used approaches for analysing aquatic food webs, owing to its balance between simplicity and ecological realism, as well as its relatively low data requirements. Originally developed to construct mass-balanced representations of marine ecosystems^{1,2}, it has been increasingly applied to aquaculture systems. However, aquaculture systems differ substantially from large-scale, open marine ecosystems. They are typically characterized by simplified community composition, short production cycles, and small-scale, engineered environments. Consequently, this emerging field of application raises fundamental methodological questions: To what extent can an Ecopath model, originally designed for natural food webs, adequately represent systems under strong human control? How should models be constructed and parameterized for rapidly changing systems of relatively short duration? Which ecosystem indicators are most relevant for aquaculture management and optimization? To date, no review has systematically examined these challenges or provided an overview of research objectives and system types addressed in aquaculture applications of EwE.

In this review, we aim to provide a comprehensive synthesis of how Ecopath has been applied to aquaculture-related questions across system types and geographic regions. Beyond cataloguing applications, we critically analyse these studies by confronting the conceptual assumptions and modelling capacities of EwE with the structural characteristics of aquaculture systems. We seek to clarify both the opportunities and limitations of EwE in aquaculture science. This work also contributes to the development of ecosystem-based aquaculture management strategies that are both ecologically robust and operationally relevant.

DEVELOPMENT OF OSMOTIC AND OXYGEN STRESS MODELS TO EVALUATE SHRIMP RESILIENCE IN EXPERIMENTAL SYSTEMS

Thanh Chau, Pyae Phyo Hein, Tam Nguyen, Loc Tran

Researcher at ShrimpVet Laboratory
Vietnam
Email: thanhchau@shrimpviet.com

Shrimp aquaculture systems frequently experience environmental fluctuations such as salinity shifts and oxygen depletion, which can significantly affect shrimp health, performance, and survival. However, many experimental trials evaluating nutritional strategies or functional feeds are conducted under relatively stable conditions, which may not fully reflect the challenges encountered in commercial farming environments.

This study presents the development of controlled abiotic stress challenge models designed to evaluate shrimp robustness and tolerance under experimental conditions. Two environmentally relevant stressors were investigated: osmotic stress induced by salinity shifts and oxygen depletion through controlled reduction of dissolved oxygen levels. The models were designed to generate reproducible stress responses while maintaining experimental consistency.

Different stress intensities were explored to address various experimental objectives. Acute stress models can be used to rapidly assess shrimp tolerance thresholds, while mild or moderate stress conditions applied over longer periods may allow shrimp to physiologically adapt and reveal more subtle differences among treatments. Such approaches may also be more appropriate for evaluating responses at different shrimp stages or sizes.

The development of standardized abiotic stress challenge models focusing on osmotic and oxygen stress may provide valuable tools for evaluating functional feeds, nutritional interventions, and management strategies aimed at improving shrimp resilience. These models may help bridge the gap between laboratory trials and real farming conditions and support the development of more robust shrimp production systems.

DIETARY PHYTOBIOTIC ADDITIVE UNLOCKS KEY MOLECULAR PATHWAYS DRIVING ACCELERATED WOUND REPAIR IN ZEBRAFISH

I-T. Chen^{1*}, C-D. Hsiao², A. Makol¹, and W. Nuez-Ortín¹

¹ Adisseo S.A.S, France

² Chung Yuan Christian University, Taiwan

*i-tung.chen@adisseo.com

Introduction

Skin integrity is essential for fish health and is the primary biological barrier against environmental stress and pathogens. While the phytobiotic-based feed additive (APEX, Adisseo) has previously been shown to accelerate wound healing and skin regeneration in zebrafish, the underlying mechanisms are not yet fully understood. This study uses transcriptomic analysis to examine how the additive modulates the molecular pathways required for skin repair and barrier restoration.

Material and Methods

Adult zebrafish (*Danio rerio*) were randomly assigned to three groups: uninjured control, wounded control, and wounded with the additive supplementation. The additive was administered orally twice a week for 14 days before wound induction. Precise 2-mm circular skin wounds were created using laser ablation. At Day 10 post-injury, skin tissues were collected to study gene activity during the active repair phase. Transcriptomic profiling was performed using Illumina paired-end RNA-Seq to identify differentially expressed genes (DEGs) based on the criteria of (|Fold Change| > 2, *p.adjust* < 0.005) and to characterize specific biological pathways influenced by the additive during the recovery process.

Results

Supplementation with the phytobiotic-based additive significantly improved wound closure efficiency, which represents an increase of nearly 40% compared to the untreated wounded control group. Transcriptomic analysis showed that untreated fish responded to injury with a broad decrease in homeostatic functions. Specifically, blood coagulation and the angiogenic cluster, including regulators such as *vegfc*, *etv2*, and *robo4*, were suppressed, indicating a disruption of the vascular infrastructure needed for nutrient delivery. In contrast, additive supplementation led to a clear reactivation of these molecular processes. The additive increased the activity of pathways related to the steroid biosynthetic process for cholesterol synthesis and cell membrane repair, blood coagulation, complement activation, and the regulation of wound healing. Furthermore, the activation of the PPAR signaling pathway and the presence of the structural protein HSPG2 show that the tissue moved successfully from the inflammatory phase into organized remodeling.

Conclusion

These findings show that the functional additive accelerates skin healing by restoring blood supply and providing essential metabolites for repair. By activating steroid biosynthesis and signaling pathways for growth, the additive effectively supports recovery, leading to faster wound closure and a return to a healthy state.

Figure 1. Zebrafish transcriptomic profiling after skin wounding. Precise laser-induced wounds were used to characterize the molecular mechanisms and signaling pathways modulated by the functional additive during skin repair.

MULTITISSUE PROTEOMIC INSIGHTS REVEAL HOW A PHYTOBIOTICBASED ADDITIVE ACTIVATES AN INTEGRATED IMMUNE DEFENSE NETWORK IN GILTHEAD SEABREAM

Introduction

Fish rely on the complex interaction of innate and adaptive immunity to manage pathogens. However, intensive production conditions create stressors like high stocking densities, temperature fluctuations, and plant-based protein sources that act as catalysts for disease. These factors often lead to chronic inflammation, immune exhaustion, and physiological depression, resulting in significant economic losses. Dietary functional additives offer a preventive strategy to support health and reduce disease severity. This study utilized high-throughput proteomics to underline how a phytobiotic-based additive (Sanacore GM, Adisseo) enhances immunocompetence in fish.

Material and Methods

This trial utilized gilthead seabream (*Sparus aurata*) with an initial body weight of 100g. These fish were reared under optimal conditions at a density of 6kg m⁻³ for 6 weeks until reaching an average size of 160g. To study the proteome profiles, primary immunoregulatory organs were collected: the anterior intestine (frontline barrier), the liver (phagocytic coordination center), and the head kidney (primary immune cell factory). The analysis was performed using shotgun proteomics (LC-MS/MS) and advanced protein network analysis to identify differentially expressed proteins (DEPs) and their associated biological functions.

Results

The proteomic analysis revealed a total of 2,197 annotated DEPs across the three tissues, revealing that the additive provides a holistic reinforcement of the fish's integrated immune defense network. Rather than independent tissue reactions, the phytobiotic-based additive facilitated a synchronized defense system starting at the frontline barrier and extending through systemic regulation. In the intestine, the additive improved early sensing of threats via the antigen presentation pathway and boosted the ability of local cells to neutralize pathogens through phagocytosis before they could enter the body. It also activated the PPAR pathway to maintain gut integrity through antioxidant and anti-inflammatory responses, reducing the overall infection pressure on the fish. The liver supported this effort by organizing the movement of immune cells via cytoskeletal reorganization and utilizing specialized chaperone proteins to keep proteins correctly folded and functional during stress. Additionally, the liver enhanced MHC class I peptide presentation to help the system mount stronger downstream responses. Finally, the head kidney acted as a high-power regulatory center by significantly increasing the production of defense molecules, including antimicrobial peptides (AMPs) and cytokines. It accelerated pathogen recognition through MHC class I and II molecules and triggered targeted apoptosis in infected cells to stop disease from spreading through the body.

Conclusion

Sanacore GM serves as a comprehensive immunoregulator that synchronizes early pathogen detection in the gut with efficient cellular coordination in the liver and powerful systemic execution in the head kidney. By reinforcing physical barriers and accelerating pathogen recognition, the additive ensures a faster and more efficient immune response under production conditions.

Ammonia nitrogen ($\text{NH}_3/\text{NH}_4^+$) is a critical water quality parameter in aquaculture. Its accumulation can cause physiological stress in aquatic species. This study presents the development of a field-deployable automated monitoring platform based on Sequential Injection Analysis (SIA). The innovation lies in the extreme miniaturization of the fluidic manifold and the integration of a custom-designed signal conditioning unit. By employing an automated air-scouring sequence and a streamlined in-line heating architecture, the platform ensures highly stable reaction conditions while maintaining a compact footprint. Experimental validation demonstrated exceptional analytical sensitivity, achieving a striking 2.52 V peak signal for trace-level ammonia (100 ppb). This synergy between custom electronics and optimized mechanical design provides a highly reliable, low-maintenance tool for real-time aquaculture management.

1. Introduction

Continuous ammonia quantification is essential for precision aquaculture. However, commercial automated sensors often suffer from excessive bulkiness, insufficient trace-level sensitivity, and high maintenance in field environments (Silva et al., 2025). To address these issues, this study develops a field-deployable SIA platform (Mesquita et al., 2020). By miniaturizing core components, the proposed system delivers highly sensitive continuous monitoring with significantly reduced software dependency.

2. Methodology

The system leverages a precision syringe pump (Cavro XCalibur) coupled with a streamlined fluidic manifold to execute fully automated sampling and reagent mixing protocols. As illustrated in the system architecture (**Figure 1A**), the platform utilizes a decoupled thermal control design. A standalone hardware PID controller is implemented to maintain stable reaction temperatures in the holding coil during the 0–420 s incubation phase, independent of the main software operation.

Furthermore, an automated in-line air-scouring step is integrated to continuously purge residual microbubbles from the flow path. For signal processing, the raw analog output from the PMT-based detector (JASCO FP-1520) is directly routed to a custom signal conditioning board. This dedicated circuit performs localized background subtraction and low-pass filtering to ensure signal clarity prior to digitization.

Figure 1. (A) Schematic diagram of the field-deployable SIA platform, detailing the integrated fluidic and electronic modules. (B) Analytical chronogram of five consecutive measurements, showing consistent peak signals and a stable baseline following the air-scouring process.

(Continued on next page)

3. Results and Discussion

The performance of the system was evaluated through consecutive automated measurements. As shown in the analytical chronogram (**Figure 1B**), the system demonstrated highly stable operation over five cycles ($n=5$). The implementation of the air-scouring mechanism effectively eradicated optical artifacts and baseline drift typically caused by microbubble accumulation. Crucially, the processed analyte signal for a trace ammonia concentration of merely 100 ppb reached a peak intensity of 2.52 V. This high signal-to-noise ratio is primarily attributed to the custom signal conditioning board, which effectively filters environmental interference and stabilizes the baseline without relying on software post-processing. By isolating the fluidic control and thermal acceleration into a streamlined, modular hardware architecture, the platform successfully overcomes the portability and sensitivity bottlenecks of conventional field-deployed sensors.

4. Conclusion

The developed SIA module demonstrates a significant advancement in hardware-centric miniaturization for aquaculture monitoring. The primary contribution of this work is the realization of an ultra-compact monitoring core ($\sim 15 \times 20 \times 20$ cm³) that integrates proprietary signal conditioning electronics for high-fidelity data acquisition at trace levels. By focusing on mechanical streamlining of the heating mechanism and hardware-level noise suppression, the system achieves stable measurements with minimal software intervention. This robust, miniaturized architecture offers a scalable solution for integration into next-generation aquaculture IoT networks.

AT THE CROSSROADS OF CLIMATE AND DISEASE: AUTOPHAGY COUNTERS NERVOUS NECROSIS VIRUS INFECTION IN *Epinephelus coioides* UNDER HEAT STRESS

Introduction

The orange-spotted grouper, *Epinephelus coioides*, is one of the most valuable aquaculture species in tropical and subtropical Asia. However, it faces two major challenges, *i.e.* infection by nervous necrosis virus (NNV) and rising heat stress due to climate change (Chen *et al.*, 2010). Both of these stressors disrupt cellular balance and activate two key protein quality control systems, namely the heat shock response (HSR) and autophagy. These systems do not work independently. Instead, they interact closely and influence whether cells adapt and survive, or collapse under stress. In this context, LC3 and HSF1 serve as useful markers. Together, they provide a practical way to study how HSR and autophagy interact during viral infection and thermal stress in fish (Dokladny *et al.*, 2015). Understanding this interaction could lead to new strategies for disease control and aquaculture management, such as targeted antiviral approaches for NNV susceptible species or improved acclimation methods to enhance resilience to warming conditions. Addressing these combined challenges is becoming increasingly important for the aquaculture industry.

Materials and Methods

Orange-spotted grouper larvae, from Taiwanese aquaculture sector, reared in the Translational Center for Marine Biotechnology of National Cheng Kung University were used. Grouper fin epithelium cell line, GF-1, was obtained from the developer and cultured until ~80% confluence before subjected to experimental treatments. The NNV used in the present study was isolated from local diseased fish and prepared according to previous report (Chen *et al.*, 2010). The relative expressions of genes of interest were measured by RT-qPCR, and the protein levels were quantified by immunoblot with specific antibodies. The NNV capsid protein, autophagosome and lysosome signals were determined by immunofluorescence staining and visualized by LSM 780 confocal microscope.

Results and Discussion

To better understand how these protective pathways function under stress, we cloned and characterized the autophagy marker LC3 from *E. coioides* (*osgLC3*). We then examined how it responds to three relevant stress conditions, including low salinity, NNV infection, and high temperature. At the molecular level, *osgLC3* encodes a conserved protein of 126 amino acids, closely related to LC3b proteins found in both Teleostei and mammals. This highlights the strong evolutionary conservation of the autophagy system. Expression analysis showed that *osgLC3* is present across all major tissues, suggesting it plays a general, ongoing role in maintaining protein balance rather than acting only during stress. Under low-salinity conditions (5 ppt), *osgLC3* expression gradually increased, along with a rise in the LC3-II/LC3-I ratio over 72 hours. This confirms that *osgLC3* is a reliable indicator of autophagy activity and shows that hypo-osmotic stress can directly trigger autophagy in groupers. During NNV infection, a different but related pattern emerged. In grouper fin (GF-1) cells, autophagosome formation was observed as early as 6 hours after infection. In infected larvae, *osgLC3* protein accumulated significantly in damaged brain tissue. Both gene expression and protein activation were concentrated in the brain and eyes, which are the main targets of the virus. This spatial pattern indicates that autophagy is activated directly at sites of viral damage. Heat stress added another layer of regulation. Exposure to 36°C enhanced both *HSF1b* and *osgLC3* expression, and overexpressing *HSF1b* alone was enough to stimulate *osgLC3* transcription. This suggests that the HSR can act upstream of autophagy. However, the relationship is not one-way. Increasing *osgLC3* levels suppressed *HSF1b* activity, revealing a negative feedback loop in which autophagy helps regulate its own activation pathway. This balance appears essential to prevent harmful overactivation of either system. The effects of these interactions on viral infection were significant. Enhancing autophagy, either with rapamycin or by overexpressing *osgLC3*, significantly inhibited NNV replication and capsid protein levels. This shows that autophagy acts as an effective antiviral defense in groupers. In contrast, heat stress and increased *HSF1b* expression promoted viral replication. This indicates that HSR and autophagy are not simply parallel responses but can have opposing effects on infection outcomes. Overall, these findings highlight

(Continued on next page)

autophagy as an important immune defense in fish and reveal a dynamic, two-way regulatory relationship between HSR and autophagy. This interaction helps explain why fish exposed to high temperatures may be more vulnerable to NNV outbreaks. It also suggests practical strategies for aquaculture, such as promoting autophagy to enhance antiviral resistance or selecting for improved thermal tolerance. Together, these approaches could help strengthen grouper farming against both disease and climate related stress.

HYDROXY-SELENOMETHIONINE SUPPORTS SELENIUM STATUS, ANTIOXIDANT CAPACITY, AND RESILIENCE ACROSS FISH SPECIES

I-T. Chen^{1*}, A. Makol¹, D. Prévéraud¹ and W. Nuez-Ortín¹

¹ Adisseo S.A.S, France

[*i-tung.chen@adisseo.com](mailto:i-tung.chen@adisseo.com)

Selenium is an essential micronutrient for mitigating oxidative stress in fish, as it is required for the synthesis of key antioxidant selenoproteins, including glutathione peroxidase (GPx) and thioredoxin reductase (TrxR). Its biological effectiveness depends strongly on the chemical form supplied in the diet. Selenomethionine (SeMet) can be incorporated into body proteins, particularly in muscle, creating a selenium reserve that can be mobilized when antioxidant requirements increase. Analysis of commercial fishmeals showed that SeMet represented only a small and highly variable proportion of total selenium, even in premium-grade fishmeal. This highlights the importance of considering selenium speciation rather than total selenium content alone.

This review summarizes evidence from studies evaluating hydroxy-selenomethionine (OH-SeMet), a pure organic selenium source (Selisseo, Adisseo), in freshwater and marine fish under different dietary and production conditions. Improved selenium status was consistently observed following OH-SeMet supplementation across studies comparing different selenium sources. Muscle selenium deposition increased by up to 80% in gilthead seabream, while increased tissue selenium deposition was also observed in giant grouper. Higher selenium deposition strengthened antioxidant protection by supporting GPx activity and limiting lipid peroxidation. Under chronic heat stress, OH-SeMet increased muscle selenium deposition and reduced lipid peroxidation by 43% in gilthead seabream, demonstrating greater protection under challenging conditions. OH-SeMet supplementation also supported reproductive performance. In rainbow trout broodstock, higher tissue selenium increased selenium transfer to oocytes and swim-up fry, supported GPx expression and activity in progeny, and improved spawning, hatching success, and early survival. Stronger antioxidant protection also helped preserve final product quality, particularly under stressful conditions. In gilthead seabream exposed to chronic heat stress, OH-SeMet improved fillet whiteness, maintained freshness during ice storage, and enhanced cooked fillet texture.

Together, these findings demonstrate that the value of dietary selenium depends not only on its total concentration but also on its source and bioavailability. By building a mobilizable tissue reserve, OH-SeMet strengthens the antioxidant system and supports reproductive performance, product quality, and resilience under challenging farming conditions

IMPROVING HEAT-STRESS RESILIENCE IN EUROPEAN SEABASS WITH A HEALTH-PROMOTING ADDITIVE

I-T. Chen^{1*}, R. Robles-Arozarena², L. Bermúdez², A. Makol¹, and W. Nuez-Ortín¹

¹ Adisseo S.A.S, France

² Testing Blue S.L., Puerto Real, Spain

[*i-tung.chen@adisseo.com](mailto:i-tung.chen@adisseo.com)

Rising seawater temperatures are becoming an important challenge for aquaculture. Marine heatwaves present an even greater risk, as sudden temperature increases raise metabolic demand while reducing appetite. Fish therefore prioritize energy for stress response and survival, leaving less energy for growth, immunity and recovery. High temperatures can also weaken intestinal integrity, reducing nutrient utilization and increasing health risks.

This study evaluated the efficacy of a functional phytobiotic-based blend of antioxidant ingredients formulated to support fish under high-temperature stress (HeatPro, Adisseo). European seabass (IBW 144 g) were distributed across six tanks in a RAS system, with 14 fish per tank, and assigned to a control or additive-supplemented diet. Fish were fed to satiation twice daily for 12 weeks. They were acclimated at 26°C for 1 week, followed by 8 weeks at 28°C. Heat stress was then induced at 32°C for 1 week, followed by 7 days at 28°C and 7 days at 30°C to simulate temperature fluctuations under farming conditions. Assessments included survival, growth performance, feed conversion ratio, plasma cortisol, glucose and lactate, and hepatic MDA, HSP70 and IGF-1 expression and esterase activity.

Under high-temperature stress, the additive increased survival by 8% compared with the control. Supplemented fish had lower plasma cortisol, glucose and lactate, together with lower hepatic MDA and HSP70 expression, indicating reduced physiological, metabolic, oxidative and cellular stress. Higher IGF-1 expression and esterase activity were also observed. These responses were accompanied by a 12% increase in individual weight gain, a 17% improvement in specific growth rate and a 20% reduction in feed conversion ratio.

Overall, supplementation supported antioxidant defense, reduced the energy required to cope with heat stress and preserved more energy for growth, resulting in better survival, growth performance and feed efficiency.

TEMPERATURE TRENDS IN FISH PONDS IN LORRAINE (FRANCE) FROM 1998 TO 2025

Introduction

Over the past four decades, Europe has warmed at twice the global average pace, becoming the continent with the fastest heating (Copernicus Climate Change Service (C3S), 2025). If the link between atmospheric warming and water body warming is well established on a global scale, a range of other local factors (area, depth, turbidity, watershed morphology, shading, and exchanges with the water table) also play a role in shaping water temperature dynamics (O'Reilly et al., 2015), the variability of which remains poorly characterized for fish ponds.

With 23% of surface area in 2018, the Grand Est region (North-East of France) was the second-largest French region in pond surface area, mainly due to the Moselle department (DRAAF Grand Est, 2021). The latter, with a semi-continental climate, is not escaping current global warming. Therefore, increasing temperature imposes limits on freshwater biodiversity (Lamouille-Hébert et al., 2024). In poikilothermic fish, temperature directly influences key biological functions, including metabolism, ingestion, digestion rate, and reproduction cycles (Souchon and Tissot, 2012). Rising water temperature can also indirectly affect fish population by reducing dissolved oxygen levels, increasing ammonia concentrations, and degrading water quality (Mugwanya et al., 2022; Reid et al., 2019). Together, these effects may favour certain species over others, with potential repercussions for fish farming activities.

In this context, the objective of this study was to analyse the evolution of the thermal regimes of eight fish ponds belonging to the “Domaine de Lindre” between two periods of eight years each separated by 20 years (1998–2005 and 2018–2025) (Hirtz & Gentilhomme).

Materials and methods

Eight ponds within the Seille watershed (4.8 to 599.4 ha, mean depth 1–2 m), hydraulically connected, were selected for their size gradient and the availability of regular thermal records (measures every two or three weeks). Water temperatures (probes mounted on dikes, 60–70 cm depth) were compared between two periods 20 years apart (1998–2005 and 2018–2025), along with daily meteorological data from the nearest Nancy-Essey weather station. Annual thermal cycles were modelled using sinusoidal fitting for each site and year, allowing the extraction of biologically relevant indicators: annual extremes, thermal amplitude, and duration below/above critical thermal thresholds related to cold chilling winter period and hot summer period (thermal stress). Inter-period changes were tested using Spearman's correlation and Wilcoxon tests. Mixed linear models were used to identify which the meteorological factors and/or pond surface area best explained water warming.

Result

The thermal trajectories varied significantly among the ponds. Lindre, the largest pond, showed the most pronounced warming (+1.89 °C mean annual temperature, +1.39 °C seasonal amplitude), while the smallest pond (Armeschouss) cooled. Warming and amplitude changes were strongly correlated with pond surface ($q = 0.929$ and 0.905 , respectively, both $p < 0.01$). Lindre alone showed significant reductions in cold-threshold duration (<9 – 12 °C) and significant increases of the periods above 15 °C and 22 °C, indicating shorter cold periods and longer thermophilic development windows. The best mixed model ($R^2 = 94.3\%$) identified the 3-day mean air temperature as the dominant predictor of water temperature, followed by sunshine duration, with minor site-specific effects.

(Continued on next page)

Discussion

The strong area-dependence of long-term warming ($q > 0.9$) suggests that pond size acts as a genuine climatic integrator rather than a confounding factor: thermal inertia dampens short-term noise in large ponds, revealing decadal trends more clearly, whereas small ponds remain dominated by local hydrology. This scale-dependence also explains why area had no significant effect in the daily mixed model ($R^2 = 0.943$, air temperature-driven), atmospheric forcing governs short-term variability, whereas pond morphology shapes how this forcing translates into long-term trends. Biologically, the asymmetric seasonal warming creates a trade-off: shortened cold spells jeopardize winter vernalization, whereas longer warm periods benefit thermophilic species but raise thermal-stress and eutrophication risks. Under the TRACC scenarios, a projected warming of +2.1 °C by 2050 and +3.3 °C by 2100 (Météo-France, 2026) is expected to intensify these opposing pressures unevenly across the pond network. These findings provide a quantitative basis for a broader project experimentally assessing how such thermal shifts affect gametogenesis, stress, and reproductive success in several fish species of aquaculture interest.

Domestication is an evolutionary process in which the target species must adapt to new captive environmental conditions, resulting in phenotypic and genetic changes (Milla et al., 2021). Some of these changes are recurrent across various mammalian and avian species, constituting the domestication syndrome (Wilkins, 2020). Although similar changes exist (Milla et al., 2021), this syndrome rarely includes teleost fish. Yet, domestication is a major bottleneck for the diversification of aquaculture and the mechanisms underlying the early adaptation of fish to captive environments remain poorly understood, as studies often focus on a single biological function and do not examine the kinetics of these changes. Unlike terrestrial livestock, wild teleost populations are still accessible, providing a unique opportunity to investigate the first stages of domestication and the emergence of domestication-associated phenotypes. Using zebrafish (*Danio rerio*) as a model species, we investigated how key phenotypic traits change during the first generations of captivity and whether these changes converge with those observed in long-domesticated laboratory strains.

Our study combined two complementary approaches: (i) a comparison of four laboratory strains (AB, SJD, TU and WIK) representing independent domestication histories, and (ii) a multigenerational monitoring of a wild-derived population from the founder generation (F0) to the third captive generation (F3). We evaluated a broad range of traits associated with domestication and aquaculture performance, including growth, morphology, behaviour, stress physiology and reproduction.

These approaches highlighted early changes but also revealed that certain traits were expressed differentially later in the process. For instance, the early generations expressed stress-related behaviours, while the domesticated reference population was more aggressive and bolder. These differences persisted at a later stage, with variations in aggression levels among domesticated strains. Likewise, reproductive performance differed between F0 and its descendants (better fertilisation rates and sperm quality) and among domesticated strains. This also applied to morpho-anatomical traits (body weight, relative brain weight). In contrast, other traits showed variations in the early generations but not between the strains, suggesting that the adaptation process may have stabilised. This was the case for pigmentation (decrease between F0 and F2) and basal cortisol levels (increase between F0 and F3). Except for serotonin levels and puberty in males, all measured traits showed significant differences between the early generations or with the domesticated population.

Overall, our results demonstrate that domestication induces rapid but trait-specific phenotypic changes, with distinct temporal trajectories across biological functions. Some traits appear to reflect a common adaptive response to captivity, whereas others remain strongly influenced by domestication history, founder effects or selective breeding. These findings provide one of the first comprehensive descriptions of the kinetics of early fish domestication and offer valuable insights for improving the domestication of emerging aquaculture species.

Introduction

Microbial management in hatcheries is particularly critical during the early larval stages, when larvae are highly sensitive to microbial imbalances and the tank microbiome is still developing. This instability increases the risk of microbial disruptions and opportunistic bacterial proliferation. Beyond pathogen suppression, modern microbial management strategies therefore focus on steering the early establishment of beneficial microbial communities that support water quality, enhance microbial stability and promote larval health. This study evaluated disinfection and MICF-based microbial management strategies during live food production (rotifers and *Artemia*) and assessed their impact on the larval rearing environment and seabream larval performance.

Materials and methods

Identification of Sanolife MIC-F *Bacillus* strains: Pure cultures of the *Bacillus* strains (*B. subtilis*, *B. licheniformis*, and *B. pumilus*) were plated on Tryptic Soy Agar (TSA) and incubated at 37 °C for 24 h. Prior to the start of the trial, strain identity was confirmed using matrix-assisted laser desorption/ionization time-of-flight mass spectrometry (MALDI-TOF MS).

Rotifer treatments: L-type rotifers were cultured on a diet consisting of 85% fresh baker's yeast and 15% Roboost and Vitalgae Nanno. Prior to larval feeding, rotifers were enriched with Easy Dry Selco (EDS). Following enrichment, rotifers were subjected to one of two treatments:

1. **Control treatment:** no use of Sanolife MICF and Sanocare SURE.
2. **Selective microbial management:** a 20min bath applying Sanolife MICF at 2.5 g L⁻¹ together with Sanocare SURE at 1 g L⁻¹ to steer the microbiota of the rotifers

The microbial community associated with rotifers was analyzed using culture-based and molecular methods. Bacterial abundance was determined by plate counts on TSA and on TCBS (Thiosulfate-Citrate-Bile Salts-Sucrose) agar. The amount of *Bacillus* spp. present in the sample were estimated by plating the sample on TSA at 37 °C for 24 h. Additionally, Illumina 16S rRNA gene sequencing was used to identify dominant bacterial phyla.

Artemia treatments: Three production protocols were evaluated. In all treatments, nauplii were produced using EG SEP-Art® or EG SEP-Art® D-FENSE, followed by specific post-hatch management:

1. **Control:** Artemia produced using EG SEP-Art® without additional microbial management
2. **SEP-Art D-FENSE-based management:** EG SEP-Art® D-FENSE cysts were hatched and transferred after 21 h to enrichment tanks, where enrichment was performed using EDS and a water conditioner.
3. **SEP-Art D-FENSE followed by microbial enhancement:** Artemia were produced as in treatment 2. After enrichment, nauplii were rinsed, concentrated to 5 million L⁻¹, and incubated for 30 min with germinated *Bacillus* (Sanolife MIC-F activated for 1 h at 30 °C in sterile 25 ppt water), followed by cold storage with 250 ppm peracetic/peroxide-based sanitizer.

As for the rotifers, identical analyses were conducted using culture-based bacterial plating and Illumina-based 16S rRNA gene sequencing to characterize associated microbial communities.

Seabream larval rearing: Larval rearing was conducted under three live-food-derived microbial management strategies:

1. **Negative control:** live food produced without microbial management.
2. **Positive control:** live food produced using microbially managed rotifers and EG SEP-Art® D-FENSE-based Artemia production.
3. **Microbial control:** live food produced under microbial management protocols combined with MIC-F microbial enhancement.

(Continued on next page)

For each treatment, two replicate 6,000L tanks were stocked with 600,000 justhatched gilthead seabream (*Sparus aurata*) larvae. Greenwater conditions were maintained during the first 30 dph by daily addition of VitAlgae Nanno (60–70 g.m⁻³). Larvae were fed treated rotifers from 3 to 30 dph, AF from 16 to 26 dph, and enriched EG SEP-Art® (D-FENSE) Artemia from 22 to 53 dph. A commercial dry diet (O.Range, INVE Aquaculture, Thailand) was introduced at 19 dph and fed until weaning at 55 dph. After weaning, medium-sized larvae were selected and monitored for an additional three weeks of post-weaning.

Tank biofilm bacterial abundance was evaluated at 30 and 56 dph by swabbing 5 cm² of tank surface, followed by homogenization and plating.

Larval performance was assessed based on survival, growth, stress resistance, deformity incidence, and fatty acid methyl ester (FAME) profiles. At 55 dph, larvae were graded to determine fry survival and quality across treatments.

Results

No significant differences in larval growth or quality were observed among treatments, but clear differences emerged in the microbial profiles of Artemia and tank biofilms. Disinfection-based treatments produced significantly cleaner Artemia, with ~2log reductions per nauplius in both total bacteria and *Vibrio* load. Probiotic *Bacillus* strains were effectively incorporated, averaging $\sim 1.6 \times 10^3$ bacilli per nauplius after 4 h of cold storage in treated Artemia. In tank biofilms, *Bacillus* spp. persisted up to 30 dph when MICF was applied to rotifers, and up to 56 dph at higher levels ($\sim 10^5$ bacilli per 0.5 cm²) when MICF was supplied via both rotifers and Artemia.

Discussion

These findings support the view that microbial management in larval hatcheries contribute to environmental conditioning. By facilitating the early establishment and maintenance of beneficial microbial communities, *Bacillus*-based microbial management strategies contribute to enhanced system stability and resilience. Such advantages are likely to become most evident under suboptimal or stressful rearing conditions, where microbial balance plays a critical role in larval health.

INTEGRATED MONITORING, METABOLOMIC PROFILING, AND MICROBIAL COMMUNITY ANALYSIS OF LAND-BASED CULTIVATION OF *Ulva reticulata* FOR BIO-BASED MATERIAL PRODUCTION

Woon-Yong Choi ^{1*}, In-Yung Sunwoo ¹, Taeho Kim ¹

Introduction

Green macroalgae of the genus *Ulva* have considerable potential as sustainable sources of food, feed, and functional biomaterials. However, reliable land-based cultivation requires optimized environmental conditions and a comprehensive understanding of the physiological, metabolic, and microbial changes occurring during growth. This study aimed to determine suitable cultivation conditions and establish an integrated monitoring framework for the land-based cultivation of *Ulva reticulata*. Its potential as a source of high-value functional compounds was also evaluated.

Materials and Methods

Wild *Ulva* specimens collected from the coastal waters of Jeju Island, Republic of Korea, were isolated and maintained under controlled land-based cultivation conditions. Species identity was confirmed as *U. reticulata* using internal transcribed spacer and **rbcl** sequence analyses. Growth responses were evaluated at nutrient concentrations corresponding to 0–200% Provasoli's enriched seawater medium and irradiance levels ranging from 0 to 100 $\mu\text{mol photons m}^{-2} \text{s}^{-1}$. Biomass production, specific growth rate, and the maximum quantum yield of photosystem II, expressed as Fv/Fm, were measured to determine suitable cultivation conditions. Water temperature, salinity, pH, turbidity, cultivation images, biomass, Fv/Fm, and nutrient concentrations were collected and integrated into a time-series dataset. Untargeted metabolomic profiling was conducted using liquid chromatography–tandem mass spectrometry with C18 and amide columns. Bacterial communities in the cultivation water of blade- and cluster-form cultures were analyzed using 16S ribosomal ribonucleic acid gene sequencing.

Results

The highest growth performance and stable photosynthetic activity were observed at 100% nutrient concentration. Irradiance levels of 50–100 $\mu\text{mol photons m}^{-2} \text{s}^{-1}$ supported efficient growth, with the highest productivity observed at 100 $\mu\text{mol photons m}^{-2} \text{s}^{-1}$. Image-based analysis indicated that green color intensity and mean brightness were more promising proxies for biomass variation than projected area alone. Untargeted metabolomic analysis detected approximately 17,000–18,000 metabolic features and more than 3,000 putatively annotated metabolites. Amino acid- and peptide-related compounds, lipids, and organic acids were predominant. Phenylalanine, threonic acid, gulose, 2'-deoxyguanosine, and oxidized fatty-acid derivatives were identified as potentially valuable compounds for industrial applications. Blade- and cluster-form cultures shared approximately 70% of high-confidence metabolites. However, cluster-form cultures exhibited greater metabolite diversity and higher relative levels of several amino acid-, peptide-, nucleotide-, and lipid-related metabolites. Distinct bacterial community structures were also observed in the cultivation water. Rhodobacterales–*Marivita*-related taxa predominated in blade-form cultures, whereas Flavobacteriia–*Winogradskyella*-related taxa were relatively abundant in cluster-form cultures.

Discussion

The results indicate that nutrient and irradiance conditions are important factors affecting the productivity and physiological stability of *U. reticulata* under land-based cultivation. Image-derived color parameters may provide a non-destructive approach for monitoring biomass changes, although further calibration using directly measured biomass is required. The differences in metabolite profiles and bacterial communities between blade- and cluster-form cultures suggest that morphological development is associated with changes in both algal metabolism and the cultivation-water microbiome. The higher abundance of amino acid-, peptide-, nucleotide-, and lipid-related metabolites in cluster-form cultures may indicate increased metabolic activity and microbial transformation of organic matter. However, further controlled experiments are required to determine causal relationships between microbial community structure, algal morphology, and metabolite production. Overall, the integration of environmental, imaging, physiological, metabolomic, and microbial data provides a foundation for developing predictive models for land-based cultivation and for controlling the production of functional compounds from *U. reticulata*.

Introduction

Quinolones are often used in the livestock and fish farming industries to treat bacterial infections. Flumequine (FMQ), the first fluoroquinolone with antimicrobial activity against a wide range of Gram-negative bacteria, was approved for use in food fish in the EU, China, Vietnam, and Taiwan. The pharmacokinetics (PK) of FMQ have been studied in several fish species, including Atlantic salmon (*Salmo salar*), cod (*Gadus morhua*), goldsinny wrasse (*Ctenolabrus rupestris*), halibut (*Hippoglossus hippoglossus*), turbot (*Scophthalmus maximus*), eel (*Anguilla anguilla*) (Hansen et al., 2000), blunt snout bream (Xu et al., 2016), and lumpfish (Haugland et al., 2019). However, no data are available on its PK and withdrawal time (WDT) in Nile tilapia and Asian seabass, two of the most important farmed fish species in Taiwan. The objectives of the current study were to determine the PK characteristics of FMQ in both species reared at 25°C following a single oral dose of FMQ via medicated feed (20 mg kg⁻¹ b.w.). Tissue depletion and the appropriate WDT of FMQ were also studied following daily oral dosing for five days.

Materials and methods

Twenty-four healthy Nile tilapia (250 ± 50 g) and 24 Asian seabass (200 ± 50 g) were obtained from a commercial aquaculture facility. The fish were reared in freshwater at 25 °C in an indoor system. For the PK study, 4 fish were orally administered a single 20 mg kg⁻¹ dose of FMQ via medicated feed. Blood samples were collected at 2, 4, 6, 8, 10, 12, 16, 20, 24, 36, 48, and 72 h post-treatment for Nile tilapia, and at 2, 4, 6, 8, 10, 12, 24, 36, and 48 h post-administration for Asian seabass. For the tissue-residue study, 20 fish were fed medicated feed at a dose of 20 mg kg⁻¹/day for 5 days. Skin-on-muscle tissues (muscle/skin) were collected from 5 fish per time point on days 1, 2, 3, and 5 post-treatment. FMQ levels in serum and muscle/skin were analyzed by high-performance liquid chromatography with fluorescence detection (HPLC-FLD) as previously described (Rodríguez et al., 2021). PK data were modeled using a one-compartmental framework and analyzed with PKSolver 2.0 under a 1/C weighting scheme. The WDT was calculated from FMQ concentrations in muscle/skin using WT 1.4 software, following EMA guidance (2018).

Figure 1. Serum FMQ concentration-time profile (mean ± SEM) and plot of WDT on Nile tilapia (A and B) and Asian seabass (C and D) following medicated feed at 20 mg/kg and reared at 25°C.

(Continued on next page)

Results

The serum concentration-time profiles and the plots of WDT calculation are presented in Fig. 1. Following a single oral dose of 20 mg/kg FMQ via medicated feed, the elimination half-life ($t_{1/2k}$), maximum serum concentration (C_{max}), time to reach C_{max} (T_{max}), and the area under the serum concentration-time curve (AUC) in Nile tilapia were calculated to be 12.15 ± 1.07 h, 4.72 ± 0.46 $\mu\text{g/mL}$, 17.03 ± 1.49 h, and 214.19 ± 11.58 h $\cdot\mu\text{g/mL}$, respectively. In Asian seabass, the $t_{1/2k}$, C_{max} , T_{max} , and AUC of FMQ were 11.2 ± 1.22 h, 8.55 ± 0.86 g/mL, 9.25 ± 2.15 h, and 261.02 ± 48.62 h $\cdot\mu\text{g/mL}$, respectively. After five consecutive daily doses of FMQ, the minimum serum concentration at steady state ($C_{min(ss)}$) in Asian seabass was 4.77 ± 3.54 $\mu\text{g/mL}$, significantly lower than in tilapia (10.84 ± 5.86 $\mu\text{g/mL}$). In the drug depletion study, FMQ concentrations in the muscle/skin of Nile tilapia and Asian seabass on Day 1 of drug withdrawal were 8.33 ± 4.56 and 5.73 ± 2.99 $\mu\text{g/mL}$, respectively, and quickly fell below the MRL of 0.5 $\mu\text{g g}^{-1}$; the WDT in both fish species was determined to be 5 days.

Discussion

After administration with medicated feed, the T_{max} for FMQ in Asian seabass was 9.25 h, indicating faster absorption than in Nile tilapia (17.03 h) but slower than in Atlantic salmon (Martinsen et al., 1995) and lumpfish (Haugland et al., 2019), where T_{max} values ranged from 6 to 8 h under similar condition. At a dosage of 20 mg kg^{-1} , the C_{max} of 8.55 $\mu\text{g/mL}$ for FMQ in Asian seabass was significantly higher than in Nile tilapia (4.72 $\mu\text{g/mL}$) and gilthead sea bream (1.7 $\mu\text{g/mL}$; Rigos et al., 2003). In contrast, the $C_{min(ss)}$ of FMQ in Asian seabass was significantly lower than in tilapia. Similarly, at 24 h of drug withdrawal, the level of FMQ residue in the muscle/skin of tilapia was higher than that of Asian seabass. By Day 3, the FMQ concentration in Asian seabass had decreased to below the maximum residue limit ($\text{MRL} < 0.5$ $\mu\text{g g}^{-1}$), while the FMQ concentration in tilapia fell below the MRL on Day 5. This study is the first to comprehensively investigate the PK and WDT of FMQ in Nile tilapia and Asian seabass. The findings indicate clear species-specific PK differences, with faster clearance in Asian seabass and greater persistence in tilapia. Accordingly, dosing and withdrawal times should be species-tailored to ensure efficacy and regulatory compliance.

Introduction

Nile tilapia (*Oreochromis niloticus*) is one of the most important aquaculture species worldwide. However, intensifying aquaculture with high stocking densities and high feeding rates has increased tilapia's vulnerability to bacterial infections, particularly streptococcosis. Florfenicol (FF) and thiamphenicol (TAP), both amphenicol antibiotics, are broad-spectrum antibiotics commonly used in veterinary or aquacultural practice. Previous studies have shown that a synergistic combination of FF and TAP is effective against several bacterial pathogens of swine, avian, and bovine origin (Rattanapanadda et al., 2019; Wei et al., 2016), but this combination has seldom been documented in aquaculture. Thus, the aim of this study was to evaluate potential synergistic effects of FF in combination with TAP against clinical isolates of *Streptococcus iniae* and *Streptococcus agalactiae* from sick tilapia, and to assess whether such combinations might serve as a novel *in vivo* therapy.

Materials and methods

Twenty clinical isolates of pathogenic bacteria from the Laboratory of Clinical Microbiology of Aquatic Animals at the National Pingtung University of Science and Technology were used to determine *in vitro* susceptibility to TAP and FF. The minimal inhibitory concentrations (MICs) were determined using the broth microdilution method as described in the Clinical and Laboratory Standards Institute guidelines (CLSI 2020). Checkerboard microdilution assay and Time-kill experiments were used to determine the synergistic effects of FF+TAP combinations, in accordance with guidelines from the National Committee for Clinical Laboratory Standards (NCCLS 1999). To determine the minimum serum concentrations of FF and TAP at steady state ($C_{\min(ss)}$), 21 healthy Nile tilapia (250±50 g) were allocated to three groups and orally administered FF solution (10 mg kg⁻¹), TAP solution (20 mg kg⁻¹), or FF+TAP solution (5+10 mg kg⁻¹) daily for 5 consecutive days, respectively. On days 1, 2, 3, 4, 5, 7, 9, and 12 after the first administration, a blood sample was collected from each fish. Concentrations of FF in the serum were determined using the HPLC-FLD method described by Wu et al. (2026).

Results

Antibiotic susceptibility was tested by broth microdilution, and the results indicated that 38% of *S. iniae* and 67% of *S. agalactiae* isolates were resistant to TAP (MIC ≥ 8 g/mL); however, all *S. iniae* and 58% of *S. agalactiae* isolates were sensitive to FF (MIC ≤ 4 µg/mL). The checkerboard microdilution assays and time-kill experiments showed a synergistic effect (a fractional inhibitory concentration index (FICI) ≤ 0.5) in 50% of *S. iniae* and 50% of *S. agalactiae* isolates. In addition, the $C_{\min(ss)}$ of FF and TAP in Nile tilapia orally administered a reduced dose of FF+TAP combination were 1.36 ± 0.24 and 2.2 ± 0.2 µg mL⁻¹, respectively. In comparison with those in fish treated with FF at 10 mg kg⁻¹ (2.63 ± 0.33 µg mL⁻¹) and TAP at 20 mg kg⁻¹ (3.7 ± 0.64 µg mL⁻¹).

Discussion

Combination therapy is occasionally used to broaden the antibacterial spectrum and slow the emergence of resistant bacteria, while allowing dose reduction to improve fish safety and reduce environmental impact. In the present study, the FF+TAP combination demonstrated *in vitro* synergy (FICI ≤ 0.5) in 50% of *S. iniae* and *S. agalactiae* isolates. Although the $C_{\min(ss)}$ of each drug under combination therapy was lower than that observed with their respective single-agent regimens, the concentrations of FF (1.36 ± 0.24 µg mL⁻¹) and TAP (2.2 ± 0.2 µg mL⁻¹) may still contribute to therapeutic efficacy with a synergistic mechanism. Notably, the combined exposure of FF+TAP remained higher than that achieved by either agent alone, further supporting the potential for maintained antibacterial activity. FF exposure decreased proportionally at half dose, whereas TAP showed a smaller reduction, suggesting a PK interaction, possibly via FF-mediated CYP3A inhibition. Nevertheless, the overall dose reduction is expected to facilitate faster residue depletion and thus shorten WDT. Accordingly, the FF+TAP combination represents a promising dose-sparing strategy; however, its therapeutic performance under reduced dosage should be confirmed by *in vivo* challenge studies.

Methodology

The aquaculture industry is increasingly seeking sustainable alternatives to traditional protein sources. This study evaluated the effects of an experimental diet containing insect meal on the growth performance, feed efficiency, yield indices, and tissue morphology of juvenile Largemouth Bass (*Micropterus salmoides*) in a recirculating aquaculture system. Two experimental diets were formulated with identical compositions, except that one included 15% Black Soldier Fly (*Hermetia illucens*) meal as a replacement for soybean meal used in the scientific control. Both experimental formulations were compared against a standard commercial control. A total of 400 fish (70.7 ± 17.9 g) of mixed sex were randomly distributed into nine tanks (50 fish per tank), with three replicate tanks per dietary treatment. Fish were hand-fed once daily at 1.5% of body weight, five days per week for five months under natural photoperiod at a mean water temperature of 21.5 °C. Furthermore, a carbon footprint assessment was conducted using literature and database data.

Results and Discussion

Both experimental diets significantly outperformed the commercial control in terms of final weight and length, while no significant differences were observed between the BSF-inclusive diet and the experimental control. This indicates that BSF meal performs as effectively as a standard high-quality formulation. Feed efficiency was notably improved in both experimental groups, characterized by a lower feed conversion ratio (FCR) and a higher specific growth rate (SGR). While somatic indices showed enhanced fillet yield in experimental groups, histological analysis confirmed a satisfactory health status across all treatments. Intestinal histomorphometry remained unaffected by diet, proving that BSF meal maintains intestinal integrity. Furthermore, reduced hepatocyte vacuolization in both experimental groups suggests improved hepatic cellular integrity compared to the commercial control. The environmental assessment demonstrated that BSF meal inclusion reduced the carbon footprint by approximately 20% (2.09 vs 2.66 kg CO₂ eq. kg⁻¹ feed). These results highlight BSF meal as a sustainable, high-performance protein source that matches the efficacy of standard experimental diets while offering significant environmental benefits for *M. salmoides* production.

Introduction

Computer vision and deep learning methods, particularly convolutional neural networks (CNNs), are increasingly used in precision aquaculture for analysing fish behaviour and appearance. These approaches have been successfully applied to tasks such as feeding monitoring, welfare assessment, and behavioural classification in tanks and sea cages (Føre et al., 2018; Yang et al., 2020). However, the vast majority of existing studies rely on offline processing, in which video data are first recorded and then analysed. Even though many works report that their methods are capable of real-time performance, this is typically demonstrated on pre-recorded datasets rather than during ongoing experiments (Zhao et al., 2019). As a result, these approaches do not allow immediate access to behavioural parameters or intervention during the experiment, and they require the recording and storage of large datasets. In contrast, online/real-time (where analysis is performed during the experiment performance) data processing has been experimentally shown in other domains to enable closed-loop systems, adaptive control, and fundamentally new experimental paradigms (Stowers et al., 2017). Online processing can be performed on-site using specialised low-cost GPU units, without the need to store or transmit data. Such capabilities allow researchers to monitor ongoing processes, detect unexpected events, and dynamically adjust experimental conditions. Despite these advantages, online processing remains largely underutilised in aquaculture research.

In this study, we demonstrate the feasibility and potential benefits of online video analysis in aquaculture by detecting and precisely localising spawning events for artificial pikeperch reproduction.

Materials and Methods

Spawning experiments were recorded using 9 IP cameras under controlled conditions. The fish pair was kept in 1m³ experimental tank with low-light underwater illumination and an artificial nest for several days. The fish exhibits a rotational pattern over the nest during the pre-spawning and spawning periods. Video streams from all tanks were recorded and observed by trained personnel to detect the egg release event. The spawning event is characterised by a short-term increased speed of fish-pair rotation and a curved fish body shape. The video streams were processed using an embedded low-cost computing platform, NVIDIA Jetson Nano. Fish detection was performed using the YOLOv8n model to predict oriented bounding boxes, enabling the estimation of fish position and orientation even under challenging conditions (e.g., overlap and low illumination). The model was trained from existing experiments and applied to the new experiment in the online/real-time regime.

Figure 1. Example of rotational activity processing. Green lines represent fish orientation. The red line indicates that the fish are close to each other, parallel, and it is used for pair rotation velocity calculation.

(Continued on next page)

Spawning behaviour was determined by analysing the mutual rotation of fish pairs above the nest. The angular change between consecutive frames was computed and transformed into rotational velocity. To robustly capture behavioural dynamics, the signal was smoothed using two temporal windows (3 s and 20 s). Spawning events were detected when the difference between short-term and long-term rotational activity exceeded a defined threshold, reflecting a rapid increase in spinning behaviour preceding spawning (see Fig 1).

The method was evaluated on annotated video recordings containing both confirmed spawning events and control sequences without spawning and during the spawning experiment.

Results and Discussion

The proposed approach successfully detected spawning events across multiple recordings and streaming, while no false detections were observed in control sequences without spawning. A short delay (~3 s) was introduced due to temporal smoothing, which remains acceptable for real-time applications. Immediately after the spawning detection, the eggs were extracted from the fish and used for artificial reproduction. This approach increases the accuracy of the pikeperch reproduction.

This work illustrates the broader advantages of transitioning from offline to online analysis. Online/real-time processing provides immediate access to behavioural parameters, enabling continuous monitoring and allowing researchers to intervene during the experiment. This can improve experimental efficiency, reduce data redundancy, and support adaptive experimental design. The presented fish spawning detection serves as a proof of concept demonstrating that current computational resources already allow online analysis of complex behavioural events in aquaculture. The transition from offline to online processing has the potential to significantly enhance both experimental research and practical applications in precision aquaculture.

FINDING THE BALANCE: EFFECT OF FEEDING LEVEL ON GROWTH, CONDITION AND BODY COMPOSITION OF SUBADULT BURBOT *Lota lota* IN RECIRCULATING SYSTEMS

Introduction

Burbot (*Lota lota*) gains attention in European intensive coldwater aquaculture due to its delicate white fillets, high nutritional value comparable to its relative, Atlantic cod, and valuable by-products such as liver, roe, and skin. Burbot exhibits environmental requirements similar to those of trout and achieves comparable growth rates, while demonstrating greater hardiness and lower disease susceptibility than other salmonids. These characteristics position burbot as a promising candidate for diversifying inland freshwater aquaculture (Oliver *et al.*, 2024). Since 2012, commercial hatcheries have emerged in Belgium and Germany and fingerling availability is no longer a bottleneck. Although burbot aquaculture remains in its early stages, Oliver *et al.* (2024) indicate that culture methods are now adequate for commercial production. However, no studies have been conducted on the longterm effects of feeding levels on growth of juvenile burbot weighing over 30 g (Trejchel *et al.*, 2014).

The aim of this study is to determine the effect of feeding levels on growth, condition and body composition of growing juvenile to subadult burbot in RAS to identify the true optimal feeding level.

Materials and methods

In 15 cylindrical 120 L tanks, 60 fish were stocked per tank, of which 32 were individually PIT-tagged. The fish had an average individual body weight of 34.66 ± 7.24 g. All tanks were connected to a single intensive RAS, and the temperature was maintained at 15 °C. Five treatments, each in triplicate, were assigned feeding levels ranging from 0.75 to 2.15% of biomass per day. Fish were fed a commercial diet (Protec, 3 mm, Skretting) using automatic feeders.

Every three weeks, all fish were sedated and sampled. Of each PIT-tagged fish, body weight and length were recorded. Specific growth rate (SGR), thermal growth coefficient (TGC) and Fulton's condition factor (K) were calculated. Total biomass per tank was measured to determine daily feed rations for each treatment and to calculate the biological feed conversion ratio (FCR_b). After the final sampling in week 15, whole-body proximate composition was determined for six randomly selected pooled fish per tank. In addition, the viscerosomatic index (VSI), hepatosomatic index (HSI), and Carcass Yield were measured in eight randomly selected individual fish per tank.

Figure 1: Effect of feeding level on specific growth rate and feed conversion ratio

(Continued on next page)

Table 1: Growth and feed utilization metrics under different feeding levels

Parameter	Feeding level (% BW day ⁻¹)				
	0.75%	1.10%	1.45%	1.80%	2.15%
Individual body weight W0 (g)	34.58 ± 7.48 ^a	34.22 ± 7.06 ^a	34.83 ± 6.28 ^a	34.63 ± 7.45 ^a	34.56 ± 8.13 ^a
Individual body weight W15 (g)	92.62 ± 23.71 ^a	109.40 ± 30.07 ^b	118.69 ± 26.25 ^c	122.61 ± 33.37 ^c	123.21 ± 32.53 ^c
Initial condition factor W0	0.61 ± 0.07 ^a	0.60 ± 0.05 ^a	0.60 ± 0.04 ^a	0.60 ± 0.06 ^a	0.61 ± 0.05 ^a
Final condition factor W15	0.62 ± 0.06 ^a	0.65 ± 0.07 ^{a,b}	0.65 ± 0.07 ^b	0.66 ± 0.07 ^b	0.67 ± 0.07 ^b
Stocking density W0 (kg m ⁻³)	17.23 ± 0.18 ^a	17.07 ± 0.10 ^a	17.30 ± 0.14 ^a	17.09 ± 0.06 ^a	17.20 ± 0.02 ^a
Stocking density W15 (kg m ⁻³)	44.34 ± 0.20 ^a	51.71 ± 2.41 ^b	58.02 ± 2.46 ^c	56.43 ± 0.31 ^c	58.56 ± 1.12 ^c
SGR W0-W15 (% day ⁻¹)	1.39 ± 0.04 ^a	1.64 ± 0.06 ^{a,b}	1.73 ± 0.04 ^b	1.78 ± 0.09 ^b	1.79 ± 0.05 ^b
TGC W0-W15	0.78 ± 0.02 ^a	0.95 ± 0.05 ^{a,b}	1.04 ± 0.04 ^b	1.07 ± 0.03 ^b	1.08 ± 0.05 ^b
FCR _b W0-W15	0.68 ± 0.01 ^a	0.94 ± 0.04 ^b	1.18 ± 0.00 ^c	1.46 ± 0.02 ^d	1.75 ± 0.04 ^e

All data are expressed as mean ± SD. Results were analyzed using a linear mixed-effects model, followed by Tukey's post hoc test. Values marked with different letters show significant differences ($P < 0.05$).

Results and discussion

SGR and TGC increase with feeding level but level off from 1.45% feeding level, while FCR_b steadily increases with further increasing feeding level. Therefore, the optimal feeding level is around 1.45% body weight per day, where SGR is near maximal and FCR_b remains relatively efficient. A feeding level of 1.10% will result in a more efficient FCR_b with only a minor reduction in growth (Figure 1). Fulton's condition factor (K) was lower in only the 0.75% feed level treatment (Table 1). Hepatosomatic Index (HSI) was significantly higher in the 1.45%, 1.80% and 2.15% feeding level treatments compared to 0.75%, while no statistic differences could be shown for Carcass Yield (data not shown).

Introduction

Gilthead seabream (*Sparus aurata*) is a key species in European aquaculture; however, its production is challenged by low-temperature stress, impairing growth, metabolism, and immune function. Increasing thermal variability in Atlantic waters is expected to intensify these challenges by subjecting fish to repeated temperature fluctuations that disrupt homeostasis and limit recovery between stress events. Functional diets enriched with protein hydrolysates from animal by-products are emerging as a strategy to enhance fish resilience under stress by providing bioactive peptides and immunostimulants. However, their effectiveness under fluctuating temperature conditions remains unclear. Therefore, this study aimed to evaluate whether dietary inclusion of poultry or swine protein hydrolysates can mitigate the impacts of fluctuating temperature on growth, nutrient utilisation, and intestinal health in gilthead seabream.

Material and Methods

Juvenile gilthead seabream (~23.8 g) were fed three isoproteic and isoenergetic diets: with 3% of commercial fish hydrolysate (CSPS90; COM), 3% poultry hydrolysate (POULTRY) or 3% swine hydrolysate (SWINE). Fish were fed three times per day to apparent satiety and maintained under constant (CT; 22 °C) or fluctuating temperature (FT; 22-15-22 °C) regimes in a recirculating aquaculture system. Growth and feed intake were monitored every 4 weeks at three time points: before, after prolonged exposure, and post-recovery. At the end of the trial, nutrient utilisation and anterior intestinal morphology were also assessed. Nutrient and energy apparent digestibility coefficients were determined in a parallel trial, at 15 °C and 22 °C.

Results

Thermal regime influenced all measured parameters, with FT reducing body weight, voluntary feed intake, nutrient utilisation, and whole-body composition. Distinct dietary effects were observed despite the influence of temperature. All dietary treatments supported growth, with a trend toward increased performance in the POULTRY group. Differences in voluntary feed intake were observed between diets, with higher values in the POULTRY diet compared to the SWINE diet, alongside differences in whole-body lipid content. Nutrient and energy digestibility was higher at 15 °C than at 22 °C and was not significantly affected by diet. While FT did not affect anterior intestine integrity, it significantly reduced the number of acid and total goblet cells; whereas the POULTRY diet increased goblet cell numbers.

Discussion

The negative effects of fluctuating temperature on performance are consistent with reduced feed intake under thermal stress. The higher feed intake observed with the POULTRY diet may be indicative of differences in palatability, likely related to the presence of low-molecular-weight peptides. This higher feed intake could be linked to the differences in lipid deposition and growth trends. In contrast, the SWINE diet maintained growth despite lower feed intake, indicating differences in nutrient utilisation. The reduction in goblet cell numbers under FT indicates impaired mucosal function, which was partially mitigated by the POULTRY diet. Digestibility was higher at lower temperatures, likely resulting from reduced feed intake at lower temperatures and longer gastrointestinal transit time, which can enhance nutrient absorption efficiency. However, digestibility was not affected by diet, suggesting that absorptive capacity was not directly linked to differences in goblet cell abundance.

*corresponding/presenting b.g.clokie@stir.ac.uk

The Norway lobster (*Nephrops norvegicus*), also known as langoustine, is economically the most important crustacean in the UK, with an annual value reaching £100 million. However, harvested langoustines spoil quickly, typically remaining fresh for only 3 to 5 days. This is caused by specific spoilage organisms (SSOs) – naturally occurring, non-harmful bacteria that grow rapidly in seafood. The accumulation of bacterial metabolites leads to unpleasant odours, resulting in ~30% of the still-edible product being rejected by the customers and discarded as a waste.

Bacteriophages (commonly known as phages) are viruses that specifically infect and kill bacteria. They are the most abundant organisms on Earth and are easily isolated from the environments where their bacterial hosts are found. Due to their high specificity and effectiveness, they are ideal candidates for biocontrol of the bacteria in sectors where antibiotic use is restricted, such as the food and seafood industry.

In this project, we identified how the microbiome changes during degradation within a 16 day period (Elsheshtawy et al., 2026). We then isolated a range of phages that specifically target the dominant SSOs responsible for spoilage in freshly caught langoustines. Subsequently, we assessed their impact on the microbiome and the formation of the malodour causing metabolites such as trimethylamine in a 14-day degradation trial. Our research demonstrated that phages can be used to manipulate the microbiome and alter the rate at which the growth of bacteria that generate undesirable smells during the storage of langoustines occurs.

Introduction

In just four years' time global demand for seafood will exceed supply by 40 million metric tonnes yet aquaculture production in Europe has stagnated, largely due to competition for marine space. Maximising spatial efficiency and sustainable development across competing Blue Economy sectors is fundamental to meeting future aquaculture needs, and thus the Sustainable Development Goals of the United Nations Agenda 2030. In Europe, offshore wind farms (OWF) dominate ocean space and present an ideal candidate for 'multi-use' with aquaculture. However, the open ocean remains largely untapped as a farming resource and consequently production potential within OWFs remains unclear. To encourage investment in and future development of multi-use of OWF and low-trophic aquaculture (LTA), scenario analyses that give an indication of site suitability, production potential, and therefore economic feasibility, are critical.

Methods

Here, we used a coupled 3D hydrodynamic-biogeochemical-sediment model combined with dynamic energy budget/growth models for two key LTA species – *Mytilus edulis* and *Saccharina latissima* – to assess harvest potential within Kriegers Flak OWF in the southern Baltic Sea. We first assessed the spatial variability of 'harvest potential' of the two species within the OWF based on the food and nutrient fluxes to the area and the maximum biomass yield given no depletion of food or nutrients. We used these metrics to assign 'high', 'medium', and 'low' harvest potential areas to both species. Using these harvest potential categories we then explored optimum farming scenarios (see Figure 1 for example) to quantify maximum harvestable biomass of *M. edulis* and *S. latissima* within the OWF area.

Results

We found significantly greater biomass for *M. edulis* farms located in the high harvest potential areas compared to the medium or low harvest potential areas. Equally, harvestable biomass of *M. edulis* significantly increased with increasing distance between farm positions, indicating a strong effect of depletion on growth. On the other hand, low salinities in the southern Baltic Sea strongly inhibited the growth of *S. latissima*, as evidenced by the results of a sensitivity analysis, and consequently no such patterns were evident for this species. Rather, harvestable biomass for *S. latissima* remained very low and non-profitable across all model scenarios. Additionally, we found little spatial overlap in high harvest potential areas for *M. edulis* and *S. latissima*, suggesting the potential benefits of co-culture of the two species in this area is limited.

Discussion

This study represents a significant advancement in spatial planning for OWF-LTA multi-use. The significant difference in *M. edulis* biomass between model scenarios suggests farm placement is crucial to ensuring the economic viability of LTA within OWF, and highlights the need for predictive models to enhance LTA production at the planning stage of multi-use. Our results support future micro-siting decisions of LTA within the Kriegers Flak OWF and, more broadly, outline a methodological framework for assessing harvest potential of LTA species using ecosystem models. This framework can be applied globally to increase the evidence-base for the viability of multi-use of OWF and LTA Blue Economy sectors.

*presenting cclubley@ecos.au.dk

Offshore Wind Farms (OWFs) present promising opportunities for multi-use co-location with Low Trophic species Aquaculture (LTA) in the North Sea and Baltic Sea, leveraging shallow coastal areas and existing infrastructure. Because LTA systems do not require external feeding, this integrated approach significantly reduces expenditure on feed production and marine logistics. Furthermore, co-location offers environmental benefits; in the eutrophic Baltic Sea, farming and harvesting LTA can mitigate excess nutrients, thereby improving localized water quality and supporting marine restoration.

In the context of the Horizon Europe OLAMUR (Offshore Low-trophic Aquaculture in Multi-Use scenario Realisation) project, we developed a Python tool which has also been integrated into the interactive web interface Operational Decision Support System <https://gis.sea.ee/odss/mstool/model>. This tool allows users to choose a location to analyze fuel cost, monthly nutrient intake, and biomass yields for blue mussel (*Mytilus edulis*) and sugar kelp (*Saccharina latissima*) at a high resolution of 200 m x 200 m. Currently optimized for the Kriegers Flak OWF in Denmark, expansions are underway to integrate the Helgoland OWF in Germany.

A key feature of the tool is its ability to model blue mussel intra-farm interactions, assessing potential nutrient depletion and subsequent biomass reduction caused by adjacent farm installations (Figure 1). This capability enables stakeholders to plan multiple farms while mitigating biomass loss.

Since 2003, the European Union has recognized Life Cycle Assessment (LCA) as the preferred framework for evaluating environmental impacts. The micro-siting tool and associated website will incorporate the total environmental footprint of sugar kelp for each cultivation site (Sains de la Maza Larrea, 2026). This integration will enable users to verify whether a given farm, when its own environmental impacts are accounted for, yields a true net environmental gain.

Introduction

This study is part of the POLYRAS¹ project (Interreg GR), which aims to optimize the sustainable production of locally important fish species, such as pikeperch, through polyculture in recirculating aquaculture systems (RAS). Polyculture, a traditional practice in pond aquaculture, aims to exploit species complementarity to improve feed utilization and overall productivity (Thomas et al., 2020). Applied in RAS, polyculture may enhance feed efficiency, increase production and support animal welfare (Kolowski et al., 2014; Thomas et al., 2020; Penka et al., 2021; Amoussou et al., 2022).

This study evaluates, in a recirculating aquaculture system (RAS), whether co-culturing pikeperch (*Sander lucioperca*) with European catfish (*Silurus glanis*), a fast-growing bottom-feeding species, can offer some benefits compared to the monoculture of each species. Specifically, we investigated whether polyculture could maintain or enhance the growth of both pikeperch and catfish, improve overall tank productivity, reduce feed waste, and support species welfare. Results on growth performances and preliminary results on fish welfare are presented in this study.

Material and Methods

The experiment took place over a 174-days experimental period in seven 1 m³ tanks in a RAS supplied with water at 23 °C under a 12L:12D photoperiod. Three experimental rearing conditions were tested: pikeperch monoculture, European catfish monoculture, and biculture of both species (ratio 1:1). The initial stocking density was 8 kg.m⁻³. Tanks in monoculture were run in duplicate and those in polyculture in triplicate. Initial mean body weights were 167 g for pikeperch and 182 g for catfish. Pikeperch were fed with floating pellets (Le Gouessant Percid Grower®, 52% proteins, 15% lipids) to satiation, while catfish received sinking pellets (Coppens Silurus Pro®, 46% proteins, 19% lipids) at a restricted rate of 1.5% of biomass. Growth was assessed monthly by individually weighing 20 fish per species and tank, and total biomass was assessed at the start, mid-point, and at the end of the experiment. Fin condition in pikeperch, as well as fin and barbel condition in European catfish, were evaluated (adapted from Policar et al., 2016) to assess fish welfare.

After a normality and homogeneity test of variances (Shapiro–Wilk and Bartlett tests), an ANOVA with Tukey's post-hoc or Kruskal–Wallis with pairwise Wilcoxon tests were applied as required ($P < 0.05$).

Results

Survival rates were up to 95% for all batches. Final mean body weights were similar between mono- and polyculture for pikeperch (respectively 612 ± 152 g ; CV=24.1% and 602 ± 145 g ; CV= 23.8%) and catfish (respectively 1186 ± 303 g ; CV = 25.1% and 1218 ± 335 g ; CV = 27.1%) with no significant differences ($P > 0.05$). Specific growth rates (SGR) were similar between mono- and polyculture for pikeperch (respectively 0.71 and 0.72) and catfish (respectively 1.05 and 1.08). Food conversion ratio (FCR) in polyculture (0.87) was intermediate between those observed in pikeperch monocultures (1.01) and catfish monoculture (0.82). Period-specific SGR analysis highlighted higher growth in polyculture under specific conditions.

After the first three months of experiment, pikeperch reared in monoculture exhibited significantly better fin condition than those in polyculture ($P < 0.05$), but this difference was no longer observed at the end of the experiment. In contrast, no difference in fin and barbel condition was detected for catfish after three months, whereas at the end of the experiment, individuals reared in polyculture showed significantly better condition than those in monoculture ($P < 0.05$).

(Continued on next page)

Conclusions and perspectives

Our results indicate that pikeperch–catfish biculture in RAS can sustain favorable growth performances without compromising survival rate and welfare of both species. To further evaluate the potential of the system, isotopic analyses are ongoing to identify the source of the ingested feed and confirm the hypothesis of the valorisation of uneaten feed by catfish. Additionally, cortisol levels in pikeperch scales will be measured to monitor physiological stress (adapted from Carbajal et al., 2018). Based on our observations, we suggest that the performance of this biculture may be enhanced through implementation of both cohort management and increased initial stocking density. Feed valorization and a comprehensive assessment of fish welfare will be addressed in future work based on the present results.

Introduction and Aim

Early larval nutrition remains one of the main bottlenecks in marine fish aquaculture, strongly influencing survival, growth, robustness and juvenile quality. Recent advances in inert microdiet technology aim to reduce reliance on live feeds while improving nutritional precision and sustainability, including the use of novel ingredients such as algae-derived components and protein hydrolysates. This work synthesises results from four controlled feeding trials evaluating innovative microdiets during first-feeding and early weaning of two important Mediterranean aquaculture species: gilthead seabream (*Sparus aurata*) and European seabass (*Dicentrarchus labrax*). The overall aim was to assess how dietary formulation and feed processing innovations can enhance larval performance, thereby supporting the development of effective alternatives to live prey in hatcheries.

Experimental design

Trials were performed at IPMA (Portugal) facilities. Larvae were reared in 300 L cylindro-conical tanks (open circulation, 36‰ salinity) under controlled conditions. Seabass were kept at 16.5 ± 1 °C and offered experimental microdiets starting at 8 or 15 days after hatching (DAH) (depending on the trial) through to 50 DAH, under a co-feeding regime with live prey. Seabream were kept at 18 ± 1 °C, with microdiets introduced at 2 or 3 DAH (depending on trial) through to 50 DAH, also in co-feeding with live feed. Dietary treatments in these trials targeted variations in feed formulation — such as peptide hydrolysis level (producing different average peptide sizes), inclusion level of marine protein ingredients, and inclusion of algal fractions — as well as feed processing technology (fluidized bed agglomeration vs. micro-extrusion). Each trial monitored key performance indicators including larval growth (length and dry weight), survival, and incidence of skeletal deformities.

Figure 1. Infographic summarizing Algae Vertical findings on how dietary formulation and feed processing innovations can enhance first feeding larval performance.

(Continued on next page)

Results and Discussion

Across all trials and for both species, the novel microdiets produced by fluidized bed agglomeration (FBA) supported good larval performance, in some cases matching or even exceeding the growth achieved with reference diets produced by standard micro-extrusion. No significant differences in survival or in the incidence of skeletal deformities were observed among dietary treatments within each trial. However, clear species-specific responses to diet were evident. In seabream larvae, diets formulated with larger peptide fractions consistently promoted greater larval length and dry weight compared to diets with more extensively hydrolysed (smaller) peptides. In contrast, seabass larvae showed an opposite trend: at an early stage (22 DAH), a diet containing smaller peptides resulted in improved growth relative to the control, but by the end of the nursery phase (50 DAH) this same diet led to depressed growth performance.

Conclusions

The optimal level and type of marine protein ingredients for maximizing growth differed between gilthead seabream and European seabass. Nonetheless, increased inclusion of algal ingredients (such as microalgae-derived components) yielded good growth in both seabream and seabass, indicating the potential of these sustainable ingredients in larval diets. Overall, these results demonstrate major progress in first-feeding strategies for marine fish, driven by advances in microdiet formulation and production technology and by the use of alternative ingredients (including algae). Crucially, the data show that optimal diet characteristics differ markedly between fish species, and even between developmental stages within a species, indicating that a “one-diet-fits-all” approach is not appropriate. Tailored, species-specific microdiets are therefore essential to maximize larval performance and quality in order to support aquaculture sustainability.

Introduction and Aim

Reliable nursery feeds for whiteleg shrimp (*Penaeus vannamei*) post-larvae need to do more than support fast biomass gain: they must also sustain survival, efficient feed use and the capacity to withstand abrupt environmental challenges. In clear-water nursery systems, where formulated microdiets provide the main nutritional input, small changes in marine ingredient profile, lipid supply or functional supplementation may therefore have consequences that are not fully visible when only final weight is considered. This study combines two controlled feeding studies designed to clarify how microdiet composition affects post-larval performance, physiological condition and robustness. The overall aim was to determine whether marine protein source, lipid level and selected functional ingredients can improve the quality of shrimp post-larvae for hatchery and nursery production.

Experimental design

Both trials were conducted under clear-water experimental nursery conditions using inert microdiets produced at Sparos Lda (Olhão, Portugal) and shrimp rearing at Riasearch Lda (Murtosa, Portugal). In the first study, five microdiets were compared over 21 days: a formulation based on a fish and squid meal blend, three diets dominated by fish meal, squid meal or krill meal, and a fish-meal diet with higher lipid inclusion. The main diet set was formulated around similar protein and moderate lipid contents, while the high-lipid fish-meal diet increased lipid inclusion from approximately 14% to 16%. Growth, relative growth rate, feed conversion ratio, survival, whole-body composition, oxidative stress biomarkers, immune parameters and the expression of antioxidant- and immune-related genes were evaluated. In the second study, shrimp were fed from 19 to 40 days after hatching with four selected treatments: CTRL-, CTRL+, SAFG and ULCTP4. These represented, respectively, a basal diet, a high-quality marine-based formulation, the later formula supplemented with beta-glucan, and the same base supplemented with broken-cell microalgae plus seaweed biomass. Weight, relative growth rate, survival, feed intake and feed conversion ratio were assessed, followed by a salinity-stress challenge to evaluate post-larval resilience.

Results and Discussion

The two datasets converged on a central message: growth was comparatively stable across diets, whereas survival, feed efficiency and condition-related indicators were more responsive to formulation. In the marine ingredient trial, final wet weight and relative growth rate did not differ significantly among treatments, with an overall mean final weight of 255 ± 26 mg and relative growth rate of $15.1 \pm 0.5\%$ day⁻¹. However, survival and feed conversion separated the diets. The fish-squid blend and krill meal formulations reached survival values close to 80%, while the high-lipid fish-meal formulation showed the lowest survival ($41.5 \pm 15.0\%$) and a higher feed conversion ratio than the krill meal diet. Single-source marine protein diets did not provide the same overall profile as the blended marine protein or krill-based diets, indicating that ingredient quality and complementarity can be more relevant than growth alone suggests.

Physiological and molecular measurements helped explain these differences. Shrimp fed the high-lipid fish-meal diet showed higher catalase, glutathione S-transferase and pro-phenoloxidase activities than shrimp fed the krill meal diet, indicating stronger activation of antioxidant and immune pathways. Gene-expression patterns also separated the fish, squid and high-lipid fish-meal diets from the fish-squid blend and krill meal groups. In particular, multivariate analysis of transcripts associated with antioxidant defence and immune condition discriminated the high-lipid and the fish meal treatments, from other formulations, supporting that excess lipid inclusion increased physiological cost without improving growth, and fish meal should not be used in as dominant ingredient.

(Continued on next page)

The functional-ingredient trial reinforced the message that growth stays stable across diets, but PL robustness does not. Final body weight and relative growth rate were not statistically different among these four diets. Nevertheless, the basal CTRL- diet had the lowest survival ($13.6 \pm 1.15\%$) and the poorest feed conversion ratio (1.63 ± 0.25), together with the highest feed intake (0.59 ± 0.05 g shrimp⁻¹). CTRL+, SAFG and ULCTP4 all improved survival relative to CTRL-, reaching $21.6 \pm 1.29\%$, $24.9 \pm 3.44\%$ and $23.6 \pm 11.37\%$, respectively. Feed conversion also improved in the same treatments, with values of 0.88 ± 0.05 for CTRL+, 0.85 ± 0.04 for SAFG and 0.97 ± 0.08 for ULCTP4. During the salinity challenge, SAFG showed the strongest survival probability among the selected treatments, indicating that beta-glucan supplementation enhanced robustness even when delivered in a high-quality marine-based formulation.

Conclusions

These studies show that similar growth can mask substantial differences in post-larval quality. Survival, feed conversion, resilience to a salinity challenge, antioxidant and immune biomarkers, and gene-expression patterns all provided information that was not captured by final weight or relative growth rate alone. The use of complementary marine protein sources or krill meal improved shrimp post-larval performance and health status under the tested clear-water nursery conditions. Increasing dietary lipid above approximately 14% in a fish-meal formulation did not enhance growth and was associated with poorer survival and higher physiological activation. Finally, beta-glucan supplementation improved robustness, including challenge resilience, even when added to a high-quality marine-based diet. Overall, diet evaluation for shrimp post-larvae should combine zootechnical, challenge and health-related indicators, because a one-parameter assessment based only on growth is insufficient for developing microdiets that deliver viable and resilient animals.

Introduction

Aquaculture represents the fastest-growing sector of animal production. However, its continued growth and long-term viability depends on developing innovative and sustainable aquafeed formulations. Chitin has recently emerged as a promising additive in aquafeeds, due to its potential to improve growth, intestinal health, and immunity of aquatic organisms. In fish, chitin can be degraded by endogenous enzymes (chitinases). However its metabolic response is dose- and particle size-dependent. At appropriate levels, chitin exhibits immunostimulatory properties and improve gut health. Reported effects include increased goblet cell density, enhanced mucus production, and strengthened intestinal barrier. At the molecular level, it modulates the expression of immune-related genes, including pro- and anti-inflammatory cytokines such as *il1 β* , *tnfa*, and *il10*.

Traditionally derived from shrimp and yeast, chitin can also be obtained from insects, which are considered a promising protein source for animal nutrition. Notably, insect farming generates by-products such as pupal exuviae and the exoskeletons of deceased adults, which are rich in chitin. This presents an opportunity to develop value-added feed ingredients. Rainbow trout (*Oncorhynchus mykiss*) is the most extensively farmed freshwater species in Europe, and efforts to improve its sustainable production remain a central research focus.

Within this framework, the ACInA project integrates aquaculture, insect farming, and agriculture into a circular-economy model. The strategy aims to improve sustainability by valorizing waste and enhancing overall resource efficiency. Insects, reared on substrates derived from agri-food by-products, enable their conversion into high-value biomass. Insects' derivatives are used to formulate functional aquafeeds, while aquaculture waste are converted into fertilizers for agricultural use.

In this context, the present study aimed to extract chitin from insects and incorporate it as functional additive into diets for Rainbow trout, to evaluate its effects on fish growth performance and overall physiological responses.

Materials and Methods

Exuviae collection. Agricultural organic by-products were used as rearing substrate for *Hermetia illucens* in a vertical farming system (Baofly S.r.l., Trento, Italy). Insect larvae were reared at 27–28 °C, 70% humidity, and in darkness. At the end of the cycle, exuviae and dead adults were collected, dried, and milled. The recovered products were used to formulate experimental trout diets.

Experimental diets. Starting from a commercial diet specific for rainbow trout (VRM S.r.l., Trento, Italy), which was used as Control diet (C), five experimental diets were obtained: (i) C+ diet, (control diet + 3% w/w chitin); (ii) IM5 diet, (control diet + 3% w/w chitin + 5% insect meal); (iii) IM7 diet, (control diet + 3% w/w chitin + 7% insect meal); (iv) IM10 diet, (control diet + 3% w/w chitin + 10% insect meal).

(Continued on next page)

Experimental design. Three hundred and seventy-five rainbow trout (initial body weight: 200-220g), were initially acclimatized for two weeks at the experimental fish facility Fondazione Edmund Mach; Centro di Trasferimento Tecnologico, San Michele a./A., Italy) and then divided into 12 open circulating tanks (800L; three tanks per experimental group), obtaining five experimental groups. Fish were hand-fed the experimental diets 5 days per week from 2% to 1.5% of the biomass adjusting it by measuring the mean body weight. At the end of the feeding trial, (upon reaching commercial size, 500g, 16 weeks) 5 fish per tank (15 per experimental group) were weighted and zootechnical parameters were measured. Samples from liver, intestine and stomach were obtained and properly stored for subsequent analyses.

Analyses. Biometric and zootechnical indexes: (i) survival rate, (ii) growth performances calculating the specific growth rate (SGR%), and weight gain (WG); (iii) feed conversion ratio (FCR), to evaluate feed efficiency; histological analyses of the liver to assess parenchymal architecture and lipid deposition, and of the distal intestine to evaluate histopathological indices and tissue integrity; molecular expression of genes involved in immune response (*il1b*, *il10*, *tnfa*) and on chitin digestion (*chia*) assessed in distal intestine and stomach, respectively.

Results

Survival was 100% across all experimental groups while no significant differences were observed in zootechnical performance, including WG, SGR and FCR. Liver histology showed a generally normal parenchymal structure in all groups. However, the degree of lipid accumulation varied among treatments. In the distal intestine, no significant differences were detected in the evaluated histopathological indices while supplemented diets affected the density of goblet cells and of supranuclear vacuoles. Considering molecular analysis, dietary treatments modulated immune-related gene expression, influencing the expression of inflammatory markers. Genes related to digestive or metabolic functions were also influenced in response to specific dietary components.

Discussion

Overall, fish maintained optimal health and growth across all dietary treatments, with no adverse effects on general welfare. Histological analyses confirmed normal tissue structure in key metabolic organs, indicating good physiological tolerance to the tested diets.

Dietary supplementation with insect meal proved to be an effective strategy, supporting positive physiological responses in fish. The moderate increase in hepatic lipid accumulation observed was not associated with pathological conditions and is likely related to the fatty acid profile of the ingredients. Differences in goblet cell abundance appears to reflect an adaptive response to chitin, a polysaccharide that can influence gut function by stimulating mucus production.

Chitin may also act as a natural immunostimulant, contributing to enhanced immune efficiency. Therefore, optimizing its inclusion level and physicochemical properties is crucial to improving the nutritional value and functional benefits of insect-based diets, while ensuring fish health and promoting more sustainable aquaculture practices.

Introduction

Climate change represents an unprecedented threat to marine ecosystems, severely impacting the survival and distribution of marine species worldwide. As climate change accelerates, understanding how marine species adapt to environmental stressors has become a critical focus in marine biology. Extreme environments such as the Arabian Gulf can serve as natural analogues for future coastal conditions under global change. Here we studied the pearl oyster *Pinctada radiata* living in extreme environmental conditions along the Qatari coast line.

Environmental Proteomics.

The environmental proteomic approach using nano-LC MS MS is a powerful tool to understand regulating pathways of adaptation to stress in marine species (Tomanek, 2014; Guo et al., 2021; Gajahin Gamage et al., 2022). We analyzed *P. radiata* oyster natural populations from three field stations with contrasted ecological parameters, during two seasons. We used a global proteomic approach using Nano Light Chromatography tandem Mass Spectrometry (nano LC MS MS) to identify regulating pathways of oyster adaptation to extreme environmental temperature and salinity. We analyzed 1 million of hemocytes cells from each oyster, cells being freeze dried for their transfer in our laboratory before total protein extraction. We were able to identify 4,437 unique proteins in each individual sample of cells.

Results and Discussion.

For the first time we were able to analyse proteomics in cells from oyster sampled in their natural habitat, to identify individual mechanisms of adaptation in each population. We identified that 25% of the cell proteome in oyster hemocytes was regulated by the season ($p < 0.001$). We demonstrated that pathways for biomineralization, immunity, response to thermal and oxidative stress, as well as DNA replication, were modified between spring and summer. In the sampling site UmmBab, the oysters *P. radiata* are adapted to extreme salinity stress, surpassing 55 ppt, and exhibited strong size reduction (Figure 1), consistent with environmentally driven dwarfism, as recorded previously (Giraldes et al. 2023; Giraldes et al. 2026). Going deeper in the statistical analysis of our proteomic individual datasets, we were able to identify 375 proteins in hemocytes ($p < 0.001$) whose expression was correlated to oyster weight. Under extreme salinity, we identified proteomic changes in pathways related to mitochondrial ATP synthesis, regulation of protein synthesis, and response to oxidative stress. Overall, our study identified major functional changes in cellular pathways combined with oyster dwarfism as key adaptive responses to extreme salinity stress.

RATIONAL SCALING IN AQUACULTURE DEVELOPMENT: SCALING OUT, NOT ONLY UP

Barry António Costa-Pierce^{1,2*}, Johan Johansen³

Aquaculture facilities of high capital intensity and large demands for space have a risk of disconnection from communities, especially in rural areas. Here, scale becomes not merely technical and economic variables but social-political ones, as all the impacts of scaling are not comprehensively addressed. Scaling requires recognizing the complexities (time, different investment types, etc.) involved in facilitating a transition to a new normal, and aquaculture, as a “new” intervention in most of the world outside of Asia, requires systemic, not simplistic, scaling strategies. Overhyped scaling-up narratives can attract capital prematurely, ignore ecosystem and social limits, and undermine credibility if failures occur.

Conventional scaling up assumes that a successful pilot can be replicated elsewhere, that increasing size equals success, and that technical solutions can simply be transferred. Controlled, pilot project environments don’t always scale up. Pilot projects often rely on external funding, high-level technical, often-imported, leadership, and temporary incentives/subsidies. Such conditions do not represent real-world complexity. Many pilots fail because markets are not ready, governance is not aligned, and producers lose sustained incentives/subsidies. Smaller, economically viable aquaculture farms located in rural areas are more manageable, involve less risk, and produce less wastes, allowing integrated landscape designs for wastes as additional income sources in circular bioeconomies in contrast to mega-farms. Scaling up production without scaling value chains is unstable. Improper planning for scaling up can increase ecological impacts, concentrate economic power leading to even greater income disparities, marginalize small-scale producers, outpace governance capacity, and create social opposition. We suggest that aquaculture development not only consider scaling up growth in size or production output but also consider all scaling options to move toward strategies that embed ecological limits, social legitimacy, participatory governance, capacity building and institutional learning as the core tenants of sectoral expansion.

(Continued on next page)

Scaling Out Strategies: Aquaculture Ecotourism

There is a path of rational scaling rarely considered in aquaculture development by governance systems or investors - *scaling out* - not only scaling up (Figure). Scaling out strategies emphasize partnerships for well developed models at scale, replication, institutional diffusion, stakeholder and governance alignment rather than simple size and production expansion. Scaling out requires inter-sectoral partnerships who develop economically viable, smaller scale aquaculture models that can be distributed widely over diversified ecologies and networks. Tourism contributes ~10% of global GNP. Aquaculture ecotourism is one practical way to add value to aquaculture without necessarily scaling production volume, as it has similar network diversity, attention to value addition, and branding. Aquaculture ecotourism is most compatible with experiential, nature-based tourism. Aquaculture ecotourism (farm visits, participatory monitoring, food experiences, place-based narratives) creates new interfaces among producers, communities, scientists, educators, policymakers, conservation NGOs, and consumers. Its main benefits are: (1) Income diversification and creation of local, mostly rural, jobs via farm tours, tastings, festivals, snorkeling/diving, and education experiences that diversify and create new revenue streams and employment that can buffer farmers from commodity price swings and create multiplier economies for communities; (2) Strengthened local food systems (shorter value chains) by creating “eat local” demands and premium pricing for traceable seafood, helping farmers and communities capture more value locally rather than exporting it. Culinary/food tourism strengthens inter-sector linkages, learning, and local economic development; (3) Increased social license and environmental stewardship in rural areas by making production visible and accessible, improving understanding and acceptance when farms are well-managed, and providing an educational and partnership platform for monitoring (citizen science), biodiversity, and conservation practices. Research has shown that increasing and diversifying stakeholder engagement is central to aquaculture’s social acceptability. Partnerships with local academia and technology providers to develop transparent, accessible monitoring platforms can turn farms into living labs and field classrooms, another way to scale out benefits beyond production.

Introduction

Aquaculture is central to the future of sustainable food systems, yet its social acceptance has not fully kept pace with its scientific and technological development. Farmed aquatic foods are still sometimes perceived as less natural, less healthy, or less desirable than wild alternatives, while concerns around animal welfare, disease, food safety, environmental impacts, and production practices continue to influence public trust. In this context, science outreach has an important role in translating research results into clear, credible, and audience-specific messages that explain how innovation can improve welfare, resilience, sustainability, and the production of high-quality aquatic protein.

In a context of global change, increasing pressure on food production, limited natural resources, climate-related stressors, disease risks, and concerns about animal welfare, large research projects must do more than generate new knowledge. They must translate results into accessible, credible, and useful outputs for the audiences that can apply, support, or better understand those results.

Approach

The Horizon Europe project ‘Improving Green Innovation for the Blue Revolution: new tools and opportunities for a more sustainable animal farming (IGNITION)’ provides a case study of strategic science outreach to inform on the sustainable practices and improve the perceptions of aquaculture. The project focuses on animal welfare under climate change scenarios, biomarker discovery, functional feeds, vaccination strategies, genomic tools, non-invasive biosensors, and prediction models for improved health monitoring and production management in aquaculture. These research areas are strongly connected to the One Health concept, recognising the links between animal health, environmental sustainability, food systems, and human wellbeing.

IGNITION’s communication, dissemination, and exploitation materials were developed progressively, following the evolution of the project itself. At an early stage, general materials such as the project flyer and poster were produced to introduce the project as a whole, explain its objectives, and provide a clear overview for broad audiences, including key stakeholders such as researchers, students, industry practitioners, policy makers, civil society, and the general public. As results became available, the materials gained technical detail and were increasingly tailored to specific target audiences and dissemination contexts.

Infographics and videos were then developed as tools to bridge the gap between technical content and public outreach. These formats translate complex project methodologies, scientific concepts, and emerging results into accessible visual narratives. Infographics support the explanation of project methods and results in a simple manner for non-specialist audiences, particularly through social media channels such as Instagram, while also serving as supporting materials in scientific and industry-focused meetings and conferences where project results are presented to specialised audiences. Videos follow a similar logic: some are designed to communicate the project to broader audiences, while others support both communication and dissemination.

Webinars, podcasts, and industry-oriented fact sheets were developed for more technical audiences, including researchers, aquaculture producers, breeders, feed manufacturers, professionals working in aquatic animal health and welfare, nutrition profiles, and other blue economy stakeholders. These materials provide more detailed access to project knowledge, allowing scientific and technical audiences to engage with specific research themes, methods, and outputs. The fact sheets, in particular, translate project findings into concise and practical insights that can support uptake and informed decision-making by the aquaculture sector.

(Continued on next page)

Educational games were developed as a dedicated outreach tool for the general public, particularly younger audiences, families and schools. These materials introduce aquaculture, animal welfare, disease detection, and sustainable production through playful interaction, making them suitable for science days, school visits to partner facilities, public events, and informal learning environments. Their purpose is not only to explain scientific concepts, but also to improve ocean and aquaculture literacy, challenge misconceptions about farmed aquatic animals, and contribute to greater social acceptance of aquaculture as a sustainable food production system.

Relevance and expected impact

This audience-specific approach supports the communication, dissemination, and exploitation responsibilities associated with European Union-funded research, increasing science literacy and the likelihood that project results reach the communities that can use them. For industry stakeholders, targeted materials can help accelerate uptake of innovations related to functional feeds, bioactive compounds, selective breeding, welfare monitoring, and resilience to climate and disease pressures. For scientific audiences, visual and narrative materials can strengthen the presentation of results and support knowledge exchange across disciplines. For non-specialist audiences, accessible outreach can help address persistent misconceptions about farmed aquatic animals and improve understanding of how responsible aquaculture contributes to food security, sustainability, and animal health.

In this way, IGNITION also contributes to improving public understanding of aquaculture as a sustainable means of producing high-quality protein in a world facing population growth, overfishing, environmental limits, and climate change. By matching content, format, language, and dissemination channels to each audience, the project shows that science outreach should not be treated as an end-of-project visibility exercise, but as a strategic process that connects research outputs with societal understanding, sectoral uptake, and long-term trust in sustainable aquaculture.

Background

Early-life stages represent one of the most critical periods in fish development, during which exposure to environmental, husbandry and nutritional stressors can compromise welfare, growth performance and survival. Mitigating stress-related impacts during these stages is therefore a major challenge for both the aquaculture industry and the biomedical research sector that relies on zebrafish (*Danio rerio*) as a model organism.

Bioactive peptides constitute a promising class of functional ingredients capable of exerting regulatory effects beyond their nutritional value. In fish, these compounds have been associated with modulation of the hypothalamic-pituitary-interrenal (HPI) axis, antioxidant protection, enhancement of innate immune functions, improved intestinal health and greater capacity to cope with environmental and husbandry-related stressors. FORTIFISH investigates the application of selected peptide fractions as dietary supplements during critical developmental windows. By targeting physiological pathways linked to stress responsiveness, inflammation, oxidative balance and growth regulation, these functional feeds are expected to improve welfare, robustness and performance in both marine aquaculture species and zebrafish used for biomedical research.

FORTIFISH is an innovative R&D project focused on the development of functional fortified feeds designed to enhance health, welfare and stress resilience in European seabass (*Dicentrarchus labrax*), gilthead seabream (*Sparus aurata*) and zebrafish (*Danio rerio*). Building upon the results obtained in the NOSTRESS project (ALG-01-0247-FEDER-047122), which demonstrated the capacity of selected bioactive peptides to reduce the impact of stressors and improve productive efficiency from the earliest developmental stages, FORTIFISH aims to translate this knowledge into novel nutritional solutions suitable for commercial application.

Methodology

FORTIFISH is led by SPAROS, a pioneering SME in aquaculture nutrition, in collaboration with ATLANTIKFISH, a Portuguese aquaculture company, and a multidisciplinary consortium comprising the Faculty of Medicine of the University of Lisbon (FMUL), Gulbenkian Institute for Molecular Medicine (GIMM), Interdisciplinary Centre of Marine and Environmental Research (CIIMAR), Portuguese Institute for the Sea and Atmosphere (IPMA), S2AQUA CoLAB, Champalimaud Foundation and the Institute for Research and Innovation in Health (i3S).

The project focuses on the formulation and validation of peptide-fortified diets tailored to larval and juvenile fish. Nutritional, physiological and molecular approaches are being integrated to evaluate their effects on stress responsiveness, health and performance. The resulting nutritional solutions are intended for industrial application in marine fish hatcheries and pre-growing systems, supporting improved welfare and more sustainable production practices. In parallel, the project will deliver innovative feeding strategies for zebrafish used in biomedical research.

(Continued on next page)

CIIMAR role in FORTIFISH is related to the study of immune-related biomarkers in fish early-stage juveniles and larvae, which will be complemented with physiological, oxidative stress and growth-related biomarkers by joining forces with S2AQUA and IPMA. Biomarkers will be analysed using enzymatic assays and real-time quantitative PCR, providing an integrated assessment of neuroendocrine, antioxidant and immune responses in fish subjected to experimental stress and pathogen challenges. This approach will enable the identification of dietary strategies that enhance stress resilience, health status and performance during early development.

Expected outcomes

By combining advanced functional nutrition with a strong industry-academia partnership, FORTIFISH aims to establish new standards for early-life-stage fish management, promoting resilience, welfare and productivity across both aquaculture and biomedical applications.

Introduction and Aim

European seabass (*Dicentrarchus labrax*), an important mediterranean aquaculture species, is increasingly threatened by bacterial pathogens, including the gram-negative *Photobacterium damsela* subsp. *piscicida*. Photobacteriosis outbreaks can decimate entire productions, leading to massive losses and economic costs. Limited strategies can be employed on the mitigation of such outbreaks. A promising approach for the industry are functional feeds as prophylactic alternatives. Functional diets with algae derivatives can enhance the immune status and growth, helping in the prevention and outbreak mitigation of pathogen-related diseases.

This study aimed to evaluate how aqueous extracts of *Tetraselmis chui* and *Ulva* sp. combined with established commercial immunostimulants, a β -glucan-rich product and a sulphated polysaccharide product, modulate the immune response and disease resistance after a short term feeding boost followed by a pathogen insult.

Figure 1 - Bubble chart of top 10 KEGG enrichment analysis (per diet) of differential abundant proteins (DAP) in the anterior gut of European seabass-fed experimental diet (Control, Diet 1, Diet 2 and Diet 3) 72 hours after pathogen exposure.

(Continued on next page)

Diet composition and experimental design

This study is comprised of two stages: 1) feeding trial, where fish were fed 4 experimental diets for 5 days. Fish were fed a control diet (CTRL) based on commercial formulations, the CTRL supplemented with a combination of an aqueous extract of *Tetraselmis chui* and, either, the commercially available supplement rich in β -glucans (Diet 1), or sulfated polysaccharides (Diet 2), or CTRL supplemented with a blend of *Ulva* sp. extract and the β -glucans rich product (Diet 3). Inclusion levels were within the range practiced by the industry for feed additives (ppt to ppm). Seabass were fed by hand at 3% fish body weight per day; 2) After the feeding trial, fish were orally infected with a pathogenic strain of *Photobacterium damsela* subsp. *piscicida* (strain: GRDL 19-1 (HK2)), and mortalities were monitored for 8 days. Fish were sampled at three sampling points, before infection, to assess the basal immune status after being fed dietary treatments, and at 6- and 72 hours after pathogen insult, to evaluate the immune response to infection. Liver and head-kidney samples were collected for gene expression analyses, anterior intestine for proteomics, liver for oxidative status, and plasma for humoral immune parameters.

Results and Discussion

Proteomic analysis of the anterior gut showed major modulation 72 hours after pathogen exposure, with major changes in proteins associated with gut integrity and metabolic pathways (figure 1). Gene expression of immune genes in the head-kidney showed a significant modulation with time after pathogen challenge, particularly at 72 hours after infection. Gene expression analysis of liver showed a dietary modulation in genes associated with fatty acid metabolism and energy production at the end of the feeding trial. It was observed a significant upregulation of these pathways-related genes in fish fed the experimental diets when compared to CTRL, being considerably higher in fish fed Diet 2. Genes related to pathogen recognition were also upregulated in the liver after feeding Diet 2. Taken together, data from the present study suggest that supplementing *Tetraselmis chui* extracts with sulfated polysaccharides can have a synergistic effect in enhancing fish basal immune status. However, in the presence of *Photobacterium damsela* subsp. *piscicida*, dietary modulation was not sufficient to elicit a differential response, as it was observed in the proteomic analysis and visual observation where it was noted a intestinal tissue degradation at 72 hours. These findings are consistent with disease resistance data observed after challenge, where fish survival ranged from 30.8% in Diet 3 to 17% in Diet 2 after 8 days, with no significant differences observed between treatments.

CONSUMER PERCEPTIONS OF ALTERNATIVE AQUAFEED INGREDIENTS FOR FARMED SALMON: A CROSS-COUNTRY SURVEY IN FRANCE, THE UNITED KINGDOM AND GERMANY

Marco Custodio^{1*}

¹ Earthworm Foundation
France

*corresponding/presenting m.freire-custodio@earthworm.org

Introduction

Global demand for aquatic foods is set to grow substantially, with the 2025 EAT–Lancet Commission projecting a 46% increase in aquatic food production to meet planetary health targets by 2050 (Rockström et al., 2025). Meeting this demand sustainably requires further diversification of aquafeed formulation. Salmon farming has traditionally relied on fishmeal and fish oil for essential EPA and DHA, critical for fish health and human nutrition (Santigosa et al., 2023). Over two decades, the European industry reduced marine ingredient dependency by shifting to plant inputs, but this increased land use, carbon emissions, and eutrophication (Kok et al., 2026), while EPA and DHA levels in farmed salmon declined (Hannisdal et al., 2025). The sector must now optimise for both nutrition and environment, requiring a broader basket of ingredients. Promising alternatives exist for both omega-3 supply and protein (Glencross et al., 2023), yet adoption remains limited by cost, retailer restrictions, and perceived consumer rejection. In multi-stakeholder workshops facilitated by Earthworm Foundation involving retailers, processors, farmers, and feed producers, consumer perception consistently emerged as a major barrier to feed diversification yet empirical evidence on actual consumer attitudes remains scarce. This study addresses that gap in the three major European salmon consumer markets responsible for these value-chain restrictions: France, the UK and Germany.

Materials and Methods

Three nationally representative online panel surveys were conducted: in France (July 2024, n = 1,000), the United Kingdom (May 2025, n = 1,000) and Germany (March 2026, n = 1,050); analyses were run on the 2,569 respondents who eat salmon. Quota sampling was applied based on gender, age, socio-professional category, region of residence, and urban area size, in line with national statistics (margin of error: 3%, confidence level: 95%). Data collection was managed by BVA Xsight (France, UK) and Moweb (Germany). The questionnaire comprised five sections: sociodemographic profile, seafood consumption habits, aquaculture and aquafeed knowledge, ingredients acceptance (three for fish oil: microalgae oil, GM plant oil, farmed salmon oil; three for fishmeal: soybean meal, insect meal, poultry meal), and psychographic profile. Data analysis included descriptive statistics, chi-square tests, logistic regression per ingredient, and mixed-effects logistic regression across ingredients with a respondent random intercept, applying Benjamini-Hochberg correction for multiple testing (RStudio, $p < 0.05$).

Figure 1. Willingness to buy farmed salmon fed with alternative ingredients in France, the UK and Germany.

(Continued on next page)

Results

Willingness to buy salmon fed with alternative ingredients was high overall, with notable cross-country differences (Figure 1). Four of the six ingredients were accepted by majorities in all three countries: microalgae oil (77–87%), soybean meal (71–84%), farmed salmon oil (70–79%) and insect meal (65–73%). Resistance was confined to GM plant oil and poultry meal. For GM plant oil, France (39%) and Germany (37%) were statistically indistinguishable while the UK reached 61%; for poultry meal, Germany (63%) and the UK (62%) were indistinguishable while France fell to 40%. Willingness to buy was driven principally by attitudes rather than demographics, with a positive view of farmed fish increasing it and opposition to GMOs reducing it; most effects differed in magnitude between countries. Opposition to GMOs reduced willingness to buy for all six ingredients.

Discussion

These results provide the first cross-country empirical evidence that consumer willingness to buy salmon fed with alternative aquafeed ingredients is higher than commonly assumed by industry actors. While multi-stakeholder consultations consistently identify consumer rejection as a primary barrier to feed diversification, majorities in all three countries would purchase salmon fed with most tested alternatives. Farmed salmon oil, restricted by several retailers on the assumption that consumers reject it, was among the most accepted ingredients tested and the first choice among fish oil alternatives for German and UK consumers. Where resistance does occur it is both ingredient-specific and country-specific, so a single European consumer position cannot be invoked to justify pan-European sourcing specifications. Younger consumers, who are also among the most frequent salmon buyers, show significantly higher acceptance of the two contested ingredients, suggesting that resistance may diminish as this segment matures. Acceptance was driven by attitudes rather than by knowledge, which had no independent effect once attitudes were accounted for. These findings challenge the precautionary stance constraining feed reformulation in European salmon supply chains and offer an evidence base for more sustainable aquafeed strategies.

ARE WE MISMEASURING ENVIRONMENTAL SUSTAINABILITY IN AQUACULTURE?

Luiz H David^{1,*}, Sara M Pinho²

¹ CSIRO, Agriculture and Food, Werribee, VIC, 3030, Australia

² School of Agriculture, Food and Ecosystem Sciences, Faculty of Science, The University of Melbourne, VIC 3010, Australia

Aquaculture is widely promoted as a more environmentally sustainable solution to meet the growing global demand for animal protein when compared to terrestrial food systems. However, this narrative is often grounded in generalised assumptions and aspirational claims rather than in consistently quantified evidence. Even when sustainability is assessed, current approaches may be fundamentally incomplete. Life Cycle Assessment (LCA) is the dominant approach to environmental sustainability assessment in aquaculture research and industry. It provides quantified indicators of environmental impacts, some of which are understood and accepted by the general public, such as greenhouse gas emissions. Yet, by focusing primarily on environmental burdens per a functional unit, LCA overlooks the ecological processes and biophysical inputs that sustain production systems. In particular, it provides limited visibility into the quality of resource inputs, the distinction between renewable and non-renewable environmental support, and the broader ecological dependencies underlying aquaculture systems.

Emergy (with “m”) synthesis offers a complementary perspective to LCA by quantifying the environmental work embodied in both natural and economic inputs, expressed in solar emjoules. This approach explicitly distinguishes between renewable environmental flows, non-renewable local resources, and purchased inputs, thereby revealing system dependency and environmental loading. Emergy synthesis has demonstrated that aquaculture systems vary significantly in their reliance on ecological versus industrial support, a dimension that is not fully captured by impact-based approaches.

Aquaculture systems operate at the interface between natural ecosystems and industrial production, resulting in a wide spectrum of system configurations and resource dependencies. For instance, systems range from extensive pond systems that rely heavily on ecosystem metabolism to intensive recirculating systems dependent on external energy and feed inputs. This variability highlights that sustainability, particularly in aquaculture but certainly not limited to it, cannot be fully understood through a single analytical lens. Despite this, LCA and emergy synthesis are still rarely considered together. As a result, critical resource dependencies, system constraints, and context-specific trade-offs remain hidden, limiting our ability to effectively improve environmental sustainability in aquaculture.

This work argues that sustainability in aquaculture has been systematically misrepresented when assessed solely through impact-based approaches. It examines what current practice overlooks, explores how a more integrative perspective could be articulated, and reflects on the implications of this shift for improving sustainability assessment and decision-making in aquaculture. Rather than proposing a formal methodological framework, we position LCA and emergy as complementary perspectives that can, and should, be applied together, offering a more comprehensive understanding of both environmental impacts and ecological support (Figure 1).

Figure 1. Integrating emergy and LCA to jointly capture ecological support and environmental impacts in aquaculture systems.

(Continued on next page)

Current practice overlooks the divergence between environmental impact intensity and system dependency, which becomes evident when impact-based metrics are interpreted alongside emergy-derived indicators. Systems characterised by low impacts per functional unit may still exhibit high environmental loading and strong dependence on non-renewable or high-transformity inputs, including compounded contributions from feed production, energy use, and water sourcing. This misalignment suggests that apparent efficiency gains can mask underlying structural dependencies, limiting the ability of current assessments to identify system vulnerabilities and long-term sustainability constraints.

A more integrative perspective can be articulated by interpreting LCA and emergy synthesis results in parallel within a consistent system boundary, allowing environmental impacts and ecological inputs to be evaluated simultaneously. This dual-perspective approach enables the identification of mismatches between impact performance and ecological support, particularly in systems where key drivers such as feed and energy act as both major contributors to emissions and dominant sources of embodied environmental work. By linking these dimensions, the integration provides a more refined basis for comparing aquaculture systems, distinguishing between improvements driven by efficiency gains and those aligned with reduced dependency on non-renewable environmental support.

The integration of these methods has important implications for sustainability assessment and decision-making in aquaculture. It enables the identification of systems that may be optimised for impact reduction but remain highly dependent on externalised environmental support, as well as systems that operate with lower ecological loading despite moderate impact profiles. This distinction is critical for guiding system design, informing sustainability certification, and supporting policy decisions that prioritise long-term resilience over short-term efficiency gains. Ultimately, advancing sustainability assessment in aquaculture requires moving beyond partial metrics and adopting approaches that explicitly capture the interaction between environmental impacts and ecological foundations.

A DECADE OF HABREPORTS: EARLY WARNING OF HARMFUL ALGAL BLOOMS AND BIOTOXINS FOR AQUACULTURE

Keith Davidson^{1*}, Dmitry Aleknik¹, Gregg Arthur², Steve Gontarek¹, Gary Groves¹, Alan MacDonald¹, Tim Szweczyk¹, Callum Whyte¹

¹Scottish Association for Marine Science (SAMS), Oban, PA37 1QA, Scotland, UK

²University of the Highlands and Islands Shetland, Port Arthur, Scalloway, Shetland, ZE1 0PX, Scotland, UK

*corresponding/presenting keith.davidson@sams.ac.uk

Introduction

Harmful algal blooms (HABs) are increases in the density of certain phytoplankton species that are harmful to humans or our use of the marine environment. In many locations, these blooms are of particular concern to the finfish and shellfish aquaculture industries. The phytoplankton genera that are detrimental to these two related sectors are, typically, distinct. Some HAB species cause “shellfish poisoning” that results from the human consumption of shellfish that have ingested toxic cells and then bio-accumulated the toxin within their flesh. Farmed fish are impacted, in general, by different HAB species through physical interference, deoxygenation or ichthyotoxicity.

The negative impacts of a human poisoning event on the shellfish industry can be far reaching. The economic consequences of HABs for the finfish industry can be very high, for example a massive fish kill in Chile in 2016 following a bloom of the dictyochophyte *Pseudochattonella* caused the mortality of 39 million salmon with a cost of \$ (USD) 800 million.

Early warning of the timing, location and magnitude of HABs and their associated biotoxins is therefore of great importance to the aquaculture industry to allow mitigation to be put in place.

Methods, results & discussion

Since 2015 SAMS has produced early warning and risk assessments of HABs and associated biotoxins in Scottish waters for the shellfish and finfish aquaculture industries. Since 2017 these have been provided on the www.HABreports.org web site (Davidson et al. 2021, Figure 1), with a parallel Malaysian (My-HABs) alerts system being developed in 2021/2.

This presentation will discuss the development and content of HABreports including its traffic light alerts, and development of a mobile phone-based App for those users who do not routinely sit at a desktop.

Figure 1: screen grab of www.HABreports.org web site

(Continued on next page)

An important component of our alert system is mathematical models. Lagrangian based unstructured grid (FVCOM) based models are used to simulate the spatial and temporal development of existing blooms to evaluate if and when aquaculture sites may be impacted. In addition, statistical ensemble models using Bayesian and other machine learning techniques are being used within HABreports to predict the onset of blooms at aquaculture prior to their occurrence (Szewczyk et al. 2025).

High resolution and taxonomically detailed monitoring of HAB taxa is crucial to early warning and risk assessment. Recent developments of our alert system have therefore incorporated automated phytoplankton imaging using two Imaging FlowCytobots sited in the aquaculture intensive Shetland Islands. AI based analysis of these image data using a neural network based on the Multi-Axis Vision Transformer allows real time reporting of HAB taxa at a temporal frequency of less than an hour (Groves et al. 2026).

The HABreports system therefore provides rapid, spatially and temporally resolved, monitoring and model based information that informs husbandry practices and business planning within the aquaculture industry protecting both human and fish health.

Early life stages of macroalgae depend on microbial communities that mediate their settlement, development, and survival, yet the ecological processes structuring these communities still remain poorly understood. In particular, the role of microbial predators in structuring host-associated microbiomes has rarely been tested experimentally, despite the ubiquity of predators in natural systems.

Here, we disentangle bottom-up and top-down controls on early macroalgal holobiont assembly and host survival using replicated, closed microcosms of the model Rhodophyte seaweed *Palmaria palmata*. We manipulated settlement substrate type, and trophic structure by independently adding probiotic bacterial communities ('microbial priming'), bacterivorous protists and eukaryovorous protists prior to and during the initial colonisation and settlement of *P. palmata* spores, respectively. Community dynamics were tracked over ten weeks using 16S and 18S rRNA gene sequencing alongside measurements of host settlement, growth, and survival rates.

Trophic complexity fundamentally restructured microbiome assembly and host outcomes. Notably, substrate type influenced spore settlement density; and bacterivorous protists increased bacterial diversity and homogenised community composition, consistent with predator-mediated regulation of lower trophic levels. Whereas eukaryovorous protists enhanced early host survival, likely by suppressing bacterivores and stabilising beneficial bacterial assemblages.

Together, these results demonstrate that microbial predators play a central yet underappreciated role in shaping early holobiont assembly and host survival. Rather than destabilising microbiomes, trophic interactions can promote diversity and host survival by regulating microbial dominance. These findings highlight the importance of incorporating multi-trophic interactions into microbiome ecology and suggest that early predator-mediated processes can have lasting consequences for host recruitment and resilience.

AMPHIBIOUS TECHNOLOGIES FOR SUSTAINABLE AQUACULTURE: INTEGRATING SATELLITE DATA AND IN SITU MONITORING THROUGH THE MAR (MULTIPURPOSE AMPHIBIOUS ROVER)

Eduardo De Francesco, Ruggero De Francesco

Se.Te.L. Servizi Tecnici Logistici srl

Via Casamari 6, Rome - ITALY

e.defrancesco@setelgroup.it, r.defrancesco@setelgroup.it

Introduction

This work presents the integration of satellite data and in situ measurements for improving coastal aquaculture monitoring and management. The MAR (Multipurpose Amphibious Rover), a fully electric amphibious platform, enables high-resolution environmental surveys in complex coastal areas. By supporting validation and calibration of satellite-derived data, MAR enhances the accuracy of water quality mapping. Its real-time sensing and data processing capabilities provide a robust tool for sustainable, data-driven aquaculture.

The project

The development of European aquaculture increasingly requires advanced technological solutions capable of improving environmental sustainability, operational safety, and data-driven decision-making. In this context, the integration of satellite-based observations with high-resolution in situ measurements represents a key opportunity to enhance the monitoring and management of coastal aquaculture systems.

The MAR – Multipurpose Amphibious Rover (www.eco-mar.it) is an innovative, modular, fully electric amphibious platform designed to operate in complex coastal environments such as lagoons, estuaries, and intertidal zones. These areas are often difficult to access and insufficiently covered by traditional monitoring infrastructures, making them ideal candidates for combined remote sensing and ground-truthing approaches.

MAR equipped with a multiparametric probe and with an underwater ROV

(Continued on next page)

This contribution explores the role of MAR as a complementary tool to satellite data, enabling the validation, calibration, and optimization of remote sensing products for aquaculture applications. By performing targeted in situ surveys, MAR provides high-frequency, geo-referenced environmental measurements that can be directly compared with satellite-derived parameters, improving the accuracy and reliability of coastal water mapping.

Key application domains include:

- Integration of satellite and in situ data for enhanced mapping of coastal water quality parameters (e.g., turbidity, chlorophyll, temperature, and detection of pollutants such as microplastics);
- Real-time environmental monitoring through onboard sensors, supporting continuous assessment of ecosystem health;
- Advanced data processing and transmission capabilities, enabling near real-time analysis and decision support;
- Surveillance and inspection of aquaculture infrastructure, combined with environmental data acquisition;
- Support for the optimization of site selection and farm management through improved spatial and temporal resolution of environmental information.

By bridging the gap between satellite observation and field data acquisition, MAR contributes to the development of a more resilient, transparent, and sustainable aquaculture sector. Its application supports the objectives of the European Green Deal and the Blue Economy, fostering innovation in coastal monitoring and strengthening collaboration between research institutions, technology providers, and aquaculture stakeholders.

The presentation aims to promote integrated pilot projects in Mediterranean regions, to demonstrate the added value of combining satellite analytics with autonomous amphibious platforms for next-generation aquaculture management.

REFERENCE GENE VALIDATION FOR BYSSUS-RELATED GENE EXPRESSION ANALYSIS UNDER OCEAN ACIDIFICATION IN *Mytilus galloprovincialis*

Background

Ocean acidification is one of the major challenges affecting shellfish aquaculture. In mussels, reduced seawater pH may alter several physiological functions, including byssus production by the foot byssal glands. Changes in byssus performance under acidified conditions have been reported, although the molecular mechanisms underlying these effects remain uninvestigated. Gene expression analyses are useful to investigate the regulation of byssus-associated proteins under future ocean acidification scenarios, although their reliability depends on the identification of stably expressed reference genes (RGs) for data normalization. Several candidate RGs have been proposed for *M. galloprovincialis* foot tissue [1]. However, their stability under ocean acidification remains to be assessed. The present study aimed to evaluate the stability of nine RGs [Actin B (*Actb*); Elongation Factor 1 α (*Ef1 α*); Cyclophilin A (*CypA*); Glyceraldehyde-3-phosphate dehydrogenase (*Gapdh*); Large Ribosomal Subunit protein eL14-like (*Rpl14*), eL32-like (*Rpl32*), eL34-like (*RPL34*); Small Ribosomal Subunit protein eS4-like (*Rps4*), and Small Ribosomal Subunit rRNA (*18S rRNA*)] in mussel exposed to seawater acidification, using hydrolysis probe-based RT-qPCR. The acidification treatment was chosen to simulate provisional surface pH for 2300 (pH 7.4), following the IPCC projections [2].

Materials and Methods

Mediterranean mussels (*M. galloprovincialis*) were purchased alive from a commercial farm (Sabaudia, Tyrrhenian Sea), randomly assigned to three tanks of a closed and controlled recirculating system, and acclimated for 10 days under control conditions (pH 8.2, 20.1 $\pm$ 0.3 °C). Mussels were fed once a day *ad libitum* with Shellfish Diet 1800® (Reed Mariculture Inc., USA). At the end of the acclimation, pH in the experimental treatment was progressively reduced by CO₂ injection into the system (0.017 pH units/h) and maintained at pH 7.4 (20.1 $\pm$ 0.3 °C). After 7 days of exposure, 5 mussels per treatment were sacrificed, the foot was excised, weighed, and immersed in RNA later solution for 24 h at 4°C. Total RNA was isolated with the GRS total RNA kit (GRISP) and quantified by the QuantiFluor® RNA 2.0 (Promega), using the Quantus Fluorometer (Promega). cDNA was synthesized through the High-Capacity cDNA Reverse Transcription Kit (Applied Biosystem), and qPCR was performed by the Xpert Fast Probe (GRISP) on the StepOne instrument. Primer sequences were selected based on previously published results [1], while custom probes were designed using Primer 3 [3]. According to the MIQE guidelines, candidate RGs were evaluated by RT-qPCR across all experimental samples. Gene expression stability was assessed using geNorm [4], NormFinder [5], BestKeeper [6], and RefFinder [7]. To avoid bias associated with co-regulated genes, the final selection considered both the algorithms' ranking and the biological function of the candidate genes.

Results and Discussion

Amplification efficiencies of the selected genes ranged from 90% to 105%, confirming the suitability of the newly designed probes for RT-qPCR analyses. Gene stability assessment produced largely consistent results across algorithms. geNorm identified *Rpl32* (M = 0.1654) and *Rpl34* (M = 0.1701) as the most stable reference genes, followed by *Ef1 α* (M = 0.1721). Similarly, NormFinder ranked *Rpl32* (stability value = 0.169) and *Rpl34* (0.228) as the most stable genes, with *Ef1 α* (0.358) also showing high stability. BestKeeper analysis revealed the highest correlation coefficients for *Rpl32* (r = 0.995), *Ef1 α* (r = 0.985), *Rpl34* (r = 0.984), and *Rpl14* (r = 0.983), whereas *Gapdh* and *18S rRNA* exhibited the lowest stability across all methods. Integration of geNorm, NormFinder, BestKeeper, and Δ Ct rankings through RefFinder identified *Rpl34*, *Rpl32*, and *Ef1 α* as the three most stable candidate RGs. Although *Rpl34* and *Rpl32* occupied the top two positions in the comprehensive ranking, both encode ribosomal proteins and may therefore be subjected to co-regulation. Notably, *Ef1 α* was consistently ranked among the most stable genes by geNorm, NormFinder, and BestKeeper, supporting its selection as an independent normalization partner, minimizing potential bias associated with the co-regulation.

(Continued on next page)

Conclusion

The probe-based assay developed in this study showed high efficiency and reliable performance. The combined application of geNorm, NormFinder, BestKeeper, and RefFinder enabled the identification of robust RGs for expression studies in the foot tissue of *M. galloprovincialis* exposed to acidified seawater. Among the candidate genes, *Rpl34*, *Rpl32*, and *Efla* displayed the highest expression stability across all algorithms. Considering both stability and biological independence, *Efla* combined with either *Rpl34* or *Rpl32* is proposed as a robust normalization strategy for future studies. These findings provide a framework for investigations on the molecular mechanisms underlying mussel responses to ocean acidification, including those involved in byssus production.

Background

Climate change affects the health of marine bivalves through a variety of environmental stressors. Among them, ocean acidification is considered one of the most pervasive long-term drivers of change to marine ecosystems. It is caused by the continuous absorption of atmospheric CO₂, which lowers seawater pH and alters carbonate chemistry. This can impair physiological functions and reduce the ability of marine organisms to cope with additional stressors [1]. As sessile filter feeders, mussels are particularly vulnerable to fluctuations in seawater chemistry, making them valuable bioindicators for assessing the biological consequences of ocean acidification.

Understanding the physiological and cellular mechanisms underlying tolerance to acidified conditions is therefore essential for the development of effective mussel farming management. This study aimed to investigate the effects of short-term and long-term exposure to reduced seawater pH on hemocyte viability, oxidative status, and innate immune responses in mussels. The experimental conditions were chosen to simulate the provisional surface pH for 2100 (pH 7.8) and the worst-case emission scenario for 2300 (pH 7.4), following the IPCC projections [2,3].

Materials and Methods

Mediterranean mussels (*Mytilus galloprovincialis*) were purchased alive from a commercial farm (Sabaudia, Tyrrhenian Sea), randomly assigned to three tanks of a closed and controlled recirculating system, and acclimated for 10 days under control conditions (pH 8.2, 20.1 ± 0.3 °C). Mussels were fed once a day *ad libitum* with Shellfish Diet 1800® (Reed Mariculture Inc., USA). At the end of the acclimation, whilst the water temperature remained unchanged, pH in the two experimental treatments was progressively reduced to target values (7.8 and 7.4) and then maintained constant by CO₂ injection. Hemolymph was sampled at short-term (10 days; T1) and long-term (35 days; T2) acidification exposure, as previously described [4]. Hemocyte viability was evaluated through the Neutral Red Uptake (NRU) assay, and Optical Density (OD) was measured with a Multiskan (ThermoFisher). Reactive Oxygen Species (ROS) production was assessed using CellROX® probe, while phagocytic activity was determined using pHrodo™-conjugated *E. coli*. In addition, phagocytosis-related oxidative burst was evaluated by subtracting the basal ROS signal from the CellROX® phagocytosis-related signal. Nuclei were counterstained with 4',6-diamidino-2-phenylindole (DAPI). Fluorescence emission was detected with the Glomax fluorometer (Promega).

An exploratory principal component analysis (PCA) was used to assess the multivariate dataset. Hemocyte immune responses were then analysed using linear mixed-effects models including pH, exposure time, and their interaction as fixed effects, and tank as a random effect. Significance of fixed effects was assessed using Type III F-tests with Satterthwaite's approximation, followed by Tukey-adjusted pairwise comparisons of estimated marginal means.

Results and Discussion

Compared to the control condition (pH 8.2), hemocyte viability was significantly reduced under the pH 7.4 treatment, regardless of exposure time, indicating that severe acidification impaired lysosomal integrity and cellular metabolic activity. Basal ROS production progressively increased with decreasing pH during short-term exposure. In contrast, no significant differences were detected after long-term exposure, which may reflect a physiological acclimation to prolonged acidification. Hemocytes did not show alteration in phagocytic capacity after short-term exposure, suggesting that compensatory mechanisms may initially preserve immune function under acidified conditions. However, phagocytic capacity was significantly reduced in both acidified treatments after long-term exposure. A similar pattern was observed for oxidative burst, which remained unchanged after short-term exposure but significantly decreased in both acidified conditions following long-term exposure, reflecting an impaired hemocyte innate immune function under prolonged seawater acidification.

(Continued on next page)

Conclusion

Overall, our results indicate that prolonged seawater acidification impairs hemocyte immune function in *M. galloprovincialis*, whereas short-term exposure elicits adaptive responses that temporarily preserve key cellular functions. These findings highlight the importance of considering exposure duration when assessing the biological impacts of ocean acidification and suggest that chronic acidification may increase mussel susceptibility to environmental stressors and pathogens. By providing new insights into the temporal dynamics of mussel immune responses under acidified conditions, this study contributes to a better understanding of the resilience of this species under future ocean acidification scenarios and supports the development of more sustainable and climate-resilient aquaculture strategies.

Background

Ocean acidification (OA) reduces seawater carbonate saturation, increasing the energetic costs of biomineralization and potentially compromising shell formation in marine calcifiers. In mussels, previous studies have reported alterations in shell mineralogy, ultrastructure, thickness, and mechanical properties under prolonged OA exposure, suggesting reduced shell protective capacity [1-3]. However, the extent to which these structural changes translate into measurable alterations of shell mechanical performance during shorter exposure periods remains poorly understood. This knowledge gap is particularly relevant for aquaculture, where shell integrity influences animal survival, handling, resistance to mechanical stress and ultimately, overall production yields. Through an integrated assessment of physiological responses to OA, the OPTIFARM project seeks to identify resilience- and vulnerability-related traits in Mediterranean mussels. In this study, we focused on shell mechanical resistance, investigating whether 35 days of exposure to reduced seawater pH alters shell compression resistance.

Materials and Methods

A total of 238 adult mussels were reared in a controlled closed system and exposed for 35 days (after a 10-day acclimation period) to three seawater pH treatments (8.2, 7.8, and 7.4 [4,5]), with three replicate tanks. Mussels were sampled before exposure (T0), after 7 days (T1, short-term exposure) and after 35 days (T2, long-term exposure). Compression resistance was measured on each valve using an Instron 5543 operated through Bluehill software. Shell area (left valve only) was quantified from digital images, and shell thickness was measured at three anatomical shell regions (posterior margin, median, and the umbo) using a digital calliper. Statistical analyses were performed in R. Shell compression resistance was analysed using linear mixed-effects models including pH, exposure time, shell side, and shell thickness as fixed effects, and mussel identity as a random effect. The relationship between shell morphology and compression resistance was further investigated using linear models testing the interaction between shell area and pH. Model assumptions and the robustness of significant relationships were evaluated through residual diagnostics and sensitivity analyses.

Results

Under the conditions tested, shell compression resistance was not significantly affected by seawater pH ($p = 0.442$), exposure time ($p = 0.058$), or their interaction, indicating that shell mechanical performance was maintained throughout the experiment. Shell thickness at the medial ($p = 0.009$) and umbo ($p = 0.010$) regions was positively associated with compression resistance, whereas posterior shell thickness showed no significant effect. In contrast, the relationship between shell size and mechanical performance differed among pH treatments (shell area $\times$ pH interaction, $p = 0.023$): under control (pH 8.2) and moderately acidified conditions (pH 7.8), compression resistance increased with shell area, whereas this relationship was no longer observed under pH 7.4. Sensitivity analyses confirmed that this pattern was robust to influential observations. These findings suggest that severe acidification does not immediately impair shell mechanical performance but may decouple shell growth from mechanical reinforcement.

Discussion and conclusions

Previous studies have shown that prolonged ocean acidification alters shell biomineralization, crystal organization, and shell composition, leading to reduced shell mechanical properties in *M. coruscus* after 40 days of exposure [3], and in *M. edulis* after 6-9 months of exposure [1-2]. In contrast, our findings indicate that shell compression resistance was maintained over 35 days of exposure in *M. galloprovincialis*, despite significant changes in the relationship between shell morphometric traits and mechanical performance. This suggests that functional shell performance may be preserved during the early stages of ocean acidification exposure. However, given that ocean acidification is a decadal-scale process according to IPCC (Intergovernmental Panel on Climate Change) projections, longer experiments integrating biomechanical, mineralogical and microstructural analyses are needed to determine whether the observed altered morphology-performance relationships precede measurable declines in shell strength. Together with complementary investigations on byssus performance, immune competence and byssus-related gene expression, this study contributes to a broader understanding of the integrated physiological responses of *M. galloprovincialis* to ocean acidification.

EFFECTS OF DIFFERENT DIETARY OIL SOURCES COMBINED WITH A HIGH HYDROPHILIC NUTRITIONAL EMULSIFIER IN TILAPIA DIETS

Matthijs de Jong ^{1*}, Steven Cools¹, Evi Croes¹, Warren Turner².

¹ Nukamel BV, The Netherlands

² Nam Sai Farms, Research & Development, Thailand

*corresponding/presenting matthijs.dejong@nukamel.com

Introduction

The increasing volatility in availability and pricing of dietary lipid sources presents a challenge for aquafeed formulation. Limited availability of traditional oils, combined with increasing competition from other industries such as biofuel production, requires nutritionists to frequently adjust dietary oil compositions. However, changes in dietary lipid sources may affect nutrient digestibility, growth performance, and fish health.

One potential strategy to increase formulation flexibility is the use of nutritional emulsifiers with a high hydrophilic-lipophilic balance (HLB), which may support lipid emulsification and micelle formation under varying dietary fat compositions, leading to better digestion and absorption of the fats. The present study evaluated the effects of different dietary oil combinations, with or without supplementation of a high HLB nutritional emulsifier, on the performance of red tilapia (*Oreochromis mossambicus* x *Oreochromis niloticus*).

Material and methods

The trial was conducted at Nam Aig Farm, part of Nam Sai Farms, Thailand, under commercial grow-out pond conditions. Each dietary treatment was tested in quadruplicate using ponds measuring 4 × 3 m with a water depth of 1.2 m and stocked with 300 fish per pond. The feeding trial lasted 24 weeks, during which fish grew from an initial average body weight of 43 g to a final harvest weight of approximately 700 g.

Fourteen experimental diets were formulated to be isonitrogenous and isolipidic, differing only in dietary oil composition and emulsifier inclusion level. A total added oil inclusion of 3% was maintained in all treatments and consisted of either 3% fish oil, 1% fish oil combined with 2% soybean oil, 1% fish oil combined with 2% palm oil, or 3% soybean oil. Diets were supplemented with 0, 250, 350, or 500 ppm of a high HLB nutritional emulsifier (Volamel Extra Aqua, Nukamel BV, The Netherlands), while the treatment with complete fish oil replacement by soybean oil was evaluated at 0 and 500 ppm only.

Water quality parameters, including dissolved oxygen and water temperature, were monitored throughout the study but not artificially controlled.

Evaluated parameters included growth performance, feed efficiency, survival, and water quality. Data were analyzed using ANOVA. Significance was declared at $P \leq 0.05$ and a trend to significance at $0.05 < P \leq 0.1$.

Results

Changes in dietary oil composition resulted mainly in numerical differences in growth performance and feed efficiency, while survival remained largely unaffected. In general, diets containing combinations of fish oil and plant oils showed improved tank biomass and feed conversion ratio (FCR) compared to diets containing only fish oil or soybean oil.

Supplementation with the high HLB nutritional emulsifier influenced growth performance, feed efficiency, and survival depending on dietary oil composition. The response to emulsifier inclusion did not follow a consistent linear dose-response pattern across all oil types, suggesting that optimal inclusion levels may depend on dietary lipid source.

In fish oil-based diets, emulsifier supplementation significantly improved FCR, while mixed oil diets showed improvements in tank biomass, mean body weight, and FCR at higher inclusion levels although optimal inclusion levels differed between oil sources. In diets containing palm oil, supplementation with 500 ppm emulsifier significantly improved tank biomass and survival. In the complete soybean oil replacement diet, emulsifier supplementation significantly reduced FCR and numerically improved growth performance.

(Continued on next page)

Conclusion

The present study demonstrated that changes in dietary oil composition only numerically affected the performance of red tilapia, indicating a high level of tolerance towards varying dietary lipid sources. Supplementation with a high HLB nutritional emulsifier improved feed efficiency and performance parameters across multiple dietary oil combinations.

The response to emulsifier supplementation did not follow a consistent linear dose-response pattern across different oil types, suggesting that optimal inclusion levels depend on dietary oil source and fatty acid composition. Partial replacement of fish oil with soybean oil appeared to respond favorably to intermediate emulsifier inclusion levels (350 ppm), whereas diets containing palm oil or complete replacement of fish oil by soybean oil showed more consistent responses at higher inclusion levels (500 ppm). Further research is needed to better understand the interaction between dietary lipid composition, emulsifier supplementation, and tilapia performance under commercial production conditions, in a pond system.

Introduction

The Atlantic bluefin tuna (*Thunnus thynnus*, ABFT) is an iconic species that has sustained human populations in the Mediterranean for millennia. Overfishing severely depleted wild stocks, but recovery measures adopted by ICCAT in 2006 have helped restore populations. However, increasing market demand can only be sustainably met through full-cycle aquaculture. Therefore, developing reliable breeding and farming techniques that complete the species' entire life cycle in captivity is essential for the future of bluefin tuna production.

The singular scientific and technical infrastructures (ICTS) are large installations, resources, facilities and services, unique in its kind, that are dedicated to cutting edge and high-quality research and technological development, as well as to promote exchange, transmission and preservation of knowledge, technology transfer and innovation. The Infrastructure for Atlantic bluefin tuna aquaculture (ICAR), belonging to the Spanish Institute of Oceanography (IEO-CSIC), is a unique scientific and technical Infrastructure (ICTS) devoted to study the full aquaculture of ABFT (www.icar.ieo.es). Located in the Murcia Region (SE of Spain), it is constituted by the Mazarrón Marine Aquaculture Plant and the Installation for the Control of the Reproduction of ABFT (ICRA).

Objectives

The objectives of the infrastructure are to provide the scientific community at national and international level, an open access, state-of-the-art and unique facilities devoted to competitive research and technology transfer for ABFT reproduction in captivity and juvenile production, in order to contribute to the sustainable production through integrated aquaculture techniques independently of fisheries, and to increase knowledge on its biology for the application in better fisheries management, thus contributing to its sustainability.

Figure 1. From left to right and from top to bottom. ICRA, ICRA RAS system, larval rearing tanks, BFT eggs and larvae hatching, pre-ongrowing tanks, ABFT swimming in the ICRA.

(Continued on next page)

Facilities

The ICTS-ICAR has the following units:

Unit A) ABFT breeding control facility (ICRA): Four tanks with a total volume of 7,000 m³. Two tanks, 22 and 20 m in diameter and 10 m deep, intended for broodstock, with the capacity to house approximately 30 ABFT weighing around 200 kg each, and another two, 14 and 8 m in diameter, for juveniles. The facility is capable of controlling the photoperiod and temperature.

Unit B) Egg incubation unit: 12 tanks with a capacity of 500 l and 50 tanks with a capacity of 100 l, with light and temperature control.

Unit C) Larval rearing unit: 7 tanks of 5,000 l, 18 tanks of 1 m³ and two experimental modules with 12 and 27 circular tanks of 170 l each. Mesocosm unit for larval rearing, comprising two 45 m³ tanks and a facility for the cultivation of phytoplankton, rotifers, *Artemia* and copepods (*Acartia*), sized to meet the requirements of larval rearing. All tanks are equipped with water treatment and recirculation (RAS) systems.

Unit D) Weaning and pre-ongrowing facilities: One 100 m³ cylindrical tank, four 50 m³ tanks and four 20 m³ tanks, equipped with recirculation and water treatment systems, as well as light and temperature control systems.

The four units are grouped in two nearby but separated buildings. The first (ICRA) contains the facilities for controlling the reproduction of ABFT. The other building (PLANT) contains the facilities for incubation, larval rearing and weaning-preongrowing (Figure 1).

Examples of access

ABT Feeding: Effect of different foods on biochemical composition of ABFT juveniles.

ENROTUNA: Improving the enrichment of rotifers used to feed ABTF larvae (Roo *et al.*, 2024).

BLUE-HEART: Using cardiac physiology to investigate spontaneous activity patterns, routine metabolic rate, and tolerance of warming in farmed ABFT juveniles (McKenzie *et al.*, 2026).

SAVETHUN/COMATHUNA: Acoustic and computer vision for estimation and non-invasive monitoring of ABFT biomass and its interrelation with the soundscape (Espinosa *et al.*, 2025).

EFFECTS OF POVIDONE-IODINE PROPHYLAXIS ON METABOLIC AND OXIDATIVE STRESS RESPONSES DURING INDUCED ASEXUAL REPRODUCTION OF THE SEA ANEMONE *Anemonia viridis*

Introduction

Induced asexual reproduction offers a promising approach for the captive propagation of sea anemones, with potential applications in aquaculture, conservation, and marine restoration (Fraser et al., 2021). Longitudinal bisection can rapidly generate new individuals (Watson and Younger, 2022), but tissue injury may increase susceptibility to infection and trigger physiological stress, as wound healing and immune defense compete for limited metabolic and cellular resources (La Corte et al., 2025). Iodine-based antiseptics, such as Lugol's solution, have been used following coral fragmentation, and recent evidence indicates that their effects on fragment survival, healing, and physiology may depend on concentration and exposure duration (Lam et al., 2025). However, the physiological consequences of povidone-iodine treatment following tissue injury remain poorly understood in sea anemones. Therefore, evaluating metabolic and oxidative stress biomarkers, such as glucose, lactate, superoxide dismutase (SOD), and glutathione peroxidase (Gpx) activities (La Corte et al., 2024; Vitale et al., 2020), may provide insight into the physiological effects of povidone-iodine treatment during induced asexual reproduction in *Anemonia viridis*.

Materials and Methods

The animals used in the study were obtained from the stock maintained at IFAPA Centro “Agua del Pino” (Cartaya, Huelva, Spain). Fifty-four *A. viridis* individuals (20.96 ± 1.55 g, mean $\pm$ SEM) were randomly assigned to two groups ($n = 27$). All individuals were longitudinally bisected. Fragments from one group were treated with povidone-iodine (0.1%, 2 min), followed by rinsing with filtered seawater for 60 s, whereas fragments from the other group received no povidone-iodine treatment (control). The fragments were maintained in 12 fiberglass trays (20 L; 6 per treatment; 9 fragments per tray) under the established experimental conditions. Within each tray, three fragments were assigned to each sampling time (6 h, 24 h, and 7 days). At each sampling time, lactate and glucose levels and SOD and GPx activities were determined. Survival was monitored in the fragments assigned to the 7-day sampling point.

Results

Mortality at 7 days was 33.3% in the povidone-iodine treatment and 44.4% in the untreated control, with no significant differences between treatment and mortality (Fisher's exact test, $p = 0.733$).

Glucose showed significant effects of time ($p = 0.002$) and treatment $\times$ time interaction ($p = 0.027$). Glucose levels were significantly higher in controls than in povidone-treated fragments at 24 h ($p = 0.019$), whereas no differences were detected at 6 h or 7 days. Lactate was significantly affected by time ($p = 0.007$), but neither the treatment effect ($p = 0.318$) nor the treatment $\times$ time interaction ($p = 0.085$) was significant. At 24 h, lactate was higher in controls than in povidone-treated fragments ($p = 0.044$). SOD activity was not significantly affected by treatment, time, or their interaction ($p > 0.05$). GPx activity showed significant effects of time ($p = 0.016$) and treatment $\times$ time interaction ($p = 0.017$). At 7 days, GPx activity was significantly higher in controls than in povidone-treated fragments (0.493 vs. 0.288; $p = 0.003$).

Discussion

The higher glucose and lactate levels observed in control fragments at 24 h are consistent with an increased metabolic demand during the early response to tissue injury. The lower levels observed in povidone-treated fragments may indicate a reduced metabolic response during this initial recovery phase. At 7 days, GPx activity was significantly lower in povidone-treated fragments, while SOD activity remained unchanged. This difference may reflect a reduced antioxidant demand during recovery. These results suggest that povidone may modulate the physiological response during recovery without increasing mortality, supporting its potential as a prophylactic treatment for *A. viridis* fragmentation. Further studies evaluating different concentrations and exposure times are needed to identify an optimal prophylactic protocol for *A. viridis* post-cutting recovery.

Introduction

Rising carbon dioxide emissions pose a critical environmental challenge leading to ocean acidification. This process can alter the physiological status of calcifying species such as bivalve mollusks, like *Ruditapes philippinarum*. The present study investigated how different pH scenarios affect the biometric parameters and behavioral functions of Manila clam, including growth, filtration, and burrowing capacity. The aim was to provide data to guide conservation strategies under ongoing ocean acidification.

Materials and Methods

A batch of 420 juvenile Manila clams, averaging 0.74 ± 0.03 g and 15 ± 1.05 mm in length were collected from the hatchery Naturesdulis located in the Goro lagoon (FE, Italy), an area with significant variability in chemical-physical parameters, especially pH.

Figure 1: Total weight (A), length (B), Condition index (C), Hepatosomatic index (D), Clearance rate (E), Burrowed clams (F), Burrowing time (G), Burrowing depth (H). Data are presented as mean $\pm$ standard deviation.

(Continued on next page)

At the University of Bologna's aquaculture laboratory, clams were exposed to four pH conditions for 90 days: one control group maintained at pH 8.2 and the others exposed to pH levels of 7.9, 7.7, and 7.4. Animals were reared in four independent systems of aquaria, were fed a mixture of live microalgae. pH levels were controlled automatically by a CO₂ injection system. The temperature was maintained at 20±1°C, and salinity at 27±1‰ throughout the experiment. Biometric indices were measured at the end of the experiment, along with the condition index and hepatosomatic index, clearance rate, and burrowing behavior was observed under different pH conditions.

Results and Discussion

Statistical analysis was performed using one-way ANOVA, and Tukey's post-hoc test was applied for significant results ($p < 0.05$). The results from total weight and length at the end of the experiment did not exhibit statistical variation, even with exposure to lower pH levels. Similarly, the condition index and hepatosomatic index remained constant across all treatments, indicating no significant loss in tissue mass or energy reserves. The clearance rate test revealed no significant changes in filtration activity, suggesting that the clams maintained stable food acquisition under conditions that were not severely stressful. Behavioral responses, such as burrowing time and depth, were also unaffected by varying pH levels (Figure 1). The absence of significant changes suggests that clams were resilient to the experimental acidification conditions. This resilience may be due to the clams' origin in the dynamic Goro Lagoon, where natural pH fluctuations (ranging from a minimum of 7.06 to a maximum of 8.9 pH during the month of May) could have fostered adaptation to acidic conditions. This study demonstrates that Manila clam possesses remarkable resistance to the ocean acidification scenarios predicted for the near future. An extraordinary plasticity likely links to the origin environmental. In conclusion, although ocean acidification represents a global threat, Manila clam could tolerate significant pH fluctuations, ensuring greater stability for future shellfish farming activities.

PROTECTING PRE-FATTENING MANILA CLAM FROM INVASIVE BLUE CRAB PREDATION: TESTING BIO-BASED ALTERNATIVES TO CONVENTIONAL COVERING NETS

Introduction

The invasive blue crab (*Callinectes sapidus*), now widespread along Italian coasts, has become a major predator of Manila clam (*Ruditapes philippinarum*), causing severe losses to clam farming. While polyethylene covering nets are currently used to protect clam plots, these conventional plastic materials raise environmental concerns over persistence and circularity. This study evaluates bio-based alternative covering materials, assessing their resistance to crab pinching force and their compatibility with clam survival.

Materials and Methods

A total of 12,000 Manila clam individuals (T2-3 size, 0.2 cm) were used at the *NaturEdulis* controlled hatchery (Goro, Italy). Clams were distributed into rectangular tanks (56×36×32 cm external dimensions) at a density of 1,000 clams per tank over a layer of sand, in order to simulate offshore seeding conditions. Test nets (0.4 cm mesh) were positioned in each tank. The experimental design comprised four treatments, each in triplicate: *Control* (uncovered), *Polyethylene* (conventional PE net), *Biopolymer A* (Ingeo™ Biopolymer 2003D, a rigid transparent PLA derived from corn-based polylactic acid), and *Biopolymer B* (Bio-Flex® N 25370, a flexible white PLA combined with biodegradable plasticizers). The trial involved assessing predation and the mechanical resistance of the covering materials in the presence of the invasive blue crab. Medium-small male crabs (35–115 g wet weight) were used. Crabs were acclimated for one week with ad libitum feeding, followed by 24 h of fasting to stimulate predatory activity before being introduced into the tanks, three crabs per tank. Predation was monitored for 48 hours after crab introduction through continuous underwater video recording. At the end of the test, predated clams (or residual biomass weighing) were registered and visual inspection of the covering materials for perforations or lacerations caused by claw action was conducted as an indicator of mechanical resistance.

Results and Discussion

Preliminary results revealed differences among covering materials in their ability to withstand mechanical stress from crab predation. The alternative materials also showed comparable effects on water flow and clam survival to the conventional polyethylene. Video monitoring and post-trial inspection of the nets allowed direct comparison of laceration patterns and predation rates across treatments, offering initial insight into whether bio-based materials can provide protection comparable to conventional plastic covers.

Conclusion

This study will provide evidence on whether bio-based, circular-economy covering materials can serve as viable alternatives to conventional polyethylene nets in protecting pre-fattening Manila clam from blue crab predation, supporting the shellfish farming sector in adopting more sustainable practices while maintaining effective predator control.

Funding

This research was undertaken under the ActFast (Actions for Climate Transition by developing Future Aquaculture Strategies and Technologies) project, which has received funding from the European Union's Horizon2020 Research and Innovation programme under grant agreement no. 101181159 (<https://www.actfast-project.eu/>).

Introduction

Recirculating aquaculture systems (RAS) have been increasingly recognised for their properties allowing a tightly controlled environmental discharge and improving resource-use efficiency, positioning them as a highly competitive alternative to traditional systems (Ahmed and Turchini, 2021; Timmons *et al.*, 2018). However, the complex water circuit in RAS generates significant turbulence and shear forces that promote and accelerate the fragmentation of organic particulate matter. This progressive breakdown of particles reduces the effectiveness of the conventional solid removal methods, consequently increasing the possibility of solids remaining in suspension. The accumulation of these suspended solids (SS) can therefore compromise water quality and animal welfare, interfere with system performance and increase the risk of operational failure (McMillan *et al.*, 2002; Schumann and Brinker, 2020). Consequently, effective SS management remains a critical key challenge in the design and operation of RAS, requiring the continuous optimisation of the already costly treatment and filtration strategies. To address the gap of effective, energy-efficient solutions, novel strategies are needed to secure an early-stage mitigation for the accumulation of SS in RAS, while being compatible with already existing operational systems. This study was based on the “floating faeces” approach (Unger and Brinker, 2013) and investigates the effects of cork (*Quercus suber* L.) as a functional feed ingredient to reduce faecal density and facilitate a direct solid removal from a full-RAS operation husbanding the freshwater phase of Atlantic salmon (*Salmo salar* L.).

Materials and Methods

A 21-week experiment evaluated the inclusion of 3% cork granules ($\varnothing$: 0.7–1 mm) in a commercial RAS diet during the freshwater phase of Atlantic salmon. Two replicate semi-technical RAS were used. Pre-smolts (74.8 ± 11.4 g) were stocked at density of ≈ 20 kg m⁻³ and fed either a control diet or the same basal diet supplemented with 3% indigestible cork granules (+Cork). After 12 weeks, diets were switched between systems to control for system effects. Fish were hand-fed to apparent satiation three times daily and feed intake was recorded. Solids in the control were managed via bottom drains and continuous surface skimming, while the +Cork tanks were equipped with an overflow pipe for buoyant faeces removal. Faecal removal efficiency was quantified weekly over 24 hours using specialised equipment. Total suspended solids (TSS) were measured weekly before morning drainage from three locations: before the drum filter (BDF), after the drum filter (ADF), and in the backwash water (BWW). Faeces were sampled for digestibility and faecal density analyses. Water samples were taken weekly from three system points for total phosphorus (TP), total bound nitrogen (TN_b) and routine water quality analyses.

Results

The +Cork treatment produced significant amounts of floating faecal material, which was rapidly aspirated by surface pipes and directed to the drum filter. No adverse effects on feeding behaviour were observed. Growth performance and feed utilisation were consistent with commercial standards in both groups, and cork inclusion did not adversely affect growth. Feed intake (TFI) tended to be higher in Control, while the +Cork treatment significantly enhanced SGR, TGC, and PER ($p < 0.05$). In line with this improved performance, FCR was nominally lower in the +Cork group, although this difference did not reach statistical significance. Reflecting the production of floating casts, faecal density was significantly lower than that of water in +Cork ($p < 0.05$). The +Cork treatment markedly improved solids and nutrient removal: overflow removed 60.27% vs. 4.27% in Control group; drum filter removal efficiency reached 86.5% in +Cork vs. 42.4% in Control ($p < 0.001$). Pre-mechanical treatment TSS was more than 3-fold higher in +Cork ($p < 0.05$), but post-filtration TSS was significantly lower ($p = 0.034$). TP and TN_b were significantly higher before filtration in +Cork ($p < 0.05$) yet lower or similar after filtration, with greater particulate nutrient removal and reduced leaching potential ($p < 0.05$).

(Continued on next page)

Discussion

This study demonstrates, for the first time in Atlantic salmon, that incorporating 3% cork granules into a commercial RAS diet reduces faecal density below that of water ($<1.00 \text{ g cm}^{-3}$). This physical shift in faeces enables rapid surface removal via overflow pipes without requiring additional energy costs, and without compromising growth, feed utilisation, or welfare—despite a slight reduction in feed digestibility induced by the cork ingredient. By facilitating immediate surface to drum filter transport, this strategy minimised faecal exposure to tank conditions, *i.e.*, flow rates, turbulence and shear forces, thereby minimising disintegration, fragmentation and nutrient leaching. Consequently, solid and nutrient management is remarkably improved; rather than accumulating within the system, TSS and critical nutrients are partitioned into a concentrated waste stream. This is reflected in significantly enhanced water quality (reduced TSS, TAN, and CO_2). This approach can be easily applied to existing RAS and other aquaculture configurations (*e.g.* net pens). Overall, incorporating cork into commercial salmon diets represents a practical and sustainable strategy for superior waste capture and nutrient recovery, supporting cleaner production and the principles of circular economy in aquaculture.

*Corresponding/presenting Evelien.Swaef@imaqua.eu

The sustainability of shrimp aquaculture depends on reducing waste streams while identifying alternative functional feed ingredients that support animal health and performance. Within the C-SHRIMP project, a circular production concept was developed in which sludge generated from a recirculating aquaculture system (RAS) for *Litopenaeus vannamei* was recovered and upgraded into microbial protein (MP). Waste solids collected from the RAS were concentrated through improved sludge management and subsequently subjected to controlled fermentation, where microbial biomass converted the organic fraction into a protein-rich product. This approach transforms residual aquaculture waste into a valuable feed ingredient with both nutritional and potential immunostimulatory properties. Two MP products with differing protein quality and composition were obtained and subsequently evaluated in feeding trials with whiteleg shrimp *Litopenaeus vannamei*.

Dietary trials assessed different inclusion levels of both MP products in shrimp feed (between 0.2% and 10%) and their effects on growth performance, immune responses, and disease resilience. Growth-related parameters included survival, feed conversion ratio (FCR), weight gain, and overall production performance. Only minor differences in weight gain were observed at higher inclusion levels, while survival remained unaffected across treatments, indicating good dietary tolerance. Effects of both MP products were observed on multiple performance indicators, demonstrating their biological activity in practical feeding conditions.

To evaluate immunomodulatory potential, several innate immune parameters were measured after 7 and 14 days of feeding, including total haemocyte count (THC), differential haemocyte count (DHC), superoxide dismutase (SOD), and phenoloxidase activity (POA). Both MP products influenced these immune markers, with responses depending on sampling timepoint, inclusion level, product type, and feeding duration. Changes in haemocyte profiles and enzyme activity suggest that dietary MP can modulate shrimp innate immunity and may enhance physiological readiness against stress or infection.

Following 28 days of pre-feeding with MP-containing diets, shrimp were subjected to challenge tests with two major pathogens: White Spot Syndrome Virus (WSSV) and *Vibrio parahaemolyticus* causing acute hepatopancreatic necrosis disease (AHPND). These trials were conducted to assess whether the observed immune effects translated into improved disease resistance.

The results demonstrate that microbial protein derived from shrimp RAS waste can be successfully incorporated into shrimp diets without compromising growth performance, while providing measurable effects on immune status and potential health resilience. This highlights the dual value of MP as both a sustainable protein source and a functional feed ingredient, supporting circular and competitive shrimp aquaculture systems.

Introduction

In salmonid production, opercula shortening and deformities are a relative common (average prevalence of 7-10%), especially in the early start feeding period (Østevik et al., 2025). Potential risk factors as indicated by the industry are linked to operational and production routines such as feed allocation, tank design, water environment and current, stocking density and water temperatures. However, there is a notable lack of controlled studies specifically addressing the implications of opercular shortening and deformities on fish health and welfare.

According to Østevik et al. (2025), concerns associated with opercular abnormalities include reduced growth performance, increased susceptibility to gill-related health challenges, and diminished capacity to cope with stressors such as vaccination, handling, and environmental fluctuations. These issues may result in direct economic losses due to impaired growth and increased mortality, as well as indirect costs linked to additional management measures, including enhanced monitoring and sorting of affected fish.

To date, limited research has gone into uncovering potential biological mechanisms involved, more detailed description of shape variations observed and opercula shortening's effect on the physiological functioning of the fish. Here we present a detailed scoring system for opercular length, relating opercular deformities to changes in the gill tissue as well as documenting the ability of opercula to improve as the fish grows. These are pivotal tools to an increased understanding of the mechanisms behind opercula shortening and the consequences for the physiology of the fish.

Research aims

This study aims, by means of applying qualitative and quantitative analysis of opercula shortening, to provide insight into the improvement potential of opercula over time. In addition, the shape of gills is analyzed in relation to the opercula shortening to evaluate how opercula deformities affect the respiratory area.

Methods

At the start of the trial, fish on average 12 grams were pit tagged with 8 mm Smartrac Glass TAGs. All individuals were photographed at start and when leaving the experiment at either approximately 30 grams or 140 grams. The total length of the trial was 7 weeks. Length and weight were recorded at the same time points and minimally 2 observers independently scored the opercula shortening based on a qualitative scoring scheme. Additionally, a selection of 48 individuals, with varying severity of opercula shortening, were sacrificed for tissue sampling (operculum, second gill arch or the entire gill basket and heart) at these two time points. The tissue samples were fixed in 10% buffered formalin. Formalin fixed gill arches were photographed.

The trial included 70 individuals with initially no visual opercula shortening and 163 individuals with opercula that had varying degrees of shortening and / or other types of deformities in opercular bone structure. The opercula shortening was evaluated based on a qualitative scoring scheme. In this scheme the operculum is divided into three different zones based on the anatomical structure of the most distal opercular bones. The severity of shortening is classified from 0 (no shortening) to 4 (more than half of the gill filaments visible) in each of the three regions. Both sides of the fish were evaluated.

(Continued on next page)

The shapes of opercula and gills are currently being analyzed following the principles of geometric morphometrics using a combination of fixed anatomical landmarks and semilandmarks indicating outline curves (Webster & Sheets, 2010; Zelditch et al., 2026). A variety of anatomical landmarks on fish shape are established to which opercula landmarks can be referenced in order to visualize the extent of shortening. Analyses will focus on evaluating how different areas of the operculum are affected. Additionally, the results of the opercula shape analyses will be overlain with those of the gill arches to investigate the effect of opercula shortening on the respiratory surface of the gills.

Preliminary results and expected outcomes

Based on the results from the live scoring of the opercula shortening at the start and end of the trial, the potential for substantial improvement of the opercula has been confirmed. The group of fish selected as those with some degree of shortening of the opercula at the start (163 individuals) had on average score 3.7 (moderate to severe shortening) at both the start and 30 grams. Contrastingly, a clear improvement was seen at 140 grams with an average score of 0.6 (very slight shortening). The group of fish selected as those with no shortening at the start of the trial (70 individuals) had an average score of 0.1 (no to very slight shortening) at the start, on average 0.9 (very slight to slight shortening) at 30 grams, and 0.3 (no to very slight shortening) on average at 140 grams. When all individuals in the trial were seen as a whole the average score was 2.6 and 2.8 at the beginning and at 30 grams respectively (slight to moderate shortening) and improved over time to an average score of 0.5 (no to very slight shortening).

More detailed insights into whether each area of the operculum has similar improvement potential will be further explored by means of the morphometrics analysis currently in progress.

Based on observations made over the course of this study, and from case-by-case evaluation of fish groups at the research station, opercula shortening seems to affect the shape of the gill filaments. A quantitative assessment combining the shape analyses from both the opercula and the (second) gill arch(es) will be used to provide further insight into the extent of the effect.

Introduction

Robust hatchery performance increasingly relies on advanced microbial management strategies. Rather than merely limiting the proliferation of harmful microorganisms, modern approaches aim to actively shape beneficial microbial ecosystems that can support animal health, improve rearing conditions and strengthen overall biosecurity. Within this framework, the targeted use of beneficial bacteria has become a key tool, contributing to a paradigm shift from corrective disease treatments towards proactive, efficiency-oriented microbial management. Live food organisms such as rotifers and *Artemia* play a critical role in early larval rearing, but they can also act as vectors for opportunistic and potentially pathogenic bacteria. Optimizing microbial control during live food production is therefore essential to reduce microbial risks at the larval stage. In this study, different strategies for the application of Sanolife MIC-F were compared in order to modulate the bacterial flora of ready-to-feed rotifers and *Artemia*, with the objective of improving bio-encapsulation efficiency of functional microorganisms and overall microbial stability of live food.

Materials and methods

Application in rotifers

Rotifers were cultured on a mixed diet consisting of VitAlgae Nanno, RoBoost and fresh baker's yeast. At the end of the culture period, rotifers were enriched with Easy Dry Selco (EDS) to optimize their nutritional profile prior to feeding. Following enrichment, several microbial management strategies were evaluated. These strategies combined the use of a natural *Vibrio* controller (Sanocare SURE) with Sanolife MIC-F, which were applied either with or without a prior germination step, and at different concentrations ranging from 2×10^7 to 2×10^8 CFU ml⁻¹. In one treatment, *Bacillus* spp. were additionally administered on a daily basis directly in the culture tank at a concentration of 2×10^4 Bacilli ml⁻¹. To characterize the microbial community associated with the rotifers, bacterial plate counts were performed on a general culture medium (Tryptic Soy Agar (TSA)) and on a selective medium for *Vibrio* spp. (Thiosulfate-Citrate-Bile Salts-Sucrose Agar (TCBS)). The presence and growth of Bacilli were assessed after incubation of TSA plates for 24 h at 37°C. In parallel, rotifer samples were analyzed using Illumina-based 16S rRNA gene sequencing in order to determine the most abundant bacterial phyla.

Application in Artemia

EG SEP-Art® D-FENSE cysts were hatched and the *Artemia* nauplii were harvested after 21h, after which they were transferred to enrichment tanks. In one treatment, Sanolife MIC-F was added directly to the enrichment water after an appropriate germination step (1 h at 30°C), at a dosage of 1 g of germinated Sanolife MIC-F per liter of enrichment water. *Artemia* nauplii were then introduced into this matured water and subsequently enriched with EDS.

In additional treatments, enriched *Artemia* were first harvested, cleaned and concentrated before the addition of probiotics. Different dosages of germinated Bacilli were tested at varying nauplii concentrations, up to a maximum of 8 million nauplii.l⁻¹. The incorporation of the different Bacilli species into the *Artemia nauplii* was evaluated at different time intervals following administration. As for rotifers, microbial plate counts were carried out and 16S rRNA gene amplicon sequencing was performed to characterize the bacterial communities associated with the *Artemia* nauplii.

Results

The results indicate that the functional & beneficial *Bacillus* species, when combined with the appropriate use of bacteriostatic products during live food preparation, can be effectively bio-encapsulated in both rotifers and *Artemia*. Across all tested application strategies, a clear modulation of the microbial community was observed. In particular, all treatments led to a reduced presence of Proteobacteria in the live food, accompanied by an increased relative abundance of Firmicutes, including *Bacillus* spp.

The use of technologies controlling bacterial development in live food, specifically SURE for rotifers D-FENSE for *Artemia*, contributed to a reduction of *Vibrio* loads in the live food. This reduction appeared to facilitate the encapsulation of the beneficial *Bacillus* species resulting in a more stable microbiota associated with the live food. Multiple application routes proved successful, highlighting the possibility to adapt microbial management protocols to different operational conditions in hatcheries.

(Continued on next page)

Discussion

This study demonstrates that targeted microbial management strategies are effective tools for modulating the bacterial communities associated with rotifers and *Artemia* nauplii. Across all evaluated application scenarios, the combined use of technologies designed to control microbial development together with the application of selected *Bacillus* strains consistently reduced the relative abundance of Proteobacteria, including *Vibrio* spp., while promoting an enrichment of Firmicutes, particularly *Bacillus* spp. within the live food microbiota. The use of SURE and D-FENSE not only limited the proliferation of opportunistic bacteria but also enhanced the uptake and bio-encapsulation efficiency of the administered *Bacillus*. Effective incorporation of germinated *Bacillus* cells was achieved through both enrichment-water application and post-harvest treatment of live food, highlighting the flexibility and robustness of the proposed approaches. Overall, these results support the integration of selective microbial management strategies with optimized bioencapsulation protocols as a proactive approach to control live food microbiota, enhance biosecurity and promote more stable microbial conditions in marine larviculture, in line with previous findings on *Bacillus*-based microbial management.

Introduction

The onset of exogenous feeding is a critical phase in early fish larval development and is often associated with high mortality, posing challenges for aquaculture (Yúfera & Darias, 2007). In Eurasian perch (*Perca fluviatilis*), larvae show considerable variability in their ability to initiate foraging (Pepin et al., 2014), with some individuals feeding immediately (early eaters), others starting days later (late eaters), and some never feeding at all (non-eaters). The current study aimed at investigating the differences between eaters and non-eaters under optimal rearing conditions using a combination of zootechnical and transcriptomic approach.

Material and Methods

Six families were produced by crossing one female with one male, and larvae were reared until weaning. Starting at first feeding (5 days post-hatching, DPH), early eaters and non-eaters were manually selected and reared in separate tanks. Subsequent selections at 6 and 7 DPH enabled the identification of larvae that later initiated foraging (late eaters), thereby ensuring accurate classification of true non-eaters individuals. Total RNA was extracted from groups sampled at 6DPH, and sequenced (150 bp paired-end, 40M reads per library). Differentially expressed genes analysis was performed using DESeq2. Gene ontology enrichment (GO) was conducted with ShinyGO. Specific genes were identified for further RT-qPCR validation.

Results and Discussion

Results indicates that the failure in foraging was the primary cause of early mortality, accounting for up to 50% of larval deaths. Eaters were larger in both length and weight compared to non-eaters, indicating that body size may influence the ability to initiate foraging. RNA-seq analysis of larvae at 6 DPH identified 3,117 differentially expressed genes (DEGs; $\text{padj} < 0.01$, $\log_2\text{FC} > 1$). Principal component analysis revealed a strong separation between eaters and non-eaters along PC1, accounting for 86% of the variance. Functional annotation indicated that these DEGs are largely involved in DNA replication and cell cycle pathways. Notably, non-eaters showed down-regulation of genes associated with lipid metabolism (e.g., *dhcr24*, *sqle*, *sc5d*). Together, these results suggest that failure to initiate foraging is associated with growth and metabolic processes, reflecting differences in physiological condition during early larval stages. This study provides a first framework for understanding the biological basis of early foraging ability in fish larvae.

Introduction

Copepods are increasingly explored as a source of live feed for larviculture, yet not all copepod species seem equally suitable. Previous studies have shown that digestibility differs strongly among copepod species, with potential consequences for larval growth and survival.

Benthic copepods offer practical advantages for larviculture, such as favourable fatty acid composition, resilience to environmental variation and short reproduction cycles, allowing for higher harvesting rates. However, adaptation to benthic habitats often involves the development of thicker cuticles to withstand coarse sediment, which may reduce digestibility for fish larvae.

Materials and methods

In this study, we developed an *in vitro* assay that allows quantitative evaluation of digestibility of multiple benthic copepod species using the enzymes trypsin and lipase. Experimental species were chosen based on culturability and their ecological relevance in the estuarine benthic food web. *Artemia franciscana* nauplii were included as a reference. Complementary analyses of total protein content were performed to broaden the nutritional assessment. In addition, the fatty acid composition of all species was analysed using gas chromatography coupled with mass spectrometry (GC-MS). Protein content, digestibility, and fatty acid data were integrated into a multi-trait ranking system to evaluate the overall nutritional quality of each species.

Results and discussion

Total protein content varied significantly among species (one-way ANOVA, $F_{4,10} = 32.93$, $p < 0.001$), with *M. littorale* reaching the highest protein content ($47.0 \pm 1.6\%$ dry matter) and *N. spinipes* the lowest ($21.7 \pm 3.5\%$). *In vitro* protein digestibility also differed significantly among species ($F_{4,18} = 11.41$, $p < 0.001$), with *A. franciscana* and *D. palustris* showing the highest digestibility and *N. spinipes* showing negligible digestibility, consistent with the absence of a systematic enzyme effect in this species. Notably, protein content and digestibility were not correlated: *M. littorale* combined a high protein content with one of the lowest digestibilities, indicating that a substantial fraction of its protein is not bioavailable to fish larvae, and that neither parameter alone is sufficient to rank species for nutritional quality. Fatty acid analysis (GC-MS) further showed that *T. discipes* and *M. littorale* were richest in DHA, while *D. palustris* contained the highest EPA levels; *N. spinipes* consistently ranked poorly across nutritional indicators. Integrating protein content, digestibility, and key fatty acid ratios (DHA:EPA, ARA:EPA, n-3:n-6, PUFA:SFA) into a multi-trait ranking revealed that no single copepod species performed favourably across all indicators, reflecting trade-offs between protein and lipid quality traits. These results highlight the added value of a multi-parameter approach for selecting suitable live feed candidates in marine fish larviculture.

Salmon lice, *Lepeophtheirus salmonis* and *Caligus rogercresseyi*, represent a major management challenge in salmonid aquaculture, imposing substantial economic losses primarily through repeated pharmacological treatments and handling events that induce physiological stress, increase susceptibility to secondary infections, and compromise growth performance. The progressive depletion of effective antiparasitic treatments, driven by escalating resistance, environmental concerns, and animal welfare constraints causing economic losses, has created an urgent need for sustainable alternatives in salmon lice management.

This study examined the integrated botanical effects and host physiological responses of Rosseus Plus®, a phytogenix drinking supplement, administered via therapeutic baths and waterborne exposure against *Lepeophtheirus salmonis* and *Caligus rogercresseyi* under both controlled in vitro conditions and commercial-scale field trials in Atlantic salmon.

Controlled in vitro bioassays employing lice motility and responsiveness as early-stage screening endpoints, alongside field trials utilizing wellboat delivery, were conducted to characterize ectoparasitic burden dynamics across developmental stages. In vitro assays demonstrated 93–100% efficacy against adult *Caligus rogercresseyi* and *Lepeophtheirus salmonis*, respectively, while field trials employing achieved parasite reductions of 98% in adults and 85% in juveniles.

Molecular, histological, and physiological analyses collectively demonstrated systemic attenuation of acute and chronic stress responses, oxidative stress mitigation, and significant reduction of gill and skin inflammatory infiltration. Treated fish exhibited preserved neuroendocrine homeostasis, evidenced by stable cortisol profiles, maintained lysozyme activity, uncompromised innate immune function, balanced osmoregulation, and consistent serotonin concentrations. Waterborne administration of Rosseus Plus® potentiated innate immune responses, attenuated key stress biomarkers, and enhanced feed intake and growth performance. The integration of antioxidant, serotonergic, and immunological biomarkers within a comprehensive multi-parametric analytical framework established a scientifically rigorous and reproducible platform for precision monitoring of host resilience, welfare, and treatment outcomes in intensive aquaculture systems.

These findings support Rosseus Plus® as a safe, effective, and environmentally sustainable solution for integrated parasite management in Atlantic salmon aquaculture, promoting welfare-focused and responsible production practices.

A FULLY NON-PHARMACOLOGICAL STRATEGY FOR *Caligus rogercresseyi* CONTROL AND WELFARE IMPROVEMENT IN ATLANTIC SALMON

mdelgado@sudvetspa.com

Sea lice (*Caligus rogercresseyi*) represent one of the most significant health, welfare, and economic challenges in Atlantic salmon (*Salmo salar*) aquaculture in Chile. Conventional control strategies rely heavily on pharmacological treatments and repeated handling events, which may negatively affect fish welfare and production performance. This study evaluated the effectiveness of a fully non-pharmacological sea lice management strategy combining Aware Plus®, a phytogenic feed additive, and a single strategic Rosseus Plus® bath under commercial farming conditions throughout complete seawater production cycles. The strategy was implemented during 12-month seawater grow-out periods and assessed using welfare, health, production, and sustainability indicators. The integrated approach enabled 9–10 months of production without antiparasitic interventions, followed by a single non-pharmacological bath prior to harvest. Cumulative mortality remained below 5%, representing a 55% reduction compared with industry averages. Antiparasitic treatments were eliminated, antibiotic-associated disease transmission decreased by 49–100%, and fasting days were reduced by 99.1%. Fish achieved an additional harvest weight of 678–845 g per individual compared with conventional production benchmarks. Additional benefits included reduced melanosis, improved skin and mucus integrity, lower cataract incidence, and improved gill condition, indicating enhanced fish health and welfare throughout the production cycle. Environmental sustainability indicators showed zero chemical residues, the use of biodegradable inputs, and a 17–23% reduction in carbon deposition. These findings demonstrate that a fully non-pharmacological sea lice management strategy can successfully sustain a complete seawater production cycle while improving fish welfare, health, productivity, and environmental performance. The results support the integration of welfare-focused and sustainable management approaches as viable alternatives to conventional parasite control in Atlantic salmon aquaculture.

PHYTOGENIC SEA LICE MANAGEMENT IN SALMON: ECTOPARASITIC CONTROL AND NEUROENDOCRINE-IMMUNE-OXIDATIVE HOMEOSTASIS RESTORATION AS A SUSTAINABLE WELFARE STRATEGY

EVALUATION OF FRESHWATER IMMERSION TREATMENTS FOR FUNGAL AND FLAVOBACTERIUM INFECTIONS IN FISH: A WELFARE PERSPECTIVE

M. Delgado^{*1,2} Schwerter.A^{1,2} Delgado.L¹

¹ Sudvet corp, 25030 Av. Tibbitts, Suite K, Valencia, Santa Clarita CA91355, USA

² Nordvet SpA, Imperial 0655, Puerto Varas, Chile

Fungal infections and flavobacteriosis are significant health challenges affecting *Salmo salar* in aquaculture systems, during freshwater phases. These pathogens can compromise fish welfare, cause lesions, and increase mortality if not promptly managed. Sal baths, Bronopol and Formaline are commonly used as a curative and preventive treatment, yet their impact on animal welfare remains underexplored. Understanding the effectiveness and welfare implications of such treatments is critical for sustainable fish health management. This study evaluated the effect on animal welfare and health of two conventional preventive and curative treatments in fresh water, Salt at 2%, Formalin at 150 ppm and 40 ppm of Bronopol with AqBiocare Plus®, a naturally formulation derived of plants with antimicrobial broad spectrum with antioxidant and anti-inflammatory properties. The in vitro and in vivo studies in Atlantic salmon demonstrated the antibacterial efficacy against key pathogens, including Flavobacterium and Saprolegnia. In vitro studies validated through absorbance and MIC assays that AqBiocare Plus® shows strong antimicrobial activity lasting 24 to 48 hours during immersion treatments and on fungal the doses of inhibiting to Saprolegnia were 50 ppm.

Beyond its antimicrobial properties, AqBiocare Plus® enhances innate immune responses, and take care the production and quality of the skin mucus, promoting the disease resistance. It significantly strengthens natural immunity by improving cutaneous, mucosal, and serum immune parameters while upregulating immune-related genes. At the molecular level, it enhances inflammatory, immune, antiviral, and antibacterial responses while mitigating oxidative stress by reducing and scavenging free radicals. The markers of anti-inflammatory AqBiocare showed a stable response (IL1b, IL10, TNFa,) and tissue remodeling indicators (Col1A1, MMP2, MMP13) suggested an reduced skin damage compared with Formalin and Salt. The formulation also demonstrates superior control over reactive oxygen species (ROS), resulting in reduced oxidative stress, with lower activity of NFEL2, SOD3, GPX, and CAT, alongside high lysozyme levels, indicating enhanced bacterial protection. Fish treated with AqBiocare Plus® showed improved physiological balance, with up to 25% lower cortisol and 18% lower glucose compared to Salt or Formalin. Welfare biomarkers remained stable even under smoltification stress, indicating enhanced stress resilience.

Histologically, AqBiocare Plus® increases mucous cell density in the skin, improve the quality and the quantity of the mucus, strengthening the fish's natural barrier, it has better effect on Lysozyme. Welfare analyses, including serotonin, cortisol, lactate, glucose and osmolality measurements, highlight its positive impact on fish well-being.

These comprehensive benefits position AqBiocare Plus® as an innovative and sustainable alternative in salmon farming, effectively protecting fish health, enhancing productivity and improving animal welfare.

EVALUATION OF A BOTANICAL FORMULATION AS AN IMMUNOPROTECTIVE AND ANTIMICROBIAL STRATEGY IN *Salmo salar* CHALLENGED WITH *Piscirickettsia salmonis*

M. Delgado^{*1,2}, Schwerter, A.¹, Delgado, L.^{1,2}

¹ Sudvet Corp, 25030 Av. Tibbitts, Suite K, Valencia, Santa Clarita, CA 91355, EE. UU

² Nordvet SpA, Imperial 0655, Puerto Varas, Chile
mdelgado@sudvet.com

Salmon Rickettsial Septicemia (SRS), caused by *Piscirickettsia salmonis*, is one of the main bacterial diseases in Chilean salmon farming. It generates high mortality rates and production losses, which has driven the search for more sustainable therapeutic alternatives.

This study evaluated the efficacy of a broad-spectrum natural botanical formulation designed to inhibit bacterial growth through multiple mechanisms: disruption of quorum sensing signaling, alteration of membrane integrity, and inhibition of protein and nucleic acid synthesis. In addition, it sought to enhance the fish's immune defenses, as well as reduce inflammation and oxidative stress.

The trials were carried out in farming centers in southern Chile. Groups of *Salmo salar* were fed the formulation for 30 days and then challenged with *Piscirickettsia salmonis* (strains LF-89 and EM-90) for another 30 days. Mortality rates, prevalence of infection, and physiological, histological and molecular analyses were carried out.

The treated fish showed a 64% reduction in infectious mortality compared to the control group. Significant activation of immune markers related to salmon rickettsial septicemia (SRS), including CD4, CD8, IFN- γ , TNF, IL-1 β , IL-10, lysozyme, and transferrin, was evidenced, indicating a potentiated adaptive immune response. Likewise, a decrease in oxidative stress was observed, reflected in lower activity of antioxidant enzymes in NFEL2, SOD3, CAT, GPX markers and in the reduction of the expression of genes associated with epithelial damage in the intestine, skin and gills, reflected by MMP2, MMP13, COL1A1.

From the histological point of view, the treated fish had higher intestinal villi height, less inflammation in enteric mucosa and greater density of mucosal cells in the skin, which suggests an improvement in the absorption capacity and in the barrier function against external agents (pathogens and inflammatory). In addition, a **significant decrease in the general histopathological score was observed**, with marked reductions in the levels of necrosis, inflammatory infiltration, and tissue damage, especially in the liver, kidney, and spleen.

Positive differences were observed in terms of production parameters, such as a 17% increase in growth and -7% FCR (feed conversion rate).

Taken together, these findings support the use of this botanical formulation as an effective and sustainable strategy for the management of *Piscirickettsia salmonis*. Its use significantly reduces mortality and strengthens the overall health of the fish, while minimizing the need for antibiotics and the associated risk of antimicrobial resistance in salmon farming.

DECIPHERING OSTREID HERPESVIRUS 1 ENTRY IN ITS HOSTS *Magallana gigas*: KEY ROLE OF THE MUCOSAL INTERFACE

*corresponding/presenting natacha.delrez@ifremer.fr

Introduction

The Pacific oyster *Magallana gigas* is the main farmed oyster species in France and worldwide, representing a major economic resource. However, intensive aquaculture practices and the introduction of exotic species have increased the risk of infectious diseases. Over recent decades, mass mortality events in juveniles have been associated with Ostreid herpesvirus 1 (OsHV-1) and have caused severe economic losses. Currently, no effective treatment exists, making disease prevention and health management critical for industry sustainability.

In bivalves, mucosal surfaces represent the first and most critical interface between the host and its environment, constituting a primary barrier against pathogen entry. Beyond its physical role, mucus is now recognized as a highly dynamic immunological compartment composed of a complex mixture of immune effector molecules and a diverse resident microbiota, considered as an integral component of host homeostasis. Despite this growing body of evidence, the role of mucus-associated immunity and microbiota in the context of OsHV-1 infection remains largely unexplored. In this context, we investigate the interactions between OsHV-1 and *M. gigas* at the mucosal interface, with the goal of identifying factors driving virulence and resistance. With this goal in mind, earliest host–pathogen interactions at the mucosal interface have been investigated through experimental OsHV-1 infections. Six different oyster lineages, produced in Ifremer facilities and expressing contrasted susceptibility to OsHV-1, have been used in order to understand whether mucosal immunity plays a role in this contrasted phenotypic response to viral infection.

Materials & Methods

Following pallial mucus collection according to time post infection, particular attention has been given to immune-related components, mucus-associated microbiota, and viral load dynamics at early stages of infection. Mucus samples have been analyzed using holistic approach, including: (i) proteomic characterization of immune-related proteins secreted in pallial mucus using liquid chromatography coupled with tandem mass spectrometry (LC-MS/MS); (ii) bacterial community profiling through 16S metabarcoding using Oxford Nanopore Technology sequencing; and (iii) viral load dynamics in pallial mucus over time post-infection.

Results

Oyster's survival rates confirmed the contrasting susceptibility between groups: low-susceptibility oysters (L) showed approximately 90% survival after one week, whereas highly susceptible oysters (H) exhibited less than 10% survival at 48 hours post-infection (hpi). Quantitative PCR analyses further revealed that viral load in pallial mucus increased significantly over time (two-way ANOVA, $p < 0.001$). Importantly, a significant interaction between time and oyster group was observed ($p = 0.0024$), indicating that viral load dynamics differed between L and H oyster families.

Moreover, preliminary analyses of the bacterial microbiota associated with pallial mucus revealed significant differences in both richness and diversity between L and H oyster families. In parallel, proteomic analyses identified more than 4,500 master proteins across all samples, including proteins involved in antiviral responses. Preliminary data visualization also suggested clear differences between oyster families.

Discussion

Ongoing analyses will provide further insight into the earliest mechanisms and interactions occurring at the mucosal interface between OsHV-1, host immune proteins secreted in mucus, and the associated bacterial microbiota. Furthermore, the generated datasets—including bioinformatic resources on mucus composition, microbiota, and responses to pathogen pressure—will be made accessible to the scientific community, fostering further research in marine biology, disease ecology, and environmental health.

PARENTAL SELENIUM NUTRITION FROM TUNA BY-PRODUCTS AND DIETARY MERCURY EXPOSURE: IMPLICATIONS FOR OFFSPRING PERFORMANCE IN RAINBOW TROUT *Oncorhynchus mykiss*

Introduction

Broodstock nutrition is a key determinant of offspring quality in salmonids. Tuna by-products (TBP) represent a promising alternative to fishmeal due to their high selenium (Se) content. However, their potential contamination with mercury (Hg) raises concerns regarding possible transgenerational effects (Berntssen et al., 2004; Donnarumma et al., 2021). This study aimed to evaluate the respective effects of parental dietary Se supplied by TBP and dietary methylmercury (MeHg) exposure in offspring on growth performance in rainbow trout (*Oncorhynchus mykiss*) fry. In addition, the regulation of selenoproteins in response to both Se supply and Hg exposure was investigated using immunohistochemical approaches.

Materials and methods

Five broodstock diets were tested: a plant-based control (VEG), a conventional fishmeal-based diet (FM60), and three diets including TBP at 15% (TBP15), 30% (TBP30), and 60% (TBP60), providing Se levels ranging from 0.3 to 8 mg Se kg⁻¹ diet. Groups of 20 females and 10 males were reared at 7 ± 1 °C and fed the experimental diets for 6 months prior to spawning. Oocytes from each female were fertilized with milt from males within the same dietary group.

The resulting fry were reared at 17 ± 1 °C and fed for 3 weeks either a plant-based control (FCO) or MeHg contaminated diet (FHG, 2 mg Hg kg⁻¹ feed). At the end of each feeding period, zootechnical performance was assessed in broodstock (growth, reproductive success) and offspring (growth, feed efficiency, survival). Data were analysed by ANOVA and expressed as means ± SD.

Results

No significant differences in growth performance were observed among broodstock dietary groups. No significant interaction between parental diet and offspring diet was detected for the measured parameters.

In contrast, offspring fed the MeHg-contaminated diet (FHG) showed significantly lower specific growth rate (SGR) and higher feed conversion ratio (FCR) compared to those fed the control diet (FCO), while survival was unaffected (Fig. 1).

Fig. 1. A) Specific growth rate (% day⁻¹), B) Feed conversion ratio (FCR; g feed·g⁻¹ body mass), and C) Survival (%) as a function of parental diet and offspring diet. Bars represent mean values for each parental diet group (VEG, FM60, TBP15, TBP30, TBP60). Colours indicate parental diets while patterns distinguish offspring diets (FCO: solid; FHG: striped). Error bars represent standard deviation. Different letters indicate significant differences among parental dietary groups ($p < 0.05$).

(Continued on next page)

Parental diet influenced offspring performance: fry originating from VEG and TBP30 groups exhibited lower SGR compared to FM60 and TBP15 ($p < 0.05$). FCR was lowest in FM60 and highest in VEG ($p < 0.05$). Survival was higher in TBP30 and FM60 compared to VEG.

Discussion

No interaction between parental diet and offspring feeding regime was detected, suggesting limited influence of parental Se transfer on early-life Hg exposure under the present conditions. Dietary MeHg exposure impaired growth performance, as reflected by reduced SGR and increased FCR. Parental diet nevertheless modulated offspring performance, with TBP-based diets showing comparable or slightly lower performance than FM60, and no clear effect of dietary Se level on growth at this stage, possibly reflecting the specific chemical form of Se provided by tuna by-products, predominantly selenoneine, whose metabolism and transgenerational transfer remain largely unexplored.

Ongoing investigations aim to decipher the mechanistic basis of Se-Hg interactions, with a particular focus on selenoprotein regulation, tissue distribution, and oxidative stress pathways, providing key insights into the nutritional modulation of mercury toxicity during early development. These results will help refine the use of tuna by-products as a sustainable ingredient in aquafeeds.

Introduction

Aquaculture technologies, in terms of equipment and machinery, have supported the increasing productivity of aquaculture. However, the benefits of aquaculture technologies depend on the adoption by fish farmers. Previous studies revealed that the adoption level of management practices by smallholder fish farmers is low to moderate. Previous studies also found that farm and farmer characteristics were associated with the adoption of management practices among smallholder fish farmers (Islam et al., 2024; Muddassir et al., 2019; Susilo et al., 2019). Despite this, most studies have analyzed the adoption of management practices in aquaculture, but rather limited studies have studied the adoption of aquaculture technologies. Furthermore, smallholder fish farmers dominate global aquaculture and play an important role in generating household income and rural socioeconomic development (Aung et al., 2023; Mantey et al., 2020). Despite their importance, technology adoption among smallholder fish farmers remains under-researched. This study aimed to understand the adoption level and determine the variables associated with technology adoption among inland smallholder fish farmers.

Material and Method

Purposive sampling was used to select Tilapia fish farmers in Ciamis, Indonesia. Tilapia was the most produced inland aquaculture product in Indonesia. The survey was conducted by face-to-face interviews. Descriptive analysis was conducted on fish farmers' characteristics and aquaculture technology adoption. To identify the variables associated with the adoption of aquaculture technology, multinomial logistic regression analysis was employed based on (Agresti, 2013) 6, and 7, we modeled binary response variables with binomial GLMs. Multicategory responses use multinomial GLMs. In this chapter we generalize logistic regression to handle multinomial response variables, with separate models for nominal and ordinal cases. In Section 8.1 we present a model for nominal responses. It uses a separate binary logistic equation for each pair of response categories. In Section 8.2 we present a model for ordinal responses, using logits of cumulative response probabilities. In Section 8.3 we use other link functions for those cumulative probabilities and consider alternative ordinal logit models. In Section 8.4 we present tests of conditional independence with multinomial responses using models and using generalizations of the Cochran-Mantel-Haenszel statistic. In Section 8.5 we introduce a multinomial logit model for discrete-choice modeling of a subject's choice from one of several options when values of predictors may depend on the option. The final section discusses Bayesian methods for multinomial response modeling. 8.1 NOMINAL RESPONSES: BASELINE-CATEGORY LOGIT MODELS For a nominal-scale response variable Y with J categories, multicategory (also called polytomous. Moreover, backward selection was conducted to select the independent variables (Mendenhall & Sincich, 2012).

Result and Discussion

Overall, the adoption of aquaculture technology levels was low. Aerators (blowers), biofloc, and paddle wheels were adopted by about 20%, 14%, and 10% of farmers, respectively. Smart technologies such as water quality sensors, smart feeders, and aerators with oxygen sensors had lower adoption levels than previously mentioned technologies (1.5%, 0%, and 3.1%, respectively). This study revealed that fish farming experience, education, and subdistrict were significantly associated with the adoption of aquaculture technology. The findings of this study suggest that policies aimed at increasing technology adoption should account both farmers' capacities and local environmental conditions. Accordingly, the study recommends: (1) prioritizing government technology programs in the region with moderate to poor water quality, (2) improving access to financial resources, (2) strengthening knowledge dissemination, and (3) providing intensive training to support proper application of aquaculture technologies.

ECONOMIC PERFORMANCE OF WATER QUALITY TECHNOLOGY APPLICATION IN SMALLHOLDER FISH FARMERS

Triana G Dewi^{1*}, Mariska van der Voort¹, Julie Ekasari², Henk Hogeveen¹

Introduction

Water quality is a crucial factor impacting fish health in aquaculture (Akhter et al., 2021). Poor water quality limited stocking density, reduced fish growth, and increased mortality, which affect the aquaculture farm's economic performance. Technologies such as biofloc and aeration technologies were developed to improve water quality. However, knowledge of the association between technology and the economic farm performance of aquaculture is limited, especially among smallholder fish farmers. This paper aims to investigate the association between water quality improvement through technology application on the economic performance of Tilapia smallholder fish farmers.

Material and Method

Cross-sectional farm characteristics and economic data were collected in 2025 from 160 fish farmers in Ciamis, Indonesia, using a structured questionnaire. Moreover, production and economic indicators (revenue, costs, and partial gross margin) were calculated per m² per year. Descriptive statistics showed the difference between farms with and without technology, as assessed by the Mann-Whitney test. Additionally, the association of technology and farm characteristics on economic performance was investigated by a multiple linear regression model using Ordinary Least Squares (OLS) (Wooldridge et al., 2009).

Result and Discussion

The general farm characteristics resulted from 160 farmers participating in this study, consisting of 88% no-adopters, 9% paddle wheel adopters, and 3% biofloc adopters. Based on descriptive statistics, water quality technology might be associated with higher production and revenue. Increasing water quality leads to increasing fish health, which causes farmers to be more confident in increasing stocking density. Moreover, the higher stocking density achieved through technology application led to higher costs for fingerlings, feed, and electricity. In addition, the greater distribution of fish production among fish farmers using biofloc, compared to those using aeration technologies, might reflect huge differences in proficiency with biofloc technology among farmers. Multiple regression results showed that technology was not associated with the partial gross margin. The reason could be that relatively few farms adopted technologies. The other reason might be that increased production was not sufficient to cover rising production costs caused by the application of technology. Improving institutional support in terms of information, capacity building, and technical support was essential to enhance the adoption and effectiveness of water quality technology applications.

Acknowledgment

Introduction

Behavior interactions are a key component of social dynamics in group-reared fish and can significantly influence welfare and production efficiency (De Verdal et al., 2019). In Nile tilapia (*Oreochromis niloticus*), aggression is often associated with feeding events, yet quantitative data comparing feeding and non-feeding contexts under commercial tank conditions remain limited (Fattah et al., 2021). The increasing need to reduce reliance on soybean meal in aquafeeds has driven interest in more sustainable alternative plant ingredients, including hempseed meal derived from *Cannabis sativa*. Hempseed meal has been proposed as a potential partial substitute for conventional protein sources in aquafeeds due to its lower environmental footprint and favourable amino acid profile. Dietary composition can influence feeding dynamics and competition, potentially affecting social interactions in group reared fish (Ward et al., 2006). However, hempseed meal effects on behaviour in socially dynamic rearing systems remain largely unexplored. This study aimed to quantify aggressive behaviour across feeding and non-feeding periods over a six week trial and to assess whether dietary inclusion of hempseed meal influences aggression patterns in Nile tilapia.

Materials and Methods

Six 200 L glass tanks (control and hempseed meal diets; $n = 3$ per treatment) stocked with 28 Nile tilapia per tank were video recorded during weeks 2, 5, and 6; with three recording sessions per week during both morning and afternoon feeding events. All tanks were connected to the same recirculating aquaculture system (RAS). The hempseed diet was formulated by replacing 30% of the control diet with hempseed meal, while the control diet represented a standard commercial formulation. Video cameras were installed at the front of each tank and recordings of 2h were conducted from 1h before feeding started. Behaviour was quantified from 20 min video segments, with one segment analysed per tank, week, replicate, and context (feeding or non-feeding), resulting in 18 segments per tank ($n = 108$ total). Segments representing non-feeding and feeding contexts were derived from morning and afternoon recordings, respectively. Recordings were annotated using BORIS (Behavioural Observation Research Interactive Software; v9.7, Friard & Gamba, Italy), and aggressive acts were classified as nipping, chasing, lateral fights, and mouth fights. Aggression counts were analysed using a generalized linear mixed model (GLMM) with a negative binomial distribution and log link in IBM SPSS Statistics (v31, IBM Corp., USA).

Results

Feeding context strongly affected aggression, with lower counts of aggressive events across all behaviour types during feeding than non-feeding periods ($IRR = 0.55, p < 0.001$). Behaviour type explained most variation ($p < 0.001$), with chasing occurring approximately twice as frequently as nipping, while lateral and mouth fights were less frequent. Aggression declined across weeks ($p < 0.001$). Diet affected aggression ($p < 0.001$), with higher counts observed in the hempseed treatment compared to the control, but also higher final weight and improved feed conversion ratio compared to the control. Recording replicate had no significant effect ($p = 0.113$), and no diet $\times$ period interaction was detected ($p = 0.328$).

Discussion

The reduction in aggression during feeding suggests that fish prioritise feeding over social interactions, leading to a temporary suppression of aggressive behaviour (Montero et al., 2009). Differences among behaviour types indicate that low intensity interactions, such as chasing, dominate the aggression profile, while more energetically costly behaviours occur less frequently. The decline in aggression across weeks may reflect progressive social stabilisation within groups. Although diet affected overall aggression levels, the absence of a diet $\times$ period interaction indicates that dietary effects were consistent across feeding contexts and did not alter the behavioural response to feeding. The higher aggression observed in the hempseed treatment may reflect increased feeding motivation rather than a direct behavioural effect (Cutts et al., 2001; Peake & McGregor, 2004).

Acknowledgment

The project leading to these results has received funding from the European Union's Horizon 2020 research and innovation programme under grant agreement No 871108 (AQUAEXCEL3.0). The fish trial was completed at Wageningen University and Research (WUR), under grant agreement PID32385 (TNA programme).

WHOLE EGG POWDER AS A HIGHLY DIGESTIBLE SOURCE OF PROTEINS AND FATS IN JUVENILE ATLANTIC SALMON (*Salmo salar*)

A. Diana^{1*}

¹VEOS GROUP
Akkerstraat 4/A
8750 Wingene (Belgium)
Email: alex.diana@veos.be

Whole egg powder represents a nutrient-dense and functionally versatile ingredient with potential relevance for the development of more sustainable aquafeed formulations. As aquaculture continues to expand, the sector faces increasing pressure to reduce its dependence on conventional marine and plant-based ingredient sources, particularly fishmeal and soy-derived ingredients, which can be associated with resource constraints, price volatility, land-use concerns, and environmental impacts. In this context, whole egg powder offers an alternative source of highly available protein, lipids, essential amino acids, phospholipids, cholesterol, vitamins, and bioactive compounds. ACTIPRO 44EP, a spray-dried whole egg powder, aims to support circular feed strategies by valorising high-quality animal-derived nutrients and reducing reliance on traditional raw materials. This study therefore evaluated the apparent digestibility and nutritional value of ACTIPRO 44EP in diets for juvenile Atlantic salmon (*Salmo salar*), with the objective of assessing its suitability as a high-quality alternative protein and fat source for salmonid aquafeeds.

The feeding trial followed a standard 70:30 digestibility model, in which the test diet was formulated with 30% ACTIPRO 44EP and 70% basal control diet. This approach allowed the digestibility of the egg powder ingredient itself to be calculated while maintaining comparability with published digestibility studies for aquafeed raw materials. Experimental diets were manufactured using a controlled extrusion process with a Clextral BC45 twin-screw extruder, producing stable 2–3 mm sinking pellets suitable for juvenile salmon. Juvenile Atlantic salmon (*Salmo salar*), with an initial mean body weight of 55.36 ± 1.21 g, were maintained in a freshwater recirculating aquaculture system (RAS) under controlled environmental conditions, including a water temperature of 15.20 ± 1.0 °C and continuous monitoring of dissolved oxygen, pH, and water quality. Fish were acclimated to the trial system and experimental diets before faecal collections began. During the digestibility phase, fish were fed to apparent satiation across three daily meals, and faeces were collected over a 42-day period using a consistent tank-level protocol designed to minimise nutrient leaching and avoid contamination with uneaten feed. Only fresh, intact, high-quality faecal material was retained for subsequent Apparent Digestibility Coefficient (ADC) analysis.

ACTIPRO 44EP demonstrated very high digestibility values for protein, energy, and individual amino acids in juvenile pre-smolt Atlantic salmon. The calculated ingredient ADC for crude protein was 96%, indicating efficient uptake and utilisation of nitrogen from the egg powder fraction. Essential amino acids also showed high apparent bioavailability, including lysine (94.53%), methionine (99.64%), and threonine (96.88%), which are central to protein deposition, growth, immune competence, and metabolic function in young salmon. In addition to the digestibility outcomes, fish fed the ACTIPRO 44EP diet showed numerically higher final individual body weights after 49 days compared with fish fed the control diet, although the digestibility design means growth performance should be interpreted as supportive rather than definitive. Throughout the trial, twice-daily clinical assessments confirmed that fish remained in good health, with no welfare concerns, abnormal faeces, or negative effects on water quality observed. Overall, the findings indicate that whole egg powder is a highly digestible and nutritionally valuable ingredient for juvenile Atlantic salmon and may represent a promising sustainable raw material for future salmonid feed formulations.

NEW APPROACH METHODOLOGIES (NAMs) FOR AQUACULTURE NUTRITION AND HEALTH

Context

Currently, nutrition testing in aquaculture relies heavily on *in vivo* feeding trials, which involve raising fish or shrimp under controlled conditions and monitoring growth, feed utilization, immune and health-related criteria. These trials are resource-intensive, time-consuming (weeks to months), and require large numbers of animals, making them costly and ethically challenging. New Approach Methodologies (NAMs) offer an opportunity to modernise aquatic nutrition by integrating mechanistic, exposure relevant and species-specific information within a framework of validated contexts of use (CoU). NAMs include a variety of technologies, methodologies, and approaches such as *in vitro* tests, *in silico* computational models, biomarkers, and modified *in vivo* assays that can fill critical information gaps and build confidence for their use in proof of efficacy and regulatory decisions.

The availability of NAMs that adequately reflect fish biology remains a key gap in aquaculture research. While *in vitro* cell culture approaches and advanced platforms such as organoids (3D miniaturised organ-like structures derived from stem cells) and organ-on-chip systems (microfluidic devices mimicking organ functions) offer clear potential as NAMs, their application in fish and shrimp remains incipient. In this context, *ex vivo* fish tissue explants provide a pragmatic and biologically relevant alternative, preserving native tissue organisation and metabolic competence while supporting the principles of Replacement, Reduction and Refinement (3Rs) in animal nutrition research.

Methodological approaches

Explants are small sections of native tissue (e.g., intestine, skin, gills, scales) maintained *ex vivo* for short-term experiments. Explants preserve native tissue architecture and microbiome, cell-cell interactions, and biochemical signalling, offering a more physiologically relevant model than traditional cell lines. The *ex vivo* tissue explants approach bridges the gap between *in vitro* cell culture and whole-animal *in vivo* trials, enabling mechanistic insights into nutrient absorption, barrier function, and immune responses without the complexity of entire organisms.

In higher vertebrates, intestinal mucus is also increasingly used as a key component in NAMs, to simulate the gastrointestinal barrier for testing nutrient/drug absorption, toxicity, and host pathogen interactions. Additionally, fish and shrimp faeces are also a matrix with the potential to harbour a series of biomarkers linked to intestinal inflammation and immune status.

Figure 1. A general view of the RIASEARCH AQUA-NAMs platform.

(Continued on next page)

Results

While presenting a schematic roadmap of New Approach Methodologies (NAMs) in aquaculture species is conceptually straightforward, their practical implementation is extremely challenging, requiring a lengthy setup of novel methodologies, the identification and qualification of context-specific biomarkers, and the generation and integration of large, high-quality datasets to robustly establish *in vivo* relevance. We are actively engaged in this process, with established experimental platforms using intestinal and skin explants and mucus host-pathogen interaction assays across Atlantic salmon, Nile tilapia and European seabass. These systems are currently being applied to evaluate raw materials, feed additives and other non-nutritional compounds, integrating multiparametric endpoint frameworks encompassing immune response, epithelial integrity, and wound healing process. A selection of results derived from these ongoing efforts will be presented to exemplify the translational potential of NAMs in aquaculture nutrition research.

Conclusions

A NAMs-based approach is highly innovative, delivering faster and ethically sound testing options while providing mechanistic insights that *in vitro* tests cannot achieve. Although, at this stage, we are still far from fully replacing classical *in vivo* efficacy and tolerance trials, NAMs can transform early-stage nutritional screening, offering a significant competitive advantage in the aquafeed innovation pipeline.

Introduction

Much of the production lost in European salmonid farming originates at the mucosal barriers: sea lice infestation, skin ulceration and delayed wound healing after handling and delousing, and multifactorial gill disorders. Functional feeds that reinforce skin-, gill- and gut-associated lymphoid tissue (SALT, GIALT, GALT) are one of the preventive strategies available to farmers, and algae are a potential source of the required bioactives — but the sustainability of the ingredient now matters as much as its function. The Horizon Europe project LOCALITY cultivates micro- and macroalgae on nutrient-rich industrial side streams and North and Baltic Sea waters and processes the biomass through a cascading biorefinery into fractions for the food, aquafeed, agriculture and textile markets.

In the aquaculture application arm of the project, it faces a problem common to all biorefinery-driven ingredient development: the biorefinery delivers many more candidate fractions than can realistically be tested *in vivo*, while each trial is expensive, slow and animal-intensive. The LOCALITY answers this with a three-tier de-risking funnel — *ex vivo* screening, controlled challenge validation, and commercial-scale field validation (Fig. 1) — designed so that only candidates with a mechanistic rationale reach animals, and only candidates that indicate improvement during a controlled challenge reach a sea cage.

Figure 1. Overall structure of LOCALITY aquaculture application. Algae biomass and biorefinery fractions produced in the project enter a tiered pipeline: *ex vivo* screening of a candidate library against mucosal targets, functional validation of selected prototypes in controlled wound-healing models, and field validation of a commercial-like scale algae-based additive.

(Continued on next page)

Materials and methods

A candidate library of 68 algae biomasses and biorefinery fractions supplied by LOCALITY project (including seaweeds such as *Ascophyllum nodosum* and microalgae such as *Phaeodactylum tricornutum*) were characterised for proximate and bioactive composition and assembled into a screening library. In tier 1, *ex vivo* screening with mucosal explants (SALT, GIALT and GALT) were obtained from Atlantic salmon (*Salmo salar*) and cultured in 48-well plates using a one-animal-per-row design (16 explants per animal, 3 animals per plate). Explants were exposed to graded doses of each candidate, with reference agonists (β -glucan, LPS, poly I:C) and vehicle as controls. Readouts were tissue viability and integrity (LDH release) and qPCR panels covering pro- and anti-inflammatory cytokines, antimicrobial peptides, tight-junction proteins, mucins and oxidative stress markers. SALT defensive properties were assessed as epithelial repair after a standardised insult. Candidates were ranked by a composite score combining viability, immunomodulatory amplitude and barrier response, and the highest ranked were formulated into extruded prototype diets.

In the second tier functional validation was performed when selected prototypes were tested *in vivo* as promoters for wound healing after a standardised skin lesion. In the last tier a field validation takes place when the best-performing prototype is produced at commercial scale and validated on farm, with fish health assessment, parasite load and performance as endpoints.

Discussion and impact

The value of this work lies less in any single candidate than in the decision architecture around it. Screening on mucosal tissue rather than cell lines preserves the epithelium–immune cell–mucus context in which a feed additive has to work, while using a fraction of the animals a comparable *in vivo* screen would require — a direct 3Rs gain, and a realistic way to interrogate a biorefinery output space of this size. The tiered design front-loads failure when cytotoxic, inert or mechanistically implausible candidates are eliminated before diet extrusion, so trial capacity is spent on prototypes with a defensible rationale. *Ex vivo* responsiveness is a necessary but not sufficient condition for *in vivo* efficacy, and correlation between explant readouts and trial outcomes is being established prospectively through paired screening and challenge trials to further support interpretation.

For the sector, the aquaculture application of LOCALITY delivers three transferable outputs: a validated set of mucosal *ex vivo* assays applicable to other species and additive classes; a mechanistic evidence package of the type increasingly required for feed additive dossiers and sustainability claims, generated under a traceable circular value chain, and a demonstration that side-stream-cultivated algae can meet functional feed specifications at commercial scale. Results are communicated to feed producers, farmers and regulators through the LOCALITY dissemination programme and the Horizon Europe Sustainable Aquaculture project cluster.

*corresponding/presenting author: inta.deimantovica@bior.lv

Introduction

The health status of returning spawners can affect both natural recruitment and the quality of juveniles produced for restocking. Antimicrobial-resistant bacteria in aquatic environments are also relevant to the One Health framework because wild fish, hatchery operations and receiving waters may facilitate the spread of resistant bacteria and resistance determinants. This study characterised the bacterial genera isolated from Baltic salmon (*Salmo salar*) and sea trout (*Salmo trutta*) spawners from the Venta River, Latvia, compared their antimicrobial resistance profiles and examined whether resistance occurrence differed between wild-origin and hatchery-origin spawners.

Materials and Methods

During the 2023 and 2024 spawning seasons, 49 salmonid spawners (26 Baltic salmon and 23 sea trout), including wild-origin and fin-clipped hatchery-origin fish, were examined. In total, 190 samples were collected from gills, skin mucus, urogenital openings, lesions, reproductive material, eggs at different developmental stages and, when available, internal organs. Bacteria were cultured on non-selective and selective media and identified by matrix-assisted laser desorption/ionisation time-of-flight mass spectrometry. Minimum inhibitory concentrations (MIC) were determined by broth microdilution for *Aeromonas* spp. (n = 62), *Pseudomonas* spp. (n = 62), *Shewanella* spp. (n = 40) and *Flavobacterium* spp. (n = 40). In addition, 76 *Aeromonas* isolates were tested against six antimicrobial agents by disc diffusion.

Results

Aeromonas spp. were detected in 125 of 190 samples (65.8%), *Pseudomonas* spp. in 93 (48.9%), *Shewanella* spp. in 74 (38.9%) and *Flavobacterium* spp. in 53 (27.9%). From several samples more than one genus was recovered. The genera showed distinct antimicrobial resistance patterns. By microdilution, *Aeromonas* isolates most frequently showed resistance to ampicillin (98.4%) and sulfadimethoxazole (72.6%), whereas no resistance was observed to ciprofloxacin or nalidixic acid. *Pseudomonas* isolates showed 100% resistance to ampicillin, cefotaxime and trimethoprim and more than 90% resistance to azithromycin, chloramphenicol and sulfadimethoxazole. In *Shewanella*, the highest resistance occurred to sulfadimethoxazole (80.0%) and ampicillin (40.0%), while resistance to the other evaluated agents did not exceed 10.0%. *Flavobacterium* isolates showed 100% resistance to trimethoprim, ceftazidime, gentamicin and cefotaxime, and 95.0% resistance to azithromycin. The descriptive comparison did not reveal a clear difference in the occurrence of resistant bacteria between wild-origin and hatchery-origin spawners.

Discussion and Conclusions

The high occurrence of several opportunistic or potentially pathogenic bacterial genera, together with genus-specific resistance profiles, supports inclusion of multiple indicator groups in salmonid health and antimicrobial resistance surveillance. The similar findings in wild-origin and hatchery-origin fish after their return to the same river environment suggest that shared environmental exposure may be important. Together, the results show that *Aeromonas* represents one informative component of a wider bacterial community with heterogeneous resistance patterns. Because validated clinical breakpoints are unavailable for some aquatic bacterial species and antimicrobials tested, the resistance results should be interpreted with caution. Continued standardised monitoring and susceptibility-guided treatment decisions are recommended for fish health management and responsible antimicrobial use.

This research was financially supported by the Ministry of Agriculture of the Republic of Latvia within the framework of the 2023–2024 study “Antimicrobial Resistance of Significant Microorganisms and Commensal (Indicator) Bacteria in Baltic Salmon (*Salmo salar*) and Sea Trout (*Salmo trutta*) Spawners in Latvia”.

VALIDATING AND APPLYING FECAL SWABS AS LESS-INVASIVE SAMPLING METHOD TO MEASURE CORTISIL LEVEL ON ATLANTIC SALMON COMMERCIAL SEA CAGES

Jingwen Ding ^{1*}, Jakob Mo ¹, Yanran Cao², May Linn Buberg ¹

¹ Salmax Research, Norway

² Department of Biological Sciences Aalesund, Faculty of Natural Sciences, Norwegian University of Science and Technology

*corresponding author: Jingwen.ding@salmax.no

Introduction

Convenient sampling methods for non-invasive stress monitoring are needed to support welfare assessment in modern salmon aquaculture. Fecal samples have been validated and used for measuring stress levels of Atlantic salmon (*Salmo salar*). The fecal sampling method in the field is usually conducted by stripping fish or collected fecal material after dissecting fish in commercial sea cages (Cao et al., 2017). In the present study, we developed and validated a fecal swab method for quantifying cortisol in Atlantic salmon under commercial farming conditions. FLOQSwabs® Minitip were evaluated across six validation components: swab material uptake, field and laboratory comparability, biological validation, analytical validation, and storage stability.

Materials and Methods

Atlantic salmon were sampled from commercial sea-cage sites in Norway. All sampling was performed during routine operational procedures, including sea-lice counting and regular health check. All procedures involving fish handling and sampling followed Directive 2010/63/EU and complied with Norwegian regulations governing the use of animals in scientific research.

Blood samples were collected from the caudal vein using 4 mL heparinized BD Vacutainer® tubes (Becton, Dickinson and Co., NJ, USA). Fecal samples were firstly collected by inserting a sterile Mini Copan FLOQSwabs® (Cambio, Cambridge, UK), through the anus until the breakpoint of the swabs, and gently rotating the swab five times along the mucosal surface. This approach ensures sampling of both feces and gut mucosa. According to Ruiz et al., (2024), this method does not elicit abnormal behavior or visible signs of stress or injury in Atlantic salmon. Additional fecal material was collected by gently applying pressure along the abdomen to expel feces through the vent. The expelled fecal matter was transferred into sterile 2 mL tubes, homogenized thoroughly and stored at –80 °C before further analysis.

Plasma and fecal cortisol concentrations were determined using a commercial Neogen cortisol ELISA kit, following extraction and analysis procedures adapted from Ding et al., (2024).

Results

Swab could sample enough material for fecal cortisol analysis. The weight of material collection by one swab was consistent across three different fecal textures (mean 0.118 g ± 0.01 g; CV = 8.23%; p = 0.609). Field swabs produced cortisol concentrations comparable to laboratory resampling (paired p > 0.05) with a strong correlation (r = 0.94). Biological validation across three different commercial sites with four net pens in Norway demonstrated significant associations between plasma and fecal cortisol among sample groups (mixed-effects model: p = 0.044; Spearman's ρ = 0.67, p < 0.001). Significant increased cortisol levels were detected by fecal swabs after fish were posted to acute handling stress. In addition, baseline fecal cortisol concentrations differed among net pens, indicating that the method is sensitive enough to detect variation associated with different farming environments. Spike-and-recovery tests showed an overall recovery of 90.5% (range 62.9–127.5%). Repeatability testing of five homogenised fecal samples yielded a mean technical CV of 10.23%. Storage stability analysis indicated rapid degradation at room temperature, stable cortisol profiles at 4 °C for up to 14 days, and high stability at –20 °C for at least 60 days.

Summary

Overall, the fecal swab method provides a practical, non-invasive, and robust tool for stress hormone monitoring in farmed salmon. This approach offers strong potential for integration into routine welfare assessments and operational decision support in commercial aquaculture.

TRAINING THE AQUACULTURE PROFESSIONALS OF TOMORROW: INNOVATIVE APPROACHES TO EDUCATION AND LIFELONG LEARNING

B. Dmochowska^{1*}, Łądkowska H.²

1 Department of Oceanography and Geography, University of Gdańsk, Poland

2 Department of Oceanography and Geography, University of Gdańsk, Poland

*b.dmochowska@ug.edu.pl

Aquaculture is increasingly recognized as a key component of sustainable food production and the blue economy, creating a growing demand for professionals with interdisciplinary knowledge, practical skills, entrepreneurial competencies, and the ability to respond to technological and environmental change. Meeting these needs requires education and training that extends beyond traditional classroom learning and supports continuous professional development.

The University of Gdańsk (Poland), together with international partners through two EU-funded projects: AquaLoop (Interreg South Baltic) and Blue Bio Techpreneurs (EMFAF), has developed innovative educational approaches linking higher education, practical aquaculture training, entrepreneurship, and lifelong learning. These initiatives provide students and early-career professionals with opportunities to address real-world challenges related to sustainable aquaculture, circular production systems, and the blue bioeconomy.

A central element is challenge-based and experiential learning, enabling participants to connect theoretical knowledge with practical applications. Within the AquaLoop cross-border student exchange programme, students undertake pilot-scale laboratory activities and study visits focused on sustainable and circular aquatic production, including aquaculture and aquaponics. These experiences develop practical competencies in resource efficiency, circularity, environmental sustainability, and innovation.

International and interdisciplinary collaboration further strengthens the training model. Students from universities in Gdańsk, Klaipėda, and Rostock work in diverse teams, combining expertise in aquaculture, marine biology, environmental sciences, biotechnology, and related fields. This approach encourages knowledge exchange and develops the collaborative and problem-solving skills needed for a sustainable and internationally connected aquaculture sector.

The Blue Bio Techpreneurs (BBT) initiative complements this approach through entrepreneurship and innovation-oriented learning. During BBT Hackathons, students work in international, interdisciplinary teams to address real-world challenges in the blue bioeconomy and develop innovative solutions for sustainable aquatic production. Methods including design thinking, innovation management, mentoring, and stakeholder engagement help participants translate scientific knowledge into practical solutions while strengthening creativity, teamwork, leadership, communication, and problem-solving skills.

Digital education and lifelong learning provide an additional dimension. The BBT Massive Open Online Course (MOOC), comprising five modules available through the FutureLearn platform, offers flexible learning opportunities for students, early-career professionals, and other learners seeking to develop blue economy competencies. Such digital formats support continuous upskilling and reskilling as aquaculture technologies, production systems, markets, and sustainability requirements evolve.

Together, AquaLoop and BBT demonstrate how experiential learning, international collaboration, entrepreneurship, digital education, and lifelong learning can be integrated into aquaculture training. The experience of the University of Gdańsk provides a transferable model for universities, training providers, and aquaculture stakeholders seeking to develop a skilled, innovative, and sustainability-oriented workforce capable of meeting the future needs of the aquaculture sector.

INTEGRATED PRODUCTION OF *Holothuria arguinensis* AND MACROALGAE (*Ulva sp.* e *Gracilaria sp.*) AS BIOREMEDIATORS OF ORGANIC WASTE FROM MARINE FISH

Introduction

Aquaculture plays a key role in global protein supply and in reducing pressure on wild fish stocks, but it faces sustainability challenges, particularly the release of nutrient-rich effluents that can lead to environmental degradation (FAO, 2022; Naylor et al., 2021). To address these issues, innovative approaches such as Recirculating Aquaculture Systems (RAS) and Integrated Multi-Trophic Aquaculture (IMTA) have been developed to improve resource efficiency and waste reuse (Granada et al., 2016; Neori et al., 2004). In this context, macroalgae such as *Ulva sp.* and *Gracilaria sp.* stand out for their ability to remove nutrients and generate economic value (Abreu et al., 2011; Bolton et al., 2009), while detritivorous species like *Holothuria arguinensis* contribute to organic matter recycling (Purcell et al., 2016; Zamora et al., 2016). The integration of these organisms within IMTA systems represents a promising strategy to enhance the environmental and economic sustainability of aquaculture (Chopin et al., 2001; Troell et al., 2009).

Materials and Methods

The experiment was conducted in a recirculating aquaculture system (RAS) integrated with a two-trophic level IMTA setup to evaluate the combined performance of macroalgae (*Ulva sp.* and *Gracilaria sp.*) and sea cucumbers (*Holothuria arguinensis*) in nutrient removal and biomass production. Four treatments were established based on macroalgae species and sea cucumber size classes (small: 0.5–2.0 g; large: 2.1–5.5 g), each in triplicate, totaling 12 experimental units. The trial lasted 51 days under controlled conditions (20 ± 1 °C; 12:12 h photoperiod). Macroalgae were cultured in photobioreactors, while sea cucumbers were maintained in tanks and fed regularly based on biomass (12% weekly). Water quality parameters (temperature, salinity, dissolved oxygen, ammonia, nitrite and phosphate) were monitored periodically. Growth performance of both organisms and nutrient removal efficiency were assessed. Statistical analysis was performed using analysis of variance (ANOVA).

Results

(Continued on next page)

An ANOVA was conducted to assess the effect of algal type and class on specific growth rate (SGR) of *Holothuria arguinesis*. The results revealed a significant effect of class on SGR ($p = 0.023$), indicating differences between the large (G) and small (P) groups. On the other hand, no significant differences were found associated with the alga factor ($p = 0.381$) or with the interaction between alga and class ($p = 0.178$). Levene's test was not significant ($p = 0.140$), confirming the homogeneity of variances.

An ANOVA was conducted to assess the effect of algal type and class on specific growth rate (SGR) of *Holothuria arguinesis*. The results revealed a significant effect of class on SGR ($p = 0.023$), indicating differences between the large (G) and small (P) groups. On the other hand, no significant differences were found associated with the alga factor ($p = 0.381$) or with the interaction between alga and class ($p = 0.178$). Levene's test was not significant ($p = 0.140$), confirming the homogeneity of variances.

Changes in macroalgal weight across multiple sampling points (T0–TF). *Gracilaria sp.* showed growth, while *Ulva sp.* did not. The best results were observed in GracG, followed by GracP. Biomass loss was observed in UlvaG and UlvaP, with the loss being more pronounced in UlvaP.

Discussion

The results show that there were significant differences in SGR among the different classes. The small class (P) exhibited a higher SGR than the large class (G), indicating that the small class (P) grew better. This can be explained by the fact that smaller cucumbers require more protein for their growth. The associated conditions also contributed to the growth of these plants. It was evident that the type of algae did not affect the growth of the cucumbers, or vice versa. The feeding habits of the cucumbers would not be affected by the algae, as these organisms feed on organic matter deposited on the bottom. Growth is due to water parameters, with temperature being a critical factor in development. According to Madruga A. (2021), individuals cultured at a temperature of 20°C showed a better SGR of 0.50% day⁻¹ and in this study reached an SGR of 2.49% day⁻¹.

Introduction

Histopathological changes in fish are recognised as biomarkers of environmental stress. While some changes represent adaptive responses that help fish cope with natural fluctuations in environmental conditions, others may indicate deteriorating water quality, environmental contaminants, the presence of parasites, or disease. Gills are especially good biological indicators due to their continuous interaction with the environment and are among the first organs to exhibit histopathological alterations in response to change in the aquatic environment (Pramnik & Biswas, 2024). However, these markers are seldom used in aquaculture settings.

Materials and Methods

Sample collection for this study was conducted in 2024 during the whole production season, covering fish from one-year-old common carp to market-ready individuals. Samples were obtained from the Srpski Miletić fish farm, located in the northern part of Serbia. This fish pond receives its water supply from the Danube–Tisza–Danube (DTD) canal. Some of the most important purposes of the DTD canal are the drainage of agricultural land and the irrigation of arid areas. Sampling was performed during three periods: spring (26 April), summer (23 July), and autumn (06 December). Fish were anaesthetised, the second gill arch was dissected, fixed in formalin, processed and stained using a combination of haematoxylin and eosin. Each sample was scored from 0 to 3 to assess the extent of tissue alterations. A score of 0 indicated no detectable change, while a score of 3 indicated that most of the sample was affected by the pathological alterations. Statistical analyses were conducted using the non-parametric Kruskal–Wallis test.

Results

In general, the highest scores in the gills of common carp were found for circulatory disturbances (such as hyperaemia and stasis) and hyperplasia. Statistical analysis revealed significant seasonal differences ($p < 0.05$) for eight histopathological changes (Tab 1). Post-hoc analysis showed that most differences occurred between summer and either spring or autumn, while differences between spring and autumn were observed only for one alteration.

Discussion

Seasonal variation in gill histopathology was evident, with different histopathological profiles during each season, but without a specific pattern that could be clearly attributed to particular factors. In summer, higher scores for the occurrence of parasites coincided with hypertrophy of the respiratory epithelium, but it is also notable that scores for hyperplasia were lower compared with both spring and autumn. Hyperplastic changes as an adaptation to the presence of parasites are among the most frequent mechanisms in gills (Dezfuli et al. 2023). However, hyperplastic changes observed here are probably more related to environmental stressors during summer than to the presence of parasites. This is further corroborated by low scores of necrosis and low presence of EGCs, which are not actively engaged in the inflammatory process, in contrast to parasite infection (Dezfuli et al. 2011). Cyprinids have a specific mechanism in the gills, and in normoxic water at lower temperatures the gills lack protruding lamellae (Sollid and Nillson 2006), which is in contrast to other fish and explains why hyperplasia is present in spring and autumn. These findings support the use of gill histopathology as a useful biomarker for detecting seasonal variations in water quality in freshwater pond culture systems.

Introduction and methodology

In recent years, the search for alternatives to fishmeal (FM) and soybean meal (SBM) has highlighted several promising ingredients, including single-cell proteins (SCPs), algae and microalgae, and insect meals, which can support feed efficiency, fish welfare, and health (Serra et al., 2024). However, their high cost may slow adoption in a sector where feed accounts for 30–60% of total production costs (Mulazzani et al., 2021). In this context, processed animal proteins (PAPs) obtained from livestock by-products, particularly poultry- and porcine-derived PAPs, represent a potentially scalable and circular solution. These ingredients can offer a competitive alternative to FM and SBM in terms of growth performance and cost (Wilkinson & Young, 2020). However, less is known about how consumers perceive them. Although insect PAPs have been widely studied, poultry and porcine PAPs remain under-researched in consumer studies. To fill this gap, the present study examines consumer attitudes toward farmed fish fed diets containing poultry and porcine PAPs, using insect-derived PAPs as a point of comparison. Specifically, it addresses the following research questions: (i) what perceptions act as barriers to consumers' willingness to consume fish raised on PAP-based diets?; (ii) to what extent are consumers willing to pay (WTP) a premium for fish raised on PAP-based diets?; (iii) and does the provision of sustainability-related information influence that WTP?

The analysis is based on an online panel survey of 1,502 consumers living in Italy, selected through stratified sampling by gender, age, and region of residence. First, respondents' perceived naturalness of the wild fish diet was assessed using a multiple-choice question to contextualize their subsequent answers. Next, perceptions of conventional ingredients (FM and SBM) and PAPs were then elicited through open-ended questions and examined using sentiment analysis. Responses were classified as positive, negative, or neutral with an Italian-language model based on the *pysentimiento* Python library. WTC for fish reared on PAP-based diets and its main barriers were measured using seven-point Likert-scale statements covering four dimensions that emerged from the literature as having a direct effect: disgust, social norms, comparison with conventionally fed fish, and perceived product safety. These items were analyzed using a random forest (RF) classifier, with WTC as the outcome variable and the barriers as predictors. As an ensemble classification method that combines multiple decision trees, RF is well-suited for modeling consumers' WTC and identifying the relative importance of the barriers that shape their decisions. WTP was measured on a percentage scale with a midpoint for no price difference, and values above or below indicating a premium or a discount. Finally, to test the role of information, respondents were shown a short objective text on the sustainability of PAP-based feeds, and WTP was elicited again using the same scale. Changes in WTP were evaluated through a paired pre-post design using the Wilcoxon signed-rank test.

Results and discussion

Results show that 83% of consumers could identify at least one possible component of the natural diet of fish. Plant-based organisms (59%), fish of other species (41%), and insects (31%) were perceived as more closely aligned with the diet of wild fish, whereas small terrestrial animals, such as mammals and reptiles (16%), were considered less likely to be part of it. Sentiment analysis revealed predominantly neutral attitudes toward FM and SBM. By contrast, insect, poultry, and porcine PAPs elicited polarized reactions in about half of the sample (43–49%). Among respondents expressing either positive or negative sentiment, insect PAPs were evaluated more favorably (59% positive), whereas poultry PAPs (69% negative) and especially porcine PAPs (75% negative) elicited more unfavorable responses. The three RF models achieved accuracies ranging from 65% to 69% and showed that the main barriers to WTC differed by ingredient. Disgust emerged as the most influential predictor in the model for insect PAPs, while perceived product safety was the leading concern for both poultry and porcine PAPs. For these two ingredients, the item concerning the perceived naturalness of the raw material emerged as the second most important limiting factor. In terms of WTP, 60% of respondents were not willing to pay either more or less for fish fed PAPs, although the tendency leaned toward discount requests. Acceptance was highest for fish fed insect PAPs (positive WTP: 17%; negative WTP: 23%), whereas fish fed poultry or porcine PAPs were more often associated with lower WTP (positive WTP: 10%; negative WTP: 30% for both). The role of additional sustainability information was statistically significant ($p < 0.0001$), increasing the share of respondents willing to pay a premium for fish fed insect (22%), poultry (19%), and porcine (18%) PAPs, while slightly reducing negative WTP to 21%, 23%, and 26%, respectively.

(Continued on next page)

Ingredients perceived as more consistent with fish's natural diet tended to elicit more favorable reactions. FM and SBM attracted limited controversy, while PAPs, especially poultry and porcine sources, polarized respondents more strongly. Within the PAP category, insect stood out as the most accepted option. They were associated with more favorable sentiment and consistently showed the highest WTP. Proximity to fish's natural diet may foster acceptance, even though disgust remains an important barrier, consistent with previous research on indirect entomophagy (Niimi et al., 2025). By contrast, reluctance toward poultry and porcine PAPs appears to be driven primarily by perceived safety concerns, possibly reflecting the legacy of past concerns surrounding TSEs, as well as the unnaturalness of the practice. The idea emerging from the results is that insect PAPs are more accepted than the other two, possibly because they may be perceived as more natural. Although the positive effect of the information treatment indicates that targeted communication emphasizing the sustainability of PAP-based feeds could help foster consumer acceptance, future studies should focus on the role of perceived naturalness in the acceptance of these circular solutions.

Introduction

The progressive replacement of fishmeal and fish oil by plant-based ingredients in marine fish diets has altered their micronutrient composition, increasing the need for vitamin supplementation, including vitamin D. Traditionally, cholecalciferol (vitamin D₃) has been used as the dietary source, which must undergo two sequential hydroxylations to be converted first into calcifediol and subsequently into calcitriol, its biologically active form.

Direct dietary supplementation with calcifediol (25 OHD₃) bypasses the first hepatic hydroxylation step, potentially enhancing vitamin D bioavailability and biological efficacy. In terrestrial vertebrates and some cold-water aquaculture species, such as salmonids, calcifediol supplementation has been associated with improved growth, mineral metabolism and physiological health (Rider et al., 2023; 2024; 2025). In contrast, information regarding its application in Mediterranean marine species remains scarce, with only one recent study conducted in juvenile gilthead seabream (*Sparus aurata*) (Domínguez et al., 2025). Therefore, the present study aims to provide new evidence on the effects of calcifediol supplementation in juvenile European sea bass, contributing to the nutritional knowledge base of Mediterranean aquaculture.

Materials and Methods

A total of 600 juvenile European sea bass (*D. labrax*; 62.0 ± 0.8 g) were randomly distributed among 15 tanks following a completely randomized design, with five experimental diets tested in triplicate. Diets were identical except for calcifediol supplementation levels (<2.0; 21.6; 53.5; 102.6 and 169.8 ppb). Fish were fed to apparent satiation three times daily for 113 days under a natural photoperiod.

On day 35, samples were collected for gene expression analyses, and a subgroup of fish was subjected to a *Vibrio harveyi* challenge, with survival monitored for 23 days. At the end of the trial, growth performance parameters (FCR and SGR) were calculated, and samples were collected for body composition, somatic indices, vitamin content, gene expression, enzymatic activity, digestive histology, and skeletal anomaly assessment. Data were analyzed using ANOVA and linear regression.

Survival following *Vibrio harveyi* challenge exhibited a non-linear, treatment-dependent pattern, with the highest protective effect observed at intermediate dietary calcifediol levels (21.6 and 53.5 ppb). This response was followed by a progressive reduction in survival at both lower and higher supplementation levels. Higher calcifediol concentrations (102.6 and particularly 169.8 ppb), as well as the absence of calcifediol supplementation, appeared to negatively affect the host response to infection, potentially linked to physiological stress, disruptions in homeostatic balance, or interference with immune regulatory mechanisms. Ongoing analyses of gene expression and enzymatic activity form part of the study and will support a more integrated understanding of the mechanisms underlying the responses observed during the *V. harveyi* challenge.

Introduction

Italy is one of European leading producers of rainbow trout (*Oncorhynchus mykiss*), and around 70% of national production is concentrated in the north-east of the country, where the Autonomous Province of Trento (TAP) and the province of Udine are the two main production areas, due to the abundance of watercourses within their territories. The health status of a fish farm is the result of the interaction of several protective factors: among these, biosecurity and the technological level of the facility play a particularly significant role. European animal health legislation (EU regulation 2016/429, Animal Health Law) emphasizes the importance of disease prevention and identifies biosecurity as one of the main tools for reducing the risk of the introduction and spread of infectious diseases, whilst a high level of technology can promote better facility management influencing its health status. The aim of this study was to assess the biosecurity and technological level of rainbow trout farms in the provinces of Trento and Udine using a standardised methodology.

Materials and methods

The study included 57 salmonid farms, 36 of which are located in the TAP and 21 in the Province of Udine, selected from the national livestock register. The farms of interest were identified in collaboration with the local veterinary authorities (ASUIT for Trento, ASUFC for Udine) and the trade association (Italian Fish Farmers' Association (API)): specifically, all farms with the business activity 'fattening for human consumption' that kept rainbow trout, among other possible species, were selected.

Data relating to the biosecurity measures applied in each farm were collected using the checklists still in use throughout the country (Annex F of Legislative Decree 148/2008, transposing Directive 2006/88/EC). The questions of the checklists were submitted to 12 aquaculture experts with different professional backgrounds (feed industry, private practice, local competent authorities). Using the expert elicitation method, the group of experts assigned a level of importance to each biosecurity measure based on its relevance in preventing the introduction and spread of infectious fish diseases.

At the same time, each expert also assigned a score to the certainty of their answer. The weighted scores were then combined with the checklist responses collected for each farm to obtain an overall biosecurity score for the farm itself. Based on the scores obtained, the farms were divided into five categories (low, low-medium, medium, medium-high, high). Following the same logical framework, a technological level index was constructed for each farm, based on the presence or absence of specific farm technologies (which were also weighted according to importance), enabling the farms to be classified into three categories (low, medium, high).

Results

With regard to biosecurity levels, the expert elicitation analysis identified five key measures requiring particular attention: 1) Trucks' cleaning and disinfection; 2) regular removal of dead fish; 3) protection against fish-eating birds; 4) use of dedicated equipment in the various areas of the farm; 5) provision of separate areas dedicated to the loading of dead fish. By combining the weights of the measures with the data on the farms, in the TAP no farm had a low or medium-low level (0%), 31% (11 out of 36) had a medium level, 61% (22 out of 36) had a medium-high level, and the remaining 8% (3 out of 36) of farms had a high level of biosecurity. In Udine province, no farm had a low, medium-low or medium level of biosecurity (0%); 10% had a medium-high level (2 out of 21) and the remaining 90% had a high level.

(Continued on next page)

Taking the technological level into account, in Trento, only one farm was classified as low (3 %; 1 out of 36), the majority as medium (64 %; 23 out of 36) and 33 % (12 out of 36) as high. In Udine, no farm was classified as low, whilst 24 % (5 out of 21) were classified as medium and 76 % (16 out of 21) as high.

Discussion

The results show that the majority of livestock farms in the two provinces under consideration have a biosecurity level ranging from medium to high, demonstrating that the most important preventive measures are generally well implemented and that the requirements laid down in EU regulation 2016/429 and the relevant delegated and implementing acts are being complied with. The level of technology was also found to be uniformly quite good across the two provinces, demonstrating that basic technologies are now widely adopted while only a few farms use more advanced solutions. This difference between the two provinces is likely linked to the type, size and investment capacity of the farms.

Conclusions

In conclusion, the results highlight an overall good level of both biosecurity and technological advancement, although there is still scope to improve both aspects and make the sector more competitive.

Introduction

Taurine is a sulfur-containing amino acid widely recognized for its physiological functions in osmoregulation, antioxidant defense, neural development, and cardiovascular health. Due to its nutritional and functional relevance, taurine has received increasing attention in aquaculture and food science research, particularly in fish species destined for human consumption. Despite the growing interest in taurine analysis, information regarding the optimization and standardization of extraction protocols for Nile tilapia flesh by HPLC-UV without use of derivatization techniques remains limited. Therefore, this study evaluated the combined effects of muscle region, extraction solvent, and extraction temperature on taurine quantification in Nile tilapia muscle using high-performance liquid chromatography (HPLC), aiming to provide methodological support for the standardization of taurine analysis in aquaculture products.

Materials and Methods

Dorsal and caudal muscle samples from three Nile tilapia (*Oreochromis niloticus*; 588.6 ± 57.3 g) GIFT strain were frozen. To obtain the extracts, samples were thawed at room temperature; 1.0 g of each sample was homogenized with 3.0 mL water milliq using an Ultra-Turrax, incubated in a water bath at 60°C or 100°C for 60 minutes (Permata et al 2014), and centrifuged at 4000 rpm (10 min, 10°C). The supernatant was filtered through a 0.45 μ m filter and stored at 4°C for 48 hours. Additionally, in 0.1 ml from extract was add ethanol making an solution 80%, stored at 4°C for 24 hours, newly centrifuged and floating was filtered. For HPLC analysis (YL9300, YL Instrument, Anyang, Korea), a taurine standard (Sigma-Aldrich-Merck) was prepared in water at concentrations of 100, 200, 400, and 800 mmol, filtered through a 0.45 μ m filter, and 20 μ L was injected into the HPLC. A LUNA column (5 μ m, RP-18, 250 cm $\times$ 4.6 mm) was used, with separation achieved using a mobile phase consisting of 10 mM sodium acetate buffer in Milli-Q water (A) and acetonitrile (B) under the following conditions: 0–1 min (20% B); 1.01–1.5 min (5% B); 1.51–8 min (4% B); constant flow rate of 1 mL/min; detection at 254 nm; and a temperature of 35°C. Retention time and peak height were visualized using Clarity 8.1 software. The taurine standard eluted at 2.98 minutes, and a standard curve was generated, yielding the equation $y = 4.2387x - 26.406$ ($R^2 = 0.98$). The data were analyzed using a generalized linear model (GLM) assuming a Gamma distribution with a log link function. The model included the fixed effects of muscle sample, solvent, temperature and their interaction. Means were compared using Tukey's test at a 5% significance level.

Results

Taurine concentrations ranged from 1.73 ± 0.02 , to 11.71 ± 0.19 μ mol/g among the evaluated extraction conditions. Marked differences were observed according to muscle region, extraction solvent, and extraction temperature. In the caudal muscle, aqueous extraction increased taurine concentrations from 1.73 ± 0.02 μ mol/g at 60°C to 4.42 ± 0.08 μ mol/g at 100°C. Conversely, ethanolic extraction decreased taurine concentrations from 11.71 ± 0.19 μ mol/g at 60°C to 7.04 ± 0.04 μ mol/g at 100°C. The highest taurine concentration was obtained from caudal muscle extracted with ethanol at 60°C. In dorsal muscle, taurine concentrations ranged from 2.75 ± 0.33 to 3.49 ± 0.39 μ mol/g across all extraction conditions. Overall, substantial differences in taurine recovery were observed among extraction conditions. A graphical summary of taurine concentrations obtained under the different extraction conditions is presented in Figure 1.

Discussion

The results demonstrate that taurine recovery in Nile tilapia is highly dependent on extraction methodology considering the tissue characteristics. The pronounced differences observed among treatments indicate that extraction solvent, temperature, and muscle region can substantially influence measured taurine concentrations. Caudal and dorsal muscle are characterized by different fiber types, exhibits varying in lipid, aminoacids and taurine concentrations, reflecting distinct metabolic activities within the organism. The greatest variation was observed in caudal muscle, where aqueous and ethanolic extractions produced contrasting temperature-dependent responses, whereas dorsal muscle exhibited comparatively stable taurine concentrations across treatments.

Introduction

Aquatic foods provide high-quality protein, omega-3 fatty acids and essential micronutrients, contributing to improved human health and nutrition (Golden et al., 2021). In addition, aquatic foods are increasingly recognized as a more sustainable source of animal protein compared to many terrestrial alternatives and can support the transition towards environmentally sustainable food systems (Hilborn et al., 2018). Despite the strong maritime tradition of Greece, seafood consumption remains lower than in several other Mediterranean countries. Understanding consumer perceptions and willingness to adopt sustainable and alternative aquatic foods is therefore important for supporting fisheries, aquaculture diversification and sustainable dietary transitions. This study presents preliminary results from the SEAFOOD project, which aims to promote awareness and sustainable consumption of ocean-derived foods through citizen-science and educational activities.

Materials and Methods

Data were collected between April and May 2026 using a structured questionnaire developed within the SEAFOOD project. The survey included questions on demographics, seafood consumption habits, attitudes towards seafood, sustainability perceptions and willingness to consume alternative aquatic foods, including cephalopods, bivalves and marine algae. Preliminary analyses were conducted using data from 246 completed questionnaires collected in Greece. Descriptive statistics were used to characterize consumption patterns and consumer perceptions.

Results

A total of 246 questionnaires were analyzed. Most respondents reported consuming seafood regularly, with 33.7% consuming seafood once per week and 33.3% 1–3 times per month, while only 1.2% reported never consuming seafood (Figure 1A). Consumption patterns varied among seafood categories (Figure 1B). White fish (61.1%) and fatty fish (54.6%) were the most frequently consumed categories, followed by crustaceans (34.6%) and cephalopods (28.3%). In contrast, consumption of bivalves (7.6%) and algae/seaweed (4.2%) was very limited.

Respondents demonstrated positive attitudes toward sustainable seafood choices. The highest agreement was observed for preference for locally sourced seafood (79.5%) and awareness of differences in environmental footprint among seafood products (77.0%). More than half of participants agreed with considering seafood origin (56.6%), replacing commonly consumed species with lower-footprint alternatives (54.9%), and increasing the consumption of cephalopods and bivalves (53.7%). Lower agreement was reported for consuming less-known seafood species (45.5%) and acceptance of algae as part of a sustainable diet (45.1%).

Discussion

The present findings suggest that while Greek consumers currently rely predominantly on conventional fish products, there is potential for greater adoption of alternative aquatic foods that could contribute to more sustainable food systems. Despite the currently low consumption of bivalves and marine algae, respondents expressed positive attitudes toward locally sourced seafood and lower-footprint alternatives. As aquatic foods are increasingly recognized as important components of sustainable healthy diets (UN Nutrition, 2021), improving consumer familiarity with underutilized resources such as bivalves and marine algae may facilitate dietary diversification and support the transition toward more sustainable seafood consumption patterns.

Are phosphorus requirements influenced by dietary fat content?

Phosphorus is essential for growth and bone mineralisation. The requirements for phosphorus are higher during increased growth rate. Farmed Atlantic salmon (*Salmo salar*) showed a fast growth (0.98 mm.day⁻¹) during warmer water temperatures (7-14 °C) and longer daylight between April-July compared to slower growth (0.62 mm.day⁻¹) at 5-9 °C and shorter daylight between December-April (Drábiková et al., 2026). Salmon in this study required 3.7 g/kg available phosphorus between December-April and 4.6 g/kg available phosphorus between April-July to achieve regular growth and bone mineralisation (Drábiková et al., 2026). As increased dietary fat is also linked to accelerated growth the current study assesses the dietary phosphorus requirements in seawater stages of farmed Atlantic salmon fed different fat levels.

Materials and Methods

In August 2024, salmon post-smolts (4800 fish) were pit-tagged to follow individual fish growth and deformity development. Fish were measured (fork length was 30 cm and weight 290 g on average), 2909 fish were x-rayed, and all fish were divided among 24 sea-cages (5.2 x 5.2 x 6 m, width x length x depth) located at MOWI Feed Research Station (Aukan), Averøy, Norway. Animals were exposed to natural photoperiod and temperature and fed one of 12 formulated diets. At the start of the trial additional 50 animals were sampled for base-line data.

We tested two dietary fat levels ('low' with 30 % and 'high' with 36 % fat content) and six levels of dietary phosphorus (P1-P6) with increasing monoammonium phosphate supplementation (5.4-13.2 g.kg⁻¹ total phosphorus (tP) in a randomised 2 x 6 duplicated factorial design. 'Diet P1' contained 5.4-7.2 g.kg⁻¹ tP, 'Diet P2' had 6.3-8.2 g.kg⁻¹ tP, 'Diet P3' contained 7.6-9.3 g.kg⁻¹ tP, 'Diet P4' contained 9.2-12.0 g.kg⁻¹ tP, 'Diet P5' was formulated according to currently used levels in commercial diets for different salmon stages and contained 8.2-10.4 g.kg⁻¹ tP, and 'Diet P6' contained 10.3-13.2 g.kg⁻¹ tP.

Following the start of the trial, salmon were individually measured in December, May, and August with 20, 12, and 33 fish sampled per cage at the respective sampling points. For the purpose of this abstract we will discuss results from the final sampling done in August 2025. The analysis included vertebral deformity assessment using x-ray images, total mineral content (ash) of vertebrae as representatives of endoskeleton, total ash content of scales as representatives of dermal skeleton, and scale mineralisation using whole mount Alizarin red stain. Alizarin red binds to calcium, i.e. mineralised part of the scale, while the non-mineralised part remains transparent but visible under brightfield light with partly closed aperture diaphragm. Assessment of scales represents a valuable non-invasive tool to assess severity of phosphorus deficiency in fish.

High energy increased salmon growth when combined with 'Diet P2'

Interestingly, at the final sampling in August, salmon fed 'Diet P2 high fat' were significantly longer (67.7 cm on average) and heavier (4200 g on average) compared to salmon fed 'Diet P2 low fat' with an average fork length of 64.9 cm and weight of 3868 g. As a result only 'Diet P2 low fat' fed salmon were significantly shorter and lighter than fish fed 'Diet P3-P4' at both fat levels with an average fork length and weight of 67.8 cm and 4200 g. Irrespective of dietary fat content, Atlantic salmon fed 'Diet P1' showed significantly reduced fork length and weight (58.7 cm, 3046 g for 'low' fat and 59.6 cm, 3020 g for 'high' fat diet groups) compared to salmon fed 'Diets P2-P6' at both fat levels.

Scale mineralisation was challenged into a greater extent than vertebrae mineralisation

At final sampling in August scale ash of salmon fed 'Diets P1-P2' at both fat levels as well as salmon fed 'Diet P3' at low fat level was significantly reduced compared to the remaining diet groups (Figure 1a). In contrast, vertebrae ash was significantly reduced only in salmon fed 'Diets P1-P2' at both fat levels relative to salmon fed 'Diets P4-P6'. Vertebrae ash of salmon fed 'Diet P3' was comparable to 'Diets P4-P6' and to those fed 'Diet P2' at high fat level (Figure 1b). Uniquely, scale mineralisation observed and quantified on whole mount Alizarin red stained scales was reduced not only in salmon fed 'Diet P1' but also in salmon fed 'Diet P2' with low fat content.

(Continued on next page)

What does this mean for skeletal health?

The observed reduction in growth and skeletal mineralisation will be elaborated in respect to the vertebral column health while potential to compensate phosphorus deficiency through the resorption of scales will be considered. We will discuss the possible advantages of either low or high fat levels with varying dietary phosphorus levels for phosphorus digestibility and reduced phosphorus excretion in seawater stages of Atlantic salmon and discuss the effect on dietary phosphorus requirements.

Background

The salmon louse, *Lepeophtheirus salmonis*, is associated with substantial losses to the salmon farming industry. These ectoparasites feed on the blood, gills, and skin of their hosts, facilitating pathogen entry and reducing immune function, leading to secondary infections. Adverse health outcomes and mass mortalities are increasing alongside the emergence of treatment resistance; therefore, the sustainability of salmon aquaculture depends on a shift towards prevention-focused sea lice control. At present, a limited understanding of sea lice transmission dynamics represents a major barrier to effective prevention. Due to the highly dispersive nature of free-living larvae and migratory salmonids, sea lice from distinct sources exhibit weak genetic differentiation (Jacobs et al., 2018)2018. Accurate determination of host origin at individual louse level would substantially advance our understanding of sea lice transmission dynamics, relationship between farmed and wild salmonid host populations, and provide evidence base for more targeted and effective management interventions.

Alternative profiling approaches to traditional genetics, such as stable isotope analysis (SIA) and mid-infrared reflectance spectroscopy (MIR), remain underexplored for assigning the parasite origin of individual sea lice. Parasite isotopic signatures reflect host diet; initial studies suggest $\delta^{13}\text{C}$ and $\delta^{15}\text{N}$ values can distinguish farmed from wild lice due to contrasting feed sources (Butterworth et al., 2004). However, SIA analysis is costly, and studies in other organisms suggest infrared spectroscopy may provide a cost-effective proxy (Sim et al., 2023). MIR can also detect differences in parasite tissue composition associated with variation in dietary lipid and carbohydrate content. This pilot study used adult sea lice from farmed salmonid hosts (n=35) and wild salmonid hosts (n=106) in Loch Etive, Scotland, to compare the discriminatory power of SIA and MIR in determining sea lice host origin. All samples underwent carbon and nitrogen SIA and MIR spectroscopy, and a subset (n=40) also underwent low-coverage whole genome sequencing, and mitochondrial haplotype frequencies were compared to provide a genetic benchmark.

Results and Discussion

Wild- and farmed-host derived sea lice shared the same fundamental spectral peaks, reflecting identical biochemical classes, but differed consistently in absorbance intensity (figure 1). MIR spectroscopy discriminated sea lice from farmed and wild hosts using partial least square discriminant analysis with a balanced accuracy of 0.838 under leave-one-out cross-validation, confirmed as non-random by permutation testing ($p < 0.001$). The primary discriminating signal localised to the CH_2/CH_3 bending region ($1350\text{--}1480\text{ cm}^{-1}$; Cohen's $d = 1.311$), with lice from farmed hosts exhibiting consistently higher aliphatic lipid absorbance across 100% of wavenumbers in this region after FDR correction. Supporting differences were observed in the amide II ($1480\text{--}1580\text{ cm}^{-1}$; Cohen's $d = 1.024$) and phosphodiester/amide III ($1200\text{--}1280\text{ cm}^{-1}$; Cohen's $d = 0.719$) sub-regions at 63% and 56% significance, respectively. In contrast, sea lice from wild hosts showed higher absorbance in the O–H/N–H stretching ($3200\text{--}3600\text{ cm}^{-1}$) and low-wavenumber ($400\text{--}600\text{ cm}^{-1}$) regions, consistent with greater hydration and variability in their biochemical composition. Mean isotope values differed between groups, with $\delta^{15}\text{N}$, $\delta^{13}\text{C}$, and $\delta^{34}\text{S}$ in farmed-origin lice depleted than in wild-origin lice by $3.92 \pm 0.15\text{‰}$, $4.34 \pm 0.18\text{‰}$, and $2.96 \pm 0.16\text{‰}$, respectively.

These differences are consistent with expectations of a more uniform and lipid-rich diet in farmed salmonid hosts and greater environmental variability in wild salmonids. Together, this work provides proof of concept for using biochemical markers to trace sea lice origin, supporting improved understanding of transmission pathways and more targeted strategies to improve salmon health.

Introduction

Integrated multi-trophic aquaculture (IMTA) is a sustainable production system that promotes nutrient recycling to minimise the accumulation and discharge of waste (Chopin et al., 2012). BLUEBOOST aims to promote the adoption of technologies based on the co-cultivation of low-trophic-level species with established fed species by providing knowledge on IMTA culture technologies and the systems environmental and economic benefits. In addition, IMTA offer potential for seafood production and ecosystem regeneration in environments that are under threat from climate change and anthropogenic pressures. The Ebro Delta, in common with many sea-level coastal areas, is under threat from climate change and land has become salinised due to reduced sediment discharge from the river, sea-level rise and storm intensification. Although IMTA systems have great potential for more sustainable aquaculture and ecosystem restoration, their application by the aquaculture sector remains limited by technical complexity and the scarcity of data to demonstrate the environmental and economic benefits (Ghosh et al., 2025). This work presents the results of a trial developed in Spain, in coastal ponds of the Ebro Delta. The experiment aims to compare a monoculture system with an IMTA system that can be positioned on salinised land to provide protection from climate change-influenced coastal processes.

Materials and Methods

The study was conducted in IRTA, La Ràpita Centre (Catalonia, Spain), between November 14, 2024, and October 20, 2025. Three coastal ponds of 100 m³ and 1 m depth, located in the Ebro Delta, were used. Seawater was pumped from the bay into a covered reservoir and pumped to the ponds without prior treatment. A venturi on the water inlet pipe maintained high oxygen levels close to the inlet point. A single monoculture pond was compared to two IMTA ponds. Each pond was stocked with 437 flathead grey mullet (*Mugil cephalus*) (53.9 ± 32.0 g weight) that were obtained from IRTA's own production. Each IMTA pond was also stocked with 1000 European flat oyster (*Ostrea edulis*) (15.1 ± 2.5 mm) obtained from The Oyster Restoration Company (TORC, Scotland), 1000 Pacific oyster (*Magallana gigas*) (15.4 ± 2.3 mm) obtained from Musclarium (Catalonia, Spain), 3161 Manila clam (*Ruditapes philippinarum*) (18.7 ± 1.1 mm) obtained from Proameixa Acuicultura (Galicia, Spain), and Ulva sp. (25 kg) from IRTA's own production. The mullet were fed ad libitum with a commercial feed (DIBAQ CATFISH 42, 4.0 mm). Daily mortalities were recorded, and biometric sampling was conducted every three months. Samples were also taken for nitrogen, phosphorus, and carbon analysis. Temperature was measured with sensors in the water column and sediment (HOBO, USA). Dissolved oxygen was measured twice daily, and pH and salinity once daily using a ProQuatro multiparameter meter (YSI, OH, USA). Inflow and outflow water samples were taken twice weekly to determine *in vivo* chlorophyll by fluorimetry, and every two weeks for nutrient analysis.

Results and Discussion

During the trial, environmental conditions ranged from 9 to 31 °C, dissolved oxygen from 2 to 10 mg/L, pH from 5.80 to 9, salinity from 26 to 38 ppt, and *in vivo* chlorophyll levels from 0.3 to 8 mg/L in the inlet water and from 0.3 to 14.3 mg/L in the outlet water. On October 12, 2025, a torrential rainfall event exceeding 300 L/m² occurred, causing a sharp decrease in salinity and significantly impacting the final survival of the bivalves. Mullet reached final weights of 342.25 ± 116.20 g and 354.83 ± 165.23 g in the IMTA ponds, and 401.30 ± 148.19 g in the monoculture. Although growth was slightly higher in monoculture, survival was greater in IMTA (65.8% and 69.0%) than in monoculture (50.9%). The proportion of survivors showed significant differences between each IMTA pond and the monoculture (chi-square test; $p < 0.0001$ in both cases), with no differences between the two IMTA ponds. The greater final weight in monoculture could be related to a lower final density due to mortality, while all three ponds reached a similar final biomass. The Pacific oyster reached 52.94 ± 12.82 mm and 47.83 ± 8.86 mm in length, with survival rates of 86.1% and 92.1% until August, respectively, but final mortality was 100% after the rain event. The European flat oyster showed slower growth (34.15 ± 8.94 mm and 26.17 ± 9.33 mm) and

(Continued on next page)

low final survival (2.3% and 2.1%) with mortalities associated with high summer temperatures. The Manila clam reached a large market size of 35.55 ± 2.22 mm and 33.93 ± 1.67 mm. Clam survival of 80% and 92% were recorded in August. However, the final survival rate was 22.2% and 33.5%. During final sampling, there was no difference in the average shell size between live and dead clams, suggesting that much of the mortality occurred shortly before the final sampling (20 Oct.) that followed the torrential rain event (12 Oct.). These results point to the clam as the most promising species in the system with growth to harvest size in a short growing period and potentially high survival. Mullet also grew well and demonstrated robustness to extreme changes in the environment, both salinity and temperature. *Ulva* sp. showed increases of 53% and 281% in a six-week cycle, although optimisation of its support and harvesting will be necessary. Overall, the results support the potential of the evaluated IMTA system. The species appear to interact positively, which needs to be confirmed by analysis of nutrient flows through the system. The system can also give economic use to abandoned salinised land to support ecosystem restoration.

HYPERSPECTRAL CHARACTERIZATION OF PHYSIOLOGICAL RESPONSES IN *Palmaria palmata* TO OPTIMIZE LAND-BASED ENVIRONMENTAL PARAMETERS

E. Durland^{1*}, Kinnby A², Cervin, G²

¹ Breeding and genetics, Nofima, Norway

² Marine sciences, University of Gothenburg, Sweden

*Presenting author; email: evan.durland@nofima.no

Background:

Seaweed farming is one of the fastest-growing sectors of European aquaculture. Despite the current market dominance of brown seaweed, native red seaweeds like dulse (*Palmaria palmata*) offer superior nutritional and phytochemical profiles, driving increased commercial interest. However, cultivation practices for these species remain in their infancy, with no established consensus on the environmental conditions required to optimize growth. Furthermore, while the antioxidant and phytochemical content of red seaweeds is a primary asset, quantifying these compounds currently requires labor-intensive laboratory procedures. In this study, we evaluated the effects of light spectra, simulated at depths of 0.5, 5, 10, and 20 meters, on the growth and physiological health of *P. palmata* within land-based systems. Using hyperspectral imaging, we characterized biochemical shifts in tissue composition across these light environments. By pairing spectral data with empirical phytochemical concentrations measured via mass spectrometry, we developed statistical models to assess the accuracy of rapid imaging as a high-throughput proxy for chemical quantification.

Results:

Preliminary results indicate that dulse populations from the Swedish west coast exhibit significantly higher growth rates under light conditions simulated at ~5m depth. Light spectra also influenced chemical composition; macroalgae grown at the shallowest simulated depth (0.5m) displayed spectral profiles distinct from those cultivated under deeper-water light conditions (Figure 1). Furthermore, we observed significant intra-thallus spectral variation along the length of the fronds. These gradients transitioned from the older, thicker base tissue to the newly developed tips, likely reflecting the maturation of photosystems as tissue ages. The extent of this transition zone (tip vs base) varied between treatments, likely reflecting not only the differential growth rates we observed, but also the quality of available light. This physiological shift is critical for cultivation strategy: while younger tissue drives biomass accumulation, older tissue may sequester higher concentrations of high-value carotenoids. Consequently, optimizing culture conditions solely for longitudinal growth may inadvertently produce less robust algae with diminished concentrations of the compounds that drive their market value.

Figure 1: TOP: Spectral profile of dulse grown at 0.5m and 20m simulated light conditions (green and red, respectively). BOTTOM: PCA of all individuals, based on average spectral profile.

Introduction

Vibrio spp. are among the most significant bacterial pathogens in shrimp aquaculture, contributing to high mortality and reduced production efficiency worldwide. Vibriosis remains a major disease affecting *Penaeus vannamei*, with species such as *Vibrio harveyi* and *Vibrio parahaemolyticus* frequently associated with outbreaks (Bhassu et al., 2024). The increasing prevalence of antimicrobial resistance in *Vibrio* populations further complicates disease control strategies (Hobe et al., 2026).

Virulence in these bacteria is closely linked to quorum sensing (QS), a regulatory system controlling gene expression, biofilm formation and pathogenicity (Ye et al., 2025). Disruption of QS (quorum quenching) is increasingly recognized as a promising and sustainable approach to control bacterial diseases in aquaculture (Saranya et al., 2025).

This study combined in vitro and in vivo approaches to evaluate the effect of a lignosulfonic acid-based feed acidifier on *Vibrio* control and shrimp performance.

Materials and Methods

In vitro assays were conducted to assess quorum sensing (QS) inhibition and biofilm formation in pathogenic bacteria (*Vibrio harveyi*, *Vibrio campbelli*, *Vibrio parahaemolyticus*, *Vibrio vulnificus* and *Pseudomonas* sp.). These analyses were performed at an accredited microbiological laboratory in Ecuador, where bacterial luminescence and biofilm formation were quantified using microplate assays following standard optical density methods. Bacteria were exposed to increasing concentrations (1000–2500 ppm) of a lignosulfonic acid-based acidifier.

In parallel, a 42-day feeding trial was conducted at the Laboratory of Aquatic Animal Nutrition (LABOMAR), Institute of Marine Sciences, Federal University of Ceará (Brazil). Juvenile *Penaeus vannamei* were reared under intensive outdoor tank conditions (75 shrimp m⁻²) and fed diets supplemented with 0, 5 and 15 g kg⁻¹ of the acidifier. Growth performance, survival and biomass production were monitored throughout the experimental period.

(Continued on next page)

Results and Discussion

The lignosulfonic acid-based acidifier demonstrated strong inhibitory effects on quorum sensing (QS) activity. Complete suppression of luminescence (100%) was observed for *Vibrio harveyi* and *Vibrio campbelli* at concentrations as low as 1000 ppm, indicating effective disruption of bacterial communication mechanisms. In contrast, a reference acidifier required higher concentrations (1500–1900 ppm) to achieve similar inhibition, highlighting the higher efficacy of the tested formulation.

Biofilm formation was also significantly affected. The acidifier achieved complete inhibition (100%) of biofilm formation in *Vibrio parahaemolyticus*, *Vibrio vulnificus* and *Vibrio campbelli* at 1200 ppm, while full inhibition for *Vibrio harveyi* and *Pseudomonas* sp. was observed at 1600 ppm. At lower concentrations (1000 ppm), partial inhibition was already evident, with biofilm formation reduced to 12.3% in *Vibrio parahaemolyticus* and 4.2% in *Vibrio harveyi*. These results indicate a dose-dependent response and a strong capacity to prevent bacterial adhesion and colonization.

In the feeding trial, shrimp survival increased markedly from 55.8% in the control group to 68.0% and 99.9% in the 5 and 15 g kg⁻¹ treatments, respectively. This resulted in a substantial increase in biomass production, with the highest inclusion level yielding more than a tenfold increase compared to the control. Although individual growth rates were slightly lower at higher inclusion levels, this was primarily associated with differences in survival and stocking density dynamics rather than reduced feed efficiency.

The consistency between in vitro antimicrobial activity and in vivo performance suggests that the acidifier reduces pathogenic pressure in the production system. The combined inhibition of quorum sensing and biofilm formation likely limits *Vibrio* colonization and virulence, contributing to improved survival and overall production outcomes.

Conclusion

A lignosulfonic acid-based acidifier demonstrated strong inhibitory effects on quorum sensing and biofilm formation of pathogenic bacteria, which translated into improved survival and production performance in *Penaeus vannamei*. These findings support the use of quorum sensing-targeted strategies as effective and sustainable tools for managing *Vibrio*-related challenges in shrimp aquaculture.

The amount of the nanoproducts released into the environment is a growing threat to organisms. There is little data on the effects of nanoproducts made of different compounds of the same element on biological objects. The copper nanoproducts are widely utilized due to their antimicrobial properties in feed industry, cosmetics, medical drug designing, and numerous others applications. Spermatozoa as a cell is a good model for studying the ecotoxic effects of nanoproducts and other chemicals on cells. The direct effect of two copper nanoproducts of Cu NPs and CuO NPs and copper ions (CuSO₄) on spermatozoa motility was previous investigated by our group by adding pollutants to the environment activating the gametes (Kowalska-Górska et al., 2019). More harmful effect of ionic form than nanoparticles was obtained in the study while diverse effects of the nanoproducts was not clear. The present study aimed to analyse the effect of these two copper nanoparticles and metal ions on rainbow trout spermatozoa during incubation, following prolonged exposure.

Nanoproducts of Cu and CuO (Cu NPs, CuO NPs) of primary particle size around 50 nm and ionic solution of CuSO₄ were used for the study. Suspension of concentration 0, 1, 5, 10, 25 and 50 mg Cu L⁻¹ as Cu NPs, CuO NPs and CuSO₄ was dissolved in an artificial seminal plasma. Milt was mixed with prepared solution and stored in a fridge for 96 h. At the defined incubation time, spermatozoa were activated for movement. Six motility parameters were evaluated using an automated system (CASA).

Copper nanoproducts made from different compounds have a different effect on cells. Cu NPs was more harmful than CuO NPs. The effect of Cu NPs was similar to an ionic form of CuSO₄. When incubated, the copper nanoproducts and ionic form exert a slightly positive effect on spermatozoa velocity, linearity, and motility duration, particularly in the initial hours of storage.

BEYOND BIGGER SMOLTS: WHY PHOTOPERIOD BALANCE MATTERS FOR DEVELOPMENT IN ATLANTIC SALMON

Lars Ebbesson^{1*}, Marius Takvam², Pradeep Lal²

Smoltification in Atlantic salmon is often operationally assessed through growth, size, and seawater tolerance. However, the biological smolt is produced by a tightly timed developmental program in which winter photoperiod history, increasing spring daylength, brain remodeling, endocrine activation, and osmoregulatory remodeling across the gill, intestine and kidney are coordinated. Evidence from neuroanatomical, endocrine, molecular, and physiological studies shows that continuous constant light can uncouple this program: fish may grow well, but key smolt-related changes in retinal–preoptic connectivity, CRF neurogenesis, thyroid hormone, growth hormone, cortisol signaling, together with coordinated development of NKA enzyme activity across the three osmoregulatory organs and subsequent seawater performance may be blunted or incomplete.

This presentation revisits the concept of smolt quality from a developmental perspective. We argue that smoltification is not simply growth plus seawater tolerance, but a seasonal brain-endocrine-osmoregulatory remodeling process shaped by photoperiod history. Thus, the use of continuous light (24:0) without a preceding winter signal may produce “pseudo-smolts” that acquire some smolt characteristics, while key aspects of developmental timing, endocrine activation and osmoregulatory remodeling may remain partly or completely uncoupled, with potential consequences for long-term seawater performance. Such mismatches between photoperiodic signaling and physiological development may also contribute to production disorders including nephrocalcinosis, looser syndrome (stunts), hemorrhagic smolt syndrome (HSS), and broader smolt quality problems. These disorders may therefore, at least partly, reflect mismatches between the biological requirements of salmon and the environmental conditions provided during intensive land-based production. The objective is to remind producers, researchers, and technology providers that photoperiod balance remains a core welfare and performance factor in modern smolt production, while its wider physiological consequences are still not fully understood. Optimized lighting protocols should preserve the biological logic of winter preparation and spring progression, rather than treating continuous light as a simple growth accelerator, as they may contribute to several production disorders currently observed in land-based salmon aquaculture

Introduction

Infectious diseases represent a major constraint on sustainable aquaculture production, driving substantial economic losses and raising significant animal welfare concerns (Hadiuzzaman et al., 2022; Vallejos-Vidal et al., 2021). In the absence of broad-spectrum prophylactic measures, the aquaculture sector has increasingly adopted non-antibiotic immunostimulants to enhance host immune competence (Vetvicka & Vetvickova, 2020). Among these, β -1,3/1,6-glucans derived from yeast cell walls (YCW) have attracted particular interest due to their capacity to act as pathogen-associated molecular patterns (PAMPs) and microbial-associated molecular patterns (MAMPs), thereby activating innate immune signalling pathways in both freshwater and marine teleost species (Rodrigues et al., 2020; Machuca et al., 2022). Upon recognition by pattern recognition receptors (PRRs) — including functional homologs of C-type lectin receptors — β -glucans trigger downstream activation of nuclear factor- κ B (NF- κ B) and the transcriptional upregulation of pro-inflammatory cytokines such as interleukin-1 β (IL-1 β) and tumour necrosis factor- α (TNF- α) (Rodrigues et al., 2020; Hadiuzzaman et al., 2022). Despite broad evidence of their immunostimulatory efficacy, comparisons between YCW products differing in yeast origin remain limited, and the influence of production method on the quality of the immune response has not been thoroughly characterised.

Materials and Methods

Immune modulatory effects were assessed using the rainbow trout (*Oncorhynchus mykiss*) intestinal epithelial cell line RTgutGC (passage 81), derived from a distal intestinal segment of an adult female and provided by aQuaTox-Solutions GmbH (Winterthur, Switzerland). Cells were exposed to one of four treatments: (1) exposure medium L-15/ex only (negative control; Neg. CON); (2) lipopolysaccharide (LPS) from *Escherichia coli* (positive control; Pos. CON); (3) a primary-grown yeast cell wall product (Primary-YCW; TechnoMos®, Biochem GmbH, Lohne, Germany); or (4) a by-product ethanol yeast cell wall preparation (Ethanol-YCW). All treatments were applied at equivalent concentrations under standardised exposure conditions. Following incubation, total RNA was extracted and reverse-transcribed, and relative gene expression of three immune markers — IL-1 β , TNF- α , and the Toll-like receptor 4 (TLR4) interactor with leucine-rich repeats (TRIL) — was quantified by quantitative polymerase chain reaction (qPCR). Expression data were normalised to appropriate reference genes and analysed for statistically significant differences between treatment groups ($P < 0.05$).

Results and Discussion

Both YCW products elicited statistically significant upregulation of IL-1 β and TNF- α relative to the negative control ($P < 0.05$), demonstrating immunostimulatory activity at the intestinal epithelial level. Critically, gene expression levels for both cytokines remained substantially lower than those induced by LPS, indicating that neither product provoked a hyper-inflammatory response. This profile of calibrated immune activation — sufficient to prime innate defence mechanisms without triggering deleterious inflammation — is considered functionally desirable in aquaculture settings, where excessive immune activation incurs energetic costs and compromises productive performance (Hadiuzzaman et al., 2022; Vetvicka & Vetvickova, 2020).

A pronounced differential response was observed for TRIL, a TLR4 accessory molecule previously identified in teleost fish and implicated in the modulation of both LPS and viral RNA recognition (Pietretti et al., 2013). The Primary-YCW induced TRIL expression at a level statistically equivalent to LPS stimulation, whereas Ethanol-YCW produced only a modest, albeit significant, upregulation above the negative control. Because elevated TRIL expression enhances PRR sensitivity to circulating PAMPs, a higher level of TRIL induction may confer an earlier and more rapid pathogen detection capacity — an effect analogous to a broad-spectrum, unspecific innate immune priming (Pietretti et al., 2013). Importantly, this TRIL-mediated sensitisation occurred without corresponding amplification of pro-inflammatory cytokine transcription, suggesting that the tested primary-grown YCW decouples heightened pathogen surveillance from overt inflammatory cascades.

(Continued on next page)

These findings are consistent with and extend prior reports demonstrating that the immunostimulatory potency of YCW products is contingent on yeast origin and production method (Machuca et al., 2022; Rodrigues et al., 2020). Published data on the pathogen-binding capacity of the mannan oligosaccharide (MOS) fraction further indicate that primary-grown yeast-derived MOS binds approximately 100 % more pathogens than MOS derived from ethanol yeast (Eckart, 2024), corroborating the functional superiority of primary-grown YCW products across multiple immune-relevant parameters.

Introduction

Zooplankton are important components in the aquatic food web, serving as a vital link between primary producers and the higher trophic level, their abundance is dictated by prevailing environmental conditions, making them a key indicator of environmental change. Over the years, there have been growing concerns about the impact of cage culture on plankton communities, associated with the increasing adaptation of cage aquaculture. The limited information on the effects of cage culture on zooplankton population in Itapaji geared this study. The study assessed the impact of fish cage culture on zooplankton abundance and water quality in Itapaji Reservoir, southwestern Nigeria.

Materials and Methods

Four cages located 50m equidistantly and tagged A, B, C, and D with cage D located upstream. Water quality and zooplankton abundance were investigated before stocking (BS), during culture (DC), before harvesting (BH). Water samples for zooplankton identification were collected from the points using a Juday net as described by Vinogradov et al., (1989), individual species were then examined under an inverted microscope at a magnification of x40 and x100 as described by Harris et al., (2000) while counting and taxonomic identification were done using a Sedgewick Rafter Cell under an inverted electron microscope (Conway et al., 2003; Kyewalyanga & Malesa 2024).

Water samples collected per point and period were measured for Dissolved Oxygen (DO), pH, temperature, phosphate, and nitrate. DO and pH were measured in situ using a CTD multi-probe (Sea-Bird Electronics, Model 19-03), and phosphate was measured in the laboratory as described by APHA (1998). Analyses were carried out using ANOVA to access spatial and temporal variation, the result expressed as mean $\pm$ standard error.

Results and Discussion

Zooplankton species identified taxonomically using appropriate keys were a total of 13,912 individuals (BS = 49.7% [6914 individuals], DC = 26.9% [3737 individuals] BH =23.4% [3261]) belonging to 3 taxonomic groups (protozoan = 70.9% [9869 individuals], rotifers=15.2% [2116 individuals] and crustacea = 13.9% [1927 individuals]) with 9 species (Euglena[10.8%], Chilomonas [0.9%], Frontonia [21.1%], Coleps [5.3%], Rotaria [15.21%], Cypridopsis[13.9%], Vorticella [3.9%], Paramecium [25.2%], and Chilodonella [3.7%]). Spatial variations in zooplankton abundance between cage sites were observed from the Principal Component Analysis (PCA), BS had PC1 (76.4%) and PC 2 (20.3%), DC had PC 1 (70.0%), PC 2 (19.8%)and PC 3(10.2%) and BH had PC1 (67.3%) and PC 2 (27.8%) accounting for the total proportion of zooplankton species.

The mean values of water quality parameters measured were dissolved oxygen (BS= 4.73 ± 0.34 mg/L, DC = 3.72 ± 0.13 mg/L, BH = 3.40 ± 0.11 mg/L), temperature (BS= 28.45 ± 0.10 oC, DC = 27.30 ± 0.13 oC, BH = 27.09 ± 0.10 oC), pH (BS= 6.19 ± 0.12 , DC = 6.05 ± 0.10 , BH = 5.73 ± 0.10), phosphate (BS= 0.21 ± 0.01 mg/L, DC = 0.17 ± 0.02 mg/L, BH = 0.12 ± 0.01 mg/L), and nitrate (BS= $0.001.19 \pm 0.00$ mg/L, DC = 0.001 ± 0.00 mg/L, BH = $0.001.00 \pm 0.00$ mg/L). The result reveals that dissolved oxygen and phosphate levels decreased during culture (DC) and before harvesting (BH), although all measured water quality parameters remained within the recommended limits for aquatic life ($p > 0.05$).

This study revealed that the zooplankton abundance varied due to the prevailing cage activities, and it is therefore essential to maintain a healthy and environmentally sustainable fish cage culture practice for the sustenance of aquatic biota.

EXPERIMENTAL CHALLENGE MODELS FOR *Ecytonucleospora hepatopenaei* IN SHRIMP: A COMPREHENSIVE REVIEW OF EXPERIMENTAL APPROACHES AND KNOWLEDGE GAPS

Ecytonucleospora hepatopenaei (EHP) is a microsporidian parasite that causes hepatopancreatic microsporidiosis in shrimp, leading to growth retardation and significant economic losses in global shrimp aquaculture. Although EHP does not typically cause high mortality, its substantial economic impact due to severe growth retardation and subclinical infection makes experimental challenge models essential for studying infection dynamics, host pathogen interactions, and mitigation strategies. However, existing EHP challenge models vary widely in methodology, reproducibility, and infection outcomes. This review critically evaluates current experimental challenge models, highlighting methodological differences, advantages, limitations, and critical knowledge gaps to improve standardization and reproducibility. A structured literature review was conducted using major scientific databases to identify studies on EHP challenge models in shrimp and synthesize current methodologies.

EHP challenge models were categorized into five groups: indirect transmission (cohabitation), enteric exposure models, environmental exposure models, artificial systemic models, and alternative hosts and vectors. Cohabitation models represent biologically relevant approaches for natural transmission between infected and naïve shrimp, although they often introduce variability in infection timing and intensity. In most cohabitation trials, infection was typically detected between 10 and 21 days post inoculation (dpi), with prevalence increasing progressively over time (Tang et al., 2016; Salachan et al., 2017). However, cohabitation models often showed greater variability compared to direct inoculation methods due to limited control over inoculum dose and environmental factors.

Enteric exposure models, including feeding of infected hepatopancreatic (HP) tissue, fecal matter, oral gavage, and reverse gavage, provide biologically relevant routes of infection but are influenced by inoculum quality and shrimp feeding behaviour. Feeding infected HP tissue is one of the most commonly used methods, due to its simplicity and biological relevance with infection typically detected within 7-14 dpi (Salachan et al., 2017; Mai et al., 2020). Fecal string based inoculation (Aranguren Caro et al., 2021, 2023) and oral gavage using purified spores (Munkongwongsiri, 2021) approaches demonstrated dose-dependent infection dynamics, although infection efficiency varied across studies. Reverse gavage studies reported higher infection consistency and sustained pathogen proliferation (Mai et al., 2020).

Environmental exposure models, including immersion and waterborne transmission (Pattarayingsakul et al., 2022), provide non-invasive approaches but often result in lower infection consistency and delayed infection onset. Artificial systemic models, such as injection into hepatopancreas, ventral sinus, or muscle, although less biologically relevant, offer controlled experimental conditions for mechanistic studies (Mai et al., 2020). In addition, several studies have explored alternative hosts and potential vectors, including polychaetes, *Artemia*, and other aquatic organisms, as sources of infection or transmission pathways. However, evidence for sustained replication in these organisms remains limited, and their role in challenge model development requires further validation.

Across studies, infection onset ranged from 5-30 days post challenge, and varied widely depending on inoculation method, inoculum quality, and shrimp developmental stage. Quantitative infection assessment using qPCR is inconsistently applied, and environmental parameters are insufficiently reported. These inconsistencies contribute to inter-study variability and limit reproducibility. Standardization of inoculum preparation, dose quantification, and reporting of experimental conditions is therefore essential to improve challenge model reliability and reproducibility.

This review highlights the urgent need for standardized EHP challenge protocols and proposes key methodological considerations to improve reliability, reproducibility, and comparability of future experimental studies, ultimately supporting the development of effective EHP management strategies in shrimp aquaculture.

Introduction:

The RAS system environment is a dynamic microbial system in which diverse microbial communities continuously interact with the host, influencing nutrient cycling, water quality, immune development, disease susceptibility, and overall fish performance. “Clean water” produced by UV and ozone sterilisation may disrupt affect microbiome development, potentially increasing vulnerability to later-life stressors. However, limited research has examined early-life microbial development and its long-term effects, highlighting a key knowledge gap in fish health and microbiome development. The aim of this study was to provide knowledge on the importance of the development of microbiome and water quality at egg, fry and alevin stages, and its effects on host health status. The resilience of the microbiome was also assessed in response to antibiotic intervention.

Methods:

A 15-week trial was conducted with rainbow trout from eyed eggs (270 degree days (DD)) to a final weight of 11.9 ± 0.96 g (1808 DD), followed by a 7-day oxytetracycline (OTC) treatment at 45 mg kg^{-1} . Eggs were reared in control recirculating aquaculture systems (RAS), RAS with ultraviolet treatment (RAS+UV), or RAS inoculated with faecal matter from healthy adult rainbow trout (RAS+FM), with four replicate systems per treatment and 200 eggs each. Water temperature was maintained at $11.3 \pm 0.5^\circ\text{C}$, DO at $8\text{--}9 \text{ mg L}^{-1}$, and flow at 3 L min^{-1} . Following exogenous feeding, fish were transferred to a common RAS and fed a commercial diet at 6% body weight daily. Water quality was maintained at $15.5 \pm 0.5^\circ\text{C}$, pH 6–7, and DO $8\text{--}9 \text{ mg L}^{-1}$, with ammonia, nitrite, and nitrate below 1.0, 0.1, and 30 mg L^{-1} , respectively. Sampling occurred at 270 DD (egg; S1), 493 DD (alevin; S2), 763 DD (fry; S3), and pre- and post-OTC fingerling stages at 1679 (S4) and 1808 DD (S5). Whole animals or intestines were sampled depending on developmental stage. Histology assessed goblet cell number and area, mucosal fold length, and lamina propria width. Parametric data were analysed using one- or two-way ANOVA with Tukey's *post-hoc* test, while non-parametric data were analysed using Kruskal–Wallis tests with Dunn's *post-hoc* test and Holm correction.

Results and Discussion:

Total Chemical Oxygen Demand TCOD during the initial egg microbial manipulation stage differed significantly among treatments ($p < 0.001$), with RAS+FM ($30.33 \pm 3.18 \text{ mg L}^{-1}$) higher than RAS ($21.08 \pm 2.22 \text{ mg L}^{-1}$) and RAS+UV ($22.00 \pm 2.81 \text{ mg L}^{-1}$), while RAS and RAS+UV did not differ ($p = 0.922$). No significant differences in growth, feed efficiency, survival, or deformities were observed (Table 1). Histology showed treatment-specific intestinal effects: before OTC, goblet cell area was greater in RAS than RAS+UV, while mucosal fold length and lamina propria width were greater in RAS+UV. Post-OTC, goblet cell area remained higher in RAS than RAS+FM, while RAS had the greatest lamina propria width; mucosal fold length differed ($p = 0.003$), with RAS+FM lower than RAS (Holm-adjusted $p = 0.00475$). OTC increased lamina propria thickness in RAS (Holm-adjusted $p < 0.001$), with no changes in RAS+UV or RAS+FM. Goblet cell numbers decreased in RAS+UV and RAS+FM, although the treatment $\times$ OTC interaction was not significant ($p = 0.478$). Overall, histological assessment indicated a less favourable intestinal health status in fish originating from the control RAS treatment following the antibiotic treatment. However, fish were transferred to a common RAS environment at the onset of exogenous feeding, reducing treatment-specific environmental and microbial exposure during subsequent development. Microbiome analysis of water communities and host-associated communities, and host gene expression profiling is in progress. These data will allow a greater understanding of the impact of the treatment effects during the experimental phase.

The Belgian pilot of the ULTFARMS project explores the integration of aquaculture within offshore wind farms, building on earlier insights from the UNITED project. Conducted in the Belgian North Sea, the pilot combines seaweed cultivation, flat oyster farming, and nature-inclusive design approaches for oysters in a highly exposed offshore environment, aiming to develop scalable and resilient multi-use systems.

Despite significant environmental, technical, and logistical challenges, the pilot achieved key advancements in offshore aquaculture design and operation. Experimental work highlighted limitations in replicating offshore conditions, which were addressed through wave flume testing and scaled prototype validation. The development and deployment of submersible longline systems in a commercial field site demonstrated enhanced storm resilience, with successful submersion strategies informing buoyancy control and material durability. Field operations were frequently constrained by weather and vessel availability, necessitating adaptive approaches such as the reuse of existing datasets and flexible deployment strategies. Technical challenges in artificial oyster reef deployment emphasized the need for robust designs and innovative installation methods, including acoustic retrieval systems to overcome restrictions on scientific diving. Offshore cultivation trials further confirmed that early-stage deployment and seeding techniques are critical for success, while losses of cultivation units underscored the importance of material selection and structural optimization.

Financial and logistical constraints, including high insurance costs and limited offshore access, reinforced the importance of strong cross-partner collaboration and resource sharing. Mitigation strategies implemented throughout the project resulted in improved system resilience, refined design methodologies, and actionable insights for industry, academia, offshore wind operators, and policy stakeholders.

Key recommendations include the integration of contingency planning for extreme weather, dedicated budgeting for offshore risks, and prioritization of nearshore test systems as stepping stones toward full offshore deployment. Overall, the Belgian pilot demonstrates that while offshore multi-use aquaculture remains challenging, adaptive design, iterative testing, and collaborative approaches can significantly enhance feasibility and scalability.

European flat oyster (*Ostrea edulis*) reefs formed extensive, biodiversity-rich habitats in the Belgian part of the North Sea until their collapse due to overfishing and disease. Within the Horizon Europe project BLUE CONNECT, an active restoration pilot is being implemented in the Vlaamse Banken Marine Protected Area, aiming to re-establish European flat oyster (*Ostrea edulis*) reefs where they historically occurred.

The Belgian demo site focuses on a carefully selected restoration location adjacent to a small shipwreck, situated within a marine reserve and Natura 2000 area. Site selection integrated historical oyster distribution data, high-resolution seabed substrate mapping, hydrodynamic assessments and extensive consultations with research, industry and governmental stakeholders. The restoration approach combines ecological realism with operational feasibility by using natural substrates that closely mimic native gravel beds of the Vlaamse Banken.

Certified *Bonamia*-free oyster larvae are remotely set on natural sedimentary rock substrates under controlled conditions before offshore deployment. Reef installation employs biodegradable bags and controlled drop-bag techniques, minimizing seabed disturbance.

An integrated monitoring framework accompanies the restoration, combining traditional diver-based surveys with innovative tools such as multibeam and side-scan sonar imaging and passive acoustic monitoring of reef soundscapes. In parallel, co-management principles are embedded through active stakeholder engagement, including local working groups and participatory tool validation.

This case study demonstrates how science-based site selection, restorative aquaculture, offshore engineering, innovative monitoring and stakeholder co-development can jointly support oyster reef restoration within marine protected areas, contributing to national and European restoration objectives.

As aquaculture expands to meet the growing demand for seafood, land-based recirculating aquaculture systems (RAS) are increasingly presented as a potentially more sustainable alternative to conventional marine cage farming. These systems offer several environmental advantages, including reduced water consumption, improved biosecurity, and limited interaction with wild fish populations. Nevertheless, several proposed large-scale RAS facilities in Europe and elsewhere have faced substantial public opposition resulting in project delays or cancellation.

This study examined why technologically innovative aquaculture projects with environmental ambitions may nevertheless encounter resistance. Three case studies involving proposed large-scale RAS facilities were compared. Each project generated debate among stakeholders, policymakers, environmental and animal-welfare organisations, and local communities. Information was collected from scientific literature, government reports, public inquiry documents, policy papers, media coverage and other publicly available sources. The cases were systematically compared to identify the principal concerns raised and the factors influencing project outcomes.

Animal welfare and environmental concerns - including wastewater discharge, energy and water use, and effects on the surrounding environment - featured prominently in all three cases. However, , landscape impacts, local community interests, trust in project developers, transparency, stakeholder engagement and governance also emerged as important sources of opposition. Importantly, the issues that dominated public debate were not necessarily the factors that ultimately caused projects to be delayed or cancelled. Project outcomes were shaped by a broader and interacting set of regulatory, governance, social and economic factors.

These findings demonstrate that technological innovation and environmental performance alone are insufficient to secure acceptance of large-scale land-based aquaculture. Developing and maintaining a social licence to operate also requires credible governance, transparent communication and meaningful stakeholder engagement. The study provides insights that can support the socially responsible development of future land-based aquaculture projects.

MICROPLASTICS IN RAS-REARED GIFT TILAPIA: POLYMER CHARACTERIZATION AND HAZARD INDEX ASSESSMENT

Several studies have reported the accumulation of microplastics (MPs) in aquaculture environments, highlighting their potential adverse effects on aquatic ecosystems and their accumulation in aquaculture products, with possible implications for food safety and human health. This study aimed to evaluate the influence of plastic covers on the occurrence and characteristics of microplastics in a Recirculating Aquaculture System (RAS) used for rearing GIFT Tilapia over a 90-day production cycle. The experimental system consisted of eighteen 500-L tanks, including nine covered and nine uncovered units. Fish samples were collected at the beginning and at the end of the experiment to assess microplastic occurrence, polymer composition, and the associated Hazard Index. Gastrointestinal tracts (GIT) of 19 specimens were dissected and digested with H₂O₂ 35%, and incubated in an oven at 60°C for 48 h. They were then filtered through a glassfiber filter (GF/F), and retained particles counted under a Nikon stereomicroscope, using the software *ImageView*. The polymeric properties of MPs were analyzed using a Shimadzu IRXross Fourier Transform Infrared (FTIR) spectrophotometer equipped with an AIRSight microscope. FTIR spectra were acquired in transmission mode over the spectral range of 4000–700 cm⁻¹ with a spectral resolution of 8 cm⁻¹ and 100 accumulated scans. Only the samples with matching spectra above 70% and which exhibited the characteristic absorption bands of the identified polymer were considered. To assess the ecological harm of MPs, the Polymer Hazard Index (Lithner et al, 2011) and polymer hazard categories were calculated. After correction of number of MPs by confirmed particles in the FTIR, a total of 1932 MPs were registered in all GIT samples, with a mean of 101.7 particles/individual. Microplastic abundance did not differ significantly among treatments or maturation stages, and no significant treatment × maturation stage interaction was detected by two-way ANOVA ($p > 0.05$). Thus, the differences observed between sites with and without plastic cover fell within the range of variation associated with these non-significant effects. The order of MPs characterization in all samples analyzed by FTIR was Polyethylene-Kaolin composite (55.7%) > Polyacrylamide (13.4%) > Polyamide (11.5%) > Talc-Polyethylene composite (5.77%) > EVOH (3.85%), followed by Styrene-Butadiene, Polyester, PVC, Polycarbonate and Acrylic adhesive, all with 1.92%. A greater diversity of polymer types was observed in adult fish. Among the groups, the adult/covered and young/uncovered areas exhibited the highest and lowest diversities respectively. The Hazard Risk derived from the polymer characterization across all analyzed samples varied between 737 – 51267, indicating that both areas and maturation stages were above Health Risk Category III (High Risk), especially the Adult/Covered Area. The diversity of polymers identified further suggests that microplastic contamination in the system originates from multiple sources. While the precise origin of each polymer cannot be established, their occurrence is consistent with the weathering of aquaculture infrastructure, feed-related materials, plastic packaging, and other polymer-based products used during system operation. Thus, this study provides baseline data on microplastic contamination in tilapia reared under different cultivation conditions, supporting future investigations into contamination pathways and risk assessment in aquaculture systems.

Acknowledgments

Aquaponic systems are promising sustainable food production technologies that integrate fish culture and plant cultivation. Their performance depends on balanced environmental conditions for fish, nitrifying bacteria and plants. This study evaluated the agronomic performance, mineral composition and essential oil profile of basil grown in a trout-based decoupled aquaponic system. Two cultivation strategies were compared over 60 days: a non-supplemented system relying exclusively on trout-rearing water and a system supplemented with mineral nutrients formulated according to the Hoagland solution. Basil grown without mineral supplementation maintained a healthy appearance and stable physiological status, with satisfactory growth, although biomass remained lower than in supplemented plants. The mineral profile showed comparable nitrate and phosphorus concentrations in non-supplemented and supplemented plants, with nitrate levels of 5.40 ± 0.29 and 5.52 ± 0.29 mg g⁻¹, respectively, and phosphorus levels of 5.46 ± 0.23 and 6.14 ± 0.91 mg g⁻¹, respectively. In contrast, potassium concentration was lower in non-supplemented plants (36.89 ± 3.31 mg g⁻¹) than in supplemented plants (55.56 ± 7.16 mg g⁻¹). Essential oil yield per cultivated surface area remained comparable between systems, reaching 2.96 and 3.09 mL m⁻² in the supplemented and non-supplemented systems, respectively. GC-MS analysis showed that linalool (about 24%) was the predominant compound in both systems. Estragole content was markedly higher in non-supplemented plants ($21.35 \pm 1.46\%$) than in supplemented plants ($5.24 \pm 0.68\%$). These results show that trout-based decoupled aquaponics can support satisfactory basil production while enhancing essential oil accumulation and modulating aroma-related composition, making this approach a promising sustainable strategy for aromatic plant cultivation.

METABOLOMIC PROFILING REVEALS POTENTIAL BIOCHEMICAL DETERMINANTS OF EGG QUALITY IN ATLANTIC SALMON

Introduction

Egg quality is a key determinant of reproductive success in Atlantic salmon (*Salmo salar*), yet the biochemical basis underlying its variation remains poorly understood. Variability in egg quality can significantly affect fertilisation success, embryo survival, hatching rate, and embryo viability, ultimately impacting production efficiencies (Bobe & Labbe, 2010; Brooks et al., 1997). In the past, egg quality in salmonids has been evaluated using post fertilisation outcomes which do not provide insight into the underlying biochemical processes that determine egg developmental competence (Aegerter & Jalabert, 2004; Lahnsteiner, 2000). Metabolomics has been applied to study fish responses to stress, nutrition, and disease, but its use in assessing egg quality remains limited. To the best of our knowledge, this is the first study to characterise the pre-fertilisation metabolomic profile of Atlantic salmon eggs, aiming to identify metabolites that distinguish egg batches by fertilisation success using a commercial Tasmanian population.

Materials and Methods

Freshly spawned unfertilised eggs were obtained from fifteen three-year-old Atlantic salmon females, and highly motile sperm was collected from two three-year-old neo-males at a Tasmanian hatchery in May 2024. Prior to fertilisation, subsamples were collected for metabolomic analysis. Each egg batch was fertilised in duplicate using sperm from both males and incubated individually in custom-made mini upwellers within a temperature and dissolved oxygen controlled freshwater recirculation system. Fertilisation success was assessed after three weeks of incubation based on neural streak formation. Eggs were subsequently freeze-dried, and metabolites were extracted using acetonitrile/methanol/water (2:2:1, v/v/v). Metabolite separation was performed using ultra-high-performance liquid chromatography (UHPLC), and annotation was conducted using a preliminary version of the Metabolite Annotation Propagation Synthesis (MAPS) pipeline (Cowled et al., 2026). Metabolic differences between high- and low-quality egg batches (defined by fertilisation success rate) were characterised using MetaboAnalyst 6.0 (Pang et al., 2024) to identify pathways associated with developmental competence.

Results and Discussion

A total of 1209 features were detected across egg samples, with 303 metabolites annotated in positive ion mode and 109 in negative ion mode. Low-quality eggs exhibited significantly higher levels of cyclic adenosine monophosphate (cAMP), spermine, D-camphor, and pivaloyltaurine. Pathway enrichment analysis reflected localised perturbations in amino acid metabolism and redox balance. These findings suggest the presence of metabolic stress, disrupted redox homeostasis, and changes in polyamine metabolism that may impair oocyte maturation and early embryonic development. High-quality eggs were characterised by increased levels of peptides and lipid-associated metabolites such as leucyl-prolyl-glycine, alanyl-valyl-proline isobutylamide, asparaginyllucine, glycyl-L-leucine, rhodanyl acetate, diphenyl sulfone, and clopidogrel. The enrichment of dipeptides and tripeptides may indicate enhanced amino acid availability for protein synthesis, while lipid-related metabolites suggest improved energy reserves and nutritional status.

Our study demonstrates distinct metabolic signatures associated with egg quality and fertilisation success in Atlantic salmon and propose potential biochemical markers for improving broodstock management and reproductive performance in Atlantic salmon aquaculture.

Introduction

Semi-intensive common carp (*Cyprinus carpio*) pond aquaculture in Central and Eastern Europe provides valuable ecosystem services, including water retention and biodiversity support, yet also contributes to nutrient pollution and the risk of eutrophication. In 2022, European (EU27) carp production reached 63,865 t with a market value of nearly €190 million (FAO, 2024). Despite regulatory limits of 1,500 kg biomass ha⁻¹ (in Poland), effluent loading from semi-intensive systems can exceed the thresholds of the EU Water Framework Directive (EU-WFD, 2000) for total nitrogen (TN) and total phosphorus (TP). Phytoremediation — the use of aquatic macrophytes to remove nutrients from water — offers a promising, low-cost nature-based solution (NbS) that can simultaneously improve discharge quality and generate marketable biomass. Watercress (*Nasturtium officinale*) is a nutrient-dense, semi-aquatic perennial valued for its vitamins A, C, and K, as well as antioxidant and cancer-protective properties (Gill et al., 2007). Duckweed (*Lemna minor*) is a fast-growing floating macrophyte that contains up to 45% protein and is widely recognised for its efficient removal of nitrogen and phosphorus (Xu et al., 2023). The integration of both species into carp farm infrastructure has the potential to diversify farm income while mitigating eutrophication at scale (Eljasik et al., 2026).

Materials and Methods

The study was conducted at a commercial 120 ha (80 ha water surface) carp farm (Maliniec, northwest Poland, 53°42'N 15°21'E) producing approximately 28 t of carp annually in a traditional 3-year semi-intensive cycle. Four production systems were evaluated: watercress cultivated in (i) an unused earthen breeding pond (w-pond, 102.95 m²), (ii) a concrete discharge channel (w-channel, 169.93 m²), and (iii) a raft aquaponics system (w-aquaponics, 25.44 m²); and (iv) naturally established duckweed in the farm discharge channel (d-channel, 145.5 m²). Water quality parameters (pH, dissolved oxygen (DO), oxidoreduction potential (ORP), conductivity, total dissolved solids (TDS), and temperature) were measured in situ. Water samples were analysed for TN, nitrogen forms (NH₄⁺-N, NO₃⁻-N, NO₂⁻-N), TP, total reactive phosphorus (TRP), total carbon (TC), inorganic carbon (IC), and potassium (K). Harvested plant biomass was analysed for dry matter, ash, N, P, K, macro- and microelements, and heavy metals. Nutrient retention efficiency (%) was calculated as: (outflow conc. – inflow conc.) / inflow conc. × 100, following Kajgrova et al. (2024), and compared against EU-WFD thresholds for safe riverine discharge (≤3.5 mg TN L⁻¹; ≤106 µg TP L⁻¹).

Results and Discussion

Watercress achieved production yields of 11.92 ± 6.71 kg m⁻² (w-pond), 7.99 ± 0.99 kg m⁻² (w-channel), and 11.54 ± 3.73 kg m⁻² (w-aquaponics). Duckweed yielded 2.54 ± 0.77 kg m⁻² in the d-channel. TN was reduced by 5.93% (w-pond) and 8.63% (w-channel), while TP removal reached 23.43% via watercress (w-pond). Duckweed outperformed watercress in nutrient sequestration, removing 19.15% of TN and 57.89% of TP, along with significant reductions in NH₄⁺ (–44%), NO₃⁻ (–3.8%), NO₂⁻ (–13.8%), TRP (–68%), and organic phosphorus (–39.8%). Combined across all systems, the average retention relative to inflow was –9.9% for N and –25.6% for P, with negligible effect on carbon. All outflow waters met EU-WFD nitrogen limits; duckweed-treated water also approached compliance with phosphorus discharge thresholds. Both macrophytes remained within EU food-grade limits for heavy metals (Pb <0.30 mg kg⁻¹ w.w.; Cd <0.10 mg kg⁻¹ w.w.; As <20 µg kg⁻¹ w.w.), confirming their safety for human consumption (EC, 2023). Watercress nutrient uptake patterns varied across systems, reflecting the stoichiometric N:P ratio of the inflow water. TRP removal was observed in the w-pond (N:P ratio 40:1) but not in the w-channel (N:P ratio 11:1), consistent with the importance of nutrient stoichiometry for macrophyte phosphorus uptake. An unexpected increase in K concentration (+170.8%) in duckweed channel outflow was attributed to cation exchange, stress-induced K⁺ efflux, and leaching from decomposing biomass. The duckweed C:N:P ratio of 185:9:1 — shifted from the aquatic plant optimum of 119:17:1 (Hillebrand & Sommer, 1999) — indicates considerable remaining capacity for N and P removal under optimised harvesting regimes.

(Continued on next page)

Conclusions

Both watercress and duckweed demonstrated significant phytoremediation potential in effluents from semi-intensive carp aquaculture, with duckweed showing superior nutrient removal efficiency. Integration of these macrophytes into existing carp farm infrastructure (unused ponds, inter-pond channels, discharge channels) requires minimal investment while producing food- and feed-grade biomass that can diversify farm income. The multitrophic design further enhances the ecosystem services value of European fishponds, already estimated at $>1,257 \text{ € ha}^{-1}$ (Frélichová et al., 2014), and supports the water quality goals of the EU Water Framework Directive. Scaling these NbS across the Central and Eastern European aquaculture landscape could substantially reduce nutrient loads to inland waterways and help prevent eutrophication.

Introduction

Blue mussel farming is a form of non-fed aquaculture with high potential for more sustainable protein production, offering diverse ecosystem services while generally requiring fewer emissions and resources than fed aquaculture, such as salmon and other finfish (van der Schatte Olivier et al., 2020). There is growing interest in expanding this sector in response to calls for a transition towards sustainable and climate-smart protein to improve the health of the planet and people (Blanchard et al., 2017). Despite this potential, the global blue mussel aquaculture industry has remained relatively stagnant in recent decades (FAO, 2009). The potential for the expansion of the sector is currently influenced by supply chain efficiency (Krause et al., 2025; Avdelas et al., 2021), environmental conditions (Steeves & Filgueira, 2019; Padin et al., 2024), social acceptance (Wood & Filgueira, 2022), regulation (Fox et al., 2020), and economic conditions (Avdelas et al., 2021). These drivers generate uncertainties that hinder the industry's ability to plan for expansion by making it difficult to anticipate potential challenges and risks, and to identify where expansion opportunities may exist. Many drivers of mussel aquaculture are related to socio-economic and cultural contexts that vary geographically. Therefore, the expansion of mussel aquaculture will require coordinated yet place-specific strategic management to account for the many complex and interconnected external factors influencing the success of the sector. This study aims to identify the most relevant opportunities and barriers to the expansion of blue mussel aquaculture using semi-structured interviews with 18 stakeholders across 12 producer countries in the North Atlantic. This aim is addressed through a qualitative investigation and coding analysis using NVivo guided by the PESTEL (political, economic, social, technological, environmental, and legal) framework.

Results

Results revealed a greater number of barriers than opportunities across all PESTEL categories. Opportunities were identified but were often described as contingent on improvements in policy support, access to technology, and market development. Across all categories, findings highlight that mussel aquaculture is not constrained by a single limiting factor, but rather by interconnected structural challenges. Social factors emerged as the most prominent influence overall, particularly in relation to consumer demand and public acceptance, followed by environmental and economic factors. Technological factors were the only category more frequently associated with opportunities than barriers. Technology was also the least prominent category for barriers, suggesting that innovation may play a key enabling role. Legal factors related to government regulations were least frequently associated with opportunities, indicating an area where governments and policymakers could provide stronger support if expansion were a priority.

Discussion

This study offers fresh perspectives on the opportunities and barriers to blue mussel aquaculture expansion in the North Atlantic. Previous research has recognized key barriers, including low profitability, labour shortages, limited seed availability, environmental uncertainty, trade disruptions, low consumer demand, and complex licensing systems (Krause et al., 2025; Fox et al., 2020). Further, the participants in this study noted that climate change, restricted access to finance and technology, competition for marine space, and fragmented governance often affect small-scale producers most severely. Key opportunities recognized by the literature included sustainability, ecosystem services, contributions to food security, and rural employment (Avdelas et al., 2021; Bianchi et al., 2022). Participants also highlighted market opportunities through ecolabelling, tourism, geo-cultural branding, and product innovation, as well as technological advances in offshore farming, hatcheries, monitoring systems, and smart farming systems. Findings also showed apparent regional differences; for example, seed shortages were major concerns in some European countries but appeared less significant among participants from North America and Scandinavia.

Overall, the study suggests that successful expansion will require place-based strategies, streamlined regulation, market development, innovation, and coordinated policy that recognizes the role of mussel aquaculture in sustainable food systems, coastal economies, and environmental management.

STAKEHOLDER PERSPECTIVES ON THE EXPANSION POTENTIAL FOR MUSSEL FARMING IN CANADA AND SWEDEN

G Elliott ^{1*}, Filgueira R², Sherren K¹, Tyedmers P¹

INTRODUCTION

Global blue mussel production reached approximately 132,000 tonnes in 2023, with Canada serving as the primary supplier to North America, producing roughly 21,989 tonnes annually (FAO, 2024). While the Canadian industry is well-developed and dominated by large-scale commercial entities, Sweden's sector is characterized by small-scale producers concentrated on the west coast, yielding approximately 1,684 tonnes annually (FAO, 2026). Growth in Sweden has been influenced by the Baltic Blue Growth project, which has promoted mussel farming primarily for nutrient removal and cycling, to support eutrophication mitigation rather than for direct human consumption. As global priorities shift toward expanding nutrient-dense, low-carbon protein sources, mussel farming represents an optimal pathway for addressing these goals (Bianchi et al., 2022). Given the differences in each country's approach to aquaculture, comparing their stakeholder perspectives is compelling because it may point to future directions for the blue economy.

METHODS

This study employs Q-methodology to identify and compare viewpoints among four stakeholder groups: industry, research, government, and NGOs. Thirty participants from Canada and Sweden took part in the study. Q-methodology combines qualitative and quantitative methods by using statistical techniques to examine subjective viewpoints. In environmental discourses, individuals often have conflicting viewpoints, beliefs, and experiences. Q-methodology studies are well-suited to identifying topics on which individuals agree by grouping responses based on shared priorities and concerns, ultimately finding areas of consensus and disagreement among groups of participants (Barry & Proops, 1999). The results of Q-methodology studies are groups of shared perspectives, qualitatively titled and described based on the observed interests of the group.

PRELIMINARY RESULTS AND DISCUSSION

Four dominant perspectives emerged from the dataset:

The Apprehensive Expansionist: Focused on commercial and economic potential, driven by market price and demand.

The Social-Acceptance Skeptic: Concerned with social and regulatory influences, such as misinformation and stakeholder conflicts.

The Eco-Innovator: Defined by an environmental focus on climate change adaptation and technological innovation.

The Production-Risk Pragmatist: Concerned with environmental threats and their impacts on production reliability and operating costs.

While "The Apprehensive Expansionist" perspective was represented across both countries, the other perspectives aligned primarily with one country. "The Social Acceptance Skeptic" is predominantly a Swedish perspective, while the "Eco-innovator" and the "Production-Risk Pragmatist" perspectives are primarily comprised of Canadian participants. This country-skewed composition of the perspectives suggests that viewpoints on expansion were not necessarily determined by stakeholder group alone, but that country-specific context may have shaped participant perceptions.

These Results suggest that market-related issues, such as demand projections and market price, remain universally relevant. In Sweden, findings indicate that clearer regulations and increased public awareness could facilitate the expansion of mussel farming. In Canada, the results reveal a strategic impasse between optimists (Eco-innovators) and risk-oriented (Production-Risk Pragmatists) perspectives, highlighting a tension that may stall future development.

Introduction

Processed animal proteins, such as poultry by-product meal (PBM), combine high nutritional quality with a low environmental footprint, aligning with circular bioeconomy principles (Galkanda-Arachchige et al., 2020). Meagre (*Argyrosomus regius*), a high-value whitefish species native to the Adriatic Sea, has gained renewed interest in Mediterranean aquaculture due to its quality, rapid growth, and adaptability to farming conditions (Kružić et al., 2016). Beyond growth and economic performance, evaluating how alternative protein sources shape the gut microbial ecosystem is essential, since intestinal bacteria and fungi play key roles in digestion, nutrient absorption, and immune homeostasis, and can serve as sensitive early indicators of dietary impact on fish health. This study presents the first combined assessment of the bacterial (16S rRNA) and fungal (ITS2) intestinal communities of meagre fed increasing dietary inclusion levels of PBM as a fishmeal substitute.

Material and methods

Three experimental diets incorporating PBM as a partial fishmeal replacement at two inclusion levels (T1, T2), plus a fishmeal-based control diet (T3/CF), were formulated to meet the nutritional requirements of meagre. The feeding trial was conducted in an open-circuit, outdoor water system at the Laboratory of Aquaculture, Institute of Oceanography and Fisheries (Split, Croatia). A total of 110 meagre (initial mean body weight: 1220 ± 154 g) were acclimated for four weeks on a commercial diet before being randomly distributed into six concrete tanks (600 L; 18 fish per tank, two replicate tanks per treatment). At the conclusion of the trial after one year, digesta content was sampled from the proximal (PI) and distal (DI) intestine of fish from each dietary group for gut microbial community characterization (12 replicates per treatment for each intestinal segment). Fungal (ITS2) and bacterial (16S rRNA V3-V4 region) community composition were characterized in parallel by amplicon sequencing on the Illumina platform. Sequences were denoised into amplicon sequence variants (ASVs) using DADA2 and taxonomically classified against the SILVA 138.2 (16S) and UNITE (ITS2) reference databases. Alpha and beta diversity were calculated for both datasets, and group differences were tested using ANOSIM and PERMANOVA (Bray-Curtis).

Results and discussion

The fungal (ITS2) community was diverse and highly individually variable, dominated by Malasseziomycetes, Dothideomycetes, Sordariomycetes, Eurotiomycetes and Saccharomycetes. Alpha diversity was consistently higher in the proximal than distal intestine, and the fishmeal control showed the lowest fungal diversity and evenness in both segments, while beta diversity and ANOSIM/PERMANOVA confirmed that dietary effects on the mycobiome were strongest distally, with T2 showing an intermediate community structure between T1 and the control.

The bacterial (16S) community was overwhelmingly dominated by Gammaproteobacteria across nearly all samples and diets, indicating a comparatively stable core bacterial assemblage relative to the fungal community. In contrast to the mycobiome, bacterial alpha diversity was highest, not lowest, in the fishmeal control, particularly in the distal intestine. Beta diversity, ANOSIM and PERMANOVA converged on a single, striking pattern: the distal intestinal bacterial community of the control group was markedly and significantly distinct from all other diet-by-segment combinations, whereas proximal communities and both PBM-fed groups (T1, T2) remained largely indistinguishable from one another regardless of gut segment.

Taken together, both microbial kingdoms indicate that PBM inclusion reshapes the meagre intestinal microbial ecosystem primarily in the distal intestine, but with contrasting directionality: PBM diets increased fungal diversity and evenness relative to the control, while the bacterial community of PBM-fed fish appeared more homogeneous than the compositionally distinct, more diverse distal bacterial community observed under the fishmeal-based diet. These complementary bacterial and fungal signatures underscore the value of a dual-kingdom amplicon approach for capturing diet-driven shifts in fish gut microbial ecology, and support poultry by-product meal as a viable, sustainable fishmeal alternative without inducing a uniformly destabilizing effect on the meagre gut microbiota.

Introduction

Ongoing climate change is likely to profoundly alter aquaculture production conditions, particularly for freshwater species such as rainbow trout. Resilience, defined as an animal's ability to be minimally affected by disturbances or to rapidly return to its pre-disturbance state (Colditz and Hine, 2016), could represent a major focus in breeding objectives to help the sector cope with global warming. In addition, sterile triploid trout intended for smoked fillet production currently account for a large proportion of French production. The aim of this study was to evaluate the genetic parameters of resilience indicators between corresponding diploid and triploid trout families.

Material and methods

Three batches of 1,200 progenies each were derived from a single semi-factorial mating design of 100 females and 90 males from a commercial line of rainbow trout (*Oncorhynchus mykiss*) of the breeding company Les Sources de l'Avance. The first diploid batch (2n_breed) was reared in the breeding farm at stable temperature of 14°C. The two additional batches, one diploid (2n_prod) and the other triploid (3n_prod), were reared in a production farm characterized by a variable thermal profile with chronic episodes of elevated temperatures. Each individual was electronically tagged to monitor body weight four to five times until reaching the average body weight of 2.5 kg. Abiotic parameters (temperature, pH, etc.) were recorded throughout the experiment. At 2.5kg, individuals were slaughtered and measured for various processing traits. Fish were genotyped for parentage assignment using 1,000 SNP markers (Roche et al., 2024) sterile triploids are commonly used for production as sterility gives them potential gains in growth, yields, and quality. However, they cannot be reproduced, and DNA parentage assignment to their diploid or tetraploid parents is required to estimate breeding values for triploid phenotypes. No publicly available software has the ability to assign triploids to their parents. Here, we updated the R package APIS to support triploids induced from diploid parents. First, we created new exclusion and likelihood tables that account for the double allelic contribution of the dam and the recombination that can occur during female meiosis. As the effective recombination rate of each marker with the centromere is usually unknown, we set it at 0.5 and found that this value maximizes the assignment rate even for markers with high or low recombination rates. The number of markers needed for a high true assignment rate did not strongly depend on the proportion of missing parental genotypes. The assignment power was however affected by the quality of the markers (minor allele frequency, call rate. Animal models using pedigree kinship adapted to ploidy level were used for additive variance estimations. Genetic parameters were then estimated, including within-group genetic correlations and pairwise between-group genetic correlations across the two environments and the two ploidy levels.

Table : Heritability of weights and headless gutted carcass yield according to batch (2n_breed in green, 2n_prod in yellow and 3n_prod in red)

(Continued on next page)

Results

Growth was faster at the breeding site than at the production site, allowing fish to be slaughtered at an average body weight of 2,127 g after 325 days post-hatching (dph) at the breeding site, whereas processing was carried out at 2,705 g for diploids and 2,575 g for triploids after 420 dph at the production site. Mortality reached 13.5% at the breeding site, compared with 27.8% for diploids and 34.2% for triploids at the production site. The difference in survival between 3n_prod and 2n_prod batches was significant during the early life stages but disappeared from 170 g (169 dph) onwards.

Headless gutted carcass yield, which is a proxy of fillet yield, at processing was 0.79 [0.01] for each batch, although the head yield is slightly higher at the production site, particularly for triploids (0.12 vs 0.11 vs 0.10, for 3n_prod, 2n_prod and 2n_breed respectively)

Heritability estimates for body weight ranged from 0.21 [0.05] to 0.45 [0.08], depending on the age at measurement, the rearing site, and ploidy level. They tended to decrease throughout fish growth. Genetic correlations for weight gain between ploidy levels at the production site were very high (>0.90), only estimation for weight gain during the autumn period was slightly lower (0.81 [0.28]). At slaughter, the genetic correlation between ploidy levels for body weight at slaughter was 0.73 [0.20], whereas that for headless gutted carcass yield reached 0.91 [0.06].

Comparison of weight gain and body weight for diploids across the two sites showed more moderate genetic correlations, ranging from 0.45 to 0.55 and 0.51 to 0.66 on comparable periods. The genetic correlation between sites for body weight of diploid fish at slaughter was 0.76 [0.17], and 0.87 [0.07] for headless gutted carcass yield. Genetic correlations between 2n_breed et 3n_prod were slightly lower.

Discussion

The results of this study highlight moderate genetic correlations for growth between the two rearing sites, suggesting that breeding strategies should be adapted according to the targeted breeding objectives for growth improvement. These differences may be partly explained by contrasting rearing conditions, particularly with regard to the thermal profiles of the farms. They become even more pronounced when the ploidy level of the breeding nucleus differs from that of the fish in production. However, genetic correlations for processing yields remained very high, suggesting no re-ranking of families for these traits according to ploidy or environment. This study provides a foundation for the development of breeding programs for diploid or triploid trout reared under contrasting environmental conditions.

BEST OF BOTH WORLDS: NOR-GRAPE SUPPLEMENTATION LESSENS THE IMPACT OF VACCINATION ON GROWTH PERFORMANCE IN NILE TILAPIA (*Oreochromis niloticus*)

P. Engler ^{1*}, Bernot J.¹, Benarbia A.¹

¹ Nor-Feed, France

*paul.engler@norfeed.net

Introduction

Despite its strong growth, disease remains a major constraint for aquaculture. With the intensification and multiplication of farms, disease has become a major constraint to the culture of tilapia. *Streptococcus agalactiae* is zoonotic and a leading cause of death (streptococcosis) in tilapia, quoted in the literature and by farmers and has been associated with infections in humans, related with the handling and preparation of infected fish. Vaccination is a key tool in improving farm protection against wild pathogens and their harmful impacts on fish health and mortality. However, vaccination events, due to their nature, can lead to momentaneous reduction of growth performance, while fish are mounting their immune response. The aim of this experiment was to evaluate the effect of Nor-Grape, a dry grape extract feed additive, for its potential to attenuate drawbacks of vaccination on growth performance in tilapia.

Materials and Methods

375 juvenile tilapias (16.6g±0.3g) were randomly distributed in 15 100L tanks (25 fish per tank) and fed for 4 weeks with 2 distinct experimental diets: a control diet (CTL, COPPENS) and a supplemented diet (NG, CTL diet + 70g Nor-Grape®/T). After one week of feeding, fish were subjected to an intra-peritoneal vaccination through injection at 0,1ml with a *S. agalactiae* vaccine (VAC). A CTL group was not vaccinated (NEG) to evaluate the impact of vaccination on growth. Feeding was continued for another 3 weeks post-vaccination. Mortality was assessed daily. Growth (Initial body weight and final body weight, weekly weight gain, specific growth rate SGR) and feed utilization (FCR) were also monitored.

Results and discussion

Fish growth was significantly impacted by the vaccination event in the CTL VAC group compared to the CTL NEG fish ($p<0.05$). However, no difference on growth performance was observed between NG fish and the CTL NEG group ($p>0.05$) showing that the supplementation lessened the impact of the vaccination on growth.

Thus, Nor-Grape can prove a useful supplementation in fish around vaccination to limit its impact on growth to get the best of both worlds: biosecurity and optimal growth.

DIETARY GREEN TEA EXTRACT INCLUSION FOR TURBOT POSTLARVAE: EFFECTS ON GROWTH, REDOX STATUS, AND MOLECULAR RESPONSE

Introduction

Marine fish larvae are particularly vulnerable to oxidative stress and metabolic imbalances during early ontogeny. The intensification of marine larviculture needs innovative strategies to enhance larval robustness and resilience. Green tea extract, rich in polyphenols such as epigallocatechin gallate (EGCG), has emerged as a promising phytobiotic due to its potent antioxidant and health-promoting properties. In species like turbot (*Scophthalmus maximus*), maintaining gut integrity and metabolic efficiency is crucial for successful weaning and subsequent performance. Incorporating botanical extracts may provide a non-invasive tool to prime the larval physiological system, potentially improving the response to common acute stressors. While the antioxidant benefits of green tea are well-documented in adult fish, its role in modulating the metabolic and molecular pathways during the fast-growing postlarval stage remains poorly understood. This study aims to evaluate the potential of green tea extract as a functional dietary supplement to strengthen turbot postlarvae, assessing its impact on growth performance, redox physiology, and the molecular regulation of key metabolic pathways before and after an acute thermal challenge.

Material and Methods

The trial was conducted using turbot (*Scophthalmus maximus*) postlarvae reared in a Recirculating Aquaculture System (RAS) from 29 to 51 days after hatching (DAH). Three experimental diets were tested in triplicate: a commercial-like control (CTRL) and two diets supplemented with green tea extract at two inclusion levels, LOW and HIGH (the latter being double the former). At 51DAH, larvae were subjected to an acute thermal shock of +5°C above the rearing temperature, followed by a second sampling. Growth performance KPIs, including dry weight, survival, total length, and relative growth rate (RGR), were recorded. Physiological redox status was assessed alongside molecular analyses. Gene expression related to redox regulation (*sod2*, *gpx4*, *cat*, *nrf2*), nitrogen metabolism (*gdh*, *glul*, *got2*), amino acid transporters (*pept1*, *lat1*), digestive capacity (*tryp*), lipid metabolism (*aco*, *fasn*, *fabp2*), gut integrity (*cldn15*, *tjp1*, *muc2*), mitochondrial biogenesis (*atp5f1a*, *ppargc1a*, *opa1*), and cellular stress (*hsp60*, *hsp70*, *sirt3*) was quantified.

Results

No significant differences were observed in survival, dry weight, total length, or RGR across treatments. Before the thermal challenge, SOD activity was lower in green tea-fed groups compared to the CTRL. Following the temperature stressor, the *gdh* gene was significantly upregulated in the LOW treatment relative to the CTRL, although *glul* and *got2* remained unaffected. Regarding the redox response post-challenge, *sod2* and *gpx4* showed no differences, while *cat* and *nrf2* expression was lower in the LOW group compared to the CTRL. Other markers for cellular stress, digestive capacity, lipid metabolism, gut integrity, and mitochondrial biogenesis were not significantly affected by the diets or the stressor.

Conclusions

Dietary inclusion of green tea extract did not alter turbot growth performance but successfully modulated key molecular pathways. The upregulation of *gdh* under thermal stress suggests a higher nitrogen metabolism adjustment during environmental challenges, with further mobilization of amino acids as energy source. Crucially, the downregulation of *nrf2* and *cat* likely reflects a direct ROS scavenging effect by green tea polyphenols, exerting a ‘sparing effect’ on the endogenous antioxidant system by reducing the need for gene activation. Overall, green tea extract shows potential to bolster metabolic resilience and physiological priming in marine larviculture.

Introduction

A growing demand for seafood and the ensuing environmental effects are pushing the need for innovation in aquaculture and a critical examination of technological advancement in several key areas, such as novel feed composition and feed technologies. The increasing need for aquafeeds and limited fish meal supply has led to alternative ingredients in feed formulations. This may result in higher carbohydrate content in diets, affecting fish digestion and environmental waste production. As known, soy protein is the major source of protein as fishmeal replacement in fish feed because of its worldwide availability and low price. However, to our knowledge there is a lack of information regarding the use of X-ray microtomography to evaluate change in microstructure of feed blends added different concentration of soybean protein concentrate (SPC). Nonetheless, significant knowledge gaps persist regarding the long-term physiological and nutritional effects of these protein sources in carnivorous species maintained in RAS. The aims of the study, therefore, were to investigate the pellet's characteristics (bulk density, expansion ratio, diameter and pellet's porosity) and their usage properties (oil leakage rate, durability, hardness and floatability) and to assess growth performance, digestibility, gut microbiome profile of European sea bass fed with experimental diets containing increasing levels of SPC over 16 weeks long-term feeding.

Material and Methods

Juvenile European seabass were obtained from a local hatchery and transferred to a marine RAS until reaching an initial mean weight of 32 g. Fish were stocked in a fully controlled RAS with 15 tanks (250 L capacity; 30 fish per tank). Five iso-nitrogenous (48% CP) and iso-lipidic (18% CL) extruded diets were formulated, including a control diet with low fishmeal content. Soybean Protein Concentrate replaced fishmeal at 25% (SPC25), 50% (SPC50), 75% (SPC75), and 100% (SPC100) levels. Fish were hand-fed twice daily to apparent satiety during acclimation and throughout the 16-week experimental period. Micro-CT analysis was performed using a Skyscan 1275 X-ray microtomograph. Faeces were collected via passive settlement systems attached to each tank outlet during the final 30 days of the trial. Total RNA was extracted from intestinal samples using TRIzol reagent according to the manufacturer's protocol. RNA quality and quantity were assessed using spectrophotometric and fluorometric methods. Raw paired-end FASTQ files were quality-checked using FastQC (v0.12.1) and MultiQC (v1.21). Taxonomic profiling was conducted using a Naïve Bayes classifier in QIIME2 trained on the SILVA 138 SSU rRNA database (99% identity, 338F/515R region). Diversity analyses were performed using QIIME2 core-metrics and the phyloseq package (v1.44) in R.

Results

Overall, increasing SPC inclusion leads to a progressive transition from a compact and uniform structure to a more porous and heterogeneous matrix, particularly for SPC75, and SPC100. This trend suggests that higher SPC levels negatively affect pellet densification and cohesion, likely influencing key functional properties such as mechanical strength, water stability, and hydration behavior. Percent porosity (total, open, closed), mean cell size (MCS) and cell size and cell wall thickness will be presented in detail. No significant differences in growth, feed intake, and feed conversion ratio were observed among the experimental diets, further indicating that high levels of SPC inclusion had a negligible effect on overall growth performance. Collectively, while dry matter digestibility remained unaffected, increasing dietary inclusion of SPC significantly reduced both protein and lipid digestibility. The reduction was more pronounced at higher inclusion levels, particularly in the SPC75 and SPC100 groups, suggesting that elevated SPC incorporation may negatively impact nutrient availability and digestive efficiency in fish. With respect to microbiome analysis, mean Shannon diversity ranged

(Continued on next page)

from 1.85 (SPC0) to 2.26 (SPC75), with no significant differences among groups. Samples generally clustered without clear dietary separation; however, outliers were observed, including samples 6323 and 6324 (SPC50) along the negative PC1 axis and sample 6329 (SPC100) along the positive PC1 axis. The gut microbiota was dominated across all dietary groups by Firmicutes, Proteobacteria, Actinobacteriota, and Bacteroidota. At the genus level, the most abundant taxa were *Lactobacillus*, Ruminococcaceae (unclassified), *Pseudomonas*, and *Photobacterium*. Genus-level abundances showed high inter-individual variability, consistent with elevated intra-group beta diversity dispersion.

Discussion

The present study showed that, although no significant differences in growth performance were observed, pellets with high Soybean Protein Concentrate inclusion exhibited a clear transition from a dense, well-integrated matrix to a highly porous and structurally heterogeneous structure, indicating reduced pellet integrity at higher inclusion levels. The host genotype appears to exert a stronger influence on gut microbiota composition than diet, which may partly explain the observed outliers, potentially reflecting genetic variability or differential sensitivity to SPC anti-nutritional factors. Individual differences in intestinal transit time, mucus composition, and innate immune status may also contribute to these microbiome deviations under high SPC dietary stress. The numerical increase in ASV richness in high-SPC groups (SPC75, SPC100) may be associated with greater availability of plant-derived substrates, such as complex polysaccharides and secondary compounds, potentially supporting a wider range of microbial taxa capable of metabolizing these compounds in the intestine of European seabass. Further investigation is required to clarify the functional implications of these observations.

Introduction

Meagre is an emerging candidate for diversification of Mediterranean aquaculture because of its rapid growth, fillet quality and adaptability to production conditions. However, species-specific information for defining feeding strategies remains limited. Accurate feeding is important to sustain growth and feed efficiency while limiting unnecessary feed use and nutrient losses. In meagre, feed-intake models have been proposed (Azevedo et al., 2025), and protein and energy requirements were also estimated (Jauralde et al., 2021). This study assessed growth performance, feed utilization, whole-body composition, and feed intake associated with zero biomass gain of meagre juveniles reared at 20 °C.

Materials and methods

Meagre (*Argyrosomus regius*) juveniles (initial body weight 43.2 g; 20 fish per tank) were distributed among 12 tanks and fed a diet formulated to target 50% crude protein and 16% crude lipid on a dry-matter basis at 0, 12.5, 25, 50, 75, or 100% of apparent satiation intake for 31 days ($n = 2$ tanks per feeding level). The two tanks assigned to 100% were hand-fed twice daily until feeding activity ceased and one or two pellets remained uneaten. Their mean daily feed intake was recalculated weekly and used to establish the restricted feeding levels for the following week, with tank allowances adjusted to the number of fish present. Growth performance, survival, feed utilisation, and whole-body dry matter, lipid, ash, and gross energy were analysed. Data were analysed by one-way analysis of variance followed by Tukey's test ($P < 0.05$). Feed efficiency and FCR used mortality-adjusted biomass gain. Relative feed intake and biomass gain were expressed per kg mean mortality-adjusted tank biomass per day. A quadratic-plateau model described growth, and a quadratic model described FCR for tanks with positive gain. Zero-gain intake was estimated from the growth model. Protein intake was estimated from the formulation target and measured feed dry matter (95.60%); gross energy intake used measured dietary energy (20.79 kJ g⁻¹ as-fed).

Results and discussion

Final body weight, weight gain, and specific growth rate increased with feeding level (all $P < 0.001$). Final body weight reached 58.4 and 60.2 g at 75 and 100% feeding, respectively, with no significant difference between these levels. Survival increased from 55.0% at 0% feeding to 100% at 75–100% feeding ($P = 0.003$). Feed efficiency peaked at 0.96 at 75% feeding and declined to 0.75 at 100% ($P = 0.001$). The quadratic-plateau growth model ($R^2 = 0.993$; $n = 12$) predicted zero biomass gain at 3.03 g kg⁻¹ day⁻¹ (Figure 1), equivalent to 20.7% of the apparent *ad libitum* feed intake by interpolation between the 12.5% and 25% treatment mean intakes. The plateau onset (14.96 g kg⁻¹ day⁻¹) was beyond the observed intake range. The quadratic FCR model had $R^2 = 0.941$ ($n = 8$). At 75% feeding, mean feed intake was 10.01 g kg⁻¹ day⁻¹, corresponding to an estimated protein intake of 4.79 g kg⁻¹ day⁻¹ and gross energy intake of 208.2 kJ kg⁻¹ day⁻¹; corresponding intakes at predicted zero gain were 1.45 g protein kg⁻¹ day⁻¹ and 62.9 kJ kg⁻¹ day⁻¹. Whole-body dry matter differed among feeding levels ($P = 0.003$), with the lowest mean at 0% (18.09%) and the highest at 100% feeding (24.7%). Values at 0% were lower than at 25–100%, and values at 12.5% were lower than at 50–100%. Whole-body lipid was also affected ($P = 0.003$), with the lowest and highest means at 0% (0.75%) and 100% feeding (3.75%), respectively. Lipid was lower at 0–12.5% than at 50–100%, while 25% was intermediate. Whole-body gross energy differed among feeding levels ($P = 0.004$), with the lowest mean at 0% (3.03 kJ g⁻¹) and the highest at 100% feeding (5.14 kJ g⁻¹). Values at 0% were lower than at 50–100%, and values at 12.5% were lower than at 75–100%, while 25% was intermediate. Ash was unaffected by feeding level ($P = 0.692$). All composition values are expressed on a fresh-matter basis. The lower lipid content and energy density under restricted feeding are consistent with reduced body energy reserves, but do not quantify nutrient retention.

(Continued on next page)

Figure 1. Relative biomass gain and FCR versus relative feed intake at 20 °C. Growth: quadratic-plateau model (left axis); FCR: quadratic model (right axis). Points represent individual tanks. Dashed lines indicate predicted zero gain ($3.03 \text{ g kg}^{-1} \text{ day}^{-1}$) and plateau onset ($14.96 \text{ g kg}^{-1} \text{ day}^{-1}$); shading denotes extrapolation. Relative intake and gain use mean mortality-adjusted tank biomass.

Conclusion

Overall, feeding juvenile meagre at approximately 75% of apparent satiation intake was sufficient to sustain growth performance while improving feed utilization under the experimental conditions. Zero biomass gain was predicted at $3.03 \text{ g kg}^{-1} \text{ day}^{-1}$ at 20 °C. The 75% treatment corresponded to approximately $10 \text{ g feed kg}^{-1} \text{ mean biomass day}^{-1}$. Increasing the ration to full satiation reduced feed efficiency without a statistically detectable increase in final body weight.

Introduction

Shrimp aquaculture has expanded rapidly over the last decades, becoming one of the fastest-growing sectors of global aquaculture. However, infectious diseases continue to be a major constraint, causing an estimated loss of nearly 40% of global production capacity and resulting in billions of dollars in economic losses each year. Viral pathogens account for a substantial proportion of these losses (Flegel & Sritunyalucksana, 2011; Underwood et al., 2013). A better understanding of the immune mechanisms of *Penaeus kerathurus*, including its cellular responses and molecular pathways, is essential for improving disease management and supporting the sustainable development of Mediterranean shrimp aquaculture. As crustaceans rely exclusively on innate immunity, mediated by both cellular and humoral components, elucidating these defense mechanisms is crucial for the development of effective, non-antibiotic health management strategies (Aguirre Guzman et al., 2009; Chong et al., 2022) because their culture is limited by the development of infectious diseases. As invertebrates, shrimp's natural immunity acts as a fast and efficient defence mechanism against the pathogens. Their immune system involve hemocytes (for encapsulation, nodule formation and phagocytosis). Therefore, the aim of this study was to characterize the humoral immune parameters of the hemolymph of *Penaeus kerathurus* and establish baseline reference values that will facilitate future immunological studies, health assessment, and the development of standardized protocols for this emerging aquaculture species.

Material and methods

Twenty wild *Penaeus kerathurus* specimens were collected with the collaboration of the Mar Menor Fishermen's Guild (Murcia, Spain) and maintained in experimental aquaria under controlled conditions ($25 \pm 1^\circ\text{C}$, salinity 35‰, continuous aeration, and appropriate substrate to promote animal welfare and natural behaviour). All individuals were morphometrically measured and sexed prior to sampling. Shrimp were anesthetized following established protocols (Rotllant et al., 2023), and hemolymph samples were collected individually under aseptic conditions. Samples were immediately stored at -80°C until subsequent analysis of humoral immune parameters.

The total protein content of the hemolymph was determined using the Bradford protein assay (Bradford, 1976). In addition, the activity of several enzymes involved in the humoral immune response was evaluated using spectrophotometric assays following established protocols. Peroxidase activity in the hemolymph was determined according to the method described by Quade and Roth, with some modifications (Quade & Roth, 1997). Protease and antiprotease activities were measured in hemolymph following the protocols described with some modifications (Hanif et al., 2004; Ross et al., 2000).

Results and discussion

The analysis of hemolymph revealed measurable levels of total protein together with detectable peroxidase, protease, and antiprotease activities in all specimens, demonstrating the suitability of these biomarkers for evaluating the humoral immune status of *Penaeus kerathurus*. Although individual variability was observed among animals, the measured values were consistent with the expected physiological range reported for healthy penaeid shrimp.

These findings provide the first baseline characterization of humoral immune parameters in *Penaeus kerathurus*, representing a valuable reference for future studies on nutrition, health, environmental stress, and disease resistance. Establishing standardized reference values will facilitate the interpretation of immune responses under experimental and farming conditions, contributing to the development of this emerging Mediterranean aquaculture species.

Introduction

Global aquaculture has expanded rapidly to meet the increasing demand for animal protein, but intensive farming practices often compromise fish health and immune competence, while the extensive use of antibiotics has promoted environmental contamination and antimicrobial resistance (Dawood et al., 2022; Orso et al., 2022). Consequently, sustainable alternatives such as plant-derived bioactive compounds are gaining attention. Rosemary (*Rosmarinus officinalis*) has been reported to enhance growth, antioxidant capacity and immune responses in several fish species, although inconsistent results regarding dosage and administration methods have limited its application (Abdel-Tawwab et al., 2024; Kolygas et al., 2025). Plant cell suspension cultures represent a sustainable source of standardized bioactive compounds, including rosmarinic acid, a metabolite with well-known antioxidant and antimicrobial properties (Bulgakov et al., 2012; Hakkim et al., 2019). Therefore, the aim of the present study was to evaluate the in vitro immunomodulatory effects of an elicited rosemary cell suspension culture extract on head kidney (HK) leukocytes of gilthead seabream (*Sparus aurata* L.), a key marine aquaculture species.

Material and methods

Rosemary cell suspension cultures were established from friable calli in liquid MS medium and elicited with 75 μ M methyl jasmonate. Phenolic compounds were extracted from lyophilized biomass using an ethanol:acidified water mixture and characterized by HPLC. Five specimens (442.6 $\pm$ 190.9 g) of gilthead seabream, were kept for two weeks in re-circulating seawater aquaria from Marine Resources Centre of IMIDA (San Pedro del Pinatar, Spain). The water temperature was maintained at 20.1 $\pm$ 2.0 °C with a flow rate of 900 L h⁻¹ and 35‰ salinity and 12 h light: 12 h dark photoperiod. Animals were killed after starving for 24h by using a overdose of clove oil. All experimental protocols were approved by the Ethical Committee of IMIDA and CEEA UPV/EHU (N° A13260703). HK leukocytes were isolated according to (Espinosa et al., 2018) and adjusted to 1 $\times$ 10⁷ cells mL⁻¹. Then, cells were incubated for 24 h with rosemary extract (0, 0.1, 1, 10 and 100 μ g mL⁻¹), and cell viability, phagocytic activity and respiratory burst were evaluated following established protocols (García Beltrán et al., 2020).

Results and discussion

Exposure to the rosemary cell suspension culture extract did not significantly affect HK leukocyte viability, indicating the absence of cytotoxic effects at the tested concentrations. Similarly, phagocytic activity remained unchanged after 24 h of incubation. However, phagocytic capacity was significantly enhanced at 10 μ g mL⁻¹, whereas it decreased at 100 μ g mL⁻¹. Likewise, respiratory burst activity increased significantly at 0.1 μ g mL⁻¹ but was significantly reduced at 10 and 100 μ g mL⁻¹. These findings suggest a dose-dependent immunomodulatory effect, in agreement with previous studies reporting that rosemary-derived bioactive compounds can stimulate innate immune responses at low concentrations, whereas excessive doses may exert inhibitory or pro-oxidant effects (Abdel-Tawwab et al., 2024; Kolygas et al., 2025). Overall, the results indicate that elicited rosemary cell suspension culture extract is a promising sustainable source of immunomodulatory compounds for aquaculture, although optimization of the effective dosage will be essential before its application as a functional feed additive.

Introduction

Morus alba, commonly known as white mulberry, has been shown to possess significant anti-inflammatory properties, primarily through the inhibition of leukocyte migration and modulation of inflammatory pathways (Chen et al., 2013). Besides, *Morus alba* leaf extract exhibits lipolipidemic, antiviral, antimicrobial, neuroprotective effects (Aghdam et al., 2024), together with a strong antioxidant activity, which is beneficial in reducing oxidative stress, increasing glutathione levels and decreased nitrite/nitrate and malondialdehyde levels (Dkhil et al., 2015). This makes it a promising candidate for enhancing the immune response in fish, such as the gilthead seabream, which is a species of economic importance in aquaculture.

Material and methods

Fresh *Morus alba* leaves were collected from a selected genotype maintained in the IMIDA Germplasm Bank (BAGERIM), freeze-dried, and milled into a fine powder. A hydroethanolic extract (70% ethanol) was prepared using orbital shaking and ultrasonic-assisted extraction. The extract was centrifuged, filtered, concentrated by rotary evaporation to remove ethanol, freeze-dried, and stored at -80°C until use in the in vitro assays. Five gilthead seabream (*Sparus aurata*) (mean body weight: 442 ± 190 g) were maintained for two weeks in recirculating seawater systems at the Marine Resources Centre of IMIDA (San Pedro del Pinatar, Spain) under controlled environmental conditions ($20.1 \pm 2.0^{\circ}\text{C}$, 35‰ salinity, 900 Lh⁻¹ water flow, and 12 h light: 12h dark photoperiod). Following a 24 h fasting period, fish were euthanized by an overdose of clove oil. All procedures were conducted in accordance with protocols approved by the Ethical Committee of IMIDA and the CEEA UPV/EHU (No. A13260703). Head kidney leukocytes were isolated as previously described by (Espinosa et al., 2018) and adjusted to a final concentration of 1×10^7 cells mL⁻¹. Cells were exposed for 24 h to different concentrations of *Morus alba* extract (0, 0.1, 1, 10 and 100 $\mu\text{g mL}^{-1}$). After incubation, cell viability, phagocytic activity and respiratory burst were assessed using previously established methodologies (García Beltrán et al., 2020).

Results and discussion

Incubation of HK leukocytes with *Morus alba* leaf extract for 24 h did not compromise cell viability at any of the concentrations tested, demonstrating that the extract was not cytotoxic under the experimental conditions. Phagocytic activity was also unaffected by treatment, whereas phagocytic capacity showed a significant reduction at the highest extract concentration. In contrast, respiratory burst activity was significantly enhanced at 1 $\mu\text{g mL}^{-1}$ but decreased markedly following exposure to 100 $\mu\text{g mL}^{-1}$ revealing a concentration-dependent effect on leukocyte function. These results are consistent with previous reports showing that low concentrations of aqueous or ethanolic botanical extracts, including oregano and other medical plants, can stimulate innate immune responses such as phagocytosis and respiratory burst in fish leukocytes, whereas higher concentrations may attenuate these responses (Beltrán et al., 2018; Camara-Ruiz et al., 2020; Fazio et al., 2017). Overall, *Morus alba* leaf extract appears to be a promising natural source of bioactive compounds for aquaculture, although further studies are required to determine the optimal concentrations for its potential use as a functional feed additive.

Introduction

The elemental composition of Atlantic bluefin tuna muscle (ABFT, *Thunnus thynnus*) may vary during the fattening phase and between coastal sites. Its analysis makes it possible to characterize the evolution of the elemental profile from capture and identify common patterns among fattening areas. The objective was to evaluate these changes by comparing tuna sampled immediately after capture with tuna maintained for three and five months in cages located at two coastal sites in Spain.

Materials and methods

Seventy-four ABFT muscle samples were analyzed and distributed into five groups: wild specimens caught in the Balearic Sea ($n = 14$) and tuna maintained for 3 and 5 months at two coastal sites in the Region of Murcia, southeastern Spain: San Pedro del Pinatar (SPP) and El Gorguel, Cartagena (EG) ($n = 15$ per group). The concentrations of Ca, Cr, Cu, Fe, K, Mg, Mn, Na, P, Se, S and Zn were determined using optical ICP, and differences between groups were evaluated (Kruskal-Wallis test). Elements showing significant differences were included in a principal component analysis (PCA) and a canonical discriminant analysis (CDA).

Results and discussion

Significant differences among groups were detected for Ca, Cu, K, Mg, Mn, Na, P and S, whereas Cr, Fe, Se and Zn did not vary significantly (Table 1). However, when recently caught specimens were compared with those maintained for five months, most of the elements studied showed no significant changes. The most relevant variations were observed in Ca and Na, whose concentrations decreased during the fattening period, and in Mn, which increased markedly, particularly at the final sampling.

The PCA retained three components, which explained 77.4% of the total variance. The first was mainly defined by K, Mg and S; the second by Ca, Na and P; and the third by Cu and Mn. Partial differentiation was observed between freshly caught specimens and those maintained at the fattening facilities. The CDA, based on K, Mg, Mn, Na and Cr, separated the five groups (Figure 1) and correctly classified 84.4% of the samples and 75.7% after cross-validation.

Overall, the muscle elemental profile varied during fattening, mainly because of decreases in Ca and Na and an increase in Mn at both sites. The classification obtained suggests that the multielement composition could differentiate newly caught and fattened specimens.

Conclusion

Fattening slightly modified the muscle elemental profile of *T. thynnus* at both sites with particularly evident changes in Ca, Na, and Mn. The multivariate differentiation observed suggests an effect of fattening time and a possible contribution of site to muscle elemental composition. These differences could be related to diet, although specific studies would be required to confirm this hypothesis.

Introduction

Fatty acids play important roles in fish physiology and contribute to the nutritional value of their tissues. Among them, long-chain n-3 polyunsaturated fatty acids (PUFAs), particularly eicosapentaenoic acid (EPA) and docosahexaenoic acid (DHA), are of particular nutritional interest. During fattening, lipid accumulation may be accompanied by changes in the fatty acid composition of muscle. The aim of this study was to evaluate the evolution of the muscle fatty acid profile of Atlantic bluefin tuna (*Thunnus thynnus*) from capture to 3 and 5 months of fattening at two coastal sites in the Region of Murcia.

Material and methods

A total of 74 muscle samples from *T. thynnus* were analyzed and distributed among five groups: wild specimens captured in the Balearic Sea (n = 14), and tuna maintained for 3 and 5 months at San Pedro del Pinatar (SPP) and El Gorguel (EG), both located in the Region of Murcia, southeastern Spain (n = 15 per group). The relative composition of saturated fatty acids (SFA), monounsaturated fatty acids (MUFA), and polyunsaturated fatty acids (PUFA), including n-3 and n-6 fatty acids, was evaluated, together with their concentrations on a fresh-weight basis. The n-3/n-6 ratio and the combined EPA+DHA concentration were also calculated. Differences among groups were assessed using ANOVA followed by the Games–Howell post hoc test. Fatty acid concentrations were additionally included in a principal component analysis (PCA) and canonical discriminant analysis (CDA).

Results

The fatty acid profile changed during fattening, with a similar pattern observed at both sites. After 5 months, the proportion of SFA decreased, whereas PUFA and, particularly, n-3 fatty acids increased at both SPP and EG.

The n-3/n-6 ratio also increased during fattening, from 3.6 in wild specimens to 8.1 and 8.3 after 5 months at SPP and EG, respectively. Similarly, the EPA+DHA concentration increased from 0.110 g 100 g⁻¹ in wild specimens to 4.724 g 100 g⁻¹ at SPP and 4.792 g 100 g⁻¹ at EG after 5 months, representing an increase of more than 40-fold compared with the initial value. The simultaneous increase in both the proportion and concentration of n-3 fatty acids indicates a substantial modification of the muscle lipid profile during fattening.

The PCA performed using fatty acid concentrations explained 93.0% of the total variance and showed a separation of samples mainly associated with fattening duration. The CDA correctly classified 100% of the samples, with 98.6% correct classification after cross-validation. These results demonstrate the high discriminatory capacity of quantitative fatty acid composition for differentiating the groups studied, while the overall pattern of fatty acid evolution was similar at both locations.

Conclusions

Fattening markedly modified the muscle fatty acid profile of *T. thynnus*, with an increase in n-3 PUFA and EPA+DHA concentrations, particularly after five months at both SPP and EG. The greater abundance of these nutritionally relevant fatty acids reinforces the value of Atlantic bluefin tuna muscle as a source of long-chain n-3 fatty acids. Furthermore, the quantitative fatty acid profile showed a high discriminatory capacity among the groups studied.

Introduction

Atlantic bluefin tuna (*Thunnus thynnus*) is a pelagic species with high swimming activity, in which maintaining the balance between oxidants and antioxidants is relevant for preserving cellular integrity and physiological function. In fish, skin mucus constitutes one of the first lines of defence against the marine environment and is continuously exposed to oxygen, microorganisms, and other potentially oxidising agents. Plasma, in turn, provides information on systemic processes in the organism. The joint analysis of both matrices makes it possible to assess whether they provide similar or complementary information on the oxidant-antioxidant balance. The aim of this study was to compare the concentrations and associations of five redox biomarkers in plasma and skin mucus from wild adult *T. thynnus* specimens.

Materials and methods

Plasma and skin mucus samples were collected from 16 adult *T. thynnus* specimens caught in the Barbate tuna trap (Cádiz, Spain). In both matrices, five redox biomarkers were determined: cupric ion reducing antioxidant capacity (CUPRAC), ferric reducing antioxidant power (FRAP), Trolox equivalent antioxidant capacity (TEACH), total thiols, and advanced oxidation protein products (AOPP). Plasma and mucus concentrations were compared using Student's *t*-test. Correlations between matrices, among biomarkers within each matrix, and between their concentrations and body weight were also evaluated.

Results and discussion

All biomarkers showed significantly higher concentrations in skin mucus than in plasma (Table 1). Differences ranged from 1.9- to 3.5-fold for CUPRAC, FRAP, TEACH, and thiols, whereas the AOPP concentration was 21.2-fold higher in mucus. The simultaneous increase in antioxidant capacity indicators and AOPP, as a marker of protein oxidation, suggests that mucus exhibits more intense local redox activity than plasma.

No significant correlations between plasma and mucus were detected for any biomarker. Within each matrix, seven of the ten possible correlations were significant in plasma ($r = 0.503\text{--}0.984$), whereas all ten were significant in mucus ($r = 0.616\text{--}0.988$). The presence of significant associations among all biomarkers in mucus indicates that antioxidant capacity and protein oxidation indicators varied in a more coordinated manner in this matrix. This pattern could be related to its direct exposure to the external environment and the local interaction between oxidant production and antioxidant defences at the body surface. In plasma, by contrast, biomarkers may be influenced by processes originating in different organs and tissues, which could explain less generalised covariation. Nevertheless, these correlations do not demonstrate that all biomarkers share the same regulatory mechanism.

The absence of correlations between the two matrices suggests that mucus does not directly reflect the systemic redox status observed in plasma. Body weight was not correlated with any of the biomarkers evaluated.

Conclusion

Skin mucus showed greater antioxidant capacity and a higher AOPP concentration than plasma, suggesting more intense local redox activity. The absence of correlations between the two matrices, together with the greater covariation of biomarkers in mucus, indicates that plasma and mucus represent distinct physiological compartments. Therefore, mucus should not be considered a direct substitute for plasma, although it may constitute a complementary and less invasive matrix for assessing local antioxidant and oxidative processes in wild adult Atlantic bluefin tuna.

CASCADE EXTRACTION OF COLLAGEN-BASED PROTEIN FROM ATLANTIC COD FILLETING SIDE STREAMS

D. Fabrikov ^{1*} and Jiménez-Quero A.¹

¹ Industrial Biotechnology Division
LIFE Sciences Department
Chalmers University of Technology
Sweden

*preseting author: fabrikov@chalmers.se

Introduction

Atlantic cod (*Gadus morhua*), part of the Gadidae family, makes up about 10% of all finfish caught globally, with an annual production of around 0.7 million tonnes. The main processing method is filleting, which yields only 33% of the fish's total weight as commercial product (Falch et al., 2005). The remaining side streams (head, backbone, and skin) constitute roughly 34% of the raw fish mass and are rich in collagen, the most abundant protein in vertebrate tissues. Depending on the extraction conditions, collagen may be obtained as its native triple helix form, as gelatin, or as partially hydrolyzed peptides. Each fraction has distinct functional and biological properties, enabling a variety of industrial applications. However, most research focuses on extracting only one fraction at a time. In this study, we employed a rapid cascade extraction process using green technologies to sequentially recover native collagen, gelatin, and peptides from Atlantic cod skin, head, and backbone.

Material and Methods

SINTEF (Norway) provided skin, head, and backbone from Atlantic cod. The frozen tissue was sent to Chalmers University of Technology in Gothenburg, Sweden, where it was ground into pieces about 2 cm in size using an electric meat grinder and stored at -20 °C. The cascade extraction began with an alkaline pretreatment using 0.1 M NaOH to remove non-collagenous proteins. These proteins were then isolated through isoelectric precipitation and freeze-dried. Next, collagen was extracted with 0.5 M acetic acid by ultrasound at 80% amplitude for 30 minutes. The collagen was obtained by salting out with NaCl, followed by dialysis and freeze-drying. The residual material from the native collagen extraction was mixed with hot distilled water and incubated with stirring to extract gelatin. The water temperature during gelatin extraction was set at 45 °C for skin and 60 °C for head and backbone. Finally, the residue from head and backbone obtained from gelatin extraction was further extracted with subcritical water extraction at 170 °C for 20 minutes. The yield was calculated relative to the initial mass of each side stream on a dry basis, and its chemical composition was characterized.

Figure 1. Cascade extraction yields from Atlantic cod skin, backbone, and head. Stacked bars show each fraction as % of raw material dry matter, with the total above; the adjacent bar shows total hydroxyproline recovered (% of that present in the raw material). Means $\pm$ SD, n = 2.

(Continued on next page)

Results

The composition results reveal a notable difference in the initial biomass makeup. Protein content in the head and backbone ranges from 37.8% to 43.9%, with minerals as the dominant component (45.0-52.1%) in these tissues. Conversely, the skin shows a high protein level (74.0%) and a more moderate mineral content (20.3%). Lipids are a small fraction in all tissues, not exceeding 4%. Figure 1 illustrates the extraction yields from each Atlantic cod tissue. The skin yields the most native collagen, followed by gelatin. For the head and backbone, subcritical water yielded the most, followed by gelatin and then collagen. The total mass recovered is higher in the skin than in the backbone and head, but the hydroxyproline recovery percentage is similar across tissues. Regarding protein content, recovered proteins after alkaline pre-treatment exceeded 60% in all tissues. Collagen from the skin had protein levels over 93%, while in the head and backbone, it was considerably lower at 44% and 27%. The same trend was observed in gelatin, with 91% protein in skin and about 80% in the head and backbone. Lastly, peptides from the head and backbone showed protein contents above 90% in both cases.

Discussion

The cascade extraction process yielded 50% protein from Atlantic cod skin. Although the total yield from the head and backbone was lower, minerals make up nearly half of their dry weight, greatly reducing the organic matter available for extraction compared with the skin. The percentage of hydroxyproline recovered provides a better perspective on the extracted collagen proteins and is similar across all three tissues. On the other hand, the difference in protein levels in the collagen of the head, backbone, and skin is due to the fact that during the acid extraction of collagen, the minerals that are part of the head and backbone are partially solubilized. While this process decreases the purity of the extracted collagen, it makes it easier to extract gelatin and peptides later, as shown by the higher protein recovery in these steps.

Introduction

Projections indicate a 10% increase in aquaculture production in the next decade (FAO, 2026). To support this, securing feed ingredients is crucial. However, recent climate and geopolitical challenges have increased the cost and reduced the availability of conventional ingredients. Black soldier fly larvae meal (*Hermetia illucens*, BSFL), recognized for its high nutritional value and ability to be reared from organic waste, has emerged as a promising substitute. BSFL contains 30% to 40% lipids on a dry basis, with over half being saturated fatty acids. Defatting boosts protein content and reduces the negative effects of lipids on the meal's sensory qualities and shelf life. Mechanical hot pressing is a widely used defatting method. Although the process involves dried larvae, studies on undried larvae are limited and mainly concentrate on soft-tissue fractions; the exuviae portion is often discarded. In this study, we evaluated the yield, composition, and *in vitro* digestibility of meals produced by mechanically pressing dry and fresh BSFL.

Materials and Methods

Defatted BSFL meal was prepared via dry mechanical pressing (DPD-BSFL), in which dried larvae were screw-pressed at 140 °C. For wet mechanical pressing (WPD-BSFL), the undried larvae were screw-pressed at 140 °C, and the exuviae fraction was oven-dried at 65 °C. The chemical composition of the BSFL meals was determined according to the methods described by the Association of Official Analytical Chemists (AOAC, 2005). For the *in vitro* digestibility assay, enzymatic extracts from three species involved in marine and freshwater aquaculture were used: red seabream (*Pagrus major*), rainbow trout (*Oncorhynchus mykiss*), and Nile tilapia (*Oreochromis niloticus*). Acid and alkaline protease activity was analyzed, and the EA:PI ratio (protease activity to dietary protein intake) was calculated for each species and extract. The *in vitro* digestibility assay included a gastric phase followed by an intestinal phase. During each phase, enzymatic activity was calibrated according to the EA:PI ratios, and digestibility was assessed by measuring the free amino groups released. Non-defatted BSFL meal (ND-BSFL), fish meal, and soybean meal were included in the *in vitro* digestibility trial.

Results

DPD-BSFL showed higher yield ($p < 0.05$) than WPD-BSFL, producing 55% versus 36% meal (dry basis). Its defatting efficiency was also superior ($p < 0.05$), with an 84% reduction in lipid content versus 80% in WPD-BSFL. In terms of composition, no significant differences were found in lipid and protein contents between the two defatted meals. WPD-BSFL had higher chitin levels ($p < 0.05$), while DPD-BSFL had higher ash levels. The EA:PI results (Figure 1A) indicated that rainbow trout displayed the highest activity of acid and alkaline proteases relative to ingested protein. The *in vitro* digestibility of soybean meal was lower than that of the other meals across all three species. No significant differences were observed in defatted BSFL and non-defatted meals digestibility among these species ($p < 0.05$), although Nile tilapia showed significantly higher fish meal digestibility compared to the other meals.

Figure 1. EA:PI ratio for acid and alkaline protease (A) and cumulative *in vitro* release of free -NH₂ groups across digestion stages (B) in three fish species. Means $\pm$ SD, $n = 3$. Within each species, meals sharing a letter do not differ (Tukey HSD, $\alpha = 0.05$).

(Continued on next page)

Disussion

This study shows that WPD-BSFL and DPD-BSFL are effective defatting methods, both producing meals with less than 10% fat and over 60% protein. Moreover, the WPD process yields an additional fraction consisting of BSFL internal tissues and lipids, which can be further processed to extract lipid and protein components that have potential as functional food ingredients (Kang et al., 2024). The *in vitro* digestibility of BSFL meals with red seabream and rainbow trout digestive extracts was similar to that of fish meal. In Nile tilapia, however, the lower digestibility of BSFL meals might result from the species' omnivorous habit, leading to decreased gastric enzymatic activity and predominantly intestinal digestion. The intestinal phase is the most significant stage for amino group release across all species. However, despite the EA:PI ratio of intestinal protease in Nile tilapia being four times higher than in red seabream, no increase in the final digestibility of BSFL meals was observed. This suggests that, although the gastric phase has a lower proteolytic hydrolysis capacity, it plays an important role in influencing digestibility during the intestinal phase.

Introduction

Improving feed efficiency while maintaining physiological robustness is a critical goal for sustainable tilapia production. Botanical bioactive compounds mainly curcuminoids and Artepilin C have attracted interest among for their potential antioxidant, immunomodulatory and anti-inflammatory activities and their ability to support fish performance [1]. This study assessed the effect of dietary Phyto AquaNity (PAN), a standardized botanical mixture of curcuminoids from turmeric and Artepilin C from green propolis, on feed efficiency and antioxidant status of Nile tilapia (*Oreochromis niloticus*) in rearing conditions. Moreover, molecular docking was used to explore the potential mechanism of action of curcumin based on antioxidant markers.

Materials and methods

Juvenile tilapia with initial body about 73g were reared in 2m³ happas for 80 days. Fish supplemented with control diet were compared with fish receiving a mixture of botanical compounds (Phyto AquaNity, PAN at 0.5 g.kg⁻¹). Growth performance, feed utilization parameters and antioxidant markers were assessed. In addition, a molecular docking was performed with curcumin against three proteins associated with oxidative stress regulation such as : kelch-like ECH associated protein 1 (Keap1), 15 lipoxygenase (15-LOX) and xanthine oxidase (XO).

Results and Discussion

Over trial duration, PAN significantly improved feed utilization through the reduction of feed conversion ratio from 1.46 ± 0.03 (control fish) vs 1.24 ± 0.03 (supplemented fish) group while protein efficiency ratio increased from 2.25 ± 0.05 to 2.69 ± 0.08 ($p < 0.05$). Although growth parameters were not significantly improved, weight gain and specific growth rate were numerically increased compared to the control group. PAN significantly enhanced antioxidant responses through the increase of antioxidant enzymes mainly superoxide dismutase (29.93 ± 2.06 vs 39.64 ± 1.41 mU mL⁻¹), glutathion peroxidase (3.47 ± 0.12 vs 4.51 ± 0.07 mU mL⁻¹), catalase (447.57 ± 12.39 vs 530.90 ± 8.61) and malondialdehyde (23.41 ± 2.51 vs 14.14 ± 1.07 mU mL⁻¹).

Molecular docking revealed predicted energies of binding -8.0, -7.1 and -9.2 kcal mol⁻¹ between curcumin and Keap1, 15-LOX and XO, respectively, with the strongest predicted interaction observed with XO. These molecular interaction suggest that curcumin may potentially modulate proteins involved in antioxidant responses.

Overall, dietary supplementation with PAN at 0.5g.kg⁻¹ improved feed efficiency and antioxidant status in Nile tilapia under rearing conditions. The complementary In silico study provides mechanistic hypothesis linking curcumin with oxidative stress regulation and support further investigation of curcumin mediated pathways underlying the physiological effect of PAN.

Introduction

Gilthead seabream (*Sparus aurata*) is the most important fin fish species in Mediterranean aquaculture, with global production of 341,000 tons in 2023. Gilthead seabream broodstocks are well adapted in aquaculture and spawn volitionally for a prolonged period of time (December to May), with very high fecundity (2 million eggs kg⁻¹ body weight) and fertilization success (Papadaki et al., 2024). Selective breeding programs have been implemented in many European countries, using family or mass selection (Janssen et al., 2017). However, the effectiveness of mass selection programs has been limiting, due to the poor male parental contribution to each day's spawning event. The objective of the present research was to examine the potential of a management method to increase male parentage contribution in gilthead seabream spawning, thus resulting in larger numbers of families and more even progeny distribution. Therefore, we abruptly replaced the males with new individuals in replicate populations and examined the effect i) on egg production and quality and later ii) on male parental contribution in the mass-spawning events immediately after new male introduction.

Materials and methods

Two broodstocks (1:4 male:female, 20 individuals), were monitored during the spawning season of 2025-2026. On 27 January 2026 (day 0), all males were replaced with new, 2-year-old spermiating males. Daily relative fecundity and fertilization success were recorded. Egg quality was evaluated at key developmental stages (24-h embryo survival, hatching, and 5-day larval survival) using 96-well plate assays. Sperm quality, including total, progressive, and rapid motility and velocity parameters, were assessed using computer assisted sperm analysis (CASA) in old and new males. Statistical comparisons between periods (before vs after replacement) were conducted using Welch's t-tests. DNA was also extracted from the breeders and from 100 eggs per spawn, 3 days before and 3 days after male exchange, from each broodstock. All samples were genotyped at 12 microsatellite loci using multiplex PCR. Fragment analysis was performed on an automated capillary sequencer, and allele scoring enabled assignment of offspring to parental genotypes. Pre- and post-replacement periods were compared using Welch's t-tests.

Results and discussion

Following male replacement, daily relative fecundity showed no significant change ($p = 0.637$). Fertilization exhibited a decreasing trend ($p = 0.091$), while the other quality parameters remained high, and no consistent differences between the periods. Sperm velocity parameters differed between the old and new males and significant reductions were observed in motility-related parameters. The percentage of motile, progressive and rapid sperm cells was markedly lower in the new males ($p < 0.001$ for all), while straightness (STR) of the trajectory remained unchanged ($p = 0.933$).

The data indicate that abrupt exchange of males during the reproductive season does not affect egg production and quality, even if the sperm motility characteristics of the new males added indicated a lower quality. Our analyses are ongoing and the final results on male parental contribution in the mass-spawning events immediately after new male introduction will be presented in the meeting.

EVALUATION OF AROMATASE INHIBITOR LETROZOLE TO INDUCE MASCULINISATION IN ADULT DUSKY GROUPEL (*Epinephelus marginatus*)

Introduction

The dusky grouper (*Epinephelus marginatus*) is a cosmopolitan species of importance for fisheries, aquaculture, and ecological interest. Like many other species in this family, dusky groupers are monandric protogynous hermaphrodites, characterized by slow-growth, late maturation and long lifespan, with natural sex inversion from female to male occurring around 80 cm total length and above 7 years old (Condini et al., 2018). These biological characteristics, combined with intense fishing pressure experienced since the last century and increasing habitat destruction, led to this species being classified as Vulnerable on the IUCN Red List in 2016. Considering its economic value, especially in Asian and Mediterranean countries, this species has long been of interest for capture-based aquaculture. However, given the high feed conversion ratio and the conservation status of wild stocks, this practice seems to be unsustainable. Furthermore, sudden mass mortality events, such as those caused by Betanodavirus in 2023 and 2024 in the Mediterranean populations (Kersting et al., 2024), have highlighted the urgent need to establish aquaculture breeding programs, allowing therefore to satisfy the market demand without impacting on the wild population, as well as to provide readily available stock for reintroduction in case of worsening conservation status. The main limiting factor in dusky grouper breeding is currently the difficulty in inducing sex inversion to males, which results in lack of sperm for fertilization. To address this issue, aromatase inhibitors have already been used in other congeners with successful and permanent results. However, in dusky groupers they have rarely been tested alone, and results were often limited to very low milt production or temporary inversion. The objective of this research is, therefore, to test letrozole, a non-steroidal aromatase inhibitor, in order to evaluate its effectiveness in inducing masculinization in individuals who are already within the natural range of sex inversion.

Materials and methods

Fifteen dusky groupers of average weight 6.3 ± 0.9 kg (mean $\pm$ SD) and around twenty-five years old were maintained in two rectangular tanks of 5 m³ in the broodstock facility of Aqualabs at the Institute of Marine Biology, Biotechnology and Aquaculture, in Crete. Starting on 11th of March and every 28 days, letrozole (InvivoChem, China) has been injected in fish dorsal muscle in two different experimental doses, both diluted in 50 μ l fish oil kg⁻¹ of fish. Fish were randomly divided in three groups receiving respectively effective dose of 1.07 ± 0.02 mg kg⁻¹ letrozole (n=5), 10.45 ± 0.18 mg kg⁻¹ letrozole (n=5) and fish oil only as control (n=5). Fish were reared together in similar stocking density. On day 0, before starting the treatment, no sperm was found in the groupers as well as no gonadal biopsies were possible to be obtained with the catheter, probably due to underdeveloped gonads, as fish were outside their reproductive season. On the same day of injection and every 14 days, the groupers were checked for sperm production and approximately 1.5 ml of blood was collected with heparinized syringes. Masculinization and spermiation will be examined every 14 days, by applying gentle abdominal pressure and collecting sperm. Sperm quality will be analyzed with Computer Assisted Sperm Analysis (CASA) for sperm density, spermatozoa motility (%), progressive motile spermatozoa (%), rapid motile spermatozoa (%), straight-line velocity (VSL, μ m sec⁻¹), curvilinear velocity (VCL, μ m sec⁻¹), average path velocity (VAP, μ m sec⁻¹) and straightness (STR, %). Plasma levels of 17- β Estradiol (E₂), Testosterone (T), 11-Ketotestosterone (11-KT) and 17 α ,20 β -Dihydroxy-4-pregnen-3-one (17 α ,20 β -P) will be quantified using Liquid Chromatography-Tandem Mass Spectrometry (LC-MS/MS).

(Continued on next page)

Results and discussion

The experiment is currently ongoing and the results are expected to be obtained around mid of June, at the end of letrozole treatment and in correspondence of the beginning of the natural spawning season. An update of this abstract will follow at the end of the experimental trial. Considering the inhibiting action of letrozole on the enzyme responsible for testosterone aromatisation into 17- β estradiol (CYP19A1), in letrozole-injected groupers the plasma concentration of 17- β estradiol is expected to decrease compared to control fish, whereas testosterone and 11-ketotestosterone should increase. The maturation inducing steroid 17 α ,20 β -dihydroxy-4-pregnen-3-one, instead, is likely to remain constant or slightly increase in treated groupers, therefore stimulating spermiation and sperm motility. Furthermore, hypothesizing a complete masculinization of groupers, a second experiment will be later conducted to evaluate their effective capability to fertilize eggs under natural spawning conditions.

Introduction

Understanding how multiple environmental stressors simultaneously affect the physiology and metabolism of farmed fish remains limited, representing a growing challenge for aquaculture under climate change and increasing production demands. Temperature fluctuations, particularly extreme cold and heat events, can alter energy demands and metabolic resource allocation required to maintain homeostasis, while microplastics (MPs), which are emerging aquatic contaminants, may interact with thermal stress and potentially exacerbate metabolic disturbances. In this context, this study investigated the combined effects of MPs and temperature on the metabolic responses of juvenile pacu (*Piaractus mesopotamicus*), a native species of relevance to Brazilian aquaculture. Fish were exposed for 96 h to two MP concentrations (0 and 20 µg L⁻¹) at three temperatures (16, 28, and 34 °C), using 24 aquaria with four replicates per treatment and two fish per aquarium. At the end of the exposure period, plasma glucose and serum triglyceride and cholesterol levels were assessed as indicators of metabolic alterations.

Results and Discussion

After 96 h, fish maintained at 28 °C exhibited the lowest plasma glucose levels, whereas higher glucose concentrations were observed at 16 and 34 °C, suggesting increased energy demand to maintain homeostasis under suboptimal thermal conditions. This pattern is consistent with previous findings in pacu showing that cold exposure promotes the mobilization of energy substrates and increases blood glucose levels (Ale et al., 2021). MP exposure further increased glucose levels at 16 °C compared with non-exposed fish at the same temperature, suggesting a potential interaction between thermal stress and MP exposure. Triglyceride levels were also lower at 28 °C, regardless of MP exposure, whereas the highest concentrations were observed in fish exposed to MPs at 16 °C, indicating alterations in lipid metabolism under combined stress conditions. Conversely, cholesterol levels were higher at 34 °C in MP-exposed fish, suggesting that MPs may modify lipid metabolism in a temperature-dependent manner. Overall, the observed changes in glucose, triglycerides, and cholesterol are consistent with disturbances in energy homeostasis reported in fish exposed to suboptimal temperatures and MPs (Ale et al., 2021; Ghosh, 2025). These findings demonstrate that extreme temperatures alter metabolic homeostasis in pacu and may modulate the physiological effects of MP exposure, resulting in temperature-dependent metabolic responses. Changes in glucose, triglycerides, and cholesterol indicate adjustments in carbohydrate and lipid metabolism under adverse environmental conditions. These results highlight the importance of considering multiple interacting stressors when assessing the adaptive capacity and resilience of farmed fish, particularly in the context of climate change and the increasing frequency of extreme thermal events in aquaculture systems.

Introduction

Bacteria infections, parasite infestations and environmental stressors present severe health challenges in Atlantic salmon (*Salmo salar*) and rainbow trout (*Oncorhynchus mykiss*) aquaculture with consequences in the health and defensive capacity of the skin mucosa. While both salmonid species share close phylogenetic traits, determining whether their skin tissues share equivalent sensitivity and responsiveness to physiological insults is crucial for understanding mucosal defense mechanisms across species. Using a controlled ex vivo skin system, this study compared the cutaneous transcriptional responsiveness of Atlantic salmon and rainbow trout exposed to identical oxidative and immune stimuli. Establishing whether both species exhibit matching response patterns under standardized conditions is essential for future cross-species applications aimed at evaluating novel nutritional strategies while complying with 3Rs policies (Replacement, Reduction, Refinement) to minimize live animal testing.

Material and methods

Skin explants were collected from anesthetized Atlantic salmon and rainbow trout and incubated for 6 h or 24 h under two controlled challenges: oxidative stress induced by hydrogen peroxide (H₂O₂) and an immune challenge simulated by two homogenates of sea lice with different processing. Cutaneous responsiveness was evaluated via real-time quantitative PCR (qPCR) targeting a panel of biomarkers for immune response (e.g. *il1b*, *il8*, *tnfa*), antioxidant defense (e.g. *cat*, *gpx1*, *nrf2*), and epithelial integrity (e.g. *tjp1*, *oc1*, *agr*). Relative gene expression dynamics were directly compared between species across all conditions.

Results and discussion

Under standardized conditions, the skin mucosa of both Atlantic salmon and rainbow trout exhibited matching transcriptional response patterns across all tested challenges. Exposure to sea lice homogenates induced a strong pro-inflammatory response (*il1b*, *il8*, *tnfa*) in both species, showing significantly greater expression at 24 h compared to the 6 h timepoint. Furthermore, biomarkers targeting antioxidant defense and epithelial integrity displayed parallel temporal modulation, with no major species-specific divergence. These uniform expression trends demonstrate a shared mucosal homeostatic strategy and equivalent biological reactivity in both salmonids when subjected to homologous stressors.

Conclusion

Atlantic salmon and rainbow trout skin display equivalent transcriptional responsiveness to oxidative and parasitic insults. Confirming that both species share identical response patterns under controlled conditions validates using one species as a direct proxy for the other. This insight provides a reliable foundation for future applications evaluating the functional impacts of nutritional and health-management strategies in skin responses, advancing formulation pipelines while fully adhering to 3Rs policies.

Introduction

Antibiotic resistance in aquaculture poses a serious threat to aquatic biosecurity and environmental health. Antibiotic resistance (AMR) in aquaculture is a critical global concern for biosecurity and environmental health. Lactic acid bacteria (LAB) isolated from aquatic environments play a dual role as potential probiotics and potential reservoirs of resistance determinants. Understanding their functional diversity and adaptive responses to antibiotic stress is essential for sustainable aquaculture management.

Materials and Methods

Two multidrug-resistant LAB strains isolated from aquaculture systems in Peru—*Levilactobacillus brevis* UC6 (resistant to 11 antibiotics) and *Lactococcus petauri* UC20 (resistant to 5 antibiotics)—were selected for integrated omics characterization. Whole-genome sequencing was performed, followed by hybrid assembly and functional annotation (Bakta, METABOLIC, CARD/RGI). Quantitative label-free proteomics was conducted using data-independent acquisition (DIA-MS) with dia-PASEF technology on an Evosep One coupled to a timsTOF Pro 2 mass spectrometer. Differentially expressed proteins (DEPs) were evaluated under basal control and oxytetracycline stress conditions. Uncharacterized overexpressed DEPs were modeled in 3D using ESMFold/AlphaFold and structurally aligned via Foldseek to identify novel functional homologies.

Results

Comparative genomic profiling revealed distinct metabolic and enzymatic capabilities among the strains. While sharing identical absolute counts of carbohydrate-active enzymes (CAZymes), *L. petauri* UC20 exhibited a significantly higher CAZyme density (27.07 per 1000 CDS) due to its simplified genome compared to *L. brevis* UC6 (20.40 per 1000 CDS). Conversely, UC6 demonstrated an expanded genetic repertoire dedicated to xenobiotic biodegradation and membrane transport. Quantitative DIA-MS proteomics identified a robust, strain-specific proteomic reprogramming under oxytetracycline exposure. Structural proteomics of major uncharacterized overexpressed proteins led to the discovery of potential novel predicted multidrug efflux transporters (MFS/ABC families) and ribosomal protection candidates that show structural 3D folding homology with established resistance proteins despite low sequence identity.

Discussion

The functional genomic divergence between *L. petauri* UC20 and *L. brevis* UC6 reflects species-specific metabolic specialization, where genome simplification determines CAZyme density, while expanded transport systems drive multidrug resistance (Du et al., 2018). Under oxytetracycline stress, the marked proteomic reprogramming observed by DIA-MS demonstrates significant remodeling driven by uncharacterized pathways alongside expected mechanisms (Nielsen et al., 2014). Crucially, demonstrating that hypothetical overexpressed proteins adopt classic 3D structural folds of MFS/ABC efflux pumps and ribosomal protection factors validates the efficacy of 3D structural comparison for uncovering non-canonical resistance determinants (van Kempen et al., 2024).

Conclusion

These findings highlight the distinct metabolic adaptation strategies and proteomic responses employed by *L. brevis* and *L. petauri* under antibiotic selection pressure. The combination of quantitative DIA-MS proteomics and 3D structural fold alignment represents a powerful workflow to uncover unannotated multidrug resistance determinants in aquaculture microbiomes.

Introduction

Only a very small portion of global aquaculture production is derived from structured breeding programs. A major bottleneck in implementing aquaculture breeding programs is the difficulty of removing aquatic animals from their water environment to measure phenotypes. Over the last decade, the development of machine learning (ML) and computer vision (CV) techniques has provided non-invasive alternatives using image and video analysis to be applied in animal production systems, opening a new possibility for high-throughput phenotyping with minimal disturbance to the animals. This study uses computer vision to predict animal weight directly from images for estimating phenotypic data in Yellowtail Kingfish (*Seriola lalandi*) under commercial conditions, simplifying the repeated measurements that are required for phenotypes such as growth rate the LnVar resilience indicator. Repeated measurements are combined with genotypes to apply genomic analyses of these image-derived measurements.

Materials and Methods

A total of 1,600 PIT-tagged kingfish juveniles were randomly distributed into two treatment tanks at The Kingfish Company (Kats, the Netherlands) and monitored via monthly biometrics over five months. During each event, automated digital imaging (Dorset ID, Aalten, the Netherlands) was performed, and a subset was physically weighed for model calibration. Subsequently, a deep-learning segmentation model processed the images to extract pixel-based area and volume (Figure 1). Quadratic regression models predicted weights for the unweighed population using extracted pixel traits, subsequently allowing the calculation of the daily growth coefficient (DGC) and the LnVar resilience proxy (Mengistu et al., 2022). Genomically, 1,140 individuals were genotyped (Benchmark Genetics, Bergen, Norway). Post-quality control, 25,160 retained SNPs were used to construct a genomic relationship matrix (GRM) via Calc_grm (Calus & Vandenplas, 2016), which was utilized in ASREML to estimate variance components and heritabilities through a univariate model accounting for the treatment effect.

(Continued on next page)

Results

By physically weighing a calibration subset of 100 fish per standard timepoint, the quadratic regression models applied to these calibration subsets yielded coefficients of determination (R^2) ranging from 0.914 to 0.977 and low Mean Absolute Percentage Error (MAPE) between 2.25% and 5.01%, successfully predicting the weights of the remaining unweighed population (up to 770 individuals per treatment per timepoint). Over the entire experiment, a total of 1,494 manual scale measurements estimated 6,299 individual weights. Heritabilities (h^2) for predicted body weight progressively increased from 0.39 ± 0.05 at early stages (WT 1) to 0.48 ± 0.05 at harvest (WT 5). Growth traits demonstrated similarly robust heritabilities, with 0.40 ± 0.05 for DGC, whereas resilience (LnVar) exhibited a low heritability of 0.04 ± 0.02 (Table 1).

Discussion

The computer vision approach utilized in this study successfully predicted the entire population-level weights by weighting only $17\% \pm 7.36\%$ of the sampled animals per timepoint, providing a significantly faster and reliable procedure. Regarding the genomic results, while overall growth measurements exhibited moderate heritabilities of approximately 0.4, the LnVar resilience index demonstrated near-zero heritability, rendering its evaluation suggestive at best. Study of growth variation and resilience remains of significant interest, which strictly requires frequent longitudinal phenotyping. The integration of computer vision combined with artificial intelligence in aquaculture provides a framework for rapid and precise phenotyping as demonstrated in this study. Nevertheless, to meaningfully improve animal welfare and eliminate handling-induced stress, future technologies must evolve to capture images without sedatives and, preferably, without any physical handling of the fish. As these computer vision systems advance toward fully non-invasive, in-water monitoring, they will become critical for evaluating complex resilience traits under commercial conditions.

Introduction

The striped red mullet (*Mullus surmuletus* Linnaeus, 1758) is a promising candidate for diversification in marine aquaculture, yet its larval rearing remains poorly developed. Early larvae are extremely small and sensitive, requiring prey of adequate size and mobility to initiate exogenous feeding (Yúfera & Darias, 2007). Copepods are considered high-quality live prey due to their nutritional profile and swimming behaviour, which can enhance feeding responses in delicate larvae (Støttrup, 2000). The main objective of the SALROC research project, funded by the Xunta de Galicia, is to contribute to the diversification of marine fish farming in Europe by optimizing farming techniques for *M. surmuletus* (Fernández *et al.*, 2025 a, b; 2026 a, b) and actually is being conducted at CIMA (Centro de Investigacións Mariñas de Galicia), CETGA (Centro Tecnológico del Clúster de la Acuicultura) and CSIC (Centro Superior de Investigaciones Científicas). Within the SALROC project, we evaluated the performance of *M. surmuletus* larvae fed exclusively with copepods during a larval trial, aiming to identify bottlenecks in survival, feeding onset and early development.

Materials and Methods

A batch of ~8000 eggs from CETGA broodstock was incubated at 15 °C in 60 L tanks (open circuit). Upon hatching, ~2600 viable larvae (hatching rate 32,5%) were transferred to two 140 L tanks at 19 °C. Copepods (*Acartia tonsa*, *Tisbe* spp.) enriched with *Rhodomonas lens* were sieved at 50 µm and supplied at ~10 ind·mL⁻¹. Larval development, survival, pigmentation, mouth opening and digestive tract condition were monitored through stereomicroscopy and high-resolution imaging.

Results

Figure 1 (a, b, c, d) shows some images of the development of *M. surmuletus* eggs and larvae obtained in this study.

A video of a developing *M. surmuletus* embryo, captured using Light-Sheet Fluorescence Microscopy (LSFM), is available at the following link:

<https://youtube.com/shorts/loSwdm6V0Os>

Figure 1. Different developmental stages of *Mullus surmuletus*. **1a:** Egg 2 DPF. **1b:** Larva 3 DPH. **1c:** Larva 9 DPH. **1d:** Larva 28 DPH. DPF: Days post fertilization. DPH: Days post hatching.

(Continued on next page)

Larval quality at hatching was heterogeneous, with frequent axial deformities. Two mortality peaks occurred: at 4 DPH (coinciding with mouth opening and yolk exhaustion) and at 10 DPH, reducing the population to ~200 larvae per tank. Although most larvae showed no clear feeding behaviour, some individuals displayed darkened stomach regions at 7–11 DPH, compatible with partial ingestion of copepods. Growth remained arrested around 4 mm total length for the majority of larvae. However, one individual reached 10.02 mm at 28 DPH, indicating sustained ingestion and effective assimilation of copepod prey.

Discussion

The study showed that the onset of exogenous feeding is the main constraint in early *M.surmuletus* rearing. Although a few larvae exhibited signs of partial copepod ingestion, most individuals failed to initiate sustained feeding and remained growth-arrested at ~4 mm. Mortality peaks at 4 and 10 DPH highlight the critical nature of the first-feeding window and suggest that copepods may not be fully adequate as initial prey.

Although copepods might initially be considered a suitable option for feeding small-mouthed fish larvae, such as striped red mullet, due to the reduced size of their nauplii and their generally favorable nutritional profile, typically rich in polyunsaturated fatty acids (PUFAs), this trial suggests that exclusive early feeding with copepods is not feasible. Copepod nauplii may be too fast to be efficiently captured by early larvae, and/or larvae may not digest them properly during the initial stages. These observations indicate that the first feeding of striped red mullet larvae should be complemented with smaller and less mobile prey, either by using copepod species with less motile nauplii or enriched rotifers of the smallest possible size, such as *Brachionus rotundiformis*.

At more advanced developmental stages, newly hatched *Artemia*, a widely established intermediate feed in marine larviculture due to its appropriate size, ease of handling and well-documented performance (Dhont *et al.*, 2013), can be incorporated into the diet. Adult copepods could then be introduced once larvae have greater robustness and feeding ability, as they are known to support superior growth in later stages (Støttrup, 2000).

Introduction

The Pacific oyster, *Magallana gigas*, is the main oyster’s species cultivated worldwide and one of the most important species in aquaculture. However, its production has begun to decrease due to degradation of the environment and to infectious disease outbreaks, more specifically by two pathogens: the virus OsHV-1 and the bacteria *Vibrio aestuarianus* (Azema et al. 2016).

Although selective breeding (SB) is a great tool to improve a trait of interest, in this case, the resistance to pathogens, some other potential factors such as the microbiome profile of the oyster can have an important role in the development and propagation of the disease.

In this sense, three families of oysters belonging to a breeding program and three unselected ones were infected with a highly pathogenic strain of *V. aestuarianus* and the microbiome content of the oyster was analyzed after 30 days of infection to determine its potential effect in the resistance/susceptibility.

Material and Methods

Six families (100 oysters/family, 32 months old), were used, , three of them were selected for their higher resistance to both pathogens and the three others were unselected. All oysters were anesthetized, and half of them (50 per family) were injected using 100 μ l (1.8×10^7 CFU) of *V. aestuarianus* suspension into the adductor muscle (injected condition), while the other half were injected with 100 μ L of sterile artificial sea water (control condition). Oysters were then transferred into 50L tanks at $19 \pm 1^{\circ}\text{C}$, in a close system with 100% water renewal every two days. Mortality was recorded daily for 28 days.

Figure 1. Genus significantly different between the unselected vs selected group at 30 days post injection.

(Continued on next page)

Bacterial DNA from gill was extracted from six live oysters per family and timepoint (24 hours and 30 days post injection). After extraction, the hypervariable region V3-V4 of the 16S was sequenced in an Illumina platform at BMKGENE (Germany). Samples were analyzed using the DADA2 (v1.16) pipeline in R studio. The identification of differentially abundant taxa between experimental groups was performed using the DESeq2 package according to Semedo and Song (2020).

Results

Mortality in selected families ranged from 29 to 36% while in unselected ones ranged from 51 to 84%. Alpha diversity showed a similar pattern among families with no differences between timepoints. This analysis showed that, in general, *V. aestuarianus* infection do not alter the bacterial community provoking major changes in richness (Chao index) or overall diversity (Shannon index). Although some differences were expected, at least between timepoints, it seems that neither the timepoint, neither the infection had a major effect on the microbial composition between families. All families presented a similar microbiota composition dominated by Gammaproteobacteria, Bacteroidia, Alphaproteobacteria and Actinobacteria regarding the class composition.

But, although no differences were found regarding the major groups, when we take a closer look at genus composition, some differences appeared. At 24 hours post injection the bacterial community was more homogeneous but, the image changed completely after 30 days post injection, with some major differences were evident between the selected and unselected oysters. For the unselected oyster, a drift to colonization of *Enterobacter*, *Cronobacter*, *Scherichia/Shigella*, *Streptococcus*, *Tenacibaculum* and *Sulfitobacter* was evidenced (Fig. 1). On the other hand, *Colwellia*, *Rothia*, *Pseudomonas*, *Pseudarthrobacter*, *Paenibacillus*, *Massilia*, *Marinomonas* and *Marifilum* became more present in the selected group (Fig 1). Although neither Chao or Shannon index showed differences between groups, it seems that, selected oysters present a more diverse and complex taxa with also more genus belonged to beneficial bacteria.

Conclusion

Some bacterial groups were directly linked to resistance or susceptibility to the *V. aestuarianus*. Bacteria from genus *Colwellia*, *Marinomonas* and *Tenacibaculum* were more present in the selected group while *Arcobacter*, *Vibrio*, *Enterobacter* and *Streptococcus* were more present in the unselected group.

It is possible to conclude that SB programs are an important key to enhance the resistance of *M. gigas*, but also the microbiome could have a potential role to improve the performance of animals.

Introduction

The production of *Penaeus vannamei* represents the main sector of global aquaculture; however, its intensification raises sustainability challenges, particularly related to fishmeal use and nitrogen waste management. Biofloc technology (BFT) has emerged as an alternative based on nutrient recycling into microbial biomass, improving water quality and providing a complementary nutritional source. However, its performance depends on multiple interrelated factors that have traditionally been studied in isolation. This study adopts an integrated approach, evaluating system optimization, nutritional efficiency, microbiota, and product quality to support more sustainable shrimp production.

Material & Methods

A series of experiments were conducted under super-intensive conditions in BFT systems. The following aspects were evaluated: (i) the effect of carbon sources (molasses, yeast, and polymers) and C:N ratios (10:1, 18:1, 26:1) on water quality, microbial dynamics, and growth; (ii) nutritional efficiency through different protein levels (30–46%) and feeding regimes (70–100%), including stable isotope analysis to estimate biofloc contribution; (iii) fishmeal replacement using isoproteic and isolipidic diets with alternative protein sources; (iv) characterization of biofloc and gut microbiota through 16S rRNA gene sequencing; and (v) preservative-free post-harvest quality, assessing slaughter methods and their effects on microbial load, spoilage, and sensory properties during refrigerated storage.

Results & Discussion

Results demonstrated that biofloc system performance is strongly influenced by carbon source and C:N ratio, affecting water quality, microbiota, and shrimp growth. Molasses, particularly at low to intermediate C:N ratios, emerged as the most suitable strategy, promoting a balanced and functional microbial community. This is likely due to greater carbon availability stimulating heterotrophic bacteria compared to slow-release sources such as polymers, despite better nitrogen control and higher diversity (Luo et al., 2019). In contrast, yeast treatment showed higher phosphate accumulation and a more dominated bacterial composition, limiting their productive advantage (Emerenciano et al., 2017). These results indicate that heterotrophic activity is more relevant than diversity per se (Samocha et al., 2020). Stable isotope analysis confirmed that biofloc contributes ~40% to shrimp nutrition allowing a 30% reduction in feeding rate without affecting growth and saving €0.95/kg biomass, confirming overestimated requirement by conventional feeding tables (Lara et al., 2017). Dietary protein was optimized to 38% in juveniles and 34% in grow-out, consistent with reduced requirements as shrimp grow (Henriques et al., 2021). Up to 92% FM replacement using alternative protein sources was feasible without compromising performance, confirming the compensatory role of biofloc and supporting reduced FM use (Chen et al., 2024). Diet also influenced product quality, with mixed diets providing the best balance between sensory attributes and reduced melanosis. Microbiota analysis revealed clear differentiation between biofloc and gut communities, mainly driven by system maturation (Kim et al., 2022) and shrimp growth (Gainza et al., 2018), rather than diet. Finally, slaughter methods affected preservative-free post-harvest quality, the most suitable method consist of a 5-minute immersion in chilled seawater with 50 ppm sodium hypochlorite followed by thermal shock in ice slurry. Overall, these results demonstrate that BFT can be optimized through an integrated approach that improves efficiency, reduces feeding costs, enhances sustainability, and improves product quality.

Introduction

Biofloc technology (BFT) enables intensive aquaculture production with low water exchange, but this can lead to the accumulation of nitrogen compounds, particularly nitrate. Nitrate buildup may affect water quality, animal performance, and system sustainability, and may also pose an environmental risk if untreated water is discharged. In BFT systems, nitrate removal has traditionally been linked to denitrification under anoxic or anaerobic conditions. However, recent evidence suggests that denitrification may also occur under aerobic conditions, highlighting the functional complexity of biofloc microbial communities.

Material and methods

Two trials were carried out to evaluate aerobic and anoxic denitrification in *P. vannamei* production system. First, a 48 h assay was conducted to optimize nitrate removal in external bioreactors using biofloc with approximately 300 mg/L total suspended solids (TSS) and water with a high nitrate concentration. Anoxic denitrification was performed by adding molasses to adjust the C:N ratio to 3:1, and removing aeration. While, aerobic denitrification was performed under controlled oxygenated conditions (>4 mg/L) and adjusting the C:N ratio to 20:1 with a carbon source composed of a mix of di-, poly- and monosaccharides (Maltose 53%, corn starch 24% and glucose 2%). Microbial populations were analyzed by qPCR to assess the functional genes associated with nitrification and denitrification under each condition. In the second trial, the denitrification strategies were applied for 4 weeks in shrimp production tanks. Once per week, between 15-20% of the tank water was subjected to a 48 h denitrification period under either anoxic or aerobic conditions and then reintroduced into the production system. In both trials, water quality was monitored through dissolved oxygen, temperature, salinity, pH, alkalinity, ammonium, nitrite, and nitrate. The pH was maintained above 8 by adding 1 M NaOH, and each denitrification period was considered complete when nitrate concentrations approached 0 mg/L.

Results and discussion

The results showed that both strategies reduced nitrate in biofloc systems, although through different dynamics. In the optimization trial, anoxic denitrification achieved the highest nitrate removal efficiency, close to 95.7%, but was accompanied by transient nitrite and ammonium accumulation and increased alkalinity after pH correction, indicating greater operational instability. In contrast, the aerobic pathway showed a more gradual and lower nitrate reduction, approximately 77.2%, but maintained greater water quality stability. The increase in TSS under this condition suggests a relevant contribution of heterotrophic assimilation, consistent with carbon supplemented biofloc systems (Ebeling et al., 2006; Avnimelech, 2009). qPCR analysis supported these differences: under anoxic conditions, the upward trend in *narG*, together with the low abundance of downstream denitrification genes, were consistent with transient nitrite accumulation; whereas, under aerobic conditions, the higher abundance of *narG*, *nirS*, and *nirK*, together with the increase in AOB and *Nitrospira* trend, suggests the coexistence of nitrification, heterotrophic assimilation, and denitrification in anoxic microenvironments within the flocs (Deng et al., 2020; Bhattacharya and Mazumder, 2021).

In the *in vivo* trials with *P. vannamei*, the weekly use of external reactors helped control nitrate accumulation. The anoxic pathway produced a more marked reduction of nitrate in the culture tanks compared with the control, reaching concentrations close to 0 mg/L in the reactors. However, it required a longer treatment time (96 h), to avoid risks associated with nitrite, ammonium, and low dissolved oxygen. In contrast, the aerobic pathway was more stable, but its impact on nitrate accumulation in the culture tanks was limited, likely because continuous nitrate production from feeding, excretion, and nitrification partially exceeded the treatment removal capacity. This agrees with the preliminary trial and with the higher relative abundance of nitrifying bacteria observed under aerobic conditions (Kim et al., 2022; Han et al., 2024). Additionally, both strategies were viable and did not compromise shrimp growth or survival, in agreement with previous

(Continued on next page)

studies using denitrified water in biofloc systems (Brandão et al., 2024). Therefore, despite requiring stricter management, anoxic denitrification appears to be the most promising strategy for effectively controlling nitrate accumulation in biofloc systems; while the aerobic pathway provides greater operational stability, but further optimization is needed to achieve comparable results under culture conditions.

Introduction

Recirculating aquaculture systems (RAS) have emerged as a promising alternative to the traditional flow-through (FT) system for land-based rearing of Atlantic salmon, offering advantages regarding water usage, biosecurity and control of environmental parameters. However, RAS is often associated with higher concentrations of metabolites and residues in the system, which lowers water quality and potentially increases the vulnerability of fish to multifactorial stressors encountered later in the marine phase. Climate change has become a significant concern in sea-based production, as it can intensify adverse environmental conditions. Elevated water temperatures, reduced oxygen levels, and exposure to jellyfish blooms have been shown to negatively affect fish growth and welfare, yet limited research has focused on the combined effects of multiple stressors. The study examines how production environments, particularly RAS and FT, influence the cardiac health and function of Atlantic salmon, and whether these systems affect susceptibility to climate-related stressors during the marine phase. The findings provide insight for developing climate adaptation strategies and reducing fish morbidity and mortality in aquaculture.

Materials and methods

For the Main Trial, Atlantic salmon parr were divided to be reared in FT or RAS. Fish were subjected to 5 weeks of continuous illumination and a gradual salinity increase to induce smoltification, with heart samples being collected 1 day and 14 days after. Seawater transfer was simulated, and the fish were divided into Control and Test groups. The Test groups were subjected to a stress test that included a gradual increase in water temperature from 12°C to 17°C (1°C per day), followed by a decrease in dissolved oxygen (DO) to 60% for 24 hours, and, lastly, exposure to macerated jellyfish. Hearts were sampled 1 day and 5 days post-exposure. Additionally, 9 fish from each group were selected for a 10-minute electrocardiogram (ECG) assessment, during which hypoxic bradycardia was induced by ceasing artificial gill ventilation in anaesthetised fish. Heart samples were sectioned into atrium, bulbus arteriosus, and ventricle, and differences in the expression of genes related to inflammation, thermal stress, angiogenesis, cardiac growth/remodelling, and hypoxia were analysed by RT-qPCR. Histology and immunohistochemistry were also conducted.

Results

The gene expression profile of the Main Trial showed statistically significant differences between the FT and RAS production environments in atrium and bulbus arteriosus samples, specifically in *ctgf* and *cyr61*, both markers of angiogenesis, with higher relative expression in the RAS groups. In contrast, ventricle samples showed no significant upregulations related to the production systems. Multiple significant differences between the two sampling points were identified across all heart compartments in cardiac growth and remodelling-related genes, including *colla* and *anp*, as well as the previously mentioned angiogenesis markers. In the climate change stress challenge, only one statistically significant upregulation in the RAS group was noted in *heat shock protein 70*, a thermal stress-related gene, within bulbus arteriosus samples. Atrium and ventricle samples showed similar expression patterns in both the FT and RAS environments. Significant differences between sampling points or between the Control and Test groups were frequent across all heart compartments for angiogenesis, thermal stress, and cardiac growth/remodelling markers. The relative expression patterns were maintained throughout the three heart regions, especially in genes associated with inflammation, thermal stress and hypoxia. Results from the ECG assessment revealed no differences between the FT and RAS groups. Induced hypoxic bradycardia was also comparable between FT and RAS, however, in the Test group, the bradycardic response was attenuated one day following jellyfish exposure, with signs of recovery evident 5 days post-exposure. Histology and immunohistochemistry samples are currently being analysed.

Discussion

Results from the gene expression analysis showed only minor differences between the FT and RAS production environments, with similar trends in relative expression observed across all three heart compartments and in both trials. This consistency was particularly evident for genes related to inflammation, thermal stress, cardiac growth and remodelling, and hypoxia. These preliminary findings suggest that land-based RAS, under the conditions in the experimental set-up, does not compromise cardiac health in Atlantic salmon, nor does it increase susceptibility to climate-related stressors encountered during the marine phase, compared with FT rearing.

Introduction

Novel functional feed-additives capable of improving fish health have gained attention in recent years. An increasing array of plant-derived compounds are being screened for their potential health safe-guarding characteristics. Recently halophytes, such as *Salicornia ramosissima*, are gaining traction as aquafeed supplements due to their potential immunomodulatory effects. Employing cells derived from Atlantic salmon (*Salmo salar*), the effects of several *S. ramosissima* extracts were assessed by conducting both functional and transcriptomic studies.

Materials and Methods

Head kidney primary cells were harvested from healthy Atlantic salmon, and adherent leukocytes (ASAL) were obtained following previously established protocols¹. In addition, we employed the gill epithelial cell line ASG-10 that has been widely employed in *in vitro* studies². These cells were exposed to different types of *S. ramosissima* extracts (labelled as EXT3, XAD and FERM), derived from distinct steps of the extraction cascade. The MTT (for ASAL) assay and propidium iodide staining-based analysis employing imaging flow cytometry (IFC; for ASG-10) determined the concentrations that are not toxic to the cell types. Suitable concentrations were then selected for the cell exposure studies.

Cells were exposed to each extract for either 3 or 24 h, followed by a challenge with inactivated pathogenic bacteria *Tenacibaculum maritimum*. Phagocytosis and reactive oxygen species (ROS) production were quantified employing IFC protocols¹. Furthermore, a wound healing assay was performed on gill epithelial cells using an automated scratch system followed by live cell imaging. In parallel, a snapshot of the changes in the transcriptome of the two cell types was captured to reveal their molecular responses.

Results and Discussion

In the case of adherent leukocytes, only XAD elicited significant responses - an enhancement of phagocytosis and ROS production after 24 h exposure. These responses occurred after the transcriptional reprogramming toward immune activation, pathogen clearance and homeostasis, with early signs of molecular priming observed at the 3 h exposure timepoint.

As for the epithelial cells, at 24 h, XAD increased ROS production without affecting phagocytic activity. In contrast, EXT3 and FERM promoted a faster wound closure. These functional effects were, to a certain extent, supported by the information from transcriptomic analysis. XAD-treated epithelial cells were associated with an enrichment of oxidative stress and metabolic pathways, including glutathione metabolic process, cellular response to xenobiotic stimulus, and cellular iron ion homeostasis, suggesting a stress-adaptive response; while EXT3 exposure was associated with pathways linked to cell migration and tissue remodeling. These results indicate that *S. ramosissima* extracts promote a cell type-specific response, with XAD primarily enhancing immune activation in leukocytes and metabolic adaptation in epithelial cells, whereas EXT3 seems to favor epithelial repair processes.

Overall, the *in vitro* observations on *S. ramosissima* point to their potential as functional additives in aquafeeds, possibly capable of enhancing immune competence and enabling epithelial integrity of gill tissues of Atlantic salmon.

Introduction

Functional feeds are a promising strategy to improve disease resistance in aquaculture. In this context, plant extracts are rich in bioactives, making them an interesting source of compounds capable of modulating fish health and resilience. Particularly interesting are halophytes such as *Salicornia ramosissima*, which are salt tolerant plants capable of growing in unproductive soils. However, there is limited knowledge about the mechanisms of action of such products, specifically their interactions with the gut microbiota of fish and aquatic animals. Hence, in the present study, we evaluated the effects of diets supplemented with halophytes extracts on survival and gut microbiota of European seabass (*Dicentrarchus labrax*).

Materials and Methods

European seabass of 23.56 ± 0.71 g were fed five experimental diets (CTRL; XAD 0.1%; XAD 0.5%; EXT3 0.1%; EXT3 0.5%) for four weeks. At the end of the feeding trial, fish were challenged with *Photobacterium damsela* subsp. *piscicida* (intraperitoneal injection). Mortality was recorded over eight days, and gut microbiota samples were collected 72 hours post-challenge.

Gut microbiota was analysed using 16S rRNA gene amplicon full-length sequencing. Sequences were processed to generate amplicon sequence variants (ASVs) following quality filtering, denoising, and chimera removal, and were taxonomically assigned using the GTDB reference database. Alpha diversity (Shannon index) and beta diversity (Bray-Curtis dissimilarity) were used to assess community structure across treatments. Differential abundance analysis was performed with metagenomeSeq to identify taxa affected by the diets.

Results and Discussion

Fish fed diets supplemented with XAD 0.1% and EXT3 0.1% had a significantly lower mortality, which indicates that halophyte extracts at lower inclusion levels provide a protective effect against *Photobacterium* infection. Microbiota analysis showed no significant differences in alpha or beta diversity between the treatments. However, despite the lack of clear clustering by diet on Bray-Curtis-based ordination, some differences in dispersion were observed, particularly in the XAD 0.1% and Ext3 0.1% groups.

In contrast, differential abundance analysis revealed some significant differences. Fish fed diets supplemented with halophyte extracts showed a reduction in the relative abundance of *Photobacterium*, with the strongest decrease in the XAD 0.1% group. The genus *Vibrio*, which includes several fish pathogens, was also significantly reduced, but only in fish fed the diets with the lower extracts inclusion (0.1%). In contrast, both XAD diets showed increased abundance of *Acinetobacter*, while both extracts promoted taxa such as *Rhodococcus gordoniae* and *Sphingomonas*, which are often considered beneficial or environmentally relevant.

These results suggest that the protective effects of halophyte extracts might be connected with shifts in specific microbial groups, including reductions in potentially pathogenic genera, rather than large changes in overall microbiota diversity. To clarify the biological relevance of these changes, key ASVs are currently being analysed to understand their closest known relatives using BLAST and phylogenetic analysis.

(Continued on next page)

Moreover, these extracts are being tested as both prophylactic and therapeutic strategies in other aquaculture species, including Atlantic salmon, rainbow trout, and whiteleg shrimp under chronic stress conditions, to understand their broad potential application in the aquaculture industry.

Introduction

Shellfish growing areas have for centuries formed a natural part of the seascape and culture of the Island of Ireland, in part due to the large natural sea loughs which provide an ideal growing environment for bivalves such as mussels, oysters, and scallops.

Bivalve shellfish aquaculture is by nature extensive, and farmers typically have some challenges with respect to stock control, environmental variables, pathogens, and other parts of the business process.

Management of shellfish growing areas is a complex problem: at the core of management is the knowledge of the types, locations, and areas of shellfish culture. The application of models to evaluate carrying capacity and environmental effects relies on sound datasets with respect to stocked areas, stocking density, and other input variables.

Fig 1 shows extensive cultivation of rock oyster (*Magallana gigas*) on trestles in Lough Foyle. Because the culture is organically extractive, rock oysters compete with the native oyster (*Ostrea edulis*) fishery.

Blue mussels (*Mytilus edulis*) were also traditionally grown in the Foyle but at present this is not a key economic resource or a major ecosystem driver.

Over the last fifty years, the industry has changed significantly, in part due to internationalisation, both in terms of Dutch and French entry into the island of Ireland and in terms of the export and branding of Irish product, which is now well recognised in demanding and distant markets such as China.

The expansion of rock oyster cultivation in the Foyle, driven in part by the resistance to oyster Herpes virus at lower water temperatures, has led to stakeholder disputes over the carrying capacity of the lough for different bivalves. The Oyster Management, Ecomodelling, and Growth Assessment (OMEGA) project was developed to: (i) determine the role of Pacific oysters in partitioning the food resource; and (ii) contribute to a fuller understanding of sustainable carrying capacity and top-down eutrophication control in Lough Foyle.

Fig 1. Pacific oyster cultivation in Lough Foyle a transboundary system on the island of Ireland.

(Continued on next page)

Fig 2. Application of machine-learning algorithms showing (left) the accurate distinction between empty trestles and those with oyster bags; and (right) the calculated skill for accurate identification of stocked and unstocked oyster bags.

Fig 3. Simulated Pacific oyster growth and environmental effects using the AquaShell model.

Methods

This paper identifies some of the key methodologies used to address these objectives. The first of these, and the main focus of this paper, was the combined use of remote sensing, in particular drone and satellite images, with machine-learning techniques to train algorithms to accurately identify and count oyster bags, which are typically smaller than 1 m². Such algorithms must be able to distinguish between stocked and unstocked trestle areas.

The resulting registry was stored in the AquaScape platform (<https://longline.co.uk/aquascape/>), a web-based geospatial framework that has been used to map about 3.5 million aquaculture structures throughout the world, corresponding to thirty million tonnes of annual production.

In parallel, the well-known EcoWin ecological model, which has been applied to a number of sea loughs on the island of Ireland (e.g. Ferreira et al., 2008; Nunes et al., 2011; Ferreira et al., 2023) was used to simulate bivalve growth and environmental effects, with an emphasis on depletion of algae and organic detritus, to examine various scenarios of future industry development.

(Continued on next page)

The accurate assessment of the actual area occupied by Pacific oyster and the geographic distribution of the structures used for cultivation was a substantial improvement to the existing carrying capacity modelling of Lough Foyle, providing a robust tool for stakeholder engagement, scenario review, and policy definition.

Results and Discussion

Fig 2 shows an example of the results obtained for image analysis of Pacific oyster culture. Not all the estuarine area can be mapped by drones due to security restrictions—satellite imagery is not as accurate for bag counts. This is a caveat for other shellfish growing areas.

Drone images allowed the mapping of individual bags and the identification of trestles without bags, whereas satellite imagery can only map groups of trestles. In the present work, drone imagery was available for two-thirds of the area (12.31 km²) and resulted in an estimation of a trestle area of 198,693 m², with a corresponding bag count of 272,897.

The total trestle area determined by remote sensing and machine learning was 272,437 m², that contained an estimated 323,935 bags; on average, 53% of the trestle area contained no bags—empty bags were removed by the growers. The ongoing application of the EcoWin model will provide detailed outcomes for carrying capacity, but simple calculations were made using the data acquired to date and the AquaShell bivalve growth model (e.g. Woźniacka et al., 2026).

Fig 3 shows the application of AquaShell to simulate one Pacific oyster, using environmental drivers extracted from the EcoWin model. The outputs were used to scale up the production and environmental effects, considering a stocking density of 80 oysters per bag and a culture period of 850 days. This would result in an annualised production of about 780 tonnes live weight and a corresponding drawdown of 830 kg of chlorophyll.

These numbers do not account for food depletion; EcoWin results will provide a clearer picture of the role of Pacific oysters in partitioning the food resource and of their contribution to top-down control of eutrophication.

Introduction

The increasing and often indiscriminate use of synthetic pesticides has caused significant environmental impacts, including soil and water contamination, changes in biological communities, and adverse effects on the health of animals directly or indirectly exposed to these compounds (Pereira et al., 2023). In this context, microbial bioherbicides have emerged as promising alternatives to conventional herbicides because they provide effective mechanisms for weed control while potentially exhibiting lower environmental persistence and impact (Hasan et al., 2021). Among these products, fungal bioinputs consisting of enzymatic extracts capable of degrading plant cell wall components are particularly noteworthy. Although they exhibit herbicidal activity and potential application in more sustainable agricultural systems, their environmental introduction requires careful assessment of ecological safety. The effectiveness of a bioherbicide against target organisms does not, by itself, ensure its environmental safety. Therefore, ecotoxicological assays using non-target organisms that are widely used in aquaculture are essential for identifying possible lethal and sublethal effects (Alves et al., 2024). Amphibians are particularly relevant in ecotoxicological assessments because their life cycles are associated with both aquatic and terrestrial environments, their skin is highly permeable, and they are highly sensitive to changes in environmental quality. Tadpoles of *Lithobates catesbeianus* (bullfrog), besides being commercially produced for human consumption, are widely used as experimental models in toxicity studies because of their hardiness, ease of handling, and ability to exhibit physiological and biochemical changes in response to contaminant exposure (Cunha & Delariva, 2009; Ikari et al., 2024). Therefore, the present study aimed to preliminarily investigate the acute toxicity of a pure fungal microbial bioinput with bioherbicidal potential through the in vivo exposure of *L. catesbeianus* tadpoles, seeking to identify concentrations that do not produce lethal effects in non-target organisms used in aquaculture.

Materials and Methods

Lithobates catesbeianus tadpoles with a mean body weight of 2.52 ± 0.28 g were randomly distributed among experimental aquaria at a density of four animals per liter. The toxicity assay was conducted under semi-static conditions for 192 hours, following the recommendations of ASTM standard E729-23e1 (ASTM, 2023), with complete renewal of the water and exposure solutions after 96 hours. Reverse-osmosis water reconstituted with sodium bicarbonate (NaHCO_3), calcium sulfate dihydrate ($\text{CaSO}_4 \cdot 2\text{H}_2\text{O}$), magnesium sulfate (MgSO_4), and potassium chloride (KCl) was used as the exposure medium. During the experimental period, the physical and chemical water parameters were monitored and presented the following mean values: alkalinity of 37.49 ± 2.94 mg/L as CaCO_3 , hardness of 40.98 ± 1.86 mg/L as CaCO_3 , pH of 7.74 ± 0.03 , total ammonia of 0.02 mg/L, electrical conductivity of 339.85 ± 156.55 $\mu\text{S}/\text{cm}$, nitrite of 0.65 ± 0.09 $\mu\text{L}/\text{L}$, dissolved oxygen of 6.7 ± 0.4 mg/L, and temperature of 23.79 ± 1.63 °C. The experimental design consisted of four treatments conducted simultaneously in duplicate: a negative control containing only reconstituted water, Treatment 1 containing 3% pure bioinput, Treatment 2 containing 6% pure bioinput, and Treatment 3 containing 12% pure bioinput. Samples were collected at 0, 96, and 192 hours, with one animal collected from each treatment at each sampling time. Fresh blood was used for the immediate determination of glucose levels using the commercially available Accu-ChekTM Performa system. The liver was subsequently removed, weighed, and processed for the quantification of total protein and total immunoglobulin concentrations using an adapted Lowry/BCA method, as described by Bach et al. (2018).

Results and Discussion

At 96 hours, differences among treatments were observed for all variables analyzed. The 12% concentration resulted in the highest blood glucose level and the lowest hepatic protein concentration and peroxidase activity, whereas the 3% treatment showed the highest protein concentration and peroxidase activity. At 192 hours, blood glucose levels did not differ among groups; however, the 3%, 6%, and 12% treatments maintained lower hepatic protein concentrations than the control. Phenolic compound levels varied among treatments and over time, without showing a linear concentration–response relationship. Peroxidase activity exhibited the most consistent alterations, with reduced values in the exposed groups and the lowest activity in the 12% treatment, even after the increase observed between 96 and 192 hours in some groups. Overall, the results indicate that the bioinput induced sublethal biochemical changes, particularly in protein metabolism and antioxidant response, with more pronounced effects at the highest concentrations. Further studies are required to define environmentally safe concentrations.

Introduction

Recirculating aquaculture systems (RAS) have emerged as a promising alternative to the traditional flow-through (FT) system for land-based rearing of Atlantic salmon, offering advantages regarding water usage, biosecurity and control of environmental parameters. However, RAS is often associated with higher concentrations of metabolites and residues in the system, which lowers water quality and potentially increases the vulnerability of fish to multifactorial stressors encountered later in the marine phase. Climate change has become a significant concern in sea-based production, as it can intensify adverse environmental conditions. Elevated water temperatures, reduced oxygen levels, and exposure to jellyfish blooms have been shown to negatively affect fish growth and welfare, yet limited research has focused on the combined effects of multiple stressors. The study examines how production environments, particularly RAS and FT, influence the cardiac health and function of Atlantic salmon, and whether these systems affect susceptibility to climate-related stressors during the marine phase. The findings provide insight for developing climate adaptation strategies and reducing fish morbidity and mortality in aquaculture.

Materials and methods

For the Main Trial, Atlantic salmon parr were divided to be reared in FT or RAS. Fish were subjected to 5 weeks of continuous illumination and a gradual salinity increase to induce smoltification, with heart samples being collected 1 day and 14 days after. Seawater transfer was simulated, and the fish were divided into Control and Test groups. The Test groups were subjected to a stress test that included a gradual increase in water temperature from 12°C to 17°C (1°C per day), followed by a decrease in dissolved oxygen (DO) to 60% for 24 hours, and, lastly, exposure to macerated jellyfish. Hearts were sampled 1 day and 5 days post-exposure. Additionally, 9 fish from each group were selected for a 10-minute electrocardiogram (ECG) assessment, during which hypoxic bradycardia was induced by ceasing artificial gill ventilation in anaesthetised fish. Heart samples were sectioned into atrium, bulbus arteriosus, and ventricle, and differences in the expression of genes related to inflammation, thermal stress, angiogenesis, cardiac growth/remodelling, and hypoxia were analysed by RT-qPCR. Histology and immunohistochemistry were also conducted.

Results

The gene expression profile of the Main Trial showed statistically significant differences between the FT and RAS production environments in atrium and bulbus arteriosus samples, specifically in *ctgf* and *cyr61*, both markers of angiogenesis, with higher relative expression in the RAS groups. In contrast, ventricle samples showed no significant upregulations related to the production systems. Multiple significant differences between the two sampling points were identified across all heart compartments in cardiac growth and remodelling-related genes, including *colla* and *anp*, as well as the previously mentioned angiogenesis markers. In the climate change stress challenge, only one statistically significant upregulation in the RAS group was noted in *heat shock protein 70*, a thermal stress-related gene, within bulbus arteriosus samples. Atrium and ventricle samples showed similar expression patterns in both the FT and RAS environments. Significant differences between sampling points or between the Control and Test groups were frequent across all heart compartments for angiogenesis, thermal stress, and cardiac growth/remodelling markers. The relative expression patterns were maintained throughout the three heart regions, especially in genes associated with inflammation, thermal stress and hypoxia. Results from the ECG assessment revealed no differences between the FT and RAS groups. Induced hypoxic bradycardia was also comparable between FT and RAS, however, in the Test group, the bradycardic response was attenuated one day following jellyfish exposure, with signs of recovery evident 5 days post-exposure. Histology and immunohistochemistry samples are currently being analysed.

(Continued on next page)

Discussion

Results from the gene expression analysis showed only minor differences between the FT and RAS production environments, with similar trends in relative expression observed across all three heart compartments and in both trials. This consistency was particularly evident for genes related to inflammation, thermal stress, cardiac growth and remodelling, and hypoxia. These preliminary findings suggest that land-based RAS, under the conditions in the experimental set-up, does not compromise cardiac health in Atlantic salmon, nor does it increase susceptibility to climate-related stressors encountered during the marine phase, compared with FT rearing.

Introduction

Organic aquaculture requires feeds that meet strict standards for fish quality, animal welfare, and regulatory compliance. In 2020, it produced 74,000 tonnes (6.4% of EU aquaculture), with gilthead seabream and European sea bass contributing only 1.5% (Estévez & Vasilaki, 2023). Its expansion is limited by strict organic rules, including scarce availability of certified feed ingredients, especially fishmeal, and the ban on synthetic amino acids, which increase costs and reduce formulation flexibility. Alternative proteins such as land-based animal meals and single cell proteins are therefore being explored to overcome these constraints (Sarmiento et al., 2025; Oliva-Teles & Gonçalves, 2001; Marchi et al., 2023). This study evaluated growth performance and quality in two gilthead seabream (*Sparus aurata*) genetic lines (fast-growing and standard) fed a novel organic diet featuring partial fishmeal replacement with hydrolysed yeast extract and inclusion of organic poultry meal.

Materials and Methods

Three isoproteic (43%) and isolipidic (17%) diets (conventional (CC), commercial organic (CO), novel organic (NO)) were tested in a 3 × 2 factorial design across eighteen 800-L tanks in a controlled RAS. The NO diet reduced fishmeal, partially replaced by hydrolysed yeast extract, and included organic poultry meal as an alternative protein source. Fish (133.5 ± 0.25 g) were PIT-tagged, reared under optimal conditions (23–24 °C; salinity 28–33 ppt; dissolved oxygen ~100%; pH 7.8–8.2; 12L:12D), and fed ad libitum until tripling in weight over 94 days. Growth performance, biometric indices, and feed efficiency were evaluated at tank level. Fillet composition and quality, gene expression (muscle, liver, and bone), and plasma biochemistry were analysed in subsampled fish to assess overall responses.

Figure

Fig. 1: Growth performance parameters: final body weight (FBW), specific growth rate (SGR), and feed conversion ratio (FCR) as affected by diet (CC, CO, NO) and genetic line (standard, in blue vs fast-growing, in light blue). Two-way ANOVA results with *P*-values reported in the figure.

Results and Discussion

Preliminary results showed that SGR, FCR, and final body weight were significantly affected by both diet and genetic line, with a post-hoc A,B,A pattern (CC, CO, NO). Feed intake was unaffected, whereas the fast-growing line exhibited improved FCR (Fig.1). Somatic indices (HSI and MFI) were unaffected across treatments, while condition factor was higher in the fast-growing line. Fillet quality was mainly diet-driven, with firmness highest in CO and lowest in NO, while no consistent differences were observed for pH or colour. These results align with previous studies showing that well-balanced organic diets can match conventional performance despite reduced fishmeal and absence of syntetic amino acids, while genetic background remains a key determinant of growth efficiency (Estévez & Vasilaki, 2023; Sarmiento et al., 2025) with fillet quality largely unaffected, except for minor diet-related differences in texture (Sarmiento et al., 2025) .

Conclusion

Reducing fishmeal through partial replacement with hydrolysed yeast extract, alongside organic poultry meal as an alternative protein source, sustains growth performance and product quality in gilthead seabream, reinforcing the scalability of EU organic aquaculture.

THE EXPERIMENTAL AQUACULTURE FACILITY AT NMFRI AS A PLATFORM FOR RESEARCH ON THE ECOLOGY AND RESTORATION OF NORTHERN PIKE *Esox lucius*

DP Fey ^{1*}, Greszkiewicz M¹, Lejk MA², Zimak, M²

¹ Department of Fisheries Oceanography and Marine Ecology, National Marine Fisheries Research Institute, Poland

² Department of Monitoring and Logistics, National Marine Fisheries Research Institute, Poland

*corresponding/presenting dfey@mir.gdynia.pl

The population of northern pike in the Baltic Sea has declined markedly over the past decade in many regions, with a particularly extreme example observed in Puck Bay, where the species has nearly disappeared. This situation highlights the urgent need to implement measures aimed at population restoration. Key strategies include stocking with hatchery-reared juveniles as well as the restoration and rehabilitation of spawning habitats. Their effective implementation requires the application of modern aquaculture methods. Such conditions have been provided since 2022 at the Experimental Aquaculture Facility of National Marine Fisheries Research Institute (Gdynia, Poland).

The Experimental Aquaculture Facility enables both experimental and breeding work in the fields of fish biology and ecology, including early life stages. It supports research on species inhabiting both freshwater and saline environments. The facility comprises several recirculating aquaculture systems (RAS) configurations, including hatchery, rearing, and experimental units, with a total working volume of 40 m³. Individual systems are equipped with mechanical filtration (microsieves), biological filtration (Trickling biofilters, moving-bed biofilters), oxygen generation and distribution systems, as well as water cooling and heating systems enabling operation within a temperature range of 5 to >25°C. In addition to tap water supply, the systems are supported by installations that allow the delivery of water with controlled and variable parameters. Key water quality parameters in individual circuits are continuously monitored using the OxyGuard Pacific system and made available online via external computers and mobile devices.

The first project conducted at the facility (PIKE) focuses on the rearing of northern pike (including egg incubation and the larval and juvenile stages) under different conditions, including acclimatization to saline waters for stocking coastal areas of the Baltic Sea. In addition to experimental trials, large-scale fry production for stocking natural environment has also been implemented.

While the impact of salinity on euryhaline fish species has been well-documented, there remains a significant knowledge gap concerning the effects on hatchery-derived brown trout (*Salmo trutta*), particularly regarding their physiology and swimming performance. To address this gap, 30 freshwater reared *S. trutta* from a landlocked population were divided into 4 treatment groups, acclimatized to brackish (9.5 – 15.0 ppt) or full-strength seawater (31.3 – 34.6 ppt) and individually tested via critical swimming speed (UCrit) trials within an inter-flow closed respirometry chamber in changing salinity regimes. The effect of salinity was measured on oxygen consumption (MO_2), and swim performance - quantified by total trial time (minutes) and maximum swim speed (m/s) – and blood biochemical markers, specifically osmolality, chloride, glucose, lactate, and cortisol. Significant differences in MO_2 responses to treatments post-trial were observed across brackish water and full-strength seawater treatment groups. Full-strength seawater groups did not exhibit reduced swimming performance during UCrit trials compared to brackish water groups. Plasma osmolality and chloride levels showed no significant differences across the experimental timeline and treatment groups, suggesting that the trout adapted well to the altered salinity among the treatments. Glucose, lactate, and cortisol levels suggested that exercise induced stress, or exhaustion did not significantly contribute to the observed results, implying alternative stressors most likely related to handling and/or the inherent stress response to salinity changes. The results suggest a complex interplay of factors influencing the physiological responses of these hatchery-derived *S. trutta*. More comprehensive studies are therefore necessary to better understand the underlying factors driving salinity tolerance for *S. trutta* in both hatchery and wild conditions.

Acknowledgement

Introduction and methodology

Since their discovery, antibiotics have been used to treat bacterial infections in human and veterinary medicine. Unfortunately, their excessive and often inappropriate use has led to the development of antibiotic resistance. This means that certain antibacterial molecules may be less effective, or may no longer be effective, because bacteria have developed the ability to counteract their mechanism of action by acquiring or developing resistance genes.

Applied to the livestock sector, this means that the effectiveness of treatments for bacterial diseases may be reduced, and the associated costs of treatment and mortality may increase leading to significant economic losses. And Mediterranean aquaculture is no exception.

Currently, in addition to vaccination, research is being conducted into probiotic microorganisms and new natural compounds to help facing bacterial infections, whilst reducing the use of antibiotics. The aim of this study was to evaluate the in vitro the growth-inhibiting effects activity of substances as pine lipid fraction and wood polyphenols against some of the most relevant bacterial fish pathogens of Mediterranean aquaculture. This study was conducted in triplicate on 90 strains belonging to eight different bacterial species, such as *Vibrio harveyi*, *Tenacibaculum maritimum*, *Lactococcus garvieae*, *Flavobacterium psychrophilum*, *Photobacterium damsela subsp. piscicida*, *Aeromonas veronii*, *Aeromonas salmonicida*, *Yersinia ruckeri*. Following the Clinical and Laboratory Standards Institute (CLSI) guidelines with some modifications, broth microdilutions in 96-well plates were performed. A 0.5 McFarland suspension of the microorganism under investigation was brought into contact with different concentrations (tested range: 0.0049 – 2.50%) of pine lipid fraction and wood polyphenols to determine the Minimal Inhibitory Concentration (MIC) and the Minimal Bactericidal Concentration (MBC). At the same time for each tested strain, the determination of MIC values against routine applied antimicrobials molecules in aquaculture was also performed.

Results and discussion

Tested plant substances, in particular the pine lipid fraction, demonstrated in vitro activity against bacterial fish pathogens. Promising results in terms of MIC and MBC have been obtained, suggesting the potential beneficial role of investigated compounds if applied in aquaculture sector. In vivo assays will be necessary to confirm these preliminary results and to further support the eventual use of these environmentally friendly substances as an alternative to antibiotics in aquaculture.

*corresponding/presenting alexandra.florea@ed.ac.uk

Introduction

Fish viral and bacterial diseases cause substantial losses for the Norwegian aquaculture sector. While vaccination and selective breeding provide protection against many of these threats, there are still a number for which limited preventative measures are available including one causal agent of ulcerative skin disease, *Tenacibaculum finnmarkense*. The aim of study was to evaluate the effectiveness and mode of action of monovalent inactivated vaccines against *T. finnmarkense* in Atlantic salmon (*Salmo salar*).

Methods

Three different vaccine regimes comprising both water-based immersion and oil- based IP vaccines were tested and immune system metrics assessed at various points in the vaccination process. Initial results demonstrated a specific IgM response against *T. finnmarkense* in all IP vaccinated fish and significant differences in mortality were observed between unvaccinated control fish and vaccinated fish, allowing us to select 100 representative head kidney and thymus samples from different timepoints of our best vaccination group.

Results

The transcriptomic data has allowed us to characterise the immune and transcriptional response of Atlantic salmon against this *T. finnmarkense* vaccine, as well as the acute stress response of a placebo vaccination, and to identify biomarkers associated with this response. Additionally, we have identified several differentially expressed genes which can be used in the future as potential disease biomarkers.

MITIGATION OF HARMFUL ALGAL BLOOMS SPECIES THAT AFFECT SCOTTISH AND NORWEGIAN ATLANTIC SALMON FISH FARMS USING MODIFIED CLAYS

Introduction

Understanding how to control microalgal species that negatively impact Atlantic salmon fish farms in fjord systems is a priority for the industry. Harmful Algal Blooms (HABs) in the waters of Scotland and Norway threaten both local food security and global aquaculture production, and they cause significant fish mortality and economic losses (Davidson et al., 2020). Several algal species can damage gill tissues or release toxic metabolites, compromising fish health and welfare in aquaculture systems (Hallegraeff et al., 2023; Planellas et al., 2026). The frequency, duration, and geographic extent of HAB events across Northern Europe are expected to increase with the changing climate (Murray et al., 2025). This increases the urgency for efficient and cost-effective mitigation strategies. At the moment, there are no widely adopted techniques in the salmon industry that are effective at mitigating the adverse effects of HAB (Anderson et al., 2025).

A promising technology is the application of modified clays (MC), which can adhere to algal cells, resulting in the flocculation and sinking of harmful species (Yu et al., 2017). These clays are modified with poly-aluminium chloride, which confers a positive surface charge on the materials, thereby altering their structure and increasing the attraction between the materials and the cells (Yu et al., 2017; Song et al., 2021). Furthermore, it is suggested that these MCs have the capacity to degrade algal toxins. In addition, MCs have been used in large-scale HABs across China, Malaysia and Turkey including open waters for fish aquaculture and enclosed culture ponds.

This study is the first in Europe to investigate the efficiency of commercially available MC (from the IOCAS) in removing seven selected HAB species from the water column under laboratory conditions at fjord-relevant temperatures and salinities. Furthermore, it will evaluate the potential impact of MCs on fish gill cell lines (RTgill-W1) as a proxy for fish toxicity. In addition, using this bioassays to assess unknown toxins and HPLC-MS/MS to detect known toxins. The study will also examine whether these materials can mitigate the toxic effects of harmful algae by adsorbing toxins.

Figure 1: Effect of MCs on *Alexandrium catenella*.

(Continued on next page)

Methodology

We performed a flocc-and-sink experiment, in which cultures of algae were mixed with two different clays (MC-1 and MC-2) at a final concentration of 0.2 g L^{-1} , and cell removal was measured after 3 and 24 hours. These experiments targeted HAB species that cause physical damage to farmed fish: *Chaetoceros curvisetus* (CCAP 1010/12), and toxic species for fish: *Alexandrium catenella* (CCAP 1119/17), *Alexandrium minutum* (CCAP 1119/49), *Karenia mikimotoi* (RCC10703), *Karlodinium veneficum* (NORCCA K-1634), *Chrysochromulina leadbeateri* (NORCCA UIO394), and *Prymnesium parvum* (CCAP 946/7). At the same time, use the RTgill-W1 cell line as a bioassay to determine whether these clays are cytotoxic (and potentially toxic to fish) and whether they can adsorb the toxic compounds produced by the algae. This experiment was conducted on the cell line exposed to MC-1 and MC-2 alone at different concentrations and then assessed whether the MCs could mitigate the effects of the three species, *A. catenella*, *K. mikimotoi* and *C. leadbeateri*.

Results and Discussion

The results showed that, on a laboratory scale, both MCs reduced cell density in the water column by at least 50% for all taxa after 24 hours. For thecate dinoflagellates and diatoms, the removal efficiency was more than 75% in both types of clay at 3 hours (Figure 1A). In addition, athecate dinoflagellates show increased removal efficiency after 24 hours. Removal efficiency varied significantly among phytoplankton species and over time (Yu et al., 2017). Additionally, the RTgill-W1 bioassay MC-1 didn't show any reduction in cell viability in any of the concentrations tested. Furthermore, the cell line bioassay results suggest that MCs could adsorb toxic compounds produced by *Alexandrium catenella*, increasing the cell viability at higher concentrations of MCs (Figure 1B). This indicates sorption capacity of MCs for harmful algal compounds, as previously suggested by Song et al. (2021).

A) Removal efficiency over time of two type of MCs.

B) Cell viability of RT-gill W1 on exposure of *Alexandrium catenella* supernatant with MCs

Overall, modified clays demonstrate considerable potential as a mitigation strategy against several HABs that affect fish. Concomitantly, it can adsorb toxic compounds, thereby increasing gill cell viability. Nevertheless, further research is required to evaluate their environmental safety and potential impacts on non-target organisms in European aquaculture, such as farmed fish.

Acknowledgments

Introduction

Bacterial diseases represent a major constraint for Mediterranean aquaculture, particularly in European sea bass (*Dicentrarchus labrax*), where increased farming intensity and environmental changes are contributing to the emergence of pathogenic species (Reverte et al., 2020). Among these, *Aeromonas veronii* has been widely recognized as an emerging pathogen associated with disease outbreaks in European sea bass, particularly under elevated temperature conditions (Tanrikul & Dinçtürk, 2021). Recent efforts have therefore focused on the development of reproducible infection models for this species, enabling the evaluation of preventive strategies under controlled conditions. In this context, the incorporation of multiple isolates from different outbreaks has become essential, as intraspecific variability in virulence has been reported for *Aeromonas spp.*, potentially affecting disease outcomes and model reproducibility (Smyrli et al., 2019). Accordingly, this study expands previous work by including new *A. veronii* strains isolated from European sea bass in different geographical and epidemiological contexts, allowing a broader assessment of pathogenicity. In parallel, *Lactococcus garvieae* has emerged as a relevant pathogen in marine aquaculture, with recent outbreaks reported in European sea bass farms in Mediterranean countries. This pathogen is associated with septicemia and high mortality rates, particularly under stressful environmental conditions such as elevated temperature and fluctuating salinity (Fouz et al., 2025). Despite its growing importance, infection models under realistic production conditions remain limited.

Therefore, the present study aims to (i) refine and expand infection models for *A. veronii* using multiple isolates and (ii) develop and validate infection models for *L. garvieae* under both controlled (Recirculating Aquaculture Systems - RAS) and semi-natural (estuarine pond) conditions representative of Mediterranean aquaculture systems where the effects of climate change are more evident.

Materials and methods

Bacterial isolates of *A. veronii* and *L. garvieae* were obtained from diseased European sea bass during field outbreaks and identified using MALDI-TOF and qPCR. Strains were cryopreserved and incorporated into the CTAQUA collection. Experimental challenges were conducted using European sea bass at pre-ongrowing and ongrowing stages. For *A. veronii*, multiple isolates were tested using intraperitoneal (IP) injection and bath immersion to evaluate dose-response relationships and inter-strain variability. For *L. garvieae*, infections by intraperitoneal (IP) injection were conducted under different experimental conditions. On the one hand, trials were performed under standard farming conditions representative of current production situation for this species and pathogens. On the other hand, additional trials were carried out under more extreme environmental conditions, including elevated temperature and salinity fluctuations, designed to simulate those typically observed in estuarine pond systems (esteros) in southern Spain, which are increasingly influenced by climate change. This approach allowed the evaluation of pathogen behavior under both current farming conditions and climate change-driven stress scenarios.

For bath infections, the water level in the system tanks was reduced or 10 L buckets were used, depending on fish size. Under these conditions, fish were exposed to the pathogen for 1 hour at the different tested concentrations, while aeration and animal welfare were continuously monitored. For IP injection challenges, 0.1 mL of bacterial suspension per fish was administered at the desired concentration. Prior to injection, fish were deeply anesthetized using benzocaine. All trials included control groups (not exposed to the pathogen during bath infections or inoculated with Phosphate Buffered Saline (PBS) during IP injection infections) and were performed in triplicate. Mortality, culture parameters, clinical signs, and bacterial re-isolation were recorded.

(Continued on next page)

Results and discussion

For *A. veronii*, dose-response relationships were consistent across the different isolates, although mortality rates differed significantly among strains (Smyrli et al., 2019). The results confirm that *A. veronii* isolates exhibit variable virulence depending on virulence factors of the strain, the route of administration, but also fish origin, size and batch, highlighting the importance of incorporating multiple strains and conditions for the development of robust infection models that allow the evaluation of different preventive measures or more versatile and universal treatments, capable of covering the pathogenicity of different strains. *L. garvieae* induced a septicemic disease in European sea bass, with infection dynamics strongly influenced by environmental conditions (Salogni et al., 2024). Higher temperatures and salinity fluctuations, simulating estuarine system conditions, affected both mortality and disease progression. Comparative analyses between standard and extreme conditions revealed more heterogeneous and severe outcomes under semi-natural conditions. Overall, these findings demonstrate the need to integrate environmental variability into infection models to better reflect real farming conditions and improve the evaluation of preventive strategies.

Introduction

Coastal marine aquaculture is increasingly expected to provide food while reducing pressures on marine ecosystems and adapting to environmental change. At the same time, many production systems remain dominated by monoculture and offer limited opportunities for species diversification. This creates a need for approaches that move beyond impact mitigation towards multifunctional aquaculture capable of combining production with ecological functions. Sea Oasis Piran is a field-scale pilot established by the YouSea Institute in the Gulf of Piran, northern Adriatic Sea, within an existing licensed marine aquaculture area. The initiative investigates whether purpose-designed underwater structures can provide a physical and ecological basis for the development of Integrated Multi-Trophic Aquaculture (IMTA), while simultaneously increasing habitat complexity and supporting marine biodiversity (Giangrande et al., 2021).

The long-term objective is to develop and scientifically evaluate a model in which aquaculture infrastructure contributes to both production and ecological functions. In particular, Sea Oasis Piran explores the potential for integrating low-trophic organisms and habitat-forming structures into a regenerative IMTA approach applicable to small-scale Mediterranean aquaculture sites.

Pilot design and monitoring framework

Sea Oasis Piran currently comprises four complementary underwater structures deployed between 2024 and 2026, representing contrasting structural complexity, substrate types and potential ecological and aquaculture functions. The structures incorporate different surfaces using concrete and limestone, open metal and mesh configurations, a three-dimensional biomimetic structure designed to increase structural complexity, and modular rope elements intended to support settlement and potential cultivation of low-trophic marine organisms, including commercial bivalve species.

Rather than functioning as artificial underwater structures spatially and operationally separated from aquaculture, the structures are conceived as experimental components of an IMTA system. Their different geometries and substrates provide an opportunity to investigate how design influences biological colonisation, habitat use, natural recruitment and compatibility with aquaculture operations. The structures therefore function both as habitat-enhancement units and as experimental platforms for evaluating design features relevant to future regenerative aquaculture applications.

Systematic quantitative monitoring is currently being established. The monitoring framework will combine repeated underwater photographic, video and remotely operated vehicle surveys with documentation of sessile colonisation and mobile fauna. Major taxonomic and functional groups will be recorded and changes in community composition and habitat use followed over time. Where low-trophic cultivation trials are implemented, biological performance will be assessed alongside relevant environmental conditions. Structural stability, maintenance requirements and compatibility with routine aquaculture activities will also form part of the evaluation.

Preliminary results

Although systematic quantitative data collection is only beginning, repeated field observations following deployment show rapid and taxonomically diverse biological colonisation of the structures. Observed sessile and associated organisms include sponges, tunicates, bivalves such as oysters, mussels and small scallops, polychaetes, bryozoans and several groups of algae. Egg masses of different gastropods and squid have also been recorded on the structures, indicating their use as reproductive substrate. Multiple wild fish and crab species have been observed around and within the structures, which aligns with previous studies (Ardizzone et al., 1989); these observations are treated as evidence of habitat use rather than as an aquaculture production outcome.

(Continued on next page)

The spontaneous settlement of locally occurring commercial bivalves (e.g. *Mimachlamys varia*, *Ostrea* sp., *Aequipecten opercularis*) and other low-trophic organisms (small sea spider *Maja crispata*) is particularly relevant to the aquaculture component of the pilot. These observations provide a basis for testing whether purpose-designed structures can facilitate natural recruitment and potentially support the collection of locally sourced seed for future low-trophic cultivation. The present observations are qualitative and are being used to refine sampling design and identify priority variables for subsequent quantitative assessment.

Significance

By integrating aquaculture potential, habitat complexity and ecological monitoring within the same operational marine farming site, Sea Oasis Piran explores a transition from predominantly monoculture-based aquaculture towards more diversified, regenerative and ecosystem-based production systems. The pilot will assess whether purpose-designed structures can simultaneously support aquaculture functions, habitat use and the natural recruitment of locally occurring low-trophic species. This could contribute to aquaculture diversification by enabling evaluation of locally recruited native species whose recruitment occurs under local environmental conditions, while reducing dependence on single-species production.

The pilot is expected to identify synergies and trade-offs between production-related activities and biodiversity enhancement and to provide a field-scale framework for evaluating multifunctional aquaculture structures. Sea Oasis Piran therefore offers a platform for developing and testing an ecosystem-based aquaculture model with potential relevance to other small-scale aquaculture sites in the Adriatic and wider Mediterranean region.

Acknowledgment

The development of Sea Oasis Piran has been supported by BAUHAUS Slovenia and collaborating partners.

Introduction

European aquaculture is increasingly challenged to remain economically viable while strengthening its environmental performance, public acceptance and connection with coastal communities. For small and medium-sized farms, diversification does not necessarily require increasing production volume; it can also involve creating complementary services that add value to existing production, knowledge and place. Aquaculture tourism offers such an opportunity by opening working farms to visitors and connecting seafood production with education, local gastronomy and direct producer-consumer interaction. Recent studies indicate that exposure to aquaculture during marine tourism can support learning and more positive attitudes towards aquaculture-tourism integration (Kim et al., 2020; Budhathoki et al., 2025).

Fonda Fish Garden in the Gulf of Piran, northern Adriatic Sea, provides a long-running Slovenian example of this approach. Established as a marine fish farm in 2003, the site gradually developed a tourism and educational programme around its core aquaculture activity. This contribution presents Fonda Fish Garden as a practice-based case study of how aquaculture tourism can diversify a farm's activities while creating a direct setting for communicating aquaculture practices, seafood provenance and the relationship between farming, the marine environment and the local coastal economy.

Aquaculture tourism model

The tourism experience is built around the operation of a real, working marine farm rather than a separate visitor attraction. Guided experiences combine a boat journey from Seča to the offshore farming area with interpretation of the Gulf of Piran, the Sečovlje Salina landscape, the fishing reserve and local marine ecosystems. At the farm, visitors are introduced to the biological and technical principles of sea bass farming, juvenile selection, feeding, growth, stocking density, fish welfare, environmental care, traceability and product quality. Manual fish feeding is demonstrated and the return route includes observation of mussel cultivation. The visit is complemented by tasting locally produced seafood together with regional products, thereby linking primary production with gastronomy and place-based identity. Additional formats developed around the same knowledge base include seafood preparation and cooking workshops and smaller educational experiences.

This format transforms farm infrastructure and day-to-day husbandry into an interpretive environment. The producer is not only a supplier of fish but also a source of first-hand knowledge, while visitors can observe where and how farmed seafood is produced and ask questions directly. The approach therefore creates opportunities to address common misconceptions about aquaculture, explain production trade-offs and distinguish evidence-based sustainability practices from generic sustainability claims. Importantly, the tourism activity remains dependent on the operational and environmental limits of the farm: group size, navigation safety, weather conditions and farming activities determine when and how visits can take place.

Building on this sustainable tourism model, the programme is progressively incorporating elements of regenerative tourism through cooperation with local marine-conservation non-governmental organisations, particularly the YouSea Institute. This collaboration connects aquaculture interpretation with ocean literacy, biodiversity conservation, responsible behaviour at sea and opportunities for public participation in marine stewardship. The aim is not only to minimise tourism impacts, but also to use the farm visit as an entry point for strengthening visitors' understanding of and engagement with the protection of the local marine environment.

(Continued on next page)

Evidence as a recognised good practice

The model has received repeated external recognition for innovation and educational value. The tourism concept received the Slovenian Snovalec recognition in 2014 and was a Sejalec finalist in 2015. In 2019, 'An Unforgettable Day at the Fonda Fish Farm' received the Jakob International Award in the category of new sustainable forms of fishing and wildlife-related tourism; the jury specifically highlighted the combination of fish farming with tourism, education and awareness-raising. The experience was subsequently included among Slovenia Unique Experiences, the national collection of boutique five-star experiences curated by the Slovenian Tourist Board.

Independent destination research also provides quantitative support for its perceived experiential value. In a 2024 study of unique tourism products in Piran and Portorož, based on 230 valid questionnaires, Fonda Fish Garden received a mean uniqueness score of 4.00 out of 5 (SD = 0.844). Its perceived uniqueness was positively associated with consumer expectations ($B = 0.152$, $p = 0.028$), while increasing knowledge of the local offer, traditions and history was the highest-rated expectation across the tourism products examined (Čivre et al., 2024). These data do not measure learning outcomes from the farm visit itself, but they support the relevance of authenticity, local character and educational content in the visitor proposition.

Significance for aquaculture diversification

The Fonda Fish Garden case shows how aquaculture tourism can create value from assets that already exist within a farm: production knowledge, skilled personnel, farm infrastructure, local ecological context, product identity and seafood quality. For smaller coastal farms, this can provide a complementary revenue stream and strengthen links with tourism, gastronomy and local producers without making higher biomass production the only route to economic development. At the same time, direct public access can make aquaculture more visible and understandable and may contribute to social licence by increasing transparency and opportunities for dialogue.

Transferability depends on more than opening a farm to visitors. The experience must remain authentic, safe and compatible with production; interpretation should be delivered by people who understand both the biology and the farming process; and the tourism product should connect aquaculture with the ecological and cultural characteristics of its location. Fonda Fish Garden demonstrates that, when these elements are integrated, a working aquaculture site can function simultaneously as a food-production area, a learning environment and a tourism product. The model therefore offers a practical example of activity diversification for small-scale European aquaculture, with the potential to evolve from sustainable towards more regenerative tourism through collaboration with marine-conservation actors. It also provides a platform for future research on visitor learning, perception, social acceptance and the economic contribution of aquaculture tourism.

Introduction

The Atlantic blue crab (*Callinectes sapidus*) has emerged as a major invasive threat to Mediterranean coastal ecosystems, fisheries and aquaculture. In the northern Adriatic, its rapid expansion has been associated with severe predation on farmed bivalves, particularly Manila clam (*Ruditapes philippinarum*). In two major shellfish-farming lagoons of the Po Delta, losses of farmed clams reached up to 100%, affecting both seed and market-sized individuals and demonstrating the species' potential to seriously disrupt established aquaculture production (Chiesa et al., 2025). In the Bay of Piran, Slovenia (northern Adriatic Sea), *C. sapidus* is now routinely caught for experimental removal in the Jernejev Canal in Seča, an ecologically important coastal area within a Natura 2000 site and the management area of the Sečovlje Salina Nature Park. Because fishing within the protected area requires a specific permit, the resulting catches cannot currently be placed on the market, creating a regulatory barrier to economically supported removal. Since 2025, within the framework of the Delicious Invasion project, the authors have tested an integrated management approach combining systematic removal fishing, culinary valorisation and ocean-literacy activities. The approach explores whether an invasive predator threatening coastal ecosystems, fisheries and aquaculture can simultaneously be transformed into a locally valorised seafood resource, creating an economic incentive for sustained population control. Consumer research elsewhere in the Mediterranean indicates substantial willingness to support blue-crab removal through its purchase and consumption (Marchessaux et al., 2024), suggesting that market valorisation may complement ecological management.

Materials and Methods

As *C. sapidus* occurs within canals that fall under a protected area, fishing was conducted under written permission for scientific research purposes from the protected area management body and Ministry of Agriculture, Forestry and Food. Between October 2025 and July 2026, blue crabs were removed from the Jernejev Canal during 41 fishing/monitoring events, using non-invasive, highly selective gear (a baited line and a hand-held net or baited crab trap) to eliminate bycatch and impact on the surrounding habitat. All individuals ($n = 1176$) were sexed and staged (juvenile, adult, ovigerous), measured (carapace width, carapace length) and weighed, and screened for epibionts. In parallel, the removal programme was linked to two complementary valorisation and engagement pathways: (i) restaurant-based culinary events testing the potential of blue crab as a locally marketable seafood resource while building consumer awareness and acceptance; and (ii) school-based fishing and cooking workshops combining direct participation in invasive-species removal with ocean-literacy education on marine invasions, biodiversity and aquaculture impacts.

Results

The sampled population was predominantly adult (979 of 1174 individuals, 83%), with 181 juveniles and 14 ovigerous females, and was male-biased overall (875 males vs 299 females). Carapace width ranged 52–191 mm (mean 131.8 ± 24.2 mm) and weight 7–473 g (mean 169.5 ± 79.7 g). Epibionts, predominantly filamentous algae, were recorded on 34.9% of individuals (410/1176). Size and population composition varied over the ten-month study period. Mean carapace width increased from 122 mm in October 2025 to a peak of 159 mm in June 2026, before declining to 146 mm in July 2026. Females outnumbered males in the catch only in February 2026 (67%). Catch per fishing event also declined over the study period, from a maximum of 61 individuals in October 2025 to single-digit catches by mid-2026 (range 6–61 overall); while consistent with the cumulative effect of sustained removal fishing, a standardised effort measure would be needed to confirm this as a true abundance trend. Restaurant tasting events and school fishing and cooking workshops were delivered regularly throughout the same period. To date, 6 local restaurants have participated, developing 15 blue-crab recipes and organising dedicated promotional events, such as blue-crab days and the inclusion of blue crab in regular seasonal menus, to raise consumer awareness and demand. In parallel, 15 educational activities engaged 225 participants, mostly primary and secondary school children, their parents and teachers. Participants reported high satisfaction and increased awareness of the blue crab invasion. The initiative also received substantial media coverage, further increasing public visibility of the issue.

(Continued on next page)

Discussion

This study demonstrates that structured, permit-based removal can generate a substantial blue-crab catch while simultaneously supporting culinary valorisation and public engagement. More importantly, sustained removal may represent a precautionary measure against the kind of pressure this predator has already caused elsewhere in the northern Adriatic (Chiesa et al., 2025). The Slovenian case therefore represents an opportunity to develop management measures before impacts on production systems reach the scale observed in neighbouring Italy. However, the socio-economic potential of such an approach is presently constrained by a legislative gap: under current Slovenian fisheries and nature-conservation legislation, catches taken under a scientific/management permit within a protected area cannot be commercially sold, while commercial fishing is generally restricted in these areas. This separates the ecological incentive to maximise removal from the economic incentive that could help sustain fishing effort. Market valorisation should not be regarded as a substitute for invasive-species management, particularly because experience from heavily affected production areas shows that economic returns from blue-crab exploitation may not compensate for losses to shellfish aquaculture. Rather, it could provide an additional mechanism for supporting targeted and continuous removal. However, any such incentive carries the inherent risk of sustaining demand for, rather than reducing, the invasive population, so derogations should permit commercial use only for catch verifiably tied to authorised removal effort, not an independent fishery. We therefore recommend: (i) a dedicated legal derogation allowing traceable commercial use of invasive alien species removed from protected areas under authorised management programmes; (ii) coordinated approval between fisheries and nature-conservation authorities; and (iii) development of a national or Adriatic-regional blue-crab management and valorisation strategy linking invasive-species control, protection of shellfish aquaculture, traceability and local seafood value chains.

Introduction

Reduced dissolved oxygen availability is an increasing challenge for salmonid aquaculture, particularly under climate change scenarios where rising water temperatures decrease oxygen solubility while increasing metabolic demand (Johnston et al., 2025). Chronic hypoxia can impair growth and feed utilization and induce physiological disturbances associated with oxidative stress and activation of stress-response pathways (Lushchak, 2011; Magnoni et al., 2018). Nutritional strategies supporting antioxidant defenses and maintaining redox homeostasis are therefore receiving growing attention (Ciji and Akhtar, 2021). Antarctic krill meal (KM) is a functional ingredient rich in antioxidant compounds, including astaxanthin, selenium and vitamins, and has been associated with beneficial effects on fish performance and health (Kaur et al., 2022). However, its role in modulating physiological stress and redox responses under hypoxic conditions remains poorly documented. Therefore, this study investigated the effects of dietary KM supplementation on stress-related and antioxidant responses of juvenile rainbow trout exposed to chronic hypoxia.

Materials and methods

Juvenile rainbow trout (37 ± 1 g) were fed a control diet (CTRL) or diets supplemented with 5% (KM5), 7.5% (KM7) or 10% (KM10) krill meal for 12 weeks under normoxic conditions. Fish were subsequently exposed to chronic hypoxia (5.9–6.5 mg/L dissolved oxygen) for 3 weeks while continuing to receive their respective diets. Plasma stress indicators (cortisol and glucose), total antioxidant capacity (TAC), hepatic glutathione redox status and expression of antioxidant- and hypoxia-related genes were assessed. Effects of diet and rearing condition were analysed by ANOVA.

Results and discussion

Chronic hypoxia significantly increased plasma cortisol concentrations (+33%, Fig. 1) and moderately elevated plasma glucose levels (+4.3%), while inducing a shift towards a more oxidized hepatic redox status, as reflected by increased GSSG levels and a reduced GSH/GSSG ratio. Hypoxia also upregulated the expression of several antioxidant-related genes, including *sod1*, *cat*, *gr* and *gclc*, indicating activation of compensatory antioxidant mechanisms. Dietary krill meal supplementation attenuated the cortisol response under hypoxia, while plasma total antioxidant capacity remained consistently 6–10% higher in KM-fed fish than in CTRL fish, irrespective of oxygenation conditions (Fig. 1). Similar responses were observed for both Q1 and Q2 antioxidant fractions. Dietary treatment also modulated hepatic redox regulation, with significant effects on GSSG content, GSH/GSSG ratio and expression of genes involved in glutathione metabolism. In particular, expression of *gr* was enhanced in fish fed the highest krill meal level, supporting a role of KM in maintaining redox homeostasis. Interestingly, expression of the hypoxia-responsive marker *egln3a* remained unchanged after 3 weeks of hypoxia, possibly reflecting physiological acclimation to the moderate hypoxic challenge and a transient activation of canonical hypoxia-signalling pathways. Together, these findings indicate that krill meal supplementation enhances systemic antioxidant capacity while modulating hepatic redox regulation, thereby contributing to improved physiological adaptation to chronic hypoxic stress.

Figure 1. Plasma cortisol and total antioxidant capacity of rainbow trout fed the experimental diets under normoxic and hypoxic conditions.

(Continued on next page)

Conclusion

These findings demonstrate that dietary krill meal supplementation modulates both physiological stress and redox responses in rainbow trout exposed to chronic hypoxia. By attenuating cortisol response, enhancing systemic antioxidant capacity and influencing hepatic redox regulation, krill meal appears to support physiological robustness under environmental stress conditions. These results highlight the potential of krill meal as a functional ingredient to improve resilience of farmed salmonids facing increasingly variable oxygen conditions.

Introduction

In recent decades, the monoculture farming of pikeperch (*Sander lucioperca*) has expanded, primarily in Europe and Central Asia, relying on recirculating aquaculture systems (RAS), land-based aquaculture systems (Pěnka et al., 2025). However, while RAS farming offers many advantages (water savings, control of rearing conditions, etc.), this system also has drawbacks, notably high production costs that increase when energy prices rise. Furthermore, pikeperch remains a species highly sensitive to stress related to rearing conditions and various handling procedures (Baekelandt et al., 2018). This vulnerability can lead to greater susceptibility to pathogens, particularly opportunistic bacteria, and consequently necessitate the use of antibiotic treatment (survey towards the European Percid Fish Culture Group, 2024). Moreover, due to its specific behavior and biological preferences, pikeperch reared in monoculture does not make optimal use of available resources in tank (diet, water volume and depth) and polyculture, with another species, would have a benefit effect on rearing conditions and fish welfare. Therefore, the aim of our study is to evaluate the effects of antibiotic therapy and polyculture with the Russian sturgeon *Acipenser gueldenstaedtii*, a highly complementary species (Pěnka et al., 2024), on zootechnical performances of both species reared in RAS and the consequences on bacterial communities of the system, which is influenced by fish species and play major roles in RAS (Changey et al., 2025).

Materials and methods

Our study was carried out at the Experimental Aquaculture Platform (PEA) of the University of Lorraine using 12 temperature-lighting-controlled independent RAS. The initial acclimatization of 110 kg of pikeperch (individual weight of 200-300 g, from La Ferme Intégrale, La Baume-d'Hostun, France) and 50 kg of Russian sturgeon (individual weight of 75-250 g from Belgium Quality Fish, Dottignies, Belgium) was done in separate specific tanks during september 2024. After this period, the batch of pikeperch was divided in two separate RAS which only one received an antibiotic therapy for 10 days (15 g of Trisulmix per 100 kg of fish added to the diet). Then fish were transferred to experimental ecotrons on October 4th (10 kg/tank). Four experimental treatments were applied in triplicate: monoculture of pikeperch without previous antibiotic therapy (P), monoculture of pikeperch with previous antibiotic therapy (P+Ab), biculture of pikeperch without previous antibiotic therapy and russain sturgeon (PE) and biculture of pikeperch with previous antibiotic therapy and russain sturgeon (PE+Ab) with 50% of each species for biculture. The experiment lasted two months at a constant temperature (23-24°C) and fishes were fed at 1.2% feeding rate (Percid Grower Le Gouessant, 52% lipids, 15% proteins and 21.4 MJ/kg energy). Water quality was controlled weekly and individual fish growth monthly (30 fish/species/ecotron), in order to characterize the growth performance of each species, biomass gains, and feed efficiency. Bacterial communities of gut, surfaces biofilm, and water was analyzed using 16S rRNA gene metabarcoding analysis.

Results and discussion

At the end of the experimental period, we observed that the mortality was very low and similar in all treatments. However, significant effects were observed on final biomass and biomass gain which were significantly higher in bicultures compared to monocultures. Lower food conversion rates were calculated in bicultures (IC = 1) compared to the monocultures among which the feed conversion ratio was significantly higher in the treatment group “pikeperch monoculture without antibiotic therapy” (IC = 2.5). Considering performances of each species, any significant difference was recorded in their final mean body weight, those of Russian sturgeon were exactly similar (1.15-1.20 kg) whereas for pikeperch, the final mean weight is close to be significantly higher in the mixed culture with antibiotic therapy” treatment compared to the pikeperch monoculture (P-value = 0.0629). We observed that pikeperch feeding behaviour was different in biculture compared to monoculture. Significant effects of antibiotic therapy and fish species on RAS bacterial communities were recorded. Antibiotic therapy induced a sharp reduction in alpha-diversity within the gut of all treated pikeperch, as well as in the water of the corresponding experimental groups. PERMANOVA results for planktonic and sessiles communities demonstrate that

(Continued on next page)

this effect significantly extends to beta-diversity in the water and in the biofilms ($R^2 = 0.3293$; P-value= $1e-4$; $R^2 = 0.2778$; P-value= $1e-4$ respectively). Notably, the polyculture with or without a previous antibiotic therapy for pikeperch, exhibited the highest similarity in terms of beta diversity for both water and biofilms, (despite remaining significantly different ($R^2 = 0.21758$ p=0.01 for water ; and $R^2 = 0.1116$; p=0.047 for biofilms) suggesting a greater resilience of biofilms formed in polyculture compared to those in monoculture.

Acknowledgments

This work was funded by the research programme Interreg GR VA PolyRAS (INTGR0100025). We thank the members of the European Percid Fish Culture for their contribution to the survey on antibiotic therapy practices for pikeperch and Mr. A. Lautraite, the referring veterinarian for the PEA.

Introduction

In recent years, insect-derived ingredients have emerged as promising sources of bioactive compounds for the development of novel functional ingredients in animal health research. Among edible insects, *Tenebrio molitor* is one of the most extensively studied species, with its larval stage being the first insect approved for human consumption in the European Union. In contrast, the adult stage is generally regarded as a low-value by-product due to its higher chitin content, despite retaining a high protein content (approximately 50%) together with other potentially valuable bioactive compounds. The valorisation of adult *T. molitor* biomass therefore represents an opportunity to improve resource efficiency within insect production systems, reduce waste, and support the transition towards a circular bioeconomy. This study aimed to evaluate the effects of proteins obtained from adult *T. molitor* on immune and oxidative status using an ex vivo intestinal explant model of European seabass (*Dicentrarchus labrax*).

Material and Methods

An initial viability screening was conducted to evaluate the effect of five protein inclusion levels (0.5, 2.5, 7.5, 15, and 20%) on anterior intestinal explants from European seabass (*Dicentrarchus labrax*). Tissue viability was assessed via the MTT assay (Erickson-DiRenzo et al., 2015), with 50% DMSO used as a non-viable control, by measuring formazan absorbance at 570 nm. Based on the screening results, the 0.5%, 1% and 2.5% levels were selected for subsequent evaluation. Explants were pre-incubated for 1 h in pre-treatment medium, Dulbecco's Modified Eagle Medium (DMEM) supplemented with 500 U penicillin-streptomycin, 10% fetal bovine serum (FBS), 2 mM glutamine, and 5.5 mM glucose. The medium was then replaced with fresh DMEM containing 100 U penicillin-streptomycin, 10% FBS, 2 mM glutamine, and 5.5 mM glucose, supplemented with the selected protein concentrations or no protein (control), and incubated for 2 h. Following this incubation, pre-challenge samples were collected and stored in RNeasy lysis buffer at -80°C , while the remaining explants were subjected to a challenge with hydrogen peroxide (H_2O_2) for 2 h under the same medium conditions. After this period, explants were collected and stored in RNeasy lysis buffer at -80°C for gene expression analysis.

Results

The viability assay showed that all the tested protein supplementations were safe for the tissue. So, three concentrations were chosen to perform the ex vivo assay.

Gene expression was assessed in the anterior intestine before and after a hydrogen peroxide challenge. Compared with pre-challenge levels, H_2O_2 exposure upregulated *casp-3*, *tgf- β* , *il-10*, and *sod*, while downregulating *cat* and *gpx*. Polynomial contrast analysis showed that increasing protein supplementation of the incubation medium induced quadratic responses in *casp-3* and *il-10* expression and linear responses in *sod* and *gpx* expression, whereas *tgf- β* expression showed no significant linear or quadratic trends. Furthermore, explants incubated in medium supplemented with 5% protein exhibited higher expression of *casp-3*, *il-10*, and *gpx* than the other treatments (Figure 1).

These findings demonstrate that proteins derived from adult *T. molitor* can modulate intestinal oxidative stress and immune responses in a dose-dependent manner, highlighting their potential as functional ingredients for aquafeeds while contributing to the valorisation of insect production by-products.

About the seaweed centre

The Norwegian Seaweed Centre is a national research and innovation infrastructure designed to advance sustainable seaweed aquaculture as a strategic contribution to future food, feed, material, and energy systems. In response to global challenges related to population growth, climate change, and increasing pressure on natural resources, the centre aims to develop scalable, environmentally responsible marine biomass production systems that support the transition to a sustainable blue bioeconomy. The centre combines fundamental and applied research with technology development and industry collaboration across the full seaweed value chain, creating a comprehensive platform for innovation and knowledge generation.

Overview of the different nodes.

The Seaweed Centre has a total of six nodes that are thematically divided into onshore facilities, offshore facilities, simulation and monitoring, vessels and logistics, preprocessing and storage as well as processing and products (Figure 1).

The **onshore facility** provide controlled environments for experimental cultivation, enabling systematic investigation of growth conditions and biomass quality. These facilities support early-stage development and testing before scaling to open-sea environments. The **sea facilities** constitute a core component of the centre, offering access to offshore and nearshore cultivation sites where large-scale production systems can be evaluated under realistic environmental conditions. These sites allow for the assessment of structural designs, deployment strategies, and ecosystem interactions associated with seaweed farming.

To support data-driven decision-making and system optimization, the centre includes a dedicated node for **simulation and monitoring**. This node integrate environmental monitoring, sensor technologies, and numerical models to analyse oceanographic conditions, biomass performance, and environmental impacts. Such tools are essential for improving site selection, predicting production outcomes, and ensuring sustainable operation. **Vessels and logistics** node provide the necessary maritime infrastructure to enable deployment, maintenance, harvesting, and transport operations, bridging the gap between experimental research and industrial-scale application.

Beyond cultivation, the Norwegian Seaweed Centre addresses post-harvest challenges through nodes focused on **preprocessing and storage**, as well as **processing and product development**. These nodes support research on handling, preservation, and stabilization of seaweed biomass, as well as its conversion into value-added products for food, feed, biobased materials, and other industrial applications. This end-to-end perspective enables holistic evaluation of technical feasibility, resource efficiency, and sustainability across the entire value chain.

Figure 1: An overview of the infrastructure and the six different nodes

(Continued on next page)

Through coordinated projects spanning integrated multi-trophic aquaculture (IMTA), blue carbon potential, environmental sustainability, and commercialization pathways, the Norwegian Seaweed Centre serves as a national and international hub for collaboration. By bringing together infrastructure, interdisciplinary competence, and stakeholder engagement, the centre aims to accelerate innovation in seaweed aquaculture and contribute to climate mitigation, coastal development, and long-term ecosystem resilience within a sustainable marine bioeconomy

Introduction

Shell-boring polychaetes of the genus *Polydora* and related taxa (Polydorini) are among the most important pests of farmed molluscs (Simon and Sato-Okoshi, 2015). These worms bore into shells, inducing the formation of mud blisters filled with sediment and faecal material (Blake and Evans, 1973; Read 2010). In oysters, infestation can induce health problems, higher susceptibility to environmental stressors, mortality, and influence negatively product quality and its market value (Korringa, 1954). Numerous non-native polydorin pests have been transported worldwide through the translocation of infected oyster adults and juveniles (Fossi et al., 2026). Recently, new non-native pests *P. caeca* and *P. websteri* have been reported in oyster farms in the Adriatic Sea, Italy (Mikac et al., 2025). Despite their recognized impact, the management of *Polydora* infestations remains challenging. A wide range of physical and chemical treatments has been proposed in different experimental and geographical contexts, often showing variable effectiveness and limitations related to host safety or operational feasibility. This study aims to identify and experimentally test the most effective and applicable protocols for the removal of shell-boring polychaetes in Italian oyster farms within the framework of the PolyFREE project.

Materials and Methods

A literature-based assessment of removal treatments for shell-boring polychaetes was conducted through a systematic search of peer-reviewed articles, technical reports and grey literature. Protocols were comparatively evaluated using a multi-criteria scoring system based on: (i) quality of the test, (ii) efficacy against the parasite, (iii) host safety, (iv) operational applicability, and (v) environmental and economic sustainability. Experimental trials will be conducted across four seasons on naturally infested oysters from two Italian farms, under controlled laboratory conditions, using replicated treatment groups and untreated controls. Treatment efficacy will be assessed by evaluating the abundance of residual live *Polydora* remaining inside oysters after their treatment and a few-days stabilization period. Worms will be extracted by immersion in a phenol solution. Oyster mortality and treatment-associated stress will also be monitored during the post-treatment stabilization period. Subsequently, the most promising protocol(s) will be tested under field conditions in oyster farming facilities located in the Emilia–Romagna region.

Results and perspectives

The literature review identified a broad range of physical and chemical treatments for the control of shell-boring polychaetes in aquaculture systems worldwide. A total of 37 publications were examined and comparatively evaluated. The evaluation highlighted substantial variability among treatments, particularly regarding treatment efficacy, oyster tolerance, and practical applicability under farming conditions. Based on the overall assessment, three non-chemical physical treatments were selected for experimental validation: (1) freshwater immersion followed by air drying, (2) hypersaline immersion followed by air drying, and (3) prolonged desiccation. Results of the experimental phase, currently underway, will be presented at the conference. They will provide the first comparative validation of *Polydora* treatment protocols under controlled laboratory and field conditions in oyster farming systems of the Emilia–Romagna region. Information on successful treatment protocols will be communicated to oyster producers, and workshops will be organized if needed. The PolyFREE project is expected to contribute to the development of standardized, sustainable and low-impact management strategies against shell-boring polychaete infestations in Mediterranean oyster aquaculture.

Introduction

Lactococcus garvieae (Lg) has recently emerged as a major pathogen in the farming of European sea bass (*Dicentrarchus labrax*) and gilthead sea bream (*Sparus aurata*), the main species in the Mediterranean aquaculture (Salogni et al., 2024; Fouz et al., 2026). *Lactococcus garvieae* is a common fish pathogen that can cause significant economic losses in several fresh and saltwater species. Despite the extensive range of hosts, *L. garvieae* infection in sea bass (*Dicentrarchus labrax*). In parallel, infections caused by *Lg* have also been reported in marine fish farms in Japan, and the isolated strains have been classified into different genetic groups: types I, II and III (the newly emerging *Lg* serotype III) (Araki et al., 2024). However, no information is available as to whether the European strains belong to the same groups as those described in Japan. The aim of this study was to characterize the *Lg* strains isolated in Spanish and Italian marine farms according to the Japanese classification system and to investigate serological variability within this pathogenic marine group.

Materials and methods

Bacterial strains: a collection of strains isolated from diseased sea bass and sea bream in Spanish and Italian farms from 2023 to 2025 was identified using PCR targeting the Glycosyltransferase family 4 coding protein gene of *L. garvieae* (Saticioglu et al., 2023). Reference strains CECT 4828 and CECT 5807, isolated from yellowtail (*Seriola quinqueradiata*) and rainbow trout (*Oncorhynchus mykiss*), respectively, were also included. All strains were routinely grown on Trypticasein Soy Agar (TSA) or TSA supplemented with 4 % of defibrinated sheep blood (TSAB) at 28 °C for 24-48 h.

Genetic classification: Bacterial genomic DNA was extracted using the boiling technique (Fouz et al., 2026) and stored at -20 °C. To determine the genetic type to which the marine isolates belong, the multiplex PCR developed by Araki et al. (2024) was carried out. Strains of type I, II (recognised as *L. formosensis*) or III generate fragments of 262 bp, 1004 bp or 500 bp, respectively.

Figure 1. Agarose gel electrophoresis of the PCR products obtained from DNA samples of pure cultures of *Lactococcus garvieae* (Lg). Amplicons of the *Lg* specific types I or II (262 bp or 500 bp, respectively) can be visualised. From left to right: **Lane (L) 1**, 100bp molecular weight DNA ladder (M); **L2**: *Lg* G1 (Spanish sea bass); **L3**: *Lg* G2 (Spanish sea bass); **L4**: *Lg* IZ811 (Italian sea bream); **L5**: *Lg* CECT 4828; **L6**: *Lg* CECT 5807; **L7**: *Lg* IZ574 (Italian sea bass) **L8**: negative control (no DNA sample).

Table 1. Genetic and serological classification of *Lactococcus garvieae* (Lg) strains isolated from diseased sea bass or sea bream in Spanish and Italian farms.

Lg strains (n)	Geographic origin	Strains of PCR-genetic type*		Strains of serotype**	
		I	III	G1	G2
12	Spain	2	10	10	2
39	Italy	0	39	35	4

*Genetic type according to Araki et al. (2024). ** Serotypes described here.

(Continued on next page)

Serology: rabbit polyclonal antisera were raised against formalin-killed whole cells of strains representative of the two putative serotypes (Ser), corresponding to Spanish isolates G1 and G2 (Fouz et al., 2026). Then, slide agglutination with whole cell suspensions (10^8 colony forming units (CFU)/mL) was performed (Pavlinec et al., 2022) a disease that threatens the long-term sustainability of aquaculture. Current research shows that the Mediterranean strains of *V. harveyi* are serologically heterogeneous, though research comparing the traits of different strains is scarce. This study aims to describe the biochemical, physiological and genetic characteristics of three serologically different strains of *V. harveyi* isolated from farmed European Sea bass (*Dicentrarchus labrax*).

Results and discussion

It was confirmed that the strains isolated from diseased sea bass and seabream corresponded to *L. garvieae* using species-specific PCR. Furthermore, most produced a 500 bp fragment following multiplex PCR, as would be expected from type III strains. Only two Spanish sea bass isolates (G2.1 and G2.2) (Fouz et al., 2026) resulted positive with the type I primers and generated a 262 bp fragment (Fig. 1 and Table 1). CECT 4828 strain tested positive for type I, whilst CECT 5807 tested negative for all three types, as expected (Aoki et al., 2024) (Fig. 1). Thus, most European marine *Lg* strains were classified as type III.

Agglutination tests revealed that the *Lg* isolates from marine species classified as genetic type III belonged to serotype G1 (Table 1). The two Spanish isolates classified as type I reacted positively with the serum raised against the G2 strain and only few Italian type III strains gave positive with this serum (Table 1).

Conclusions

Most strains of *L. garvieae* isolated from diseased sea bass and seabream in Spanish and Italian farms are classified as type III by PCR multiplex and belong to a dominant serotype within the emerging marine group, serotype G1. This study highlights the serological diversity of *Lg* strains responsible for lactococcosis in marine fish, a growing threat to aquaculture that underscores the urgent need to update surveillance and control strategies.

*corresponding/presenting viniciusfrn1@gmail.com

Introduction

Brazilian tilapia is the most important aquaculture species produced in the country and plays a strategic role in domestic fish supply. Although exports account for only a small share of total production, the sector has experienced increasing integration with international markets, particularly through exports of value-added products such as fresh fillets. At the same time, the production chain is organized around distinct regional hubs that differ in production systems, governance structures, and market relationships. These characteristics create a complex environment in which domestic and external factors may jointly influence price dynamics across the value chain.

Monthly data from January 2022 to December 2025 were collected for farmgate prices in the main production hubs (Grandes Lagos, Norte do Paraná, and Oeste do Paraná), wholesale prices, export prices for fresh fillets and frozen whole tilapia, and the BRL/USD exchange rate. All series were transformed into logarithmic returns and tested for stationarity prior to analysis. Return connectedness was assessed using the Diebold and Yilmaz framework, based on the Generalized Forecast Error Variance Decomposition (GFEVD) derived from a Vector Autoregressive (VAR) model (Diebold & Yilmaz, 2012). Total, directional, and net connectedness measures were estimated to quantify the intensity and direction of shock transmission among markets and to identify the main transmitters and receivers of return spillovers within the Brazilian tilapia value chain.

Results and Discussion

The results revealed a strongly interconnected spillover structure across the Brazilian tilapia value chain, with the Total Connectedness Index remaining above 70% during most of the study period. As illustrated in Figure 1, fresh fillet export prices emerged as the dominant net transmitter of shocks, followed by the BRL/USD exchange rate and the Oeste do Paraná production hub. In contrast, wholesale prices, Grandes Lagos, and frozen whole tilapia exports acted primarily as net receivers. The dynamic analysis further showed that connectedness intensified during the sample period, indicating that a large share of price variability was driven by cross-market interactions rather than by idiosyncratic shocks. Robustness analyses confirmed the stability of these findings across alternative forecast horizons.

The network representation (Figure 1) highlights the central role of fresh fillets markets and exchange-rate dynamics in transmitting shocks throughout the system. These findings suggest that, despite its predominantly domestic orientation, the Brazilian tilapia sector remains exposed to external market conditions through export-price and currency channels. Fresh fillets and frozen whole tilapia displayed distinct spillover patterns, indicating functional segmentation between export products and highlighting the greater influence of value-added products on price transmission. Regional differences were also evident, with Oeste do Paraná occupying a central role in domestic shock propagation, potentially reflecting its stronger cooperative structure and higher degree of production coordination. Conversely, Grandes Lagos exhibited greater susceptibility to incoming shocks. Overall, the results emphasize the importance of governance arrangements, market organization, export activities, and exchange-rate dynamics in shaping risk transmission within aquaculture value chains.

Introduction

Accurate assessment of spawned eggs number and embryonic development in fish eggs and larvae is a critical step in hatchery management, directly influencing survival rates, production efficiency, and decisionmaking throughout the early life cycle. Current assessment practices in hatcheries are predominantly based on rapid visual inspection and general stage estimation, often complemented by additional manual checks. While these methods are practical, they remain subjective, speciesdependent, and limited in their ability to consistently evaluate developmental quality. This variability reduces comparability across hatcheries and increases reliance on expert interpretation.

To address these limitations, SnappArt 360 E-Sense has been introduced, a species-specific, automated imaging and analysis solution designed to accurately determine the number of the eggs spawned, the embryonic development from fertilization to the early larval stages, but also define the stage of eggs maturation in case of ovarian biopsy by cannulation. Integrated into the SnappArt 360 platform, the E-Sense tool combines high-resolution imaging with advanced image analysis algorithms to automatically identify developmental stages, quantify key morphological features, and generate standardized quality metrics. A species-specific approach ensures that algorithms and reference models are biologically relevant and tailored to distinct embryological patterns.

By replacing subjective evaluation with a consistent, data-driven methodology, SnappArt 360 E-Sense aims to improve accuracy, reduce labor dependency, and enable harmonized embryonic assessment across hatchery operations.

The aim of this study is to explain how an AI model, trained on images labeled by experts, along with digital support systems that can recognize and track egg stages of different species as *Sparus Aurata*, *Dicentrarchus labrax*, *Lates calcarifer*, *Solea Senegalensis*, *Scophthalmus maximus* ex *Psetta maxima*, *Gadus morhua*

In addition to the device, an integrated software platform processes the collected data and generates clear reports on periodic spawning events and corresponding hatching rates. This functionality supports hatchery managers in effectively monitoring broodstock egg production and maintaining operational control.

Materials and Methods

A known volume egg sample collected from the eggs collector was processed and prepared to be easily divided into a 3x4 cell culture plate, with 1ml per cell. Images of the wells are acquired using the SnappArt 360 device, a digital imaging system, consisting of a camera connected to a local edge-computer device based on the Nvidia Jetson Platform developed by Aris in collaboration with INVE. The captured images were transferred to CVAT (Computer vision annotation tool) for annotation by trained experts. The dataset consists of the following classes: viable eggs fertilized, viable eggs embryo (about 20h from fertilization), non viable eggs (degenerated eggs), healthy larvae, dead larvae, membranes, stage A-B-C-D depending on the maturation of the unfertilized eggs in the case of a preliminary maturation check of the oocyte in seabass. These expert-annotated images were used to train and validate an AI model based on the YOLO (You Only Look Once) object detection architecture. Afterwards, this trained model was installed on the SnappArt to be tested in the field by technicians. After deployment on the SnappArt, it requires only basic input from the user, such as tank origin, tank volume, and sample volume. After a fast image capture of each separate well, the SnappArt delivers a comprehensive report detailing the number of viable eggs, the degenerated ones, and the number of eggs per stage (egg fertilized or embryo). An associated data management platform enables long-term tracking and analysis of broodstock production and quality of the spawn, keeping traceability of the hatching rate from fertilization to hatch.

(Continued on next page)

Results

The accuracy of the Snappart AI system was evaluated by comparing automated counts with manual counts performed by an experienced technician using a stereomicroscope. Manual counting requires high operator expertise to correctly identify viable and degenerated eggs, avoid miscounting, and involves substantial time investment. The time required for manual counting is roughly double that of Snappart360.

In contrast, the Snappart AI system, based on the E-Sense model, allows result verification through realtime image recording and demonstrated 100% correct eggs detection for up to 200 items per well. Overall, the system achieved a total counting accuracy of 99%.

Discussion

The most advanced model is currently applied to fertilized seabream and seabass eggs and provides a broad overview of periodic spawning, supporting effective monitoring and planning of the hatchery.

The detection of the oocyte developmental stage before hormonal induction is another key capability of the system. Within a few minutes, the system provides the percentage distribution of the different egg developmental stages prior to spawning. This enables fast and informed decision-making regarding the most appropriate induction protocol to be applied to the selected breeders.

The automated approach eliminates the need for expert assessment of developmental stages, increasing process standardization and significantly reducing analysis time and accuracy with multiple replicates.

SUBSTRATE AND TIMING ARE KEY TO SUCCESSFUL *Fucus* SEEDING IN A NATURAL BED

*kifr@ecos.au.dk

Along the Danish coastline, *Fucus serratus* is a key habitat-forming brown algae. Due to its commercial use (e.g., as food, in pharmaceuticals, and cosmetics), it is widely harvested, yet, unlike Laminariales, rarely cultivated. As a result, knowledge on reproductive phenology, seeding methods, optimal deployment timing, and yields is limited. This study addressed these gaps by evaluating the gamete production and in vitro fertilization success, followed by the monthly deployment of seeded and unseeded substrates (concrete H-blocks and ropes) in Begtrup Vig (Baltic Sea, Denmark) over 1.5 years within a natural *Fucus* spp. bed. Mature *F. serratus* receptacles were present year-round with a peak abundance per individual from August to February. Fertilization success was maximal from October to January with a male:female gamete ratio of >50:1. The seeding on ropes showed low success (maximum 54 individuals m⁻¹ after one year). In comparison, concrete substrates had a density of up to 69,185 ± 9,862 individuals m⁻², particularly when deployed in April. Overall, a deployment in April and May resulted in three months earlier visibility in comparison to other deployments and higher growth rates (up to 9.9% d⁻¹). While *F. serratus* was artificially seeded, *Fucus vesiculosus* relied on natural recruitment. However, *F. vesiculosus* clearly dominated, reaching a maximum yield of 54.26 kg m⁻², outperforming *F. serratus* (maximum 16.19 kg m⁻²) despite not being actively seeded. The study indicates that year-round seeding is possible, but spring seeding is most favourable. Deploying unseeded stones to be seeded by natural recruitment, and following harvested, may be a promising approach to mitigate the impacts of wild harvesting, while rope-based cultivation requires further research.

UPCYCLING MYCOTOXIN CONTAMINATED CARBOHYDRATES IN EU FOOD SYSTEM VIA INSECT BIOREFINERIES

Pavel Franta*, Radek Gebauer, Jan Mráz, Koushik Roy

University of South Bohemia in České Budějovice, Faculty of Fisheries and Protection of Waters, South Bohemian Research Center of Aquaculture and Biodiversity of Hydrocenoses, Institute of Aquaculture and Protection of Waters, České Budějovice 370 05, Czech Republic.

*Presenting author: pfranta@frov.jcu.cz

Introduction

Insect biorefineries are increasingly recognized as a circular solution for sustainable animal feed production, offering an efficient conversion of underutilized organic resources into protein- and lipid-rich biomass. Their environmental and economic benefits, however, depend strongly on the use of low-value or contaminated waste streams rather than conventional feed materials that compete with food production, although the use of such substrates is currently restricted under EU legislation. Among such underexploited resources are carbohydrate-rich food products discarded due to mycotoxin contamination. Here, we investigate the potential of insects to upcycle ochratoxin-contaminated bakery waste into valuable biomass while generating insect-derived products free of mycotoxins.

Materials and Methods

Four-week-old larvae of *Tenebrio molitor* (yellow mealworm) were reared for 12 weeks on five different dietary substrates: (i) 100% wheat bran, used as the commercial control diet; (ii) 100% breadcrumbs derived from mycotoxin-contaminated bakery products (naturally mold-contaminated bread and bread rolls); (iii) 100% commercially produced breadcrumbs (Penam Plc, Czech Republic); (iv) a mixed diet consisting of 50% wheat bran and 50% mycotoxin-contaminated bakery products; and (v) a mixed diet consisting of 50% commercially produced breadcrumbs and 50% mycotoxin-contaminated bakery products. Final larval body weight, survival rate, and Fulton's condition factor were determined. In addition, the initial and final mycotoxin contents of the 100% wheat bran and 100% mycotoxin-contaminated bakery product treatments were analyzed in an accredited laboratory (AGRO-LA LLC, Czech Republic) using HPLC-MS/MS and a semi-accredited protocol (SOP 8.136.) with detection limits as low as $0.05 \mu\text{g kg}^{-1}$.

Results

After 12 weeks of rearing, the ochratoxin-contaminated moldy bread treatment proved to be as suitable a substrate as the commercial control diet, with no significant differences observed in final larval biomass, body weight, survival rate, or Fulton's condition factor ($p > 0.05$). Among all tested substrates, only treatments containing commercially produced breadcrumbs resulted in significantly lower larval body weight and final biomass ($p < 0.05$). The initial ochratoxin concentration in the contaminated substrate was $13.8 \mu\text{g kg}^{-1}$, corresponding to a total ochratoxin load of $0.828 \mu\text{g}$. During the experiment, this load decreased by 51.5% to $0.401 \mu\text{g}$ as a result of substrate conversion by the larvae. Nevertheless, ochratoxin was not detected in larvae reared on the contaminated substrate.

Discussion

Large amounts of fungi- and mycotoxin-contaminated carbohydrate-rich materials (e.g., grains, bread, and tubers) are discarded worldwide each year and are typically composted, biodegraded, incinerated, or landfilled. Insects, however, have evolved to utilize such microbially colonized substrates, and our results support this adaptation by demonstrating the production of mycotoxin-free larval biomass from mycotoxin-contaminated feedstocks, with growth performance comparable to that achieved on a standard uncontaminated rearing substrate. Furthermore, mealworm feeding reduced the overall ochratoxin load by decreasing the amount of contaminated substrate. These findings highlight the potential of future insect biorefineries to upcycle ochratoxin-contaminated carbohydrate streams into valuable insect-derived protein and lipids for animal feed, thereby contributing to a more circular food system.

Despite this potential, current EU legislation classifies insects together with vertebrate livestock as 'farmed animal' or 'food-producing animal', creating barriers to the full utilization of insect bioconversion. Establishing a separate regulatory category for insects, with more flexible regulations for their production as feed for 'farmed animal', would be an important step toward more effective and sustainable insect farming in Europe.

Introduction

Aquaculture represents a particularly critical sector amongst animal production concerning antimicrobial usage (AMU) and its potential impacts on animal health and the surrounding environment. In Italy, official AMU data are not systematically collected: while some regions have performed the collection in regional datasets, others lack reliable information (Scoppetta et al., 2018). Within Italian aquaculture, rainbow trout holds a central role, as it constitutes the most extensively produced species, placing Italy among the leading European producers. Approximately 70% of national trout production is concentrated in North-eastern Italy where, there is a representative spectrum of structural, managerial and environmental conditions across different farming systems. This research project aims to quantify AMU and to estimate the trend of antibiotic consumption in the provinces of Trento and Udine (primary areas of rainbow trout farming in the North-East of Italy). This activity constitutes a preliminary step towards the development of a standardised national methodology for data collection and a subsequent investigation into the factors influencing the AMU.

Materials and Methods

To define the study population, data from the national livestock registry were used. These data were processed to create lists divided by the provinces involved (Udine and Trento), including all establishments intended for human consumption that kept at least the species rainbow trout. These lists were submitted both to the competent territorial veterinary authorities (ASUIT and ASUFC) and to the trade association (API) for validation. ASUIT and ASUFC provided data on pharmacological treatments carried out in the selected establishments over the three-year period 2022–2024, through access to the national information system which collects all prescriptions issued for farmed animals. Production data, expressed in kilograms of slaughtered and/or marketed fish for each selected establishment, were provided by API, which collects them annually.

AMU was calculated using a dose-based methodology, which makes it possible to take into account the potency of each commercial formulation in relation to a specific treatable biomass, known as the Population Correction Unit (PCU). The data were processed in Define Daily Dose Animal for Italy (DDDAit) to obtain a tailored profile for the commercial products used in Italy. Briefly, the DDDAit of an antimicrobial medicinal product refers to the quantity of active substance, expressed in milligrams, that should be given per kilogram of live body weight each day of treatment, in accordance with the summary of product characteristics (SPC). This metric is the one established during the development of the ClassyFarm management system (it is a national IT platform that collects and processes a significant amount of data relating to animal welfare, biosecurity on farms, antimicrobial consumption and susceptibility, etc.), which currently does not consider fishes but only some terrestrial species. In Italy, the trout slaughter weight varies depending on the type of final product required; for the purposes of this study, we have estimated an average weight of 1 kg. According to the literature (Narbonne et al., 2021), a reasonable treatment weight can be taken as half the slaughter weight meaning in our case 0.5 kg. The total number of fish can be approximated by dividing the annual slaughter biomass by this 1 kg reference weight. This estimated fish count, together with the assumed average treatment weight of 0.5 kg per animal, can then be used to calculate the PCU for each selected establishment.

Results and Discussion

Overall, data were collected for 57 farms. The AMU derived from the calculation represents the number of days of antimicrobial treatment to which each animal farmed on the establishment may have been potentially exposed during the period considered, in our case one year. The results show high variability between different farms as well as within the same farm over the years: there are indeed years in which no pharmacological treatments were administered and others in which the AMU value dramatically increases. This aspect will be investigated further through the subsequent statistical analysis planned within the project, in which possible associations between AMU and risk and protective factors will be assessed.

(the factors taken into account will include both management and environmental considerations). There are farms (21%) that did not carry out any treatments over all three years considered. An investigation into their characteristics showed that these are farms with a favourable geographical location (altitude, and therefore ideal water temperature, and considerable distance from other farms) and which did not experience relevant bacteriological issues. In these cases, as well, it will be of interest to examine whether the only protective factors are geographical, or whether there are also management-related aspects. According to the EMA's proposed classification of antimicrobials, by examining the data from all the farms, 2022 alone saw a peak in the use of class B antimicrobials; on closer inspection, this was attributable to a single farm that used large quantities of flumequine, having resorted to this class of drugs due to serious fish health issues. In both 2023 and 2024, however, class B accounted for the smallest percentage of antimicrobials used, with classes C and D predominating.

Conclusions

In conclusion, this study highlighted the feasibility of applying a dose-based approach to calculate AMU in trout farms. Preliminary data show considerable variability both between farms and over time, with a non-negligible proportion of farms showing no treatments over extended periods. The subsequent analysis of risk factors will allow for a better understanding and explanation of the observed variability.

Acknowledgment

This research is funded by the Ministry of Health, RC 06/24 "Assessment of environmental, management, and structural factors for reducing antibiotic consumption in farming and improving the health and welfare of rainbow trout (TROUTment)" (CUP: B23C24000880001).

Introduction

Aquaculture breeding programs rely on a high number of full-sib families with large number of offspring, which has facilitated the uptake of genomic selection (GS). These sib-testing schemes yield high prediction accuracies but require genotyping large training populations and many candidates for effective selection. Lowering genotyping costs could broaden GS use for smaller companies while for larger ones, that have already been implementing GS, reducing the individual cost of genotyping would allow the genotyping of additional candidates, resulting in an increased selection intensity and genetic gain. Recent efforts focused on designing low-density (LD) panels combined with genotype imputation to achieve accuracy similar to medium or high-density panels. In this study we compared scenarios to optimize reference populations for accurate LD-genotype imputation in Atlantic salmon. We investigated how robust or suboptimal imputation affects prediction accuracy for resistance to cardiomyopathy syndrome (CMS), pancreas disease (PD), and growth (GW).

Materials and Methods

Genotypes, pedigree and phenotypes were obtained from salmonids were obtained from MOWI Norway Atlantic salmon breeding programme. All the phenotyped fish and the parents were genotyped with the ThermoFisher Axiom 57K SNP array. After standard quality controls 47,061 SNPs and 1,094 fish for resistance to CMS (gill score), 1,448 for resistance to PD (binary survival) and 2,998 for GW (guttured weight at harvest) were retained. A LD-panel containing 554 pre-established SNPs, was created *in silico* by masking the genotypes of phenotyped fish (LD-target population). The “missing” genotypes of individuals from the LD-target population were imputed to the high density (HD) using the FImpute software. The impact of the design of the HD-genotyped reference population for imputation was tested in three different scenarios with the HD-genotyped reference population composed of i) all the parents (**RPO**: Reference Parents Only), ii) the offspring from the validation set only (1/10th of the offspring; **RVO**: Reference Validation Only) and iii) all parents and the offspring from the validation set (**RPV**: Reference Parents Validation). The accuracy of imputation was estimated as the Pearson’s correlation between the true and the imputed genotype for each individual.

The quality of genomic prediction using pedigree, LD, HD and imputed genotypes was tested in a standard 10-fold cross-validation approach where (genomic) estimated breeding values ([G]EBV) were computed using the BLUPF90 software with a mixed linear animal BLUP model. Accuracy of prediction was computed as the mean over 10 replicates of the Pearson’s correlation coefficient between the (G)EBV and the true phenotypes of fish in the validation group, divided by the square root of the genomic based heritability estimated with the HD-panel.

Figure 1. Accuracy of imputation and predictions for three traits and different imputation scenarios.

(Continued on next page)

Results and discussion

Imputation was overall very accurate (>0.8) for all traits. Scenarios that contained HD-genotyped parents and offspring (RPV and RPV) resulted in the highest accuracy while the scenario with only HD-genotyped offspring (RVO) resulted in a significantly lower imputation accuracy. The genotype of individuals with one or both parents missing from the dataset was badly imputed (correlation <0.5) in scenarios with only parents and the imputation accuracy of those individuals was significantly improved when siblings were added to the HD-reference panel.

For all three traits the accuracy of GEBVs increased significantly with imputation compared to the un-imputed LD-panel. The comparison between the accuracy of prediction obtained from the HD panel and from the imputed panel varied slightly across the traits. For GW, the accuracy of the HD-panel was significantly better than all imputed scenario except for the RPV scenario. For resistance to PD, the predictions with the HD-panel were always significantly more accurate than the predictions obtained with imputed panels. For resistance to CMS, all imputation scenarios were as good as the HD-panel and as good as each other to predict the GEBV of the fish. Those differences may be due to different genetic architecture of the trait with GW being highly polygenic, PD being oligogenic and CMS being monogenic. Interestingly, the difference in the accuracy of imputation obtained between scenarios was not always reflected in the accuracy of genomic prediction. Indeed, the genomic predictions were robust even when genotype imputation was sub-optimal (RVO, Figure 1), although if this scenario resulted in slightly under-dispersed GEBV for GW and CMS.

Conclusion

As aquaculture breeding programmes rely on phenotypes measured on a training population composed of collaterals (full/half-sib) of the selection candidates, an imputation strategy relying on including offspring in an HD-reference panel is particularly suitable for low-cost genomic selection. This strategy could be used to only perform HD-genotyping every two generations, either reducing the cost of genotyping or increasing the selection intensity with minimal decrease in the accuracy of prediction.

Introduction

Aquaculture systems across Europe are increasingly exposed to the impacts of climate change, with rising temperatures, heatwaves, floods, droughts, and extreme storm events already disrupting both freshwater and marine production. Among the most affected sectors is bivalve aquaculture, where the impact of more frequent and intense harmful algal blooms (HABs) is clear. These events pose significant risks to food safety, farm productivity, and coastal economies, particularly when toxin-producing microalgae are present. The EarlyTOX project was implemented to develop a rapid molecular detection approach based on quantitative real-time PCR (qPCR) and digital PCR (dPCR) technologies to detect and quantify toxin-producing microalgae in aquaculture environments, such as *Gymnodinium catenatum*, *Gambierdiscus* spp., and *Ostreopsis* spp..

Results and Discussion

To strengthen earlywarning capacity and improve risk management, molecular detection tools have become essential. qPCR, and dPCR enable rapid, sensitive, and species-specific identification of toxic microalgae in environmental samples. This is especially critical for taxa such as *G. catenatum*, where morphologically similar nontoxic species coexist within the same genus. By targeting genes directly involved in toxin biosynthesis, species-specific primers allow precise discrimination between toxic and nontoxic strains, reducing false positives and supporting current monitoring programs, that are time consuming, labour intensive, and highly dependent on taxonomix expertise, which can delay regulatory decisions. qPCR detection was already achieved for *Gymnodinium catenatum*, *Gambierdiscus* spp. and *Ostreopsis* spp., and dPCR will be optimized to enable highly sensitive and accurate identification and quantification of target species in more complex environmental samples. Results will be compared with monitoring data issued by The Portuguese Institute for the Ocean and Atmosphere (IPMA). This will validate the molecular tool under real-world conditions and evaluate its capacity to support early detection and risk assessment during HAB events. Optimization of detection protocols for other relevant species are ongoing (*Dynophysis acuminata*, *Pseudo-nitzschia*, *Alexandrium*, etc.)

Conclusions

The EarlyTOX project highlights the growing importance of molecular diagnostics in safeguarding aquaculture under climate stress. Integrating advanced detection methods with environmental monitoring provides a robust framework for mitigating HAB-related risks and enhancing the resilience of European aquaculture in a rapidly changing climate.

A NEW FEED SOLUTION IMPROVES GROWTH PERFORMANCE AND MODULATES PHYSIOLOGY OF ATLANTIC SALMON *Salmo salar* DURING SMOLTIFICATION

Stephane Frouel*

MIXSCIENCE

2, Avenue de Ker Lann

CS 17228 - 35172 Bruz Cedex - France

Corresponding / presenting stephane.frouel@mixscience.eu

Background: Smoltification is a critical physiological transition in Atlantic salmon production, during which fish must adapt from freshwater to seawater while maintaining growth, osmoregulatory capacity, and metabolic stability. This study evaluated whether a novel dietary feed solution, MIXA (MIXSCIENCE, France), could support growth performance and physiological robustness during the freshwater phase and after seawater transfer.

Material and Methods: Atlantic salmon parrs were fed for 12 weeks in a 2 × 2 factorial design combining two basal formulations, a practical smoltification diet and a non-smoltification diet, with or without MIXA at 200 g/ton. The trial included a 6-weeks freshwater phase followed by a 6-weeks seawater phase after direct transfer to full-strength seawater. Growth performance, feed utilisation, survival, plasma biochemical markers, free amino acids, nitrogen-related metabolites, and molecular indicators of gill osmoregulation and intestinal integrity were assessed before and after seawater transfer.

Results: During the freshwater phase, growth performance was mainly driven by the basal formulation: fish fed the smoltification diet showed higher final body weight, weight gain, specific growth rate, protein efficiency ratio, and improved feed conversion compared with fish fed the non-smoltification diet. MIXA induced a modest but significant increase in final body weight, while survival remained 100% in all treatments. In freshwater, MIXA also produced a clear higher metabolic signature, significantly reducing circulating concentrations of most essential amino acids, several non-essential amino acids, and nitrogen-related metabolites including taurine, SAM, SAH, homocysteine, cystathionine, ornithine, GABA, hydroxyproline, and beta-alanine. After seawater transfer, the growth effect of MIXA became more evident, with significant increase in final body weight and weight gain during the seawater phase. The same reduction in plasma free amino acids and nitrogenous metabolites persisted 48 hours after transfer, whereas classical plasma biochemical indicators remained only moderately affected, suggesting good physiological tolerance.

Discussion/Conclusion: The practical smoltification formulation was the main determinant of freshwater performance, whereas MIXA provided an additional growth benefit that was particularly visible after transfer to seawater. The consistent decrease in circulating amino acids and nitrogen-related metabolites suggests that MIXA modulated amino acid turnover, methylation-related pathways, and nitrogen metabolism during smoltification and early seawater acclimation. Overall, these findings support the potential of targeted dietary feed solutions to improve post-transfer growth while maintaining physiological stability in Atlantic salmon undergoing smoltification.

Introduction

Aquaculture is continuously expanding as a consequence of the demand for healthy and nutritious food, which, along with the global saturation of wild fishery production, has encouraged considerable growth of the sector (Tacon et al., 2025). However, aquaculture is plagued by a plethora of bacterial pathogens, and the rearing of fish at high population densities in aquaculture systems makes them particularly susceptible to disease outbreaks, causing massive mortalities (Behringer et al., 2020). The aquaculture sector has suffered major economic tragedies due to infectious diseases, estimated at around \$6 billion annually (Maezono et al., 2025). The effective control of bacterial diseases, including streptococcosis, through the use of antibiotics has become increasingly challenging in aquaculture as a consequence of antimicrobial resistance (Manage, 2018). Therefore, alternative antimicrobial agents, such as phytogenics, are being sought after to reduce reliance on antibiotics (Bhanja et al., 2023). Oregano essential oil (OEO), has demonstrated an unwavering number of benefits as an aquafeed additive, including well-documented efficacy in improving health, disease resistance, and performance of various aquaculture species (Alagawany et al., 2020). Anpario's Orego-Stim Powder (OSP) is a phytogenic feed additive containing 100% natural, single-source OEO which contains over 100 active compounds, with the primary highly-functional compounds being carvacrol, thymol, *p*-cymene, β -caryophyllene, γ -terpinene, and linalool. These OEO compounds work in synergy to provide a complex mode of action, including antioxidant, anti-inflammatory, immunomodulatory, antimicrobial, and growth-promoting functions (Alagawany et al., 2020), highlighting OSP's potential as an effective nutritional strategy to mitigate disease-related challenges and improve resilience in aquaculture species.

Materials and Methods

This independent feed trial was conducted for 85 days by the State University of Western Paraná in Brazil. A total of 200 juvenile Nile tilapia (*Oreochromis niloticus*), with average initial weight of 50 g, were equally and randomly distributed in 20 conical tanks, each with a usable water volume of 500 L. The trial consisted of five dietary groups with four replications being evaluated; one basal control diet, used as a negative control (NC) during the feeding phase and as a positive control (PC) during the 10day *Streptococcus agalactiae* challenge, and four experimental diets supplemented with either OSP or another phytogenic product at 1 or 3 kg/t of feed. *For the purposes of this abstract/presentation, results from three dietary groups are reported, representing a subset of the full dataset.*

At the end of the trial, zootechnical performance parameters were analysed, including final length, final weight, weight gain, specific growth rate, feed conversion, hepatosomatic index, feed intake, condition factor, and cumulative mortality. The remaining parameters, including digestibility, carcass composition, intestinal enzyme activity (protease, amylase, and lipase), haematology (white blood cell count, lysozyme activity, and antioxidant enzymes), liver and intestinal histology, and intestinal microbiota are still under analysis.

Preliminary Results

The results in Fig. 1 demonstrate a significant effect of dietary groups on cumulative mortality ($p < 0.05$). Among the dietary groups, only OSP 1 kg/t showed a significant effect, indicating an approximate reduction of 86.5% in the risk of death compared with the PC group.

Additionally, greater individual resilience was observed in the OSP 1 kg/t group, with a mean time to death (MTD) of 5.0 ± 1.41 days, higher than that observed in the PC group (MTD = 3.75 ± 0.96 days). Thus, the protective efficacy of OSP 1 kg/t is corroborated by the lower specific mortality rate (SMR) observed in the experiment (SMR = 1.82), indicating a slower progression of the pathogen in this group.

On the other hand, the OSP 3 kg/t diet showed a trend towards statistical significance ($p = 0.067$), with a longer MTD (7.0 ± 2.58 days) and an approximate 60% reduction in mortality relative to the PC.

Introduction

The rapid expansion of global aquaculture has intensified the need for sustainable, safe, and effective alternatives to antibiotic growth promoters and chemotherapeutics. Increasing concerns over antimicrobial resistance, environmental impact, and residue accumulation in aquatic products have driven research toward natural bioactive compounds with multifunctional benefits.

Plant-derived polyphenolic phytochemicals, particularly hydrolysable tannins (HT), have emerged as promising candidates due to their well-documented antimicrobial, antioxidant, immunoregulating and gut-modulating properties. Natural chestnut extracts, rich in ellagitannins, a specific type of HT, have demonstrated significant potential in terrestrial animal nutrition; however, its application in aquaculture remains relatively underexplored.

In fish and shrimp farming systems, maintaining an optimal growth performance while ensuring disease resistance is critical. Hydrolysable tannins from chestnut extract may enhance feed efficiency, modulate gut microbiota, improve intestinal integrity, support the immune system, and exert antimicrobial activity against pathogenic bacteria commonly affecting aquaculture species.

Materials and Methods

Pathogen-free Pacific white shrimp (*Penaeus vannamei*) were fed four experimental diets during 90 days, after the corresponding acclimation period and placement in the corresponding tanks. The dietary treatments were as follows: Control (commercial feed), T1 (including 1 kg HT/ton of feed), T2 (including 2kg HT/ton of feed), and T3 (including 3 kg HT/ton of feed). After these 90 days, shrimp were collected and sampled for assessment of the growth performance, hepatopancreatic histology and immune-related gene expression.

Results and Discussion

The dietary inclusion of HT resulted in a significantly lower ($p < 0.05$) FCR of shrimp compared to the Control group. In addition, shrimp fed diets T1 and T2 had significantly higher ($p < 0.05$) final body weight (FBW) and specific growth rate (SGR). Shrimp fed diet T1 also had a significantly higher ($p < 0.05$) weight gain (WG) than those fed diet Control. The improvement in the growth performance obtained with the inclusion of HT in the diets was in agreement with the results reported by Novriadi et al. (2023), who also observed a better growth performance in Pacific white shrimp when using similar dietary levels of inclusion of HT.

Regarding the histology of the hepatopancreas, and compared to the Control group, shrimp fed diet T1 had a higher number of vacuoles in the B cells, a lower amount of hemocytes in the intertubular regions, thicker epithelial tissue, presence of R cells, more lipidic reserves and no tissue atrophy. These results were in line with those reported in Pacific white shrimp by Novriadi et al. (2023) with the inclusion of 2 and 3 kg of HT per ton of feed. The hepatopancreas is the main digestive gland of shrimp, and a key indicator of their metabolism (Novriadi et al., 2023). Thus, the observed beneficial effect of the inclusion of 1kg HT per ton of feed on the hepatopancreas, could be indicative of an improved digestive function, when compared to the Control group.

In relation to the immune response, genes related to the immunity, stress tolerance, and antioxidant capacity, were evaluated to assess the effect of the dietary inclusion of HT on the defense system of shrimp. The results indicated a higher ($p < 0.05$) transcriptional response of two out of a total of five genes analysed, these two belonging to the immune and antioxidant responses, in shrimp fed diet T1 compared to those fed diet Control. These results were in agreement with previous studies reporting antioxidant and antimicrobial activity of HT in shrimp, such as that by Huang et al. (2024). Results on the gene expression, as well on the abovementioned parameters, will be further presented and discussed.

To conclude, results from the present study indicated an overall beneficial effect of the dietary inclusion of HT on cultured Pacific white shrimp, suggesting 1kg of HT per ton of feed as the optimal level of inclusion in shrimp diets.

Introduction

Aquaponics is increasingly recognized as a sustainable food production strategy that integrates aquaculture and hydroponics through internal nutrient recycling, reducing water use and dependence on synthetic fertilizers. This approach is particularly relevant in arid and semi-arid regions where freshwater scarcity and harsh climatic conditions constrain conventional agriculture. However, aquaponic productivity depends not only on system design but also on biological stability, especially the establishment of nitrifying microbial communities responsible for converting toxic ammonia into plant-available nitrate. During early operation, many systems experience instability characterized by pH decline, ammonia accumulation, and reduced fish and plant performance.

Floating raft and media-based systems are among the most common aquaponic configurations. Media-based systems may promote faster microbial colonization because of increased surface area, whereas floating systems are often simpler and easier to manage. Despite these differences, comparative evidence under hot arid conditions remains limited, especially using high-value marine or euryhaline fish species.

Asian seabass (*Lates calcarifer*) is an economically important species with tolerance to a wide salinity range, making it a strong candidate for aquaponics in coastal dry regions. Basil (*Ocimum basilicum*) and mint (*Mentha sp.*) are commercially attractive herbs commonly grown in aquaponics due to rapid growth and moderate nutrient demand.

This study compared floating and media-based aquaponic systems for integrated production of Asian seabass, basil, and mint under greenhouse conditions in Oman. We hypothesized that although system design may influence early-stage water quality dynamics, both systems would converge toward similar performance once nitrification processes were established.

Materials and Methods

The experiment was conducted over 115 days at the aquaponics research facility of Sultan Qaboos University. Six independent aquaponic units were used, each consisting of a fish tank (80 × 40 × 40 cm), sedimentation drum, and plant tank (80 × 40 × 20 cm). Three units were configured as floating raft systems and three as media-based systems using hydrostones.

Asian seabass with an initial mean weight of 163.05 ± 66.95 g were stocked at 7–8 fish per tank to equalize biomass. Fish were fed 2–3 times daily according to feeding response. Basil seedlings were initially planted (8 plants per tank), followed by mint seedlings (3 plants per tank) after basil harvest.

Fish weight and length were measured monthly. Plant height was monitored monthly. Water temperature, dissolved oxygen (DO), and pH were recorded weekly, while ammonia, nitrite, nitrate, phosphate, and silicate were analyzed monthly using standard seawater analytical methods. Differences between treatments were evaluated using independent sample t-tests.

Results

No significant differences were observed between floating and media-based systems for temperature, DO, overall pH, ammonia, nitrate, phosphate, silicate, fish growth, or plant growth.

However, transient instability occurred during Weeks 3–5, when the floating system exhibited significantly lower pH than the media-based system ($p = 0.02$). During the same period, reduced fish feeding activity and slower plant performance were observed.

(Continued on next page)

Ammonia concentrations were highest during the first two to three months and declined thereafter, indicating progressive establishment of nitrification. Nitrite also decreased over time, while nitrate remained relatively stable in both systems.

Final fish weights were 275 g in floating systems and 281 g in media systems, with identical specific growth rates (1.8% day⁻¹). Final fish lengths were approximately 27 cm in both treatments. Survival rates were 62.5% and 67.3% in floating and media systems, respectively.

Basil and mint showed comparable growth between systems, although slightly greater final plant height was recorded in floating units.

Discussion

The results indicate that system stability rather than physical design was the principal determinant of long-term aquaponic performance. Although media-based systems likely offered greater surface area for microbial attachment during start-up, both configurations converged toward similar water quality and biological outputs once nitrifying communities became established.

The early pH depression and elevated ammonia observed in the floating system are consistent with immature nitrification and insufficient buffering capacity. Nitrification releases hydrogen ions, which can lower pH and temporarily reduce feed intake, nutrient uptake, and fish welfare. Once microbial communities matured, nitrogen transformation improved and both systems achieved comparable functional performance.

Despite similar growth rates, survival remained moderate in both treatments. This suggests that fish survival is more sensitive than growth to short-term environmental stress, particularly fluctuations in pH, temperature, and early nitrogen accumulation. Abrupt seasonal cooling from 30°C to 20°C may also have weakened immunity and increased disease susceptibility.

From an applied perspective, both floating and media-based systems are suitable for aquaponic production in arid regions. However, success depends on rapid system maturation, effective biofiltration, and control of pH and temperature during the initial operational phase.

Conclusion

Both floating and media-based aquaponic systems successfully supported the co-production of Asian seabass, basil, and mint under greenhouse conditions in Oman. No major long-term performance differences were detected between system types. Instead, early-stage environmental instability and delayed nitrification had stronger effects on fish survival and short-term productivity than system configuration itself.

Introduction

Mechanical dewatering using a twin-screw press not only reduces biomass moisture content but also facilitates the partitioning of valuable biochemical components between liquid and solid fractions. While mechanical dewatering is commonly applied as a low-energy pre-treatment step, its potential as a fractionation strategy for brown seaweed biorefinery remains largely unexplored. Pressure-driven separation generates a liquid fraction containing soluble compounds and a solid fraction enriched in structural biomass components. In this study, different pre-treatments were combined with twin-screw pressing to evaluate their influence on the distribution of protein-bound amino acids, fucose, and uronic acids in *Alaria esculenta*. The results demonstrated distinct partitioning patterns, with higher concentrations of all three component groups generally retained in the solid fraction, highlighting the potential of mechanical dewatering as an initial fractionation step in cascading seaweed biorefinery. This approach aims to establish mechanical dewatering as a scalable, low-energy entry point for downstream processing, supporting efficient valorization and zero-waste processing.

Methodology

Fresh *Alaria esculenta* was cultivated from Måsskjæra, Norway and harvested on June 2022 (Seaweed Solutions, AS-Norway), this seaweed was subjected to twin-screw pressing without any chemical treatment served as a control (AE.1), washing with freshwater (AE.2), 0.1% KOH treatment (AE.3), or 0.1 M HCl treatment (AE.4) were pressed. Biomass was immersed in each pretreatment solution at a solid-to-liquid ratio of 1:4 for one min before pressing. Dewatering efficiency was assessed through liquid yield, dry matter content of the solid fraction, and solid biomass recovery. The resulting solid and liquid fractions were dried at 50°C and analysed for protein-bound amino acid by HPLC-DAD, fucose by the Dische colorimetric assay, and uronic acids using a modified carbazole method. Whole seaweed biomass served as the baseline reference.

Figure 1 Distribution of protein-bound amino acids, fucose, and uronic acids in solid and liquid fractions of twin-screw-pressed *A. esculenta* (AE1-AE4). Values are expressed as mg g⁻¹ DW.

(Continued on next page)

Results

Dewatering efficiency varies strongly among treatments, with the highest yield in AE.2 (86.95%), followed by AE.3 (66.92%), AE.4 (54.07%), and AE.1 (51.98%). With the solid fraction had the highest DM% in AE.4 (35.40%), while AE.2 showed the lowest solid recovery (37.75%), indicating greater transfer of material into the liquid phase. Processing loss was highest in control sample (AE.1 = 20.11%) and lowest in AE.3 and AE.4 (7.22% and 8.02%), suggesting better mass retention by mild acid/alkali treatment.

Protein

Twin-screw pressing retained protein-bound amino acids mainly in the solid fraction by the given treatment in the range of 129–185 mg AA/g DW, with HCl pretreatment (AE.4) achieving the highest retention/enrichment, compared to baseline value of 133 mg AA/g DW. Essential amino acids (leucine, valine, isoleucine, and phenylalanine) were enriched after pressing, this confirms that majority of essential amino acids were in the pressed solid fraction, whereas liquid fractions contained polar amino acids in the range of 73–104.2 mg/g DW, indicating that these amino acids can be recovered by further processing. Overall, pressing enabled selective fractionation of protein-rich solid and soluble amino acid streams for biorefinery applications.

Fucose and uronic acid

Mechanical dewatering influenced the partitioning of both fucose- and uronic acid-containing polysaccharides in *A. esculenta*, but with different retention patterns. Uronic acid remained highly concentrated in the solid fractions (157–187 mg/g DW), representing 82–97% of the raw biomass level, indicating retention of alginate-bound polymers, whereas liquid fraction has uronic acid in the range of 104.8–149.9 mg/g DW, this confirms soluble sugars moved to the liquid fraction. In comparison, fucose showed greater enrichment in the solid fractions (22.8–28.1 mg/g DW; 111–137% of raw biomass level), suggesting removal of salt concentration enriched fucoidan availability which reflects on the fucose content. The liquid fractions contained considerably lower fucose concentrations (6.3–13.0 mg/g DW) compared to uronic acid (104.8–149.9 mg/g DW). Overall, screw press dewatering acted as a selective fractionation step, retaining fucose-rich fucoidans and alginate-related uronic acid in the solid fraction while generating a liquid fraction enriched in soluble compounds.

DEWATERING EFFICIENCY OF HYDRAULIC PRESSING OF *Ascophyllum nodosum* BIOMASS

Abirami Ramu Ganesan*, Michael Streicher, Dominykas Salvaitis, Gjermund Bahr

Department of Biomarine Resource Valorisation
Division of Food Production and Society
Norway Institute of Bioeconomy Research (NIBIO)
Styrhuset, Mørkvedbukta 30, 8020 Bodø

*corresponding/presenting author: abirami.ganesan@nibio.no

Introduction

Brown seaweed *A. nodosum* has been widely used for feed and biostimulant purposes for many years. However, due to its *high-water content* (ranging >80% MC) it presents challenges like increasing costs of transportation and storage for downstream processing. Therefore, an effective dewatering step is essential to reduce the moisture content, concentrate the biomass and improve handling and processing efficiency. Mechanical dewatering is commonly applied as a pretreatment step in biorefining as it removes readily mobile water and reduces the moisture available for microbial deterioration during handling and storage. However, the efficiency of mechanical dewatering can be limited by the strong water-holding capacity of seaweed tissues and cell-wall components, resulting in substantial residual moisture in the pressed biomass. In this context, this study evaluates calcium chloride (CaCl_2) and magnesium chloride (MgCl_2) as pretreatment agents prior to hydraulic pressing of *A. nodosum*, assessing their effects on dewatering efficiency and the partitioning of protein-bound amino acids between the liquid and solid fractions.

Methodology

Ascophyllum nodosum was harvested at Mørkvedbukta (Bodø) in Norway in February 2022 during low tide and cleaned with seawater. Firstly, *A. nodosum* was minced using a meat mincer to reduce the particle size to ~1 mm, during this mincing process 5% (w/w) CaCl_2 was added to one batch (AN. CaCl_2), and 5% (w/w) MgCl_2 was added to another (AN. MgCl_2) and a third untreated batch served as a control. The salts were incorporated during the mincing process for uniform distribution throughout the biomass. These were then pressed using a hydraulic press (~0.138 MPa), and the resulting liquid and solid fractions were collected to evaluate dewatering efficiency (%). The latter was defined as the proportion of water recovered in the liquid fraction relative to the initial water content of the fresh biomass. The initial water content was calculated from the fresh weight and dry matter (DM %), while the water recovered in the liquid fraction was determined by subtracting the dry matter content from its total mass. The fractions were dried and further analysed for mineral distribution by ICP-OES and total protein-bound amino acid composition by HPLC-DAD.

Results

Dewatering efficiency

The dewatering efficiency (DE %) of *A. nodosum* differed considerably between AN. CaCl_2 and AN. MgCl_2 treatments, AN. CaCl_2 removed 36.15% of water of, while the AN. MgCl_2 treatment only removed 27.84%, and only negligible amounts of water were removed from untreated *A. nodosum*. The solid fraction obtained after AN. CaCl_2 treatment exhibited a higher dry matter content (38.96 DM%) compared to the AN. MgCl_2 treatment (36.52 DM%). These results demonstrated that AN. CaCl_2 created a more concentrated solid fraction that could be advantageous for downstream processing and biomass preservation (Figure 1). The high liquid ash content indicates substantial partitioning of inorganic components/salts into the liquid fraction, with a stronger effect observed for AN. CaCl_2 . Overall, the CaCl_2 pretreatment enhanced water removal more effectively, while both treatments retained most of the biomass dry matter in the solid fraction.

Total protein-bound amino acids distribution

The control solid fraction had the highest total protein-bound amino acid concentration (53.62 ± 4.37 mg AA/g DW) (Figure 2). Whereas, salt pretreatment reduced the amino acid concentration in the solid fraction to 36.07 ± 1.04 mg AA/g DW with AN. MgCl_2 and 34.95 ± 1.69 mg AA/g DW with AN. CaCl_2 . Relative to the control, this represents a decrease of 32.7% with MgCl_2 and 34.8% with CaCl_2 .

Conclusion

Overall, salt-assisted dewatering improved biomass dewatering while enabling selective fractionation of nutrient between the liquid and solid streams with better retention of protein-bound amino acids. suitable for downstream biorefinery applications, while both treatments generated a inorganic components in the liquid fraction, the solid biomass enrichment with essential compounds for further valorization.

The Netherlands

*corresponding/presenting raul.garcianieto@wur.nl

Aquaculture production has risen steadily over the past 40 years, surpassing capture fisheries around 2022 (FAO, 2024). Sustaining this growth requires more aquafeed and improved, sustainable formulations. Due to rising costs and limited supplies of fish meal and fish oil, feeds are increasingly shifting to plant-based and novel ingredients—such as insect meals, single-cell proteins, and industrial by-products—supporting more circular and sustainable production, to keep up with the demand. Additionally, this increases the variability in ingredient and macronutrient composition of new aquafeeds. Aquaculture is characterized by a high species diversity with specific nutritional requirements, thereby highlighting the need for accurate species-specific fish feed evaluation systems. Providing a more accurate energy-based formulation results in a more efficient diet by better predicting energy retention and growth performance. Currently, dietary energy evaluation and feed formulation for fish is established on a digestible energy (DE) basis. This system is based on the DE obtained from the diet using the general efficiency (fraction from 0 to 1) of utilization of the dietary energy for retaining energy (RE), also fulfilling basic metabolism of the animal. This system projects a linear relationship between the RE obtained from a certain DE intake. Estimating an equation (i.e., $RE = \mu + \beta DE$), where the slope (β or KgDE) is the utilization efficiency of DE for energy gain, and the minimal metabolism (μ) known as the fasting heat production. This system does not make a distinction between the source of energy (protein, fat, and carbohydrate) in the diets, thus assumes one generalized efficiency. Nevertheless, recent studies have demonstrated this to not be true, obtaining different efficiencies of energy use between diets differing in macronutrient composition. To consider this variability in the utilization of the different macronutrients, the KgDE is divided into three types of digestible nutrient intake; protein (dCP), fat (dFat), and carbohydrates (dCarb), estimating how efficiently the animal can obtain energy from each one of them. This is known as the net energy (NE) system, already being used in cows, pigs, and poultry, and currently being developed for fish. In this method RE is a function of the three separate macronutrients (i.e., $RE = \mu + \beta_1 dCP + \beta_2 dFat + \beta_3 dCarb$) where the different slopes (β_1 , β_2 , and β_3) are coefficients of the utilization (KgNE) of each digestible macronutrient intake individually (KgNE;dCP, KgNE;dFat, and KgNE;dCarb) for energy gain. Those coefficients can be used to calculate the efficiency of utilization by dividing the coefficient (β_1 , β_2 , and β_3) by the energetic value of each macronutrient; 24.6, 39.5 and 17.2 kJ for protein, fat and carbohydrates, respectively. This approach allows to obtain different recommended NE intakes based on the macronutrient variation of the diets, with species-specific formulas of RE. Recently, NE equations for several fish species have been estimated: rainbow trout, Nile tilapia, barramundi, snakehead, among others (Phan, 2022; Schrama et al., 2018). A relatively low variability in efficiencies was detected in dCP (47% to 64%) and dFat efficiencies (78% to 93%). However, the highest variability occurred in the dCarb fraction, with efficiencies ranging from 5 to 70%, being relatively low in carnivorous (high trophic) fishes. This variation remarks the species-specific nature of the nutrient utilization, supporting the need for species-specific formulations, as is currently being addressed. Recently, new NE equations for relevant carnivorous fish species of production interest such as: Atlantic salmon (*Salmo salar*), European Seabass (*Dicentrarchus labrax*), and Yellowtail Kingfish (*Seriola lalandi*) have been estimated. New estimations of RE have been made using separate coefficients for dCP, dFat and dCarb. In addition, this coefficients also allow to calculate the utilization efficiency of energy in the form of protein, fat, and carbohydrate (those will be presented). This approach enhances the accuracy of estimating retained energy. This enables to make a more accurate prediction in new aquafeeds with high variability of macronutrient composition; hereby supporting the shift to novel ingredients.

THE ECONOMICS OF RECIRCULATING AQUACULTURE SYSTEMS: A SYSTEMATIC REVIEW AND SYNTHESIS OF COST STRUCTURES, PROFITABILITY, AND PERFORMANCE DRIVERS

Sergio Garmendia-Lemus¹, Victor Lobanov¹, Alyssa Joyce¹

¹Department of Conservation-Gothenburg University
Natrium Medicinaregatan 7B 413 90 Göteborg

Introduction

Global food systems increasingly require production models that improve resource efficiency while reducing environmental impacts. In this context, aquaculture has become one of the fastest-growing food production sectors and is expected to play a key role in future food security.

Intensive aquaculture systems such as Recirculating Aquaculture Systems (RAS) have gained attention due to their ability to reduce water use, recycle nutrients, and sustain high production densities under controlled conditions. However, despite their environmental advantages, their long-term economic sustainability remains uncertain (FAO, 2024; Palm et al., 2018; Verma et al., 2023). An integrated agri-aquaculture system, is an interdisciplinary approach that addresses the water-food-energy nexus of United Nations' sustainable development goal and increasing demands of global population at minimal ecological cost. Embracing the 'circular bio-based economy' concept, aquaponics has exhibited immense potential for reduced resource utilization, discharge mitigation, nutrient, energy, wastewater recycling, and production of highly nutritious food within the system. Aquaponics has attained increased public interest in recent years in urban areas, in line with the trend towards greater productivity with limited resources, driving it from small-scale operation to brink of commercialization. The holistic analysis of scientific articles on aquaponics has perceived the transition of research trends from optimization of system performance (component ratio, hydraulic loading rate, etc.). Several commercial ventures have faced financial and operational difficulties linked to high capital investment, energy dependence, biological risk, and management complexity (Engle, 2023; FS, 2025; SalmonBusiness, 2024).

Existing studies show that profitability is highly sensitive to factors such as electricity prices, labor costs, stocking density, survival rates, and market access. Nevertheless, economic evidence remains fragmented and difficult to compare due to differences in scale, technology, and performance indicators. Most research emphasizes technical efficiency rather than systematic assessments of economic risk, scale effects, and long-term viability, creating uncertainty for investors, policymakers, and producers (Babatunde et al., 2023; Benjamin et al., 2020; Blidariu & Grozea, 2011).

Materials and Methods

This study applies a systematic literature review (SLR) to evaluate the economic and financial performance of RAS. A structured review process was used, including database searches, screening, eligibility assessment, and qualitative synthesis of findings. Peer-reviewed studies (n=74) published between 2010 and 2025 were collected primarily from Scopus and complemented with Google Scholar searches. The review focused on publications addressing economic performance, profitability, investment, and techno-economic aspects of RAS, while purely technical studies without economic analysis were excluded. After screening and selection, relevant studies were analysed to identify recurring economic drivers, cost structures, profitability patterns, methodological gaps and key challenges affecting the long-term viability of RAS.

Results and Discussion

The reviewed literature on RAS and aquaponic systems has expanded considerably since 2010, particularly across Asia, Europe, and North America, reflecting the growing interest in intensive and resource-efficient food-production systems. However, despite this increasing body of research, substantial methodological and economic heterogeneity remains across studies. For example, energy and feed expenditures consistently emerged as the most recurrent operational cost drivers, yet their reported contributions to total operating costs varied widely depending on system configuration, species, scale, and analytical assumptions. Several studies highlighted that energy-intensive infrastructure associated with pumping, oxygenation, and thermal regulation may represent a major barrier to economic viability, while feed costs alone accounted for approximately 24–70% of operating expenses across different production systems.

At the same time, the literature revealed persistent gaps in standardized economic reporting, including the lack of disaggregated energy-consumption data, inconsistent functional units, and limited treatment of stochastic risks such as energy-price volatility and infrastructure dependency. These findings are particularly relevant for industry stakeholders and policymakers, as they highlight the need for more comparable, risk-oriented, and scale-sensitive techno-economic assessments to support investment decisions and the sustainable expansion of RAS technologies.

Introduction

The cultivation of the European flat oyster, *Ostrea edulis* (Linnaeus, 1758), in Croatia has a tradition that goes back centuries, and it is still the most important farmed bivalve in the country. When in the early 1970s and 1980s two diseases caused by protozoa, *Marteilia refringens* and *Bonamia ostreae*, began spreading and drastically reducing *O. edulis* production in almost all traditional European farming areas, Croatian populations were not affected, so this species remains the only cultivated oyster in the country. Since the farming of *O. edulis* relies on the collection of spat from the natural environment, it is of the utmost importance to ensure a healthy broodstock. Bucephalid trematode larval stages are known to be common parasites of commercially important bivalve species. They invade the interstitial connective tissues and obstruct digestive gland tubules, thereby affecting food absorption and destroying the surrounding gonadal tissue. Depending on how intense the infection is, these trematodes can completely destroy the gonads by replacing the host tissues, severely affecting the reproductive ability and survival of both, wild and farmed oyster broodstock (Gadelha, et al., 2025). The first case of bucephalid infection of *O. edulis* in Croatia was reported in 2009 in Mali Ston Bay, the largest oyster-producing area (Gavrilović et al., 2009). Keeping in mind the economic importance of oysters, the aim of this study was to examine the presence of digenean parasites in the digestive gland and gonadal tissue of *O. edulis* in wild and farmed populations along the Croatian coast.

Materials and Methods

At the beginning of May 2025, *O. edulis* specimens were collected randomly at five sampling locations (Figure 1). Samples were taken at three farming locations (1 - Mali Ston Bay, 3 - Krka River estuary near Šibenik, 5 - Medulin Bay), while in the Neretva River estuary (2) and near the island of Vrgada in Pakoštane area (4), samples were taken from wild populations. At each location 20 oysters were sampled, except for locations 1 (22 specimens) and 5 (29 specimens). For the purpose of histological examination, visceral parts of oyster soft tissue were fixed in Davidson's fixative. After routine histological processing, material embedded in paraffin was serially sectioned at 5 µm. Sections were stained with hematoxylin and eosin (H&E) and studied by light microscopy. The infection was evaluated in histological sections, and its prevalence was calculated at each sampled location.

Results and discussion

The observed prevalence of parasites varied depending on location (Figure 2). In wild oysters from Vrgada Island, no infection was detected. The highest prevalence of parasites was found in farmed oysters in the Medulin Bay (44%), followed by the Neretva Estuary (40%). In the Mali Ston Bay, the prevalence was 18%. If the results from the Mali Ston Bay are compared with the results of Gavrilović et al (2009) for the same area, it could be assumed that the prevalence has not changed significantly. These authors found temporal variations in the level of infection, where the monthly prevalence ranged from 0-20%, with the maximum in November. During the winter months, from December to March, no infection was detected, which could be due to mortality caused by starvation from severe infection. These results showed that bucephalid trematode infection occurs in *O. edulis* along the Croatian coast, raising concerns about potential effects on broodstock reproduction and survival. In heavily infected European flat oysters it can be reflected in the lack of recruitment. Considering the economic importance of this species, it would be advisable to further investigate the exact bucephalid species using molecular methods and identify its final host.

EVALUATION OF LOW OPPORTUNITY COST BIOMASS FEED FOR LOW-TROPHIC-LEVEL FINFISH AQUACULTURE: A STUDY WITH NILE TILAPIA

Introduction

Aquaculture increasingly relies on refined feed ingredients that may compete with resources suitable for human food production. Greater use of low-opportunity-cost biomass (LOCB), including processing by-products and other underutilised resources, could improve feed circularity (Verreth et al., 2023), provided fish performance and edible-product quality are maintained without unacceptable trade-offs in nutrient utilisation or waste management. Nile tilapia (*Oreochromis niloticus*) is well suited to testing this concept. We evaluated whether increasing LOCB use could reduce feed-food competition while maintaining production performance and edible-product nutritional quality.

Materials and Methods

Two diets were formulated: a conventional control (CON) based predominantly on refined ingredients and a treatment (TREAT) with increased locally available LOCB. Both targeted comparable predicted digestible protein and energy; TREAT contained higher crude nutrient concentrations to compensate for expected lower digestibility of selected LOCB ingredients. Both diets met essential amino acid requirements and were produced as floating extruded pellets.

A 90-day feeding trial used mixed-sex Nile tilapia (~144 g initial body weight) in three tanks per feeding system. CON and TREAT were maintained in separate ~4,500-L recirculating aquaculture systems and fed three times daily at 2% biomass. Growth, feed utilisation, survival and fillet nutritional quality were evaluated. Because diet was confounded with RAS, comparisons were exploratory and based on tank means. A separate replicated trial (four tanks per diet) determined apparent digestibility and faecal particle integrity. Resource-use indicators quantified LOCB and food-competing feed/protein inputs and conversion into edible fish nutrients.

Results

LOCB inclusion increased from 21.5% in CON to 52.4% in TREAT, while food-competing ingredients decreased from 76.5% to 44.6%. FCR was comparable (1.74 ± 0.03 vs. 1.76 ± 0.04 ; $p = 0.410$), while exploratory comparisons indicated higher weight gain (202.7 ± 5.0 vs. 216.0 ± 3.8 g fish⁻¹; $p = 0.024$) and SGR (0.976 ± 0.015 vs. $1.015 \pm 0.008\%$ day⁻¹; $p = 0.030$) in TREAT; survival exceeded 97% in both systems. Food-competing feed input decreased by 41% (1.331 to 0.785 kg kg⁻¹ biomass gain) and food-competing protein input by 54%. With similar net edible protein gain, TREAT converted food-competing dietary protein into edible fish protein approximately 2.2-fold more efficiently. Final fillet yield (36.31 ± 2.28 vs. $36.47 \pm 1.39\%$), proximate and amino-acid composition, and EPA+DHA concentration (0.468 ± 0.018 vs. 0.446 ± 0.036 mg g⁻¹ wet weight; $p = 0.423$) were comparable. TREAT showed lower apparent protein digestibility (82.1 vs. 90.1%) and more disintegrable faeces (54.0 ± 11.1 vs. $25.7 \pm 4.4\%$; $p < 0.01$), with fewer easily removable solids (46.0 ± 11.1 vs. $74.3 \pm 4.4\%$; $p < 0.01$).

Discussion

Increasing LOCB use substantially reduced dependence on food-competing biomass and protein without an evident penalty in feed conversion, survival, fillet yield or nutritional quality. This advantage became clearer when feed efficiency was evaluated according to resource opportunity cost rather than total feed or protein input. However, lower protein digestibility and poorer faecal particle integrity reveal a trade-off between food-system circularity and nutrient and solids management in intensive RAS. LOCB-based formulation is therefore promising, while digestibility and physical waste quality remain important optimisation targets.

Introduction

Freshwater scarcity is becoming a major operational constraint for inland aquaculture and sustainable production planning (FAO, 2022). The red swamp crayfish (*Procambarus clarkii*) is a high-value freshwater decapod, but intensive culture commonly relies on regular water renewal to control nitrogenous wastes and maintain microbial stability (Boyd & Hanson, 2010). Limited water exchange can reduce water consumption, yet its interaction with probiotic supplementation and host-associated microbiota remains insufficiently understood. Previous work indicates that crayfish gut microbiota is closely linked with growth stage, metabolism and health status (Chen et al., 2021; Liu et al., 2023). This study evaluated whether low-volume weekly water exchange combined with probiotics can sustain growth, innate immune response and gut microbial balance in juvenile *P. clarkii*.

Materials and Methods

Juvenile crayfish were reared for 84 days in a 3 × 2 factorial design combining three weekly water exchange rates (1%, 3% and 6% of tank volume) with or without probiotic supplementation. Six treatments were tested in triplicate: 1WE, 1WEP, 3WE, 3WEP, 6WE and 6WEP. Each 40 L tank was stocked with 12 juveniles and maintained under continuous aeration. The probiotic mixture, containing *Lactobacillus plantarum*, *Lactobacillus acidophilus*, *Lactobacillus salivarius* and *Bacillus subtilis* at 1 × 10⁹ CFU mL⁻¹, was applied at 1 mL 100 L⁻¹, consistent with the use of lactic acid bacteria and *Bacillus* spp. in crustacean culture (Foysal et al., 2020). Crayfish were fed a 35% crude-protein diet at 3% biomass day⁻¹. Water quality was routinely monitored following standard aquaculture principles (Boyd & Hanson, 2010). Growth performance, survival, feed utilization, total haemocyte count, and gut microbiota were evaluated. Midgut samples were pooled by replicate for 16S ribosomal ribonucleic acid sequencing, and phylum-level microbial composition and diversity indices were calculated (Chen et al., 2021; Liu et al., 2023).

Results

Water quality remained within suitable ranges for juvenile crayfish. Probiotic-supplemented groups showed lower total ammonia nitrogen and nitrite concentrations, especially under 3% and 6% water exchange. The best overall performance was obtained in 3WEP, with the highest final body weight (8.0 ± 0.5 g), weight gain (156.4 ± 5.2%), specific growth rate (1.42 ± 0.03% day⁻¹), survival (95.8 ± 2.1%) and total haemocyte count (7.2 ± 0.4 × 10⁶ cells mL⁻¹). Probiotic supplementation significantly improved all measured growth parameters at 3% exchange, while its effect was weaker at 1% and not significant at 6%. Gut microbiota was dominated by Proteobacteria, Bacteroidota, Firmicutes and Actinobacteriota. The 3WEP group showed the lowest Proteobacteria proportion (42%), higher Bacteroidota (28%) and Firmicutes (20%), and the highest Shannon, Simpson and Pielou evenness values.

Discussion

These findings suggest that 3% weekly water exchange provided a favourable balance between waste dilution and microbial stability, supporting both water-quality control and reduced freshwater demand (FAO, 2022; Boyd & Hanson, 2010). Under this condition, probiotics appeared to improve feed utilization, innate immune readiness and gut microbial balance, consistent with previous reports on probiotic effects in freshwater crustaceans (Foysal et al., 2020). The lower Proteobacteria and higher Bacteroidota and Firmicutes in 3WEP indicate a more balanced gut profile, although phylum-level data should be interpreted cautiously and supported by future genus-level or metagenomic analyses (Chen et al., 2021; Liu et al., 2023). Overall, the 3WEP strategy reduced water use by approximately 97% while maintaining high survival and improving performance, suggesting a promising water-saving approach for juvenile crayfish culture. Commercial-scale validation is still needed before farm-level recommendations are made.

Introduction

The molly fish (*Poecilia sphenops*) is one of the important ornamental fish species that, due to its diverse coloration, high adaptability to environmental conditions, and ease of reproduction, holds a special position in the aquarium industry. In the culture of ornamental fish, in addition to proper growth, improvement of body coloration is also of great importance, and nutrition plays a fundamental role in achieving these objectives. The use of natural pigment sources such as astaxanthin and the microalga Spirulina in the diet can lead to improvement in growth performance and coloration in fish. The aim of the present study was to investigate the effects of astaxanthin and Spirulina supplements on growth indices and coloration characteristics of molly fish.

Materials and methods

In this study, 90 molly fish with an initial mean weight of 1.5 ± 0.1 g were allocated to three treatments including a control treatment (without supplement), an astaxanthin treatment (10 μ g astaxanthin per 10 g dry weight of feed), and a Spirulina treatment (*Arthrospira platensis*) (0.5 g Spirulina powder per 9.5 g feed), with three replicates and ten fish per replicate. The fish were cultured for a 40-day experimental period and were fed once daily. Fish were maintained in glass aquaria under controlled conditions at a temperature of 27 ± 0.5 °C. Growth indices including final weight, weight gain, total length, length increase, mean total weight gain, daily weight gain, specific growth rate, and feed conversion ratio were calculated. In addition, colorimetric indices were measured using a spectrophotometer based on the CIELAB color system including L*, a*, and b*, and derived color indices were also calculated. The data of the treatments and replicates of the three experimental groups were analyzed using multivariate statistical analysis in PRIMER V6 software and nMDS analysis (non-metric multidimensional scaling).

Results

The results showed that the experimental groups were clearly separated and different from each other based on the set of growth indices and color indices (2D Stress = 0.000). The Spirulina-supplemented treatment showed the greatest effect on growth indices and led to increases in final weight, length increase, mean weight gain, specific growth rate, and improvement in feed conversion ratio compared with the control treatment. In contrast, the astaxanthin treatment had the greatest effect on color indices and caused significant increases in redness (a*), yellowness (b*), and color brightness (stress < 0.05).

Discussion

In conclusion, dietary supplementation significantly affected both growth performance and coloration in molly fish. Spirulina improved growth-related indices, including weight gain, length increase, and feed conversion efficiency. In contrast, astaxanthin had a stronger effect on pigmentation and enhanced color intensity. Multivariate analysis confirmed clear differences among treatments based on growth and color indices. These findings indicate that Spirulina and astaxanthin can be effective dietary supplements in molly fish culture.

A LOW-COST UNMANNED SURFACE VEHICLE FOR STATISTICALLY-INDEPENDENT MULTI-DEPTH WATER SAMPLING IN AQUACULTURE PONDS

Introduction

Sustainable pond aquaculture depends on water-quality data that is representative both laterally and across the vertical profile because dissolved-oxygen, temperature, and ammonia gradients drive fish welfare, feed conversion and disease risk, and these gradients sharpen under Aquaculture in Global Change conditions. Manual grab sampling caps the number of stations, the sampling rate and the consistency of QA/QC protocols, while commercial autonomous samplers (Teledyne ISCO, Hach Sigma SD900, OceanAlpha ESM30) cost roughly US\$11,000–110,000 and earlier academic low-cost USVs (e.g. Madeo et al., 2020; Jo et al., 2019) follow fixed-grid or manually-piloted protocols and do not enforce a statistical-independence criterion between samples. We address this gap with an unmanned surface vehicle (USV) costing less than US\$5,000. Concrete contributions: (i) an integrated low-cost USV platform (catamaran hull, ESP32 control, peristaltic pump, 7-position bottle carousel, stepper-winch depth probe with end-of-tube weight; Fig. 1) demonstrated end-to-end in a half-Olympic pond; (ii) a correlated random walk (CRW) “bump-and-turn” navigation policy with a $\tau_{\min}$ -gated sampling rule enforcing a minimum separation $D_{\min} = 2l$ without on-board GPS; (iii) an overhead ArUco optical-tracking pipeline that reconstructs each sample position post-hoc as a spatial-statistics ground truth; (iv) a paired simulator/field validation including a documented wall-stuck failure mode and its planned firmware fix (Codling et al., 2008; ISO 5667-1; USGS-NFM). The platform targets the small-to-medium land-based ponds and raceways that dominate Mediterranean and inland aquaculture.

Materials and Methods

The USV is a catamaran with twin PVC pontoons and a 3D-printed deck (1.0 m × 0.55 m, 4.5 kg), driven by twin DC motors with air propellers and supervised by an ESP32 microcontroller that delegates the sampling sequence to an Arduino UNO over UART. Multi-depth sampling uses a peristaltic pump (5.0–5.2 mL s⁻¹; 100 mL fill in 19.3–20.5 s), a drain/bottle selector valve, and a 7-position carousel; depth is set by winch position, eliminating the need for a pressure transducer. Navigation is a CRW with a “bump-and-turn” rule: front micro-switches with 20–40 ms software debounce trigger a short reverse and a random turn (30°–90°), yielding directional persistence in a confined geometry. A minimum separation $D_{\min} = 2l$ is enforced as a design constraint; l is a conservative engineering design value ($l = 2$ m, giving $D_{\min} = 4.0$ m), with an in-situ semivariogram refinement on the validation roadmap. The constraint becomes a real-time decision rule $\tau_{\min} \approx D_{\min} / v \approx 20$ s for $v = 0.20$ m s⁻¹, so the platform enforces sample separation without on-board GPS — appropriate for covered or indoor ponds and raceways where GPS is unreliable. QA/QC is enforced via a purge ratio $t_{\text{flush}} = k \cdot V_{\text{dead}} / Q$ with $k \in [2,3]$ per ISO 5667-1 and USGS-NFM (Chapter A4). Independence is verified post-hoc with Moran’s I on ArUco-reconstructed sample positions; ground truth comes from a single overhead 1920×1080 wide-FOV (90°–100°) camera at 7 m with 22–25 cm ArUco markers (≥ 70 px at the far edge).

Results and Discussion

A 40-min CRW simulation on a 12.5 × 20 m pond (matching the field pool) reached 93 % coverage with 10 sample stops and a near-uniform spatial distribution ($I_X = +0.04$, $I_Y = +0.10$; $R = 1.59$), confirming the design behaviour. The field trial (Fig. 2) captured 147 ArUco positions along a continuous trajectory and 14 sample stops on Pool-2; mean inter-sample distance was 4.16 m and the maximum 11.1 m. Of 91 all-pair distances, 16 (18 %) fell below $D_{\min}$ and 5 of 13 consecutive pairs reached $D_{\min}$ (Fig. 2c). Sample volume was consistent (mean fill 25.9 mL across 7 bottles vs. a 27 mL target, ~96 %); blank–tracer–blank cross-contamination stayed below the 1 % carry-over threshold, consistent with ISO 5667-1 and USGS-NFM purge/flush guidance. The raw 14-point set departs from the independence target: permutation Moran’s I (Anselin, 1995) yields $I_X = +0.40$ ($p = 0.003$), $I_Y = +0.50$ ($p = 0.001$), $R = 0.82$ — driven by the wall-stuck cluster (#10–13 within ~0.5 m, Fig. 2b). As a sensitivity analysis with this post-hoc cluster excluded, the same statistics drop to $I_X = +0.26$ ($p = 0.05$), $I_Y = +0.20$ ($p = 0.22$), $R = 0.90$, closer to the simulator’s design behaviour; the raw value remains the primary statistic. Six wall-hugging modes were logged in the post-trial debrief and are closed in the next firmware revision (stuck-motor diagnostic + escape-spin). Capital cost remained at ~5 % of the closest commercial alternative.

(Continued on next page)

Figure 1. (a) Labelled exploded view of the assembled low-cost USV. Catamaran hull on two PVC pontoons; the surface platform carries the ESP32 control box, the 7-position water-sampling carousel with sample-dispensing nozzle, the stepper-winch depth probe (the depth-setting tube driven by a stepper motor on a winch drum), the front bumper with bump sensors used by the bump-and-turn rule, the battery pack, and twin DC motors with air propellers for thrust. (b) Field deployment of the same platform in the 12.5 × 20 m half-Olympic Pool-2 (28-04-2026); the white ArUco target on the deck is visible to the overhead camera used for the field trajectory in Fig. 2b.

Figure 2. Design verification and field validation. CRW = correlated random walk; wall-stuck = sample logged while the platform was immobilised against the wall (samples #10–13 here); pair $k = \#k \rightarrow \#k+1$, shown red and hatched iff at least one endpoint is wall-stuck (so pair 9 = #9 → #10 is red because endpoint #10 is wall-stuck); design threshold $D_{\min} = 2\ell = 4.0$ m follows from the conservative correlation length $\ell = 2$ m used at design time. (a) CRW-simulator design path on the same 12.5×20 m pool (40 min, 10 stops; $\bar{L}_X = +0.04$, $\bar{L}_Y = +0.10$; $R = 1.59$). (b) Pool-2 field trial (28-04-2026, 12.5×20 m half-Olympic pool): 147 ArUco-tracked positions as one continuous trajectory with 14 sample stops; wall-stuck samples #10–13 are red squares inside a dashed red ellipse; samples #1, #5, #9 and #14 are labelled (trajectory endpoints and midpoints). The dashed grey line marks the boat's maximum northward reach in the 9-min window. (c) Inter-sample distances vs. $D_{\min}$. The red bracket spans pairs 9–13 (the segment touching the wall-stuck cluster, including the recovery jump on pair 13 = #13 → #14). Statistics are reported in the body. Clark–Evans $R = 0.82$ raw, 0.90 excluded.

Conclusion and Aquaculture Relevance

A USV that is simultaneously low-cost, QA/QC-compliant and statistically auditable lowers the practical barrier to dense, multi-depth water-quality monitoring in small and medium pond aquaculture. By replacing manual grab sampling with autonomous, ground-truth-verified bottle collection, the platform makes gradient-resolved measurements of dissolved oxygen, temperature, ammonia and emerging contaminants tractable for facilities that cannot justify stationary commercial samplers. In future trials, exclusion criteria will be pre-specified against the documented wall-hugging failure modes, eliminating any post-hoc selection.

COMMUNICATING SCIENCE: THE IMPORTANCE OF MEETING JOURNALISTIC STANDARDS**

RD Gilbert^{1*}

¹CEO and Publisher

International Aquafeed Magazine

Cheltenham, United Kingdom

*corresponding/presenting rogerg@perendale.co.uk

For decades, trade magazines have served as a central communication platform for industry, delivering timely news, technical features, market insights and sector representation. Historically, these publications - predominantly in print - acted as the connective 'glue' within industries, informing stakeholders, shaping discourse and reflecting both technological and political developments.

The rapid rise of digital communication has fundamentally altered this landscape. Today, organisations, associations and individuals can publish and distribute content instantly to global audiences through websites, social media and professional platforms. This shift has challenged traditional publishing models, requiring established magazines such as *International Aquafeed* to adapt while maintaining the editorial standards and credibility associated with print.

This presentation examines the transition from print to digital publishing within the aquaculture sector and explores the continuing relevance of traditional media. It considers how audience engagement has evolved, particularly in response to search engines, SEO-driven content discovery and, more recently, AI-driven generative engines that deliver rapid, curated responses with embedded references.

Central to this discussion is the importance of applying journalistic standards when communicating scientific and technical information to non-specialist audiences. By bridging scientific communication and journalistic practice, this work highlights how clarity, accuracy and presentation can significantly improve the reach, impact and uptake of technical information in a rapidly evolving media environment.

Key Practical Considerations

1. Identifying the target audience

Effective communication begins with a clear understanding of the intended audience. Whether addressing editors, journalists, industry professionals, or consumers, each group has distinct editorial expectations. Tailoring content to these needs significantly improves the likelihood of publication, citation and wider dissemination.

2. Preparing content

Scientific findings must often be translated into accessible, engaging formats. This requires clear structure, concise language and logical flow. Short sentences, well-defined paragraphs and consistent style help present complex information in a form that is both readable and relevant to non-specialist audiences.

3. Presenting content

Consistency in formatting and presentation is essential. Submissions should follow a clear layout, including author identification, contact details and location. Opening paragraphs should be concise and engaging, while accuracy and clarity remain paramount. Supporting materials such as images should be properly captioned, numbered and supplied in high resolution to meet editorial standards.

4. Distributing content

Understanding distribution channels is critical. Social media platforms, digital publications and traditional print outlets each have distinct requirements. Direct communication with named editors, supported by a clear covering message and properly formatted attachments, increases the likelihood of successful publication. Visual content, including images and video, plays an increasingly important role in audience engagement.

5. Adapting scientific content for media use

There is significant value in repurposing scientific material for broader audiences. Abstracts can be adapted into introductory summaries, while traditional section headings such as 'Methods' and 'Results' may be replaced with more engaging, reader-focused subheadings. Emphasis should be placed on outcomes and practical implications rather than formal academic structure.

(Continued on next page)

6. Maximising reach and impact

Publication should not be viewed as a single event but as part of a broader communication strategy. Sharing content across multiple platforms, encouraging reposting and clearly referencing original publication sources enhances visibility while maintaining transparency and professional integrity.

Context: extensive fish pond production in Europe and France

Historically, Europe has been home to many pond landscapes, usually used for extensive fish farming (Aubin *et al.*, 2017). This is the case for the Auvergne-Rhône-Alpes region of France, which contains several pond areas (Dombes, Forez, and Dauphiné). Fish farming persists in these areas but faces many challenges, including the impacts of climate change. In these extensive production systems, up to 70% of productivity comes from natural resources provided by the pond ecosystem (Robin *et al.*, 2016). This natural productivity can be enhanced through several management practices (liming, fertilization, feeding, and a dry period every 4-5 years) (Wezel *et al.*, 2013; Girard *et al.*, 2024). However, stocking strategies (fish species composition and density) are not always adapted to the productive potential and ecological functioning of individual ponds.

Materials and Methods

The FISHMIX project (2023–2026) aimed to evaluate new fish species assemblages suited to ponds, their productive potential, and their biological functioning, in the context of climate change. Over a three-year period, we monitored 46 fish ponds in the Dombes region, in which five scenarios of fish species assemblages were implemented. These assemblages were designed in collaboration with fish farmers, removing species that are more vulnerable to climate change, adding species uncommon in the region, and adjusting the proportions of the species. Fish production (yields and economic margins) and ecological parameters (water and sediment physicochemistry, phytoplankton, zooplankton, macrophytes, and macroinvertebrates) of all ponds were measured. We also monitored meteorological parameters and water temperature throughout the production season.

Figure 1:

Violin plots of net fish yields of 46 ponds stocked with one of five scenarios of fish species assemblages: full carp (80-90% common carp), grass carp (traditional scenario + grass carp), resilience (5-6 species, with two size cohorts for each), profitability (tench, whitefish, and largemouth bass), and traditional (60-70% common carp, 20-30% tench and whitefish, and 10% pike or pikeperch). Whiskers equal 1.5 times the interquartile distance. The dashed horizontal line shows the mean net fish yield of all ponds.

(Continued on next page)

Results and Discussion

Temperature and precipitation varied greatly among the three years, which caused pond functioning to vary greatly as well, thus illustrating impacts of climate change. Low water levels in ponds, especially at the end of winter, and high temperatures during the summer limited fish production. Despite high variability among sites and years, one highly diversified species-assemblage scenario (called “resilience”) showed promising performances, with a higher mean net fish yield (Figure 1) and economic margin.

The data generated by the project highlighted direct impacts of climate change on pond functioning and productivity potential. The increase in mean temperatures observed, along with prolonged droughts and heat waves, is forcing managers to rethink species assemblages. Introducing new species to the region such as largemouth bass (*Micropterus salmoides*), which is more resistant to high temperatures, or grass carp (*Ctenopharyngodon idella*), a herbivorous species that uses natural food resources not used by other fish species, may represent promising adaptation options. In light of these changes in production, market perspectives must also be adjusted. The scenarios tested provide potential pathways for sustainable pond aquaculture that combine acceptable farm income, production resilience, and ecosystem services such as biodiversity conservation.

Acknowledgments

The FISHMIX project was funded in the PEPIT programme by the Auvergne-Rhône-Alpes region.

ECONOMIC ANALYSIS OF OPTICAL DELOUSING AS A CONTROL STRATEGY AGAINST SALMON LICE

D. Goedert*, L. A. S. Haugen, J. H. Pettersen, B. Frenzl, M. Worm

Stingray Aqua Research
Stingray Marine Solutions AS
Stålfjæra 26, 0975 Oslo, Norway

Introduction

Parasitic salmon lice (*Lepeophtheirus salmonis*) remain a significant economic and welfare challenge faced by the salmon farming industry. Studies show that salmon lice account for a significant proportion of biological losses and the consequent loss of revenue to the industry (e.g. Walde et al. 2023). While reactive treatments can mitigate these losses (Mustafa 2001) the most common types of treatments used today have been linked to an increased prevalence of injuries and wounds, reduced growth, and increased mortality rates (Overton et al. 2001). In response to this welfare paradox, several innovative technologies for the prevention or control of salmon lice infestations are increasingly utilized. While some of these have been shown to successfully reduce the infestation burden or need for reactive treatments (e.g., Cerbule & Godfroid 2020; Grøntvedt et al., 2018; Stien et al., 2016; Worm et al., 2026), studies investigating the economic impact of such strategies are still scarce. Yet, this knowledge can unlock the potential for production optimization, providing an invaluable contribution to the future of salmon farming. We therefore provide an economic analysis of one of these innovative technologies: optical delousing. Optical delousing is a non-handling, in-pen, control strategy in which laser pulses are used to remove lice from salmon and has previously been shown to decrease by half the number of reactive treatments (Worm et al. 2026).

Methods

We used a bioeconometric model incorporating baseline mortality and temperature-dependent growth for the grow-out phase, with temperature predictions for each of the 13 production areas (PAs) defined by the Norwegian Traffic Light System. We parametrized the model with empirical data from the literature and from reports submitted by farmers to the Norwegian government, and calculated production cost, revenue and net profitability for the production cycles obtained. To contrast the cost of salmon lice under scenarios in which production cycles utilize or not optical delousing as control strategy, we simulated 2000 reactive treatment schedules per scenario. We used temperature-dependent weekly probabilities of treatment obtained from Worm et al. (2026), where treatment probability depends on the use of the control strategy. Based on the literature, we assumed treatments incurred lost feeding days (i.e., lost growth), excess mortality, and decreased product quality at harvest. Frequencies for different treatment types were calculated from official reports (BarentsWatch, n.d.), and excess mortality rates per treatment type were obtained from Walde et al. (2021).

Results

Our simulations recovered the expected effect of the control strategy on reducing the number of treatments across all 13 production areas analysed. This reduction in treatments due to the use of the control strategy led to a ca. 45% average (across the 2000 simulated treatment schedules for each of the 13 PAs) mitigation in the excess mortality resulting from treatments observed in scenarios when no control strategy was deployed. This resulted in a mean increase in live biomass at the time of harvest of over 400 tones, and a mean increase in profit of 3.79 (NOK kg gutted⁻¹). This increase in profit was despite the increase in total costs resulting from the added cost for the control strategy, as well as the increase in cost for feed, due to the reduction in lost feeding days.

Conclusions

Our results demonstrate that optical delousing is an economically viable control strategy. The economic benefit of control incorporates increased growth by avoiding lost feeding days, reduction of handling-related mortality, and better product quality at harvest. Even more, our results reinforce the idea that investing in welfare of farmed fish can provide good economic returns to the industry.

LCDV - INDUCED GENOTOXICITY IN GILTHEAD SEABREAM: EFFECTS OF DIETARY PHYTOBIOTICS

*presenting author: egolom@uth.gr

Introduction

Lymphocystis disease (LCD), caused by the lymphocystis disease virus (LCDV), affects over 125 wild and cultured fish species and represents an important health and economic concern in Mediterranean seabream aquaculture (Borrego et al, 2017, Muniesa et al, 2010). LCDV–host interactions involve apoptosis and cellular DNA damage responses, which may contribute to infection-associated genotoxicity (Lilley et al, 2007, Hu et al, 2004). This study evaluated the effects of dietary *Origanum vulgare* and *Cinnamomum zeylanicum* essential oils on LCDV-induced genotoxicity in the liver and spleen of infected gilthead seabream.

Materials and Methods

The study was conducted in the experimental aquarium facilities (EL-43BIO/exp-01) of the Aquaculture Laboratory, Department of Ichthyology and Aquatic Environment, University of Thessaly, Greece, in accordance with the EU Directive 2010/63/EU. All procedures were performed by trained personnel under the supervision of FELASA-accredited scientists. Gilthead seabream (*Sparus aurata*) (M.W.: 5±0.32g) experimentally infected with LCDV were fed diets supplemented with *Origanum vulgare* or *Cinnamomum zeylanicum* essential oils at 1% and 2%, administered either preventively (90 days before infection) or therapeutically (at infection). The 11 experimental groups included naïve, infected, recovered, and control fish (Figure 1). Infection prevalence was assessed every 15 days post-infection, and cumulative mortality was calculated at the end of the experiment. Following the experimental period (90 days post-infection (dpi)), liver and spleen samples were collected from three fish per aquarium for DNA damage assessment using the comet assay. DNA damage was quantified as the percentage of tail DNA using fluorescence microscopy and Comet Assay IV™ software. Data were analyzed using one-way ANOVA followed by Tukey's post hoc test.

Results

LCDV clinical signs appeared from 15 dpi, with a significantly lower prevalence in prophylactically treated fish, particularly CIN90.1 ($p < 0.05$). Mortality was highest in the OR1, OR2, and PC groups, whereas prophylactic treatment, especially CIN90.1 and CIN90.2, markedly reduced mortality to control levels. The infected groups exhibited significantly higher DNA migration than the non-infected NC and RF groups in both liver and spleen cells ($p < 0.05$). The experimental diets did not induce higher genotoxicity compared to the positive control group in either organ. However, in the CIN90.1 group in spleen cells, the DNA damage was clearly pronounced ($p < 0.05$). The comet assay indicated increased DNA fragmentation in spleen cells compared to than in hepatocytes. Additionally, no differences were observed in DNA strand breakage between the non-infected NC and RF groups. Genotoxicity induced in both liver and spleen cells following experimental infection of gilthead seabream fed with diets supplemented with essential oils is shown in Figure 1.

Discussion

LCDV infection increased DNA damage in both liver and spleen cells, with a stronger response observed in the spleen. This may reflect the spleen's major role in antiviral immunity, haematopoiesis, and viral replication, whereas the liver primarily performs metabolic and detoxification functions (Valverde et al, 2017, Zhang et al, 2023). Therapeutic supplementation with *O. vulgare* and *C. zeylanicum* reduced DNA damage compared to that in the positive control, suggesting a protective effect against LCDV-associated genotoxic stress. Notably, CIN90.1 showed high DNA damage but very low mortality, potentially indicating an enhanced host response that limits disease severity. Overall, the findings suggest tissue-specific genotoxic responses to LCDV and a modulatory effect of phytochemicals on infection-related DNA damage.

Introduction

The problematic of plastic litter in aquatic environments is well-established and studied. Conventional petroleum-based plastics are associated with a high carbon footprint, environmental persistence and microplastic pollution. These microplastics can affect behavioural and neurological functions, metabolism, and intestinal permeability of fish (Jacob et al., 2020). Farmed fish species are of major concern, since they can be exposed to microplastics directly through seawater, from fragmentation of aquaculture infrastructures, daily maintenance materials, and aquafeeds. Additionally, microplastic presence in such species poses further risks for human health, due to the consumption of contaminated products (Mossotto et al., 2025).

In recent years, there has been an increasing concern to develop bio-based, sustainable and environmentally-friendly alternatives to conventional petroleum-based plastics. However, as any other disposable material, these bio-alternatives might accidentally end up discarded into marine environments and fragment into microplastics. The current knowledge is very limited in regard to the toxicological effects of bio-microplastics in fish species, especially concerning behavioural and neuronal alterations. Accordingly, it is essential to validate the eco-friendly claims of these emerging bio-based plastic alternatives.

The present study investigated the neurotoxicity and behavioural effects of chronic oral exposure to different bio-microplastics in the commercially and ecologically-relevant fish species gilthead seabream (*Sparus aurata*).

Materials and Methods

Farmed *S. aurata* juveniles (18.78 ± 0.51 cm total length, 103.46 ± 5.52 g weight) were kept in recirculating aquaculture systems (RAS) under optimal rearing conditions. During the 28-day exposure trial, specimens were fed 1% body weight with a commercial-based diet (CTR) or with three contaminated diets, containing either i) polylactic acid microplastics (PLA); ii) polypropylene 2,5-furandicarboxylate microplastics (PPF), or iii) mixed polymer PLA/PPF microplastics. The three contaminated feeds contained ~60 particles g⁻¹ feed, each ranging between 500 and 1000 µm.

During the trial, swimming activity was assessed twice a week (n = 8 fish per treatment) through direct observations to evaluate behavioural alterations elicited by bio-microplastics. After 28 days of trial, fish (n = 7 per treatment) were randomly collected and euthanized for dissection and collection of plasma and brain tissue. To evaluate the neurotoxic and stress effects of biobased microplastics, the following endpoints were assessed: brain condition index; plasmatic cortisol levels; neurotransmission (acetylcholinesterase activity, AChE); antioxidant defences (superoxide dismutase activity, SOD; catalase activity, CAT; glutathione S-transferase activity, GST; and glutathione peroxidase activity, GPX); and cell damage (ubiquitin content, UBI; lipid peroxidation, LPO; and caspase activity, CASP). Statistical differences between treatments were analysed through Generalized Linear Mixed Models (GLMMs) for swimming activity data, or via one-way ANOVA for all other endpoints.

Results and Discussion

No statistical differences were found for swimming activity, brain-somatic index, AChE activity and cortisol concentration. These findings indicate that the bio-microplastics investigated do not severely alter neural transmission, affect the overall physiological condition of the brain, or elicit a generalized stress response in seabream. Concerning antioxidant defences, all three biopolymers increased the activity of CAT, GST and SOD. This activation of the antioxidant systems is most likely related to an increase in reactive oxygen species (ROS) in brain cells. However, severe lipid damage did not occur (i.e. no increase in LPO).

(Continued on next page)

Although data analysis is still ongoing, preliminary results suggest that the exposure to PLA, PPF and the mixed polymer do not lead to severe toxic effects in brain health and function in *S. aurata*. These findings are optimistic for the bioplastic industry, which should strive to develop and produce plastics that are not only more environmentally sustainable, but also pose no harm to wildlife. Equally, these findings are useful to the aquaculture industry, since it should shift towards the use of bioplastics in tools and packaging that are non-toxic to farmed species. Nonetheless, these results need to be complemented with further research on other *S. aurata* tissues and other aquaculture-linked species.

Introduction

Seawater temperature is a critical environmental factor that significantly affects the fitness and aquaculture industry of commercially important marine invertebrates, including sea urchins. Early life stages are particularly vulnerable to ocean warming (OW), which can reduce survival and growth by up to 80% under 2-4°C increases. Increasing broodstock food resources and availability may reduce the negative impacts of OW by increasing larval tolerance. Emerging studies assess offspring success after pre-exposing parents to warming conditions, which suggests the existence of beneficial carryover effects known as transgenerational effects. However, whether transgenerational acclimation to OW and nutrition is possible in sea urchins remains largely unknown (Zhao et al., 2018). Because sea urchins cannot synthesize carotenoids *de novo*, dietary provision of these pigments is essential as they play a critical role in egg production and offspring quality (Shpigel et al., 2006). This study evaluated whether maternal conditioning to high and low carotenoid diets influences the resilience of *Paracentrotus lividus* (Lamarck, 1816) larvae to increased temperatures, aiming to optimize hatchery production strategies against OW.

Materials and Methods

Paracentrotus lividus broodstock (N=120) was acclimated in recirculating aquaculture systems (RAS) and reared for four months on two temperature scenarios: local environmental temperature (18°C) and predicted warming temperature 21.5°C (+3.5°C), following IPCC predictions for 2100. During conditioning, the individuals were fed with two isoproteic and isolipidic formulated diets: a high carotenoid diet (HC) enriched with *Nannochloropsis* sp., and a low carotenoid diet (LC). At the end of the conditioning trial, proximate composition of female gonads ((e.g., carotenoids; eicosapentaenoic acid - EPA; total polyunsaturated fatty acids-PUFA; omega-3 (n-3) PUFA)) was assessed. Sea urchins were induced to spawn through injection with 0.5 M KCl in the peristomal membrane. To isolate maternal investment and minimize paternal genotypic variance, all eggs were fertilized using a sperm pool from males conditioned at 18 °C x HC. Following spawning, oocytes (n = 50 eggs per female) and fecundity were quantified in four females per broodstock treatment. The larval experiments followed a 2x2x2 factorial approach. Larvae from each maternal conditioning treatment were exposed to both 18 °C and +3.5 °C. Within these temperature treatments, two distinct larval nutritional treatments were established to assess larval survival: 1) an exogenous nutrition treatment, where larvae were reared under a standard mixed microalgal diet (*Chaetoceros calcitrans* and *Rhodomonas lens*), and 2) an endogenous nutrition treatment, where larvae were left unfed to isolate and quantify the direct impact of maternal egg reserves. Larval rearing was conducted in 600 mL beakers stocked at 2.5 larvae/mL. To evaluate survival, larvae from each treatment were sampled at the 4, 6, 8-arm and competence stages, with the corresponding age in days post-fertilization (DPF) recorded.

Results

Conditioning temperature and diet significantly influenced the proximate composition of female gonads. Females fed HC diet and exposed to +3.5°C showed enhanced accumulation of carotenoids (67.46 µg.g⁻¹ DW), EPA (10.68%), n-3 PUFA (16.45 %), and total PUFA (36.60 %). Egg diameter (90-97 µm) was not affected by temperature or diet treatments. Fecundity was affected by diet, with the highest yields observed in females fed the HC diet and exposed to 18 °C (8.4 × 10⁴ eggs.g⁻¹). Maternal conditioning had a significant influence on larval survival across both fed and unfed treatments. When females were conditioned at 18 °C, fed larvae from both HC and LC diets reached the competence stage at 20 DPF

(Continued on next page)

when reared at 18 °C. However, survival was higher in larvae from the HC diet, with 13 %. Conversely, when exposed to +3.5°C, larvae from the LC diet stopped development at the 4-arm stage, while those from the HC diet developed to the 6-arm stage and reached 16 DPF with a survival of 9%. A similar pattern was observed when females were conditioned at +3.5 °C. When larvae were reared at 18 °C, fed larvae from both maternal diets achieved competence at 20 DPF, with higher survival observed on those from the HC diet (13%). However, when kept at +3.5°C, larvae from LC diet stopped at the 4-arm stage and died by 8 DPF, while larvae from HC reached the 6-arm stage and reached 20 DPF with 3.39% survival. Among the unfed larval treatments, maternal HC diet consistently extended larval longevity. When females were conditioned at 18 °C and fed an HC diet, their unfed larvae survived until 12 DPF in both temperature conditions (18 °C and +3.5 °C). Similarly, when females were conditioned at +3.5°C and HC diet, unfed larvae survived until 12 DPF at 18°C and until 10 DPF at +3.5°C.

Discussion

This study demonstrates that the synergistic effects of temperature and diet quality strongly influence maternal provisioning and offspring resilience. Specifically, a combination of an HC diet and + 3.5°C was found to significantly enhance the accumulation of carotenoids and critical fatty acids (EPA, n-3 PUFA, and PUFA) in female gonads. This represents a maternal investment strategy to help offspring cope with thermal stress. This was further evidenced by larval survival rates under different temperature conditions. Fed larvae from females conditioned to the HC diet and +3.5°C achieved the competence stage with significantly higher survival rates when reared at 18°C compared to larvae from the LC diet. These maternal carry-over effects were evident when the larvae were exposed to +3.5°C, with higher survival capacities observed in both fed and unfed larvae. These findings highlight that optimizing broodstock nutrition is a vital strategy to trigger beneficial carry-over effects that enhance larval survival. Incorporating high-quality diets into hatchery protocols offers the aquaculture industry a promising solution to support production and build resilience against increasingly challenging environmental conditions.

Introduction

The bulk of aquaculture production takes place in developing nations (FAO, 2024), whereas most of the tools used to support the activity have been developed in Western countries (Ferreira et al., 2012). The consequence is an information divide that presents a major challenge for sustainable growth of the sector.

The use of mathematical models to simulate growth and environmental effects of cultivation, both for licensing and monitoring, is far more prevalent—and consigned in legislation—in countries such as Norway and Canada than in Asia and South America. The use of such tools extends to nations such as the US and various EU Member-States where aquaculture production is insignificant both from a global perspective and to their internal economies.

These issues should be a key part of the sector's agenda for sustainability over the next decades (Costa-Pierce et al, 2026).

There is widespread use of informal licensing approaches for aquaculture in many parts of the world, both on land and in coastal waterbodies—this is a problem on many levels, including assessment of accurate production data and waste footprints, biosecurity, and access to private capital. Tools based on remote sensing, machine learning, and AI can be leveraged on a global scale to provide solutions to some of these challenges. This paper describes the development of AquaScape, a global mapping tool designed to address a number of important issues in this domain, and exemplifies how it has been applied in collaboration with the Aquaculture Stewardship Council (ASC) to improve the quality of certification of shrimp culture in India.

Methods

AquaScape (<https://longline.co.uk/aquascape/>) was originally conceived as a platform for communicating science to management, using a mapping metaphor to provide a simplified representation of complex simulations. This involved sophisticated scientific and technical requirements whereby the outputs of hydrological, hydrodynamic, and ecological models (Nobre et al., 2010) needed to be archived, retrieved, and synthesised on the platform—the technical challenges included accurate geospatial storage of aquaculture structures such as ponds and cages, overlaying model results using cutting-edge design, and since the platform is web-based, optimising retrieval and display speed.

Since Indonesia was the first country where AquaScape was applied, this was fundamental in bridging the information gap referred above; the various simulation tools and their outputs were displayed in the context of the world's second largest aquaculture producer (14.9 X 10⁶ t including seaweeds, FAO, 2024), which allowed a comprehensive understanding of scaling and complexity and presented an enormous computational challenge to ensure a rich and responsive user experience.

The lack of geodata on aquaculture structures of different types was identified as a key gap for management, and it was recognised that little could be achieved in the application of more sophisticated models without a solid geographical baseline.

The resulting registry was stored in the AquaScape platform, which now contains about 3.5 million aquaculture structures throughout the world, corresponding to thirty million tonnes of annual production, or 32 % of world production of aquatic animals (94.4 X 10⁶ t, FAO, 2024).

Ponds, cages, shellfish rafts, and other structures (**Error! Reference source not found.**) were mapped using a combination of remote sensing, human validation, and machine learning. Currently, AI plays a major role in improving data quality and helping to identify key features in the dataset that can be used to convert data into information.

(Continued on next page)

Fig. 1. Fish farm clusters in an area of the South China Sea under Hong Kong jurisdiction.

Fig. 2. AquaScape registry of shrimp ponds in Andhra Pradesh, India, showing data tags for a selected production unit.

Fig. 3. Schematic representation of landscape connectivity analysis.

(Continued on next page)

Fig. 4. AquaScape assessment of pond numbers and activity status by district in Andhra Pradesh.

AquaScape is now realising its potential as a platform for sustainability; it (i) enables informal aquaculture to be part of a registry, using a tag-based system to provide standard information such as area and volume, production status (e.g. for shrimp ponds: intensive, semi-intensive, fallow), and where applicable, lease data; and (ii) allows for models to be applied at scale to determine production, dissolved and particulate emissions, connectivity, and other key performance indicators.

An example of this kind of potential application was the connectivity assessment in Andhra Pradesh (India) executed by the ASC and Longline.

This application used data from AquaScape for shrimp pond location, complementary remote sensing data and machine learning to examine activity status, using e.g. aeration and water and vegetation colour indices, and combining these outputs with GIS multicriteria evaluation to determine suitability.

Synthesis of case-study outcomes

270,622 ponds were identified in the coastal districts of Andhra Pradesh using pond detection analysis, with over 97% used for shrimp production. Total activity in each district averaged 72% in 2022 (Fig. 1).

All these ponds are connected to their surrounding landscape through land, water, habitat, and climate. Farming on unsuitable land or within a 100-metre buffer zone from sensitive features (as per ASC standards) raises ecological and environmental concerns, along with highlighting significant risk to the sector due to climate change.

Srikakulam, Sri Potti Sriramulu Nellore, and Yanam are the most promising districts in Andhra Pradesh for potential certification and further shrimp farming investment due to their favourable land conditions, limited environmental conflicts, and potential to revitalise unused ponds. SPS Nellore stands out for its ideal soil, flat terrain, and low ecological impact, while Srikakulam and Yanam offer suitable sites with manageable climate risks and minimal mangrove loss.

East Godavari also has strong potential, though it requires careful planning to address environmental risk in some areas. In contrast, districts like Krishna, Vizianagaram, and West Godavari face significant challenges from mangrove degradation, flood risk, and regulatory complexity, making further expansion more difficult without major environmental restoration.

(Continued on next page)

Remote sensing has emerged as a powerful tool for monitoring and analysing aquaculture activities and their broader environmental and socio-economic contexts. By leveraging satellite imagery and geospatial analysis, this approach provides scalable, cost-effective, and data-driven insights into aquaculture farming operations and their interactions with the surrounding landscape.

This Environment Intelligence approach can be broadly applied at scale and used to evaluate very large production areas.

Environmental Intelligence can thus be used to bridge the information divide between sustainability tools and major farming areas to improve the quality of local management and global certification.

INTRODUCTION

Atlantic salmon (*Salmo salar*) aquaculture faces significant challenges associated with skin integrity loss, driven primarily by sea lice (*Lepeophtheirus salmonis*) infestation, but also mechanical handling and crowding stress. Skin lesions constitute major welfare and biosecurity concerns, functioning as entry points for opportunistic pathogens and are directly linked to reduced growth, increased mortality, and substantial economic losses. The wound microenvironment involves dynamic shifts in local microbial community composition alongside a transcriptional immune response both at the lesion site and in surrounding epithelial tissue, processes that have been increasingly characterized in recent years. Functional feeds represent a promising non-pharmacological strategy to actively support skin recovery following injury. Marine algae are of particular interest given their diverse bioactive compounds — including sulfated polysaccharides, phlorotannins, fucoxanthin, EPA, and β -glucans — with documented immunomodulatory, anti-inflammatory, and antimicrobial properties. *Ascophyllum nodosum*, *Phaeodactylum tricornutum*, and *Chaetoceros muelleri* have shown relevant biological activity in *ex vivo* assays and preliminary feeding trials, yet their therapeutic capacity to modulate wound healing at both the microbial community and transcriptional level in Atlantic salmon needs to be further explored. The present study evaluates the effect of dietary supplementation with these three algae, on the wound healing response in Atlantic salmon subjected to wound model, characterizing wound microbiota and local transcriptional profiles to provide an integrated assessment of host–microbiome dynamics during cutaneous recovery.

METHODS

Atlantic salmon were subjected to a two-step wound protocol, as an attempt to mimic the establishment of a sea lice-associated lesion, combining a standardized perifocal abrasion of mucus and scales followed by a central punch biopsy. Immediately following wounding, fish were assigned to one of four experimental diets administered throughout the 45-day recovery period: a control diet (CTRL) and three diets supplemented with *Ascophyllum nodosum* whole biomass (ASCOP), *Phaeodactylum tricornutum* hydrolysed biomass (PHAEO), or *Chaetoceros muelleri* broken biomass (CHAETO). Wound closure was monitored photographically over the full recovery period, encompassing the main healing stages: re-epithelization, inflammation, granulation, and maturation. At key time points corresponding to each stage, wound tissue samples were collected for microbiota community profiling and transcriptional analysis of stage-specific marker genes.

RESULTS

Photographic analysis of wound closure indicates a trend towards faster healing in fish fed PHAEO and CHAETO diets compared to CTRL and ASCOP. Transcriptional profiling across the four healing stages revealed differential expression of genes associated with immune activation (*il1b*, *tnfa*, *mhcII*), inflammatory regulation (*il10*, *il6*, *cox2*, *ptgs2*), and tissue remodeling (*mmp9*, *mmp13*, *fn1*, *krt*) between dietary groups. Microbiota community composition at the wound site differed among treatments, with further characterization currently underway. These findings suggest that therapeutic dietary inclusion of selected microalgae, particularly *P. tricornutum* and *Chaetoceros muelleri*, initiated immediately following injury, may actively support wound healing in Atlantic salmon. These results point to the potential of algae-based functional feeds as a post-injury nutritional intervention with practical welfare implications for salmon aquaculture. Further analysis will clarify the microbial and transcriptional mechanisms underlying the observed differences in healing dynamics.

INTRODUCTION

Skin wound healing in Atlantic salmon (*Salmo salar*) is a multistep biological process encompassing re-epithelialisation, inflammation, granulation tissue formation and tissue remodelling. Impairment of any of these phases' compromises barrier restoration and fish welfare, with significant consequences for performance and resilience against pathogens like the ectoparasite sea lice. Comparative studies between salmonid species provide compelling insights into the biology of resistance. Coho salmon display near-complete resistance to sea lice, associated with a rapid epithelial hyperplasia response driven by accelerated keratocyte migration during re-epithelialisation (Salisbury et al., 2024). Furthermore, coho salmon mount a rapid, well-localised, neutrophil-dominated inflammatory response within 24–48 hours of louse attachment, whereas Atlantic salmon exhibit a delayed and poorly localised reaction that facilitates parasite establishment (Sveen et al., 2025). These observations collectively suggest that both the kinetics of re-epithelialisation and the quality of early inflammatory priming are critical determinants of effective skin defence. We hypothesise that targeted dietary interventions can recapitulate, in Atlantic salmon, key aspects of the wound-healing phenotype observed in resistant salmonid species. To test this, we employ an Atlantic salmon skin explant model, as New Approach Methodologies (NAMs), enabling mechanistic, tissue-level interrogation of nutritionally driven repair processes while reducing reliance on *in vivo* experimentation. Two complementary explant-based trials specifically address the identified rate-limiting steps in skin defence: (i) acceleration of keratocyte migration during re-epithelialisation (Trial 1), and (ii) induction of a rapid, acute inflammatory response at the wound site (Trial 2).

METHODS

Skin sections from Atlantic salmon were collected in the area between the dorsal fin and the lateral line and used as a standardised liquid-submerged skin explant culture system using an inert, non-porous support to maximise tissue viability and functional performance. Skin dissection procedures, ex-vivo wound infliction and culture conditions had a specific emphasis on preserving the skin secretome (i.e. the full set of proteins and metabolites released by the explant). Bacterial growth in culture media was monitored by optical density at 600 nm and maintained below 15% relative to baseline through scheduled medium changes. Explant viability (72 hours) was assessed via metabolic activity (Alamar Blue - resazurin assay) and membrane integrity (total protein release). Tissue stress and goblet cell activity were evaluated by quantifying total secreted mucus in the culture medium using Alcian Blue or Periodic Acid–Schiff staining coupled to colorimetric analysis. Healthy explants were defined by sustained metabolic activity and limited protein leakage throughout the assay duration. Following SOP establishment for maximal basal viability, the skin explant functional performance was used to gain new insights on the role of bioactive compounds with demonstrated or hypothesised capacity to enhance keratocyte migration (Trial 1) and compounds signalling a pathogenic insult (PAMPs), and a positive immunological control. Endpoints across both trials included gene expression profiling using panels targeting skin re-epithelialisation and inflammatory pathways.

RESULTS

Differential effects of the tested compound categories on the transcriptional upregulation of genes associated with keratocyte motility, cytoskeletal remodelling and epithelial proliferation generated new insights, on the mechanisms to accelerate the re-epithelialisation process in a wounded skin. Moreover, PAMP-based dietary treatments and insult signalling compounds primed a faster and localised neutrophilic response at the wound site, reflected in earlier upregulation of acute-phase inflammatory genes. Together, these new generated data provide integrated evidence in Atlantic salmon that several compounds (with the potential to be afterwards delivered via feed) have the potential to accelerate the re-epithelialisation phase and amplify early inflammatory priming following standardised skin wounding.

(Continued on next page)

CONCLUSION

This work establishes Atlantic salmon skin explants as a practical NAM-based platform to investigate nutritionally driven modulation of skin wound healing. The data indicate that selected bioactive compounds can accelerate re-epithelialisation and enhance early inflammatory priming following skin injury, two processes that are critical for effective barrier restoration and characteristic of resistant salmonid species. These findings support the use of explant models as a screening and mechanistic tool to prioritise functional ingredients for subsequent feed formulation and *in vivo* validation. Ultimately, this approach may accelerate the development of nutritional strategies aimed at improving skin integrity, welfare, and resilience to ectoparasites in commercial salmon aquaculture.

Introduction

Tactile stimulation (TS) is defined as a positive sensory experience resulting from physical contact (touch) between individuals or via artificial devices (Bolognesi et al., 2019; Soares et al., 2011). TS is involved in various relationships between animals, such as grooming in primates (Dunbar, 2010), cooperative interactions between fish (Bshary and Würth, 2001), therapeutic massage in humans (Field et al., 2005), and in the context of animal husbandry (Gauy et al., 2022). In these contexts, TS plays a crucial role in promoting animal welfare and strengthening social bonds. To the moment, the association between DA and TS has only been observed in cleaner-client context, i.e. always the presence of a fish as a “reward” (Messias et al., 2016a, 2016b). Here, we aimed to test if the TS per se can have the rewarding role, not given by other living organisms but provided by an artificial apparatus. Thus, we investigated the role of DA in modulating the response to tactile stimuli and the choice of TS in an important commercial species of teleost fish, the gilthead seabream (*Sparus aurata*). We predicted that if TS is processed as a reward (or positive valence) and modulated by exogenous changes in available DA levels, blocking endogenous levels would function as an omission of reward, resulting in behavioural compensation characterised by the seeking the physical stimulation. Conversely, increased DA levels would induce the opposite effect.

Materials and methods

Fish were first exposed to an artificial apparatus consisting of a rectangular PVC frame fixed in the centre of the aquarium, with vertically attached sticks lined with silicone bristles providing TS as fish swam through them. Groups of four individuals received seven days of TS and were then randomly assigned to one of three exogenous treatments: D1 agonist, D1 antagonist, or saline (12 groups per treatment). Fish then returned to an aquarium containing an apparatus with sticks half with/half without silicone bristles for analysis of post-treatment preference (60 min of video recording).

Secondly, to test the efficiency of our DA exogenous manipulations, we needed to understand the effects that intramuscular injections would have on the DA brain level of *Sparus aurata* individuals, which areas would be affected, and how long the effects would last. Four timepoints were defined at which the fish would be euthanised by deepening anaesthesia, following an intramuscular injection of one of three treatments: 15 minutes, 30 minutes, 45 minutes and 60 minutes. Six individuals were euthanised at each time point for each compound, totalling n = 24 in each treatment, for subsequent brain HPLC analysis of DA and DOPAC.

(Continued on next page)

Results and discussion

We found that all treatments sought the TS at a similar frequency but those under DA blockage showed a greater relative preference for the TS area, having a higher relative frequency of crossing the bristles than those receiving other treatments. In the second experiment, fish treated with D1 blocker showed a significant reduction in DA concentration in the forebrain after 60 min, confirming the antagonist's effectiveness. These results suggest that TS is associated with dopaminergic reward pathways in fish, similarly to mammals. Although TS in the natural environment of *S. aurata* is not described in the literature as in other species (see Soares et al., 2011), it seems however able to generate positive responses associated with reward. It is thus possible that TS occurs in a more subtle way for *S. aurata*, such as through touch between conspecifics and elements present in their natural environment, or even from water movements that produce tactile perception between individuals. Our results suggest that body tactile stimulation enrichment may have a great potential for aquaculture application, particularly in this important commercial species.

Introduction

Aquaculture of ornamental fish is among the fastest-growing activities worldwide. Nevertheless, the several stages of the ornamental fish trade can impair fish welfare, from initial capture to final housing. In this context, environmental enrichment is a key approach to mitigate such negative impacts, particularly in housing aquaria. Recently, body tactile stimulation (TS), akin to gentle touch or therapeutic massage, has emerged as a promising tool of sensory enrichment for fish. Studies have shown that artificial TS reduces stress in reef species (Soares et al., 2011), diminishes fear in zebrafish (Schirmer et al., 2013), and limits aggression while promoting growth in Nile tilapia (Gauy et al., 2022; 2023). Considering that enrichment can affect species differently, we evaluated the effects of TS on aggressive behavior and stress in two widely reared ornamental species, the Siamese fighting fish (*Betta splendens*) and the cichlid angelfish (*Pterophyllum scalare*). Given that monoamines mediate TS mechanisms in vertebrates, we also investigated the association between TS and brain Dopamine (DA) and serotonin (5-HT) levels, specifically in *B. splendens*.

Methods

Fish were exposed for 22 days to either an artificial TS apparatus or to an identical one without bristles, serving as a control (Fig. 1). Then, we evaluated individual aggressive behavior using mirror tests and pair fights, and stress by cortisol levels in both species. Brain DA, 5-HT, and their metabolites were measured by HPLC only in *B. splendens* due to logistical reasons.

Results and discussion

TS reduced aggression in male angelfish without altering cortisol levels, whereas in *B. splendens*, it increased restrained fighting and cortisol levels. Brain monoamines analysis in *B. splendens* revealed decreased 5-HT and increased 5HIAA/5HT turnover. DA levels remained unchanged, indicating no activation of the neural reward pathway. These contrasting outcomes may reflect species-specific differences in ecological history and behavioral traits. *P. scalare*, for instance, inhabits macrophyte-rich environments where substrate contact is frequent. Conversely, artificial selection for heightened aggressiveness or prolonged social isolation may render TS stressful rather than rewarding for *B. splendens*. Overall, our findings suggest that the efficiency of tactile enrichment is species-dependent, highlighting the importance of tailoring welfare interventions accordingly.

Figure 1 – Tactile stimulation. The TS apparatus consisted of a rectangular PVC frame filled with vertical plastic sticks, with silicone bristles on their sides that promote TS (A), and without silicone bristles for control (B). Both apparatuses were placed in the middle of the tank, and fish received TS when passing through the bristles (C). N = 20 *per treatment, per species*.

Introduction

Body tactile stimulation (TS), similar to gentle touch or therapeutic massage, has emerged as a promising form of sensory enrichment for fish. Previous studies have shown that artificial TS alleviates stress in reef fish (Soares et al., 2011), reduces fear-related behavior in zebrafish (Schirmer et al., 2013), and mitigates confinement stress in gilthead seabream (Soares et al., 2026). In Nile tilapia, *Oreochromis niloticus*, TS has been shown to reduce aggressive interactions and enhance growth performance. However, these behavioral and productive benefits are not accompanied by a reduction in cortisol levels (Gaury et al., 2022, 2023). In the present study, we investigated whether allowing Nile tilapia to freely choose to receive TS would result in greater welfare benefits by reducing group aggression and cortisol levels. A preference test was used as it provides an important approach for assessing the affective valence of environmental enrichment, helping to determine whether animals actively seek or avoid a given stimulus and, consequently, whether it is likely to improve Nile tilapia welfare.

Methods

Groups of 4 adult male fish were exposed for 21 days to one of three treatments: “with TS”, “no TS”, and “choice TS” (Fig.1). A rectangular apparatus featuring plastic rods with silicone bristles on their sides (Fig.1A); without silicone bristles for control (Fig. 1B); and a half-with / half-without silicone bristles to allow fish choice (Fig. 1C). The apparatuses were placed in the middle of the tank (Fig. 1D), and fish received TS when passing through the bristles. Aggressive interactions were video recorded (10 min each) every three days. Biometric measurements and blood samples were collected at the beginning and end of the period to analyze growth and cortisol levels, respectively.

Figure 1 – Tactile stimulation. The TS apparatus consisted of a rectangular PVC frame filled with vertical plastic sticks, with silicone bristles on their sides that promote TS (A), without silicone bristles for control (B), and a half-with / half-without silicone bristles to allow fish choice. The apparatus were placed in the middle of the tank, and fish received TS when passing through the bristles (an example in D). “no TS” (n = 13), “with TS” (n = 15), and “choice TS” (n = 14) groups *per* treatment.

(Continued on next page)

Results and discussion

Fish crossed by the apparatus more frequently in the “no TS” than in the “with TS” treatment. In the choice treatment, fish passed through the bristles side beginning with ~10% and increasing to ~40% over time. One-way ANOVA revealed that group aggression was higher ($p < 0.0001$) and the specific growth rate was lower in the “no TS” treatment compared to the other two treatments ($p < 0.01$). These variables were similar between the “with TS” and “choice TS” ($p > 0.21$). We also found a positive Spearman rank correlation between crossings by the apparatus and aggressiveness in the “no TS” treatment; no significant correlations in “with TS” treatment, whereas a negative correlation was found in the “choice TS” treatment for bristles choices. Repeated measures ANOVA showed that cortisol levels increased in the “no TS” ($p = 0.003$) and “with TS” ($p = 0.03$) groups. Nevertheless, cortisol remained unchanged in the choice group ($p = 0.38$) and was lower than the other two treatments ($p < 0.01$). We conclude that allowing Nile tilapia free choice of tactile stimulation (TS) yields more beneficial outcomes by reducing aggressiveness and social stress while enhancing growth. Overall, free-choice TS represents a more effective environmental enrichment strategy for this species.

Introduction

Shrimp juvenile rearing is one of the most important processes of shrimp aquaculture worldwide, enhancing the production of millions of tons of shrimp annually and providing employment for thousands of people (Cuéllar-Lugo et al., 2018). Throughout history, multiple diseases caused by various viruses and bacteria have led to millions of dollars in crop losses. To combat viruses and bacterial diseases in juvenile production instead antibiotics that have increased pathogen resistance (Morales-Covarrubias et al., 2011) the use of phenolic extracts plant extracts in Mexico due to their antibacterial and antiviral pharmacological properties (Banerjee et al., 2008) has shown successfully results. In the present study, the effects of the addition of microencapsulated phenolic extracts from plant species from the tropical deciduous forest in Mexico on the growth, survival, and gene expression of shrimp juvenile has been determined.

Material and Methods

Results

Discussion

The higher concentrations of total phenols, flavonoids, and condensed tannins in *M. emarginata* leaves than those reported by Vasavilbazo-Saucedo et al. (2018) could be related to the ecological characteristics of the sampling sites. Those authors collected samples on a sandy island without a high diversity of herbivores and with extreme dry weather. In contrast, the specimens collected in this study face higher herbivore competition, less water stress, and parasites. These factors stimulate phenolic compound production as a defense mechanism (Nieto Ramírez et al., 2018).

(Continued on next page)

No previous reports regarding *P. blakeana* have been published. Compared with other species from the Pereskioideae subfamily, such as *Opuntia* spp, *Cylindropuntia rosea*, *Tacinga inamoena*, and *Austrocylindropuntia cylindrica*, the phenolic compound profiles vary (Chen et al., 2023; Dantas et al., 2013; Ko et al., 2025; Pensamiento-Niño et al., 2021; Torres et al., 2023; Vieira et al., 2024). These phenolic compounds variation has been shown to affect antioxidant capacity and antiviral or antibacterial activities. In this sense, Zhang et al. (2016) and Sanathkumar et al. (2014) have reported significantly higher mortality compared to the present results in shrimp co-infected with WSSV and *V. parahaemolyticus* applied to *P. vannamei* post-larvae. This difference could be attributed to the fact that simultaneous infections with two major pathogens tend to trigger an antagonistic interaction, reducing the effect or response of one of them in the shrimp (Rubio-Castro et al., 2016). Consistent with this, Pang et al. (2019) who supplemented feed with phosphatases, corroborated this phenomenon and a lower mortality in organisms infected simultaneously by WSSV and *V. parahaemolyticus* compared to those subjected to sequential infections at different times and in different order were reported.

Seaweeds and dune coastal plants have seen an increase in interest within the medicinal field, due to the identification of a variety of bioactive compounds (Narayanan et al., 2025; Holdt & Kraan, 2011). However, common extraction methodologies require the use of organic solvents that can be harmful to human health and the environment. Extracts performed from extraction techniques following the principles of green chemistry (Chemat et al, 2012) remain understudied. In this study, 5 species of seaweeds and 6 species of plants found along the Portuguese coastal dunes, were selected. Extracts were carried out using the green extraction techniques subcritical water extraction (SWE) and ultrasound-assisted extraction (UAE) under multiple extraction conditions. For UAE the influence of extraction time and solvent to solid ratio was evaluated. The influence of temperature and pressure was evaluated for SWE. Phenolic content and antioxidant activity of the extracts were determined by TPC method and by DPPH[•], ABTS^{•+}, [•]NO and [•]OH scavenging assays. Chemical composition of the plant extracts was determined by HPLC-DAD and LC-MS. The antimicrobial potential of the seaweed extracts was tested on *Staphylococcus aureus*, *Bacillus cereus*, *Pseudomonas aeruginosa*, *Salmonella enteritidis* and *Escherichia coli*. The best conditions of extraction were determined based on the antimicrobial and antioxidant potential of the extracts. Following the conclusion of this research, the extracts will be evaluated for antimicrobial activity against the fish pathogen *Vibrio sp.* and potential inclusion in feeds for *Gilthead seabream* will be investigated.

INTEGRATING DUCKWEED INTO INTENSIVE CATFISH CULTURE THROUGH CLOSED-LOOP WATER RECYCLING

Introduction

Intensive production of African catfish, *Clarias gariepinus*, generates water containing suspended solids and dissolved nutrients, particularly nitrogen and phosphorus compounds. Although recirculating aquaculture systems reduce water consumption, nutrient removal and the management of accumulated organic matter remain important operational and environmental challenges. Duckweed, particularly species of the genus *Lemna*, grows rapidly on nutrient-rich water and can assimilate dissolved nutrients into protein-rich plant biomass.

This work presents an integrated production concept combining indoor catfish culture in a recirculating aquaculture system, outdoor catfish tanks and duckweed cultivation within a single water-recycling loop. The objectives are to improve water reuse, recover nutrients and produce a locally available feed supplement for juvenile catfish.

System Concept and Operation

Water discharged from the indoor and outdoor catfish production units first passes through mechanical filtration for the removal of floating and larger suspended solids. The mechanically treated water, which retains dissolved nitrogen, phosphorus and other metabolites, is subsequently directed to shallow duckweed cultivation ponds.

Duckweed assimilates dissolved nutrients during rapid vegetative growth and thereby acts as a biological polishing stage. The treated water is then returned to both catfish production units, closing the water-recycling loop and reducing the requirement for fresh water and nutrient discharge.

Under favourable temperature, nutrient and light conditions, expected duckweed productivity is approximately 10–30 g dry matter m⁻² day⁻¹, with harvesting carried out every one to two days. Regular harvesting prevents excessive surface density and continuously removes assimilated nutrients from the water.

Duckweed Processing and Nutritional Use

Harvested duckweed is washed, dried and milled before being incorporated into formulated feed for catfish larvae and fingerlings. Depending on species and cultivation conditions, duckweed may contain approximately 35–45% protein on a dry-matter basis. It also provides essential amino acids, vitamins, minerals and carotenoids.

The harvested biomass can therefore partially convert nutrients originating from fish production into a valuable feed ingredient. Further trials will determine suitable inclusion levels and evaluate effects on feed intake, growth, feed conversion, survival, fish health and water quality.

Discussion and Conclusion

The proposed system links intensive fish production, water treatment and feed-resource generation in a circular production process. Duckweed closes part of the nutrient loop by recovering dissolved nutrients that would otherwise be discharged or require additional treatment. Its integration may reduce water exchange, nutrient emissions and operating costs while providing a renewable supplementary feed material.

The concept is particularly relevant for intensive inland aquaculture facilities seeking to improve resource efficiency without substantially increasing the complexity of water treatment. Operational validation will focus on nutrient-removal efficiency, duckweed productivity, seasonal stability and the nutritional value of the harvested biomass. The integrated approach offers a practical pathway towards more circular, water-efficient and resilient catfish production.

FIRST DETECTION OF *Streptococcus iniae* ASSOCIATED WITH DISEASE IN FARMED EUROPEAN SEABASS *Dicentrarchus labrax* IN EAST GREECE

Introduction

Streptococcus iniae is a well-recognized bacterial pathogen affecting a wide range of marine and freshwater fish species, causing significant economic losses in aquaculture worldwide (Austin & Austin, 2016). It has been widely reported in species such as tilapia and rainbow trout, where it causes septicemia and meningoencephalitis (Austin & Austin, 2016; Agnew & Barnes, 2007). In the Mediterranean aquaculture industry, European seabass (*Dicentrarchus labrax*) is one of the most commercially valuable species; however, reports of *S. iniae* infections in this host remain scarce. The emergence and spread of *S. iniae* have been associated with environmental stressors, including elevated water temperatures and high stocking densities (Mian et al., 2009). The present study describes the first confirmed occurrence of *S. iniae* infection in farmed European seabass in marine aquaculture facilities in East Greece, highlighting its clinical, microbiological, and epidemiological characteristics.

Materials and Methods

During the summer of 2025, increased mortality (8-10%) was observed in seabass populations from two marine cage farms located in South-East Aegean (Greece). Samples of moribund European seabass (average weight 90–500 g) were collected and subjected to clinical and laboratory examination. Gross pathological assessment was performed, followed by bacteriological analysis using standard culture techniques on blood agar. Isolated colonies were identified based on colony morphology, Gram staining, and biochemical characteristics, and further confirmed by molecular methods, including PCR targeting 16S rRNA followed by sequencing (Mata et al., 2004). The genome of the isolate was extracted and subsequently sequenced using both short- and long-read technologies followed by hybrid assembly. Antimicrobial susceptibility testing was performed using the disk diffusion method.

Results

Affected fish exhibited clinical signs consistent with streptococcosis, including anorexia, lethargy, erratic swimming behavior, ocular opacity and exophthalmia. External examination revealed redness of the head, anemia of the gills, petechial hemorrhages on the operculum and at the base of fins. Internally, ascites, splenomegaly, discoloration of the liver, enteritis with distended intestine hemorrhages, serous fluid within the lumen and congestion of visceral organs were observed. Pure bacterial cultures yielded Gram-positive, β -hemolytic, catalase-negative cocci arranged in chains. Biochemical profiling and genomic analysis confirmed the isolates as *Streptococcus iniae*. Antimicrobial susceptibility testing showed sensitivity to florfenicol and oxytetracycline. The outbreak coincided with elevated seawater temperatures (25–27°C), a known predisposing factor for streptococcal infections (Agnew & Barnes, 2007).

Discussion

This study represents the first documented case of *S. iniae* infection in farmed European seabass in Eastern Greece, expanding the known host range and geographical distribution of this pathogen. The clinical signs and pathological lesions observed are consistent with previous descriptions of streptococcosis in other fish species (Austin & Austin, 2016; Agnew & Barnes, 2007). The emergence of *S. iniae* in seabass raises concerns regarding its potential impact on Mediterranean aquaculture, particularly under conditions of elevated water temperatures, which may favor disease outbreaks. Early diagnosis through combined bacteriological and molecular methods proved essential for accurate identification. Genomic analyses provided insights regarding the virulence factors of the isolate and its phylogenetic position. Environmental conditions, particularly increased water temperature, likely played a critical role in the onset of the outbreak, as previously suggested (Mian et al., 2009). The observed antimicrobial resistance patterns emphasize the need for responsible antibiotic use (CLSI, 2020; Shoemaker et al., 2001). Preventive strategies, including vaccination, biosecurity measures, and improved farm management practices, should be considered to mitigate future outbreaks. Further epidemiological studies are required to assess the prevalence and impact of *S. iniae* in Mediterranean seabass aquaculture.

LIFE CYCLE ASSESSMENT OF EUROPEAN SEABASS (*Dicentrarchus labrax*) FED TWO MARINE PEPTIDES-SUPPLEMENTED FEED FORMULATION STRATEGIES

Gras C¹*, Bardera G¹, Dehasque M¹, Nuez-Ortín WG¹

¹ Adisseo, France

*presenting author celine.gras@adisseo.com

Introduction

Fish meal is widely used in aqua feeds because of its high quality nutritional profile. However, the catch of wild fish is linked to substantial environmental concerns, notably pressure on wild fish stocks and marine ecosystems. Limiting reliance on fish meal while preserving zootechnical performance has therefore become a key lever for enhancing the environmental sustainability of aquaculture. Feed formulation approaches typically include reducing fishmeal inclusion levels, lowering the quality of marine-derived ingredients, or replacing marine proteins with alternative sources such as plant-based or functional ingredients. Although these strategies aim to mitigate the environmental impacts associated with fishmeal use, they must be evaluated using standardized assessment tools such as Life Cycle Assessment (LCA), which quantifies environmental impacts across multiple categories (e.g., climate change, eutrophication). This study evaluated through LCA the environmental impacts of two formulation strategies, by partially replacing fish meal or using a lower quality fish meal in the diet with a supplementation of a marine peptide concentrate (Pepsea F) in European seabass (*Dicentrarchus labrax*).

Material and Methods

Data from Bardera *et al.* 2026 (presented in a separate abstract for EAS 2026) were used for LCA, including fish performance, feed and some farm data. Experimental diets included Pepsea F (Adisseo) and consisted of two formulation strategies: (i) partial replacement of high-quality fish meal (with 68% crude protein), reducing inclusion from 20% to 10%, and (ii) substitution of fish meal quality, from 68% to 60% of crude protein, at a constant 20% inclusion level. All experimental feeds were formulated to be isoproteic, isolipidic and isoenergetic. Performance parameters, including feed intake, specific growth rate (SGR), and feed conversion ratio (FCR), were measured.

LCA for Pepsea F at plant gate was conducted following ISO 14040/44, PEFCR and FAO LEAP guidelines, where applicable. LCA from cradle to farm gate (per kg of fish) was performed using feed ingredient list, growth performance and feed efficiency outputs, and Turkish seabass farm data. GFLI v2.2 database (2024) was used, and LCA followed FAO LEAP (2020) and PEFCR guidelines, where applicable. Feed ingredient origins reflected Turkish, European or Global import values when no other data was available. Five impact categories were assessed: climate change, acidification, eutrophication freshwater and marine, and water use. In addition, the Environmental Return on Investment (EROI) was calculated as the ratio of the carbon footprint avoided at the animal product level to the impact generated by additive production at the plant level.

Results

At the cradle to farm gate level, formulation strategy (i) with partial replacement of fish meal combined with Pepsea F supplementation, led to a marginal reduction in climate change impacts, from 5.92 to 5.85 kg CO₂eq/kg fish (-1%), compared to the basal diet. This strategy also resulted in reductions in marine eutrophication (-12%) and water use (-3%), while slightly increasing acidification (+1%) and freshwater eutrophication (+1%) per kg of fish.

In contrast, formulation strategy (ii), based on fish meal quality substitution at constant inclusion levels, yielded more pronounced LCA indicators improvements. Climate change decreased from 6.08 to 5.66 kg CO₂eq/kg fish (7%). In addition, there was an improvement in acidification (-1%), freshwater eutrophication (7%), and water use (3%) compared to the basal diet. However, marine eutrophication was slightly higher for the lowquality fish meal supplemented with Pepsea F (+4% per kg of fish) relative to basal diet.

The EROI calculated for the first strategy (i) resulted in 6, while it reached 38 from the second strategy (ii), indicating that for an investment of 1 kg CO₂eq due to feed additive production, its use resulted in these studies in savings of 6 or 38 kg CO₂eq on the value chain depending on the formulation strategy.

(Continued on next page)

Discussion & Conclusion

These results show that, additionally to performance improvements obtained in Bardera *et al.* 2026 (EAS 2026), Pepsea F associated with different formulation strategies can reduce different LCA environmental impacts in European seabass, with magnitude depending on the strategy applied. The second strategy, having more significant effects on climate change, appears especially relevant for companies with carbon reduction objectives, as CO₂ emissions represent one of the main indicators used to evaluate corporate sustainability performance.

In contrast, the first strategy relied on partial fish meal replacement with soy protein concentrate ingredient, which increased the climate change impact of the feed compared to the basal diet. Consequently, despite improved fish performance associated with Pepsea F supplementation, the final climate change reduction at the farm gate was limited and considered non-significant. This finding aligns with Kok *et al.* (2026), who emphasized that substituting marine ingredients with plantbased alternatives can modify the distribution of environmental pressures across ecosystems. In particular, the use of soy imported from South America is still associated with landuse change impacts, highlighting the importance of carefully evaluating tradeoffs between marine resource use and terrestrial environmental constraints when designing more sustainable aquafeeds.

Besides, the magnitude of the observed environmental benefits is influenced by methodological assumptions. In the second strategy (ii), identical fish meal proxies from the GFLI v2.2 database were applied to both high and lowquality fish meal, due to the lack of supplierspecific data and differentiated datasets. This conservative assumption likely underestimates the environmental gains, as lowerquality fish meal, potentially derived from byproducts, can reasonably be expected to have a lower environmental footprint under economic allocation. Consequently, the mitigation potential associated with Pepsea F marine peptide supplementation and fish meal quality decrease may be greater than reported here.

Taken together, these findings illustrate both the potential and the limitations of LCA for assessing fish meal reduction strategies. Further studies combining LCA with complementary indicators, such as Fish-In Fish-Out ratios (FIFO) and emerging biotic resource depletion or biodiversity metrics, would enable a more comprehensive evaluation of feed reformulation strategies and their implications for marine resource use and ecosystem integrity.

Croatian Veterinary Institute
Zagreb, Croatia

*corresponding/presenting grbin@veinst.hr

Introduction

Vibriosis caused by *Vibrio harveyi* is an important bacterial disease affecting Mediterranean aquaculture, including European seabass (*Dicentrarchus labrax*) and gilthead sea bream (*Sparus aurata*). Genomic and proteomic characterization of *V. harveyi* may contribute to a better understanding of its pathogenicity and virulence mechanisms.

Materials and methods

Two *V. harveyi* isolates, 94/17 and A27, isolated from diseased and clinically healthy European seabass in Croatia, respectively, were subjected to whole-genome sequencing using Oxford Nanopore MinION and Illumina HiSeq platforms. The genomes were de novo assembled and analysed for the presence of virulence-associated genes using the Virulence Factor Database (VFDB). To complement the genomic analysis, proteomic profiling of bacterial cell fractions was performed using liquid chromatography–mass spectrometry (LC–MS).

Results

A total of 226 and 227 virulence-associated genes were identified in strains 94/17 and A27, respectively. The distribution of virulence genes was highly similar between the two strains, indicating a largely conserved virulence-associated gene repertoire. Comparative genomic analysis revealed a broad repertoire of putative virulence-associated genes involved in motility and flagellar assembly, quorum sensing, secretion systems, iron acquisition, membrane-associated functions, and toxin production. Proteomic analysis identified 389 and 292 protein entries in strains 94/17 and A27, respectively. Integration of genomic and proteomic data demonstrated concordance for several major virulence-associated systems. Both strains expressed abundant flagellar proteins, including FlaB and additional flagellins, quorum-sensing-associated proteins LuxS and a LuxP-like autoinducer-2-binding periplasmic protein, as well as outer membrane and transport-associated proteins including OmpA, OmpK, OmpW and TolC-family proteins. Notably, strain 94/17 showed a distinct virulence-associated proteomic profile, including detection of a zonular occludens toxin family protein, the type II secretion system component GspG and the quorum-sensing regulator LuxT. In contrast, strain A27 showed proteomic evidence of an active type VI secretion system through detection of an Hcp1-family effector and the contractile sheath component TssC.

Conclusion

These findings indicate that the genomic virulence potential of the two *V. harveyi* strains is partially reflected at the protein level while also revealing strain-specific differences in the detectable virulence-associated proteome. The combined genomic and proteomic approach highlights toxin- and secretion-associated features in strain 94/17 and type VI secretion in strain A27 as particularly interesting targets for further functional investigation.

SURVIVAL RATES FOR *Penaeus vannamei* AND *Penaeus monodon*: EVIDENCE FROM ASC STAKEHOLDER ENGAGEMENT ACROSS ASIA AND LATIN AMERICA

M Green*, Unibazo J¹, Castanheira MF¹

¹Aquaculture Stewardship Council

The Netherlands

*Presenting author: marianne.green@asc-aqua.org

Survival rate is one of the most critical performance indicators in commercial shrimp aquaculture. It was formally incorporated into the Aquaculture Stewardship Council (ASC) requirements, in 2022, through minimum grow-out survival thresholds within its Shrimp Standard, ranging from $\geq 25\%$ for unfed, non-permanently aerated systems to $\geq 45\%$ for fed systems without permanent aeration, and $\geq 65\%$ for fed, permanently aerated ponds. Despite these benchmarks, published datasets often fail to capture the full variability observed under commercial farming conditions.

This study presents survival rate data for *Penaeus vannamei* (whiteleg shrimp) and *Penaeus monodon* (giant tiger prawn) collected directly from industry stakeholders across key producing regions in Asia and Latin America, providing a commercially grounded perspective on species and system performance.

Across all regions surveyed, survival rates under normal commercial conditions broadly ranged from 65–75%, with well-managed farms consistently achieving 80–90%, and disease outbreaks or environmental stressors reducing survival to below 60%. Considerable variation was recorded both within and between regions, reflecting differences in farming system intensity, species, climate, and disease pressure.

In Asia, *P. vannamei* farms in India reported average survival of 60–65%, with top-performing farms reaching 85–90%. Seasonal variation was marked, with summer crops in semi-intensive systems achieving 70–85% compared to 65–75% in winter crops, where monsoon rainfall and low temperatures in northern states increased the risk of crop failure. *P. monodon* performance in India diverged sharply by system type, with extensive farms relying on wild seed averaging just 30% survival, against 65–75% in semi-intensive operations in Andhra Pradesh and Gujarat. Vietnam reported strong *P. vannamei* performance at around 75%, while *P. monodon* survival of 60–80% across extensive, semi-intensive, and intensive systems represented a notable deviation from the generally lower performance observed for this species elsewhere. In Indonesia, successful *P. vannamei* crops achieved 75–85% survival, although disease events reduced this range to 60–75%. Thailand reported average *P. vannamei* grow-out survival of around 70%, with wide variability, and *P. monodon* survival reaching 85% in successful crops but averaging 65–75% in practice.

In Latin America, *P. vannamei* survival in Ecuador ranged from 75–80%, while Brazil showed strong performance of over 70%—occasionally exceeding 80%—outside of colder months, when White Spot Syndrome Virus (WSSV) outbreaks drove survival below 50% during affected periods. Mexico performed below regional peers, with survival of 55–70% at higher stocking densities in Sonora and 45–50% at lower densities in Sinaloa extensive fed systems. Honduras and Guatemala reported survival of 60–70% and 60–80% per cycle respectively, with inter-cycle variability in Guatemala reaching 60–90%.

Disease pressure, particularly WSSV, and seasonal environmental fluctuation emerged as the primary drivers of survival loss across both species and all regions. System intensity was consistently associated with improved outcomes, most notably in *P. monodon* culture.

The variability captured in this stakeholder-derived dataset highlights the gap between experimental benchmarks and commercial reality, and underscores the value of industry-sourced evidence in establishing meaningful regional performance expectations for the global shrimp farming sector.

Commercial shrimp survival is far more variable and context-dependent than current standard benchmarks suggest, with biological and environmental drivers outweighing system classification.

CIRCULAR FEEDING STRATEGIES INTEGRATING SEA URCHINS AND SEA CUCUMBERS IN INTEGRATED MULTI-TROPHIC AQUACULTURE (IMTA)

Luca Grosso^{1*}, Mohammad Magdy¹, Davide Pensa¹, Marco Melita², Stefano Amalfitano², Arnold Rakaj¹

¹ Laboratory of Experimental Ecology and Aquaculture, Department of Biology, University of Rome Tor Vergata, Italy

² Water Research Institute, National Research Council of Italy (IRSA-CNR), Monterotondo, Rome, Italy

*Presenting author: e-mail: lucagrosso94@gmail.com

Introduction

Integrated multi-trophic aquaculture represents one of the most promising approaches to improve the sustainability of marine farming by coupling fed and extractive species within the same production system. In this framework, organic by-products generated by one species can be reused as a trophic resource by another, reducing waste outputs while producing additional biomass of commercial value (Ridler et al., 2007). Low-trophic marine invertebrates, such as sea urchins and sea cucumbers, are particularly suitable for this approach because of their complementary feeding ecology and high market value (Grosso et al., 2021). *Paracentrotus lividus* is a valuable echinoid mainly fed on macroalgal resources, whereas *Holothuria tubulosa* is a deposit-feeder able to ingest and assimilate organic biodeposits, potentially acting as an extractive species in benthic integrated systems. However, the development of echinoderm co-culture still requires sustainable diets able to support growth while maintaining the circularity of the system. In this context, circular aquafeed ingredients such as probiotics and single-cell proteins may represent promising tools to improve nutrient utilization and reduce dependence on conventional marine-derived protein sources (Eroldoğan et al 2023). Therefore, this study aimed to investigate, for the first time, the growth performance and survival of *P. lividus* and *H. tubulosa* in co-culture using sustainable dietary supplements. Three macroalgal-based diets were tested as the sole food source to sustain both species rearing: a control diet (macroalgae), a probiotic-enriched diet and a diet enriched with methanotrophic bacterial single-cell protein.

Materials and Methods

Sub-adults of *Paracentrotus lividus* (N = 90) were collected from the central Tyrrhenian Sea, while sub-adults of *Holothuria tubulosa* (N = 90) were obtained through artificial reproduction at the Laboratory of Experimental Ecology and Aquaculture, University of Rome Tor Vergata. After acclimation at 20 ± 0.5 °C and a two-week fasting period, specimens were allocated to recirculating aquaculture systems for a three-month feeding trial. Three macroalgal-based diets, composed of *Ulva* sp. and *Laminaria* sp. in equal proportions, 1:1 dry weight, were tested: a control diet containing only macroalgae (CTL); a probiotic-enriched diet supplemented with *Bacillus subtilis*, *Lactobacillus casei* and *Lactobacillus plantarum* (PRO); and a single-cell protein-enriched diet supplemented with the methanotroph *Methylococcus capsulatus* (META). Sea urchins were reared and fed in floating baskets, while sea cucumbers were placed on the sediment-enriched tank bottoms. Sea urchin feces passing through the basket mesh represented the only food source for sea cucumbers. Growth was assessed through somatic growth rate in both species, while the gonado-somatic index was calculated for sea urchins. Absorption efficiency was estimated from the organic matter content of food and feces.

Results

Survival was high throughout the experiment, with only two *P. lividus* specimens dying during the first days and no mortality recorded for *H. tubulosa*. All diets supported significant somatic and gonadal growth in sea urchins and positive somatic growth in sea cucumbers. However, the methanotrophic-enriched diet produced the highest overall performance. In *P. lividus*, META resulted in the highest somatic growth rate and gonado-somatic index, reaching 0.61%, and 13.76%, respectively. Sea cucumbers also showed the highest growth under META, followed by PRO and CTL, with final biomass increases of 50.17%, 41.90% and 33.80%. Absorption efficiency was high in both species, especially under META, where sea urchins absorbed 58% of dietary organic matter and sea cucumbers absorbed 60% of sea urchin biodeposits. Overall, the META diet reduced residual organic waste to 17%, compared with 30% in PRO and 36% in CTL.

(Continued on next page)

Discussion

This study demonstrates for the first time that sustainable dietary supplements, particularly methanotrophic bacterial single-cell protein, can support echinoderm integrated multi-trophic aquaculture. The high survival of both *Paracentrotus lividus* and *Holothuria tubulosa* confirmed the compatibility of these species in co-culture and the suitability of the tested diets. The single-cell protein diet was the most effective treatment, significantly improving sea urchin somatic growth, gonadal development and absorption efficiency, with performances comparable to those reported for fishmeal-enriched diets (Fernandez and Boudouresque 2000). It also enhanced sea cucumber growth, producing higher somatic growth rates than previous integrated aquaculture trials (Tolon et al., 2017; Grosso et al., 2021). These results suggest that methanotrophic bacterial meal can represent a sustainable alternative to fishmeal protein in low-trophic aquaculture. The probiotic-enriched diet had species-specific effects. It did not significantly improve sea urchin growth compared with the control, suggesting that the selected strains and dose were not effective for *P. lividus*. Conversely, it improved sea cucumber growth and absorption efficiency, supporting the key role of bacteria in deposit-feeder nutrition. Overall, both supplemented diets enhanced the circularity of the system, but the single-cell protein diet provided the best production and bioremediation outcomes. Under this treatment, only 17% of the ingested organic matter remained as final waste, highlighting the potential of this co-culture system for circular and regenerative echinoderm aquaculture.

Introduction

Integrated multi-trophic aquaculture can improve the sustainability of marine farming by converting dissolved and particulate wastes from fed species into new biomass through extractive and low-trophic organisms (Chopin et al., 2012). In this framework, sea cucumbers are highly promising candidates because of their deposit-feeding behaviour and ability to process organic matter accumulated in sediments (Zamora et al., 2018). Among Mediterranean species, *Holothuria tubulosa* is particularly relevant for aquaculture diversification and bioremediation-oriented systems (Grosso et al., 2021). However, its successful integration into circular aquaculture requires suitable feeds that mimic natural detrital resources while enhancing the nutritional role of associated microbial communities. Biofloc-based diets offer a valuable approach because they rely on heterotrophic microbial biomass growing on organic carbon sources and nitrogen inputs (Avnimelech, 2015). In integrated systems, nitrogen-rich aquaculture waste can therefore be reused to upgrade low-value agricultural by-products into nutritionally enriched feeds. The carbon-to-nitrogen ratio is a key factor in this process, as it regulates microbial growth, nutrient immobilization and the final quality of the biofloc available to deposit feeders. This study tested the growth performance of *H. tubulosa* fed biofloc-based diets produced from agricultural by-products and enriched with nitrogen derived from aquaculture waste. Three plant-based diets were compared with a seagrass-detritus control to assess whether carbon-to-nitrogen optimization and microbial conditioning can support sustainable sea cucumber production within integrated multi-trophic aquaculture systems.

Materials and Methods

Specimens of *Holothuria tubulosa* were collected by scuba diving from infralittoral habitats from the central Tyrrhenian Sea and transported to the Laboratory of Experimental Ecology and Aquaculture, University of Rome Tor Vergata in aerated seawater under controlled temperature. After acclimation in quarantine tanks, specimens were fasted for 15 days to allow gut evacuation, then weighed and selected for the feeding trial. The experiment was carried out in independent recirculating aquaculture tanks adapted for sea cucumber rearing, each containing a fine silica sand substrate suitable for deposit-feeding activity and bacterial colonization. Four biofloc-based diets were tested: seagrass detritus as natural control, corn stalks with nitrogen addition, wheat husks with nitrogen addition, and corn stalks without nitrogen addition. Agricultural by-products were dried, ground, sieved and matured in aerated bioreactors with probiotic supplementation. Nitrogen, derived from aquaculture waste, was added to selected diets to optimize the carbon-to-nitrogen ratio and promote heterotrophic microbial development. Sea cucumbers were stocked at 500 g m⁻² and fed twice weekly. Water quality was monitored regularly, while survival and somatic growth were assessed monthly through drained weight measurements.

Results

The second feeding trial showed that all upcycled plant-based biofloc diets were suitable for *Holothuria tubulosa*, with 100% survival and positive somatic growth under all conditions. However, growth differed significantly among diets. Sea cucumbers fed *Posidonia oceanica* detritus showed the highest performance, with mean growth rates above 35%. Wheat husks with nitrogen addition supported similar growth, around 27%, and did not differ significantly from the natural control. Corn stalks with nitrogen addition also promoted high growth, around 25%, while corn stalks without nitrogen addition showed the lowest growth, around 19%, confirming the importance of nitrogen enrichment and carbon-to-nitrogen optimization.

(Continued on next page)

Discussion

The second trial showed that *Holothuria tubulosa* can efficiently exploit sustainable plant-based diets derived from agricultural by-products, confirming its trophic plasticity and suitability for low-trophic aquaculture. All diets supported positive somatic growth, but clear differences emerged according to substrate type and nitrogen availability. The highest growth was obtained with *Posidonia oceanica* detritus, confirming the ecological relevance of seagrass debris as a natural food source for Mediterranean sea cucumbers and providing a suitable reference diet (Boncagni et al., 2019). Notably, wheat husks and corn stalks enriched with nitrogen produced growth performances close to the seagrass control, despite their lignocellulosic and intrinsically low-protein composition. This suggests that microbial conditioning in biofloc systems can upgrade low-value agricultural residues into nutritionally effective feeds. The poorer performance of corn stalks without nitrogen addition confirmed that nitrogen availability and carbon-to-nitrogen optimization are key factors for biofloc development. A balanced carbon-to-nitrogen ratio likely stimulated heterotrophic microbial growth, improving substrate digestibility and generating protein-rich microbial biomass available to deposit feeders. Overall, these findings indicate that nitrogen-enriched agricultural by-products can support sustainable *H. tubulosa* aquaculture, while future metagenomic and transcriptomic analyses may clarify the microbial mechanisms driving nutrient upgrading.

SPINAL HEALTH OF EARLY-LIFE PIKEPERCH IN RELATION TO GRADING STEPS: A PROJECT REPORT

George P. Franz^{1*}, Bianka Grunow¹

¹ Working Group Fish Growth Physiology
Research Institute for Farm Animal Biology (FBN)
Dummerstorf, Germany

*corresponding/presenting franz@fbn-dummerstorf.de

Introduction and Background

Aquaculture of pikeperch (*Sander lucioperca*) has advanced greatly during the last decades. However, some barriers remain, e.g. the production of sufficient larvae and strong fluctuations in their quality between the reproduction cycles. One issue is the variable and occasionally high occurrence of spinal deformities, which negatively influence animal welfare and production efficiency (Policar et al., 2019). In a pretrial study (Franz et al., 2025), the overlap of grading procedures with fundamental spinal development was found. Grading, although necessary to reduce cannibalism in this species, poses a risk to negatively influence the early developing structures of the spine. Consequently, this EPFC co-funded project follows up on the previous pretrial. It covers a series of grading steps of early-life pikeperch from a RAS hatchery, analysing their development, occurring spinal changes, and potential links to related factors as age, size group, and selected fatty acid (FA) influences (El Kertaoui et al., 2021). Here, project results are presented and potential adaptations in rearing procedures are discussed. This could help to reduce spinal deformities resulting from mechanical stress on these developmental stages of pikeperch, and simultaneously aid facility output and skeletal health of the animals.

Sampling and Methods

Specimen sampling encompassed a series of grading steps starting from the first (34 dph) to fourth (57 dph) routine size sortings within the facility. These consisted of three manual gradings, using grid boxes (first to third step), and machine grading (fourth step). Specimen were sampled from the resulting size groups, including normal and deformed spinal conditions. The analysis consisted of morphometric measurements, histological preparation of cleared and stained specimens to allow for spine morphology observations, and FA analyses of specimen from the groups and additional influential maternal and feed factors using gas chromatography (HR-GC).

Results and Discussion

Morphometric measurements highlighted the increasing size differences between the groups. Increasingly, differences in length between the deformed and non-deformed specimen within the same size groups were found. Body width comparisons indicated some level of squeezing being applied to the specimen during the grading steps. HR-GC data showed a pattern shift at around 42-43 dph, during the late larval to early juvenile transition. Hereby, the before trends in the developmentally influential polyunsaturated FAs and monounsaturated FAs proportions changed. We concluded this to indicate some transition either in the digestive or metabolism capabilities in these age groups (Reis et al., 2020). Skeletal analyses highlighted the regional specific occurrence of compressed and fused vertebrae, with compressions predominantly occurring in mid and posterior spine areas, while the less frequent fusions mainly occurred in the posteriormost sections. Analyses of single steps indicated that an accumulation of deformities occurs over time, highlighting the meaning of long-term observations. Within the earliest stages, another spinal variation type was observed in smaller specimen, showing their higher fragility.

Studies on skeletal deformations remains difficult, as influential factors are broad (Boglione et al. 2013). Here, no direct uniform influence of grading on spine deformities was found, however, indications for this further accumulated. Follow-up studies should take into account that control groups are practically unavailable, and are recommended to use the separation of spine areas in % of length regions. Still, the project could demonstrate that adaptations of grading are already possible within the given setup. These include postponing the first grading, and adapting the grid passages to more selectively remove largest specimen only. It was found that focusing on specimen with double the mean group length can be considered a conservative detection threshold for cannibals within the size groups.

Introduction

The rapid expansion of global aquaculture has increased the need for innovative, sustainable and ethically responsible research tools. Fish cell culture systems have evolved into a versatile platform that bridges the gap between basic biology, disease research, toxicology and the production of alternative proteins. This study provides an overview of recent advances in the establishment, optimisation and application of cell lines derived from fish, with a focus on species of importance to European aquaculture.

We are investigating current methods for isolating primary cells, techniques for immortalisation, and the development of three-dimensional (3D) culture systems that better replicate the conditions found in living organisms. We place particular emphasis on the role of fish cell cultures in researching the interactions between pathogens and hosts, in vaccine development, and in environmental impact assessments, including responses to pollutants and climate-related stressors.

Furthermore, we discuss the potential of fish cell cultures in the emerging field of cellular aquaculture, highlighting challenges relating to scalability, cost-effectiveness and regulatory acceptance. Comparative analyses show that, whilst significant progress has been made in optimising growth media and bioreactor conditions, further research is required to develop commercially viable production systems. Overall, fish cell culture technologies represent a promising tool to enhance sustainability and innovation in aquaculture, and reduce animal experiments.

Results

At our laboratory at the Research Institute for Farm Animal Biology, Fish Growth Physiology group, a total of 63 fish cell lines from 17 fish species are currently stored. Of these, 55 cell lines derived from 13 species were established in-house, propagated, and cryopreserved as long-term cultures in liquid nitrogen ^[1-8].

All cell lines were characterised regarding to their growth behaviour and morphology. In addition, molecular validation using standardised genetic markers was performed to confirm their origin (DNA barcoding). Selected cell lines were further analysed in detail, including assessments of growth kinetics, mitochondrial function (e.g., using Seahorse extracellular flux assays), as well as protein and gene expression profiling.

Discussion

Fish cell culture systems represent a powerful tool to advance the principles of the 3Rs (Replacement, Reduction, Refinement) in aquatic research and aquaculture. First, they provide clear opportunities for replacement of live animal experiments in areas such as toxicology, pathogen screening, and environmental monitoring. In vitro models allow controlled, reproducible testing conditions and enable mechanistic studies that would be difficult to achieve in whole organisms.

Second, fish cell lines also play a key role in reducing animal experiments by minimising the number of animals needed for experimental validation and, in some cases, enabling full replacement. Once established, these cell lines can be propagated indefinitely, supporting high-throughput screening approaches. This capability reduces the need for repeated animal sampling across different experiments and laboratories.

Third, cell culture approaches support refinement by decreasing the severity of procedures involving live fish. Early-stage screening of stressors, pollutants, or pathogens can be conducted in vitro, thereby limiting in vivo experiments to only the most relevant conditions and reducing animal distress.

Despite these advantages, limitations remain. Fish cell cultures cannot fully replicate the complexity of whole organisms, including systemic immune responses, endocrine regulation, and tissue–tissue interactions. Therefore, they should be viewed as complementary tools within integrated experimental frameworks.

(Continued on next page)

Overall, the establishment of diverse fish cell lines—such as those presented in this study—substantially strengthens the toolbox for ethically responsible research. Continued development of advanced models (e.g., 3D cultures, co-culture systems) will further enhance their relevance and accelerate the transition toward more sustainable and animal-friendly aquaculture research.

Introduction

Meagre (*Argyrosomus regius*) is an emerging Mediterranean aquaculture species characterised by rapid growth, favourable feed conversion and desirable flesh quality; however, species-specific functional feeds are needed to support its sustainable production (Güroy et al., 2024). Macroalgae, particularly *Ulva* sp., are promising functional ingredients because they provide nutrients, minerals, vitamins and bioactive compounds capable of supporting fish growth, immunity and antioxidant capacity (Wan et al., 2019). However, their nutritional effectiveness may be constrained by variable composition and nutrient accessibility, while biological or enzymatic processing may improve digestibility and functional value (Wan et al., 2019; Wiszniewski et al., 2019; Qudratullah et al., 2025). Therefore, this study compared raw, yeast-fermented, and bromelain-processed *Ulva* sp. products at three dietary inclusion levels in juvenile meagre.

Materials and Methods

Juvenile meagre with an initial body weight of approximately 5 g were randomly distributed into 400-L tanks at 15 fish per tank, with three replicates per treatment. In addition to a control diet, nine experimental diets were formulated with raw, yeast-fermented or bromelain-processed *Ulva* sp. products at inclusion levels of 2, 4 and 8 g kg⁻¹. Fish were fed to apparent satiation three times daily for 12 weeks under a 12 h light:12 h dark photoperiod and were weighed every two weeks following 24 h fasting and mild clove-oil sedation. Growth and feed-utilisation parameters, somatic indices, whole-body composition, haematological parameters, innate immune responses, and digestive and antioxidant enzyme activities were evaluated. Three fish were randomly sampled from each tank. Data were analysed by one-way analysis of variance followed by Tukey's multiple-comparison test, with significance accepted at $P < 0.05$.

Results

Diets containing bromelain-processed *Ulva* sp. significantly improved growth and feed-utilisation performance ($P < 0.05$). The highest final body weight (38.10 g), specific growth rate (2.41% day⁻¹) and protein efficiency ratio (1.99), together with the lowest feed conversion ratio (1.04), were recorded in fish fed 8 g kg⁻¹ bromelain-processed *Ulva* sp. The viscerosomatic index was reduced in the bromelain-processed groups and in the 4 g kg⁻¹ yeast-fermented group, while the mesenteric fat index was significantly lower at 4 and 8 g kg⁻¹ bromelain-processed *Ulva* sp. than in the control. Condition factor and hepatosomatic index were unaffected.

The highest red blood cell count, haemoglobin and haematocrit values were observed in fish fed 8 g kg⁻¹ bromelain-processed *Ulva* sp. This treatment also produced the highest protease, amylase and lipase activities. In contrast, the 2 g kg⁻¹ inclusion level of bromelain-processed *Ulva* sp. elicited the strongest responses in most innate immune indicators, including extracellular oxidative radical production, lysozyme, alternative complement pathway activity, bactericidal activity and phagocytic activity.

Discussion

The superior growth, feed utilisation and digestive enzyme activities observed with bromelain-processed *Ulva* sp. suggest that enzymatic pre-treatment enhanced nutrient accessibility and utilisation, consistent with improved digestive capacity and feed efficiency reported following bromelain supplementation (Wiszniewski et al., 2019; Qudratullah et al., 2025). The comparatively weaker responses to raw *Ulva* sp. indicate that restricted nutrient accessibility may limit its nutritional effectiveness, whereas processing can improve the digestibility and functional properties of macroalgal biomass (Wan et al., 2019). The stronger innate immune responses recorded at the 2 g kg⁻¹ inclusion level indicate a dose-dependent functional effect, consistent with evidence that seaweeds and their bioactive compounds can enhance fish immunity, although responses vary among species and dietary inclusion levels (Thépot et al., 2021). Overall, bromelain-processed *Ulva* sp. appears to be a promising functional ingredient for juvenile meagre, with the 8 g kg⁻¹ inclusion level favouring growth and digestive performance and the 2 g kg⁻¹ inclusion level eliciting the strongest innate immune responses.

Effective genetic improvement in finfish aquaculture begins with choosing the right breeding strategy, whether based on mass selection, family-based selection, or genomic selection. Each strategy varies in cost, complexity, and potential genetic gain, and selecting among them requires balancing breeding objectives, operational capacity, and expected commercial outcomes. Straightforward traits such as growth can be improved with simpler strategies, whereas complex traits - such as robustness, disease resistance, and correlated traits - benefit from more advanced strategies supported by modern genetic tools.

Within these strategies, genotyping, germ cell transfer (GCT), and genome editing (GE) serve as powerful tools to accelerate or enhance breeding outcomes. Genotyping enables accurate estimation of breeding values, improves selection intensity, and supports genomic selection programs for traits that are difficult or costly to measure. GCT offers a reproductive tool to boost efficiency by allowing sterilized surrogate hosts to produce donor-derived gametes. This is particularly useful for species with long generation intervals or challenging reproductive biology, enabling faster turnover of elite genetics and expanding breeding capacity. GE provides a precision tool that can introduce targeted modifications within a single generation, complementing the broader selective breeding strategy rather than replacing it.

Robust genetic progress ultimately relies on integrating phenotypic data, genotypic data, and operationally feasible breeding structures. This presentation evaluates how various genetic tools - genotyping technologies, germ cell transfer, and genome editing - can be embedded within well-designed breeding strategies to deliver sustainable, long-term improvements across multiple species. By aligning tools with strategy and commercial priorities, producers can build resilient breeding programs that strengthen husbandry foundations, enhance performance traits, and maximize returns on investment throughout the production cycle.

AN EGYPTIAN CASE STUDY ON THE IMPACT OF PISCIVOROUS BIRDS ON AQUACULTURE IN THE CONTEXT OF CLIMATE CHANGE

Mohamed Ibrahim Habib

PhD Student

Email: mrhydro35@hotmail.com

Aquaculture is a vital economic and food-security sector in Egypt, yet its expansion has intensified conflicts with wildlife. This study presents the first comprehensive, multidisciplinary assessment of piscivorous bird impacts on coastal and brackish-water aquaculture in Port Said, Egypt. Through a 24-month mixed-methods case study integrating ornithological surveys, bioenergetics modeling and exclusion experiments, the research quantifies ecological and economic losses while situating the conflict within global change drivers. Key findings reveal that Little Egret (*Egretta garzetta*), Slender-billed Gull (*Chroicocephalus genei*), and Grey Heron (*Ardea cinerea*) dominate predation, causing direct economic losses averaging 8.7% of annual production value—equivalent to roughly EGP 11.25 million (USD ~360,000) annually for Port Said. Indirect impacts, including elevated fish stress, disease risk, and infrastructure damage, further compound losses. Farmer surveys indicate that current deterrents are largely ineffective and that bird predation ranks among the top challenges faced. The conflict is exacerbated by climate change, wetland degradation, and overfishing, which collectively increase system vulnerability. The study concludes by proposing an Integrated Bird Management (IBM) framework to promote sustainable coexistence, emphasizing physical exclusion, modern non-lethal deterrents, improved farm practices, and supportive policy measures. This work provides an empirical foundation for managing human-wildlife conflicts in aquaculture under changing environmental conditions.

THE IMPACT OF PISCIVOROUS BIRDS ON AQUACULTURE IN THE CONTEXT OF CLIMATE CHANGE: AN EGYPTIAN CASE STUDY

Mohamed Ibrahim Habib*, PhD student

Introduction

Aquaculture is a cornerstone of food security in Egypt, the largest producer in Africa, yet its expansion along the Mediterranean coast has intensified conflicts with piscivorous birds. Despite the global recognition of bird predation as a major economic constraint—with documented losses exceeding 30% of production in some regions—Egypt lacks empirical data on this conflict. The northern Delta lakes, including Lake Manzala adjacent to Port Said, are critical wetlands along the African-Eurasian flyway, hosting millions of migratory waterbirds. Concurrently, climate change, wetland degradation, and overfishing are eroding natural prey bases, potentially forcing birds toward aquaculture ponds. This study aims to conduct the first comprehensive assessment of piscivorous bird impacts on brackish-water aquaculture in Port Said, quantifying species-specific predation, economic losses, and the efficacy of current mitigation strategies within the context of global environmental change.

Materials and Methods

A 24-month mixed-methods case study (January 2024–December 2025) was conducted across 35 aquaculture farms in Port Said Governorate. Systematic ornithological surveys (point counts, transects, and 520 hours of focal behavioral sampling) were performed to characterize bird communities and foraging strategies. Exclusion experiments compared fish survival between netted ($n=15$) and open ponds. Bioenergetics modeling estimated consumption rates, while production records from 10-hectare seabass (*Dicentrarchus labrax*) operations quantified economic losses. Farmer interviews ($n=50$) assessed perceptions, mitigation costs, and management challenges. Spatial analysis using GIS mapped bird distribution relative to Lake Manzala.

Results

Thirty-three piscivorous bird species were documented, with three species dominating predation: Little Egret (*Egretta garzetta*) (28.5% of observations), Slender-billed Gull (*Chroicocephalus genei*) (18.7%), and Grey Heron (*Ardea cinerea*) (9.1%). Winter congregations reached exceptional densities: 48,266 birds at Lake Manzala North East and 28,555 at Port Fouad El Malaha. Direct economic losses averaged 12.7% of stocked biomass per cycle (range: 5–31%), equivalent to EGP 148,750 (USD ~4,950) per hectare per cycle. For a 10-hectare seabass operation, feeding-time predation alone caused seasonal losses of EGP 10,800–27,000. Extrapolated regionally, total annual losses reach approximately EGP 11.25 million (USD ~360,000). Indirect impacts included 220% higher cortisol levels and a 15.7% reduction in growth. Current deterrents were largely ineffective (mean efficacy 2.8/5); 65% of farmers admitted to lethal control despite legal protections.

Discussion

This study provides the first empirical evidence that piscivorous birds cause substantial economic losses to Egyptian aquaculture, with impacts exacerbated by climate-driven degradation of natural habitats. The convergence of migratory birds at aquaculture ponds reflects broader ecosystem stress—birds are increasingly ‘squeezed’ between a degraded Lake Manzala and an overfished Mediterranean Sea. The identification of species-specific foraging strategies and risk classifications enables targeted management. Cost-benefit analysis reveals that targeted netting of feeding areas (3.6-year payback) and automated laser systems (3.2-year payback) offer economically viable alternatives to current ineffective practices. These findings highlight the need for an Integrated Bird Management framework balancing aquaculture productivity with avian conservation obligations under Egyptian Law 4/1994 and international agreements.

Introduction and objectives

The genetic improvement of the ratio of the edible part in shrimps is presently not undertaken in commercial breeding programs (Ren et al., 2025). We aim to fill this gap by estimating genetic parameters of abdominal yields and morphological predictors of those in the Pacific blue shrimp (*Penaeus stylirostris*) based on lengths measured by electronic caliper or on digital images, also integrating water loss after cooking. With these parameters, we estimate expected genetic gains on abdominal yields by sib-based selection or by mass selection on the predictor.

Material and methods

A total of 49 full and half-sib families were created by inseminating each dam with spermatophores from 2 sires (Haffray et al. 2025 and 2026). A sample of 1200 progenies were assigned to their parents with SNP markers and phenotyped at commercial size (≈ 14.5 g) by measuring body length and abdominal length on uncooked individuals, either with an electronic caliper or by computer vision from 2D pictures. The whole shrimps were weighted uncooked or after cooking by boiling, and abdomen weight was measured after cooking. We calculated the ratio of the cooked abdominal weight either to the uncooked body weight or to the cooked body weight. The water loss ratio after cooking was also calculated as the difference between uncooked and cooked body weights divided by uncooked body weight. We estimated genetic parameters for these traits and genetic gains obtained either by sib-based selection on tail yield or mass selection on the residual of the regression of abdominal length to total length.

Results

Heritability estimates were intermediate for the ratio of the cooked abdominal weight to the raw or cooked body weights (0.33-0.24), and lower when considered as residuals of the numerators to the denominators (0.20 and 0.12). The heritability of the ratio of abdominal length to total length increased when using computer vision instead of the electronic caliper (0.20 vs 0.07). The genetic correlations between predictors and the yields or residuals to predict were high (0.67-0.94) and higher when the predictors were measured by computer vision.

The simulated genetic gains per generation were similar between sib-selection and mass selection at similar selection pressures and increased with the increased selection pressure permitted by mass selection (10-30 %), compared to lower selection pressure possible by sib-selection (30-50 %).

Conclusions and perspectives

These results show it is possible to genetically improve abdominal yield by mass or by sib selection in the Pacific blue shrimps. The short interval of generation in shrimp is favorable for it progressive and slow improvement to better characterize potential impacts on other traits or relative organs development. The simple and highly genetically correlated indirect predictor evaluated is promising and future advances in 3D vision and AI may further improve phenotyping accuracy and increase heritability of future predictors. The negative genetic correlation between water loss at cooking and uncooked abdominal yield is also paving the way to better characterize the interaction between improvement of yields and flesh quality traits.

Introduction

Meeting the aquatic protein demands of a growing global population necessitates increased aquaculture production. In Norway, further expansion of the salmon aquaculture industry depends on identifying alternative sources of marine proteins and lipids that support animal welfare. Polychaete biomass have emerged as promising substitutes for fish meal and fish oil in aquafeeds. Notably, *Hediste diversicolor* has demonstrated the ability to biosynthesize long-chain (C20-24) polyunsaturated fatty acids (LC-PUFAs) de novo, positioning it as an ideal candidate for converting low-value side streams into high-quality biomass within circular value chains. We hypothesize that the biosynthetic capacity of *H. diversicolor* to de novo synthesize LC-PUFAs is linked to the role of docosahexaenoic acid (DHA, 22:6n-3) and eicosapentaenoic acid (EPA, 20:5n-3) in oogenesis and reproduction: in conditions of limited dietary LC-PUFAs, endogenous synthesis may compensate, ensuring sufficient allocation of these lipids to oogenesis and spermatogenesis. In this 200-day experiment, we fed immature *H. diversicolor* a PUFA-deficient diet spiked with ¹³C-labelled palmitic acid (C16:0), a potential elongation/desaturation precursor, to test whether the worms biosynthesize EPA and DHA for maturation and whether this depends on dietary input.

Materials and Methods

Juveniles of *H. diversicolor* were collected from mudflats of Leangen Bay (63°26'24.5"N, 10°28'27.7"E) in the intertidal zone at low tide (as described in Machado et al., 2024). Red-colored, immature individuals (73.8±46.5 mg WW; n=48) of unknown sex were randomly distributed in transparent, cubical boxes (10 x 10 x 10 cm L x W x H; n=6) filled with a 5 cm thick layer of sand, supplied with continuous water flow (34 ppt salinity; 10 °C), using a 16h:8h light:dark cycle. The polychaetes were fed 50 mg of a LC-PUFA deficient diet spiked with ¹³C palmitic acid (16:0) tank⁻¹, three times per week, over a period of 200 days, in triplicates. Growth, survival, gamete development, fatty acid (FA) content and composition, and compound-specific stable isotope analysis (CSIA) of fatty acids of body tissues (somatic tissue) and gametes (reproductive tissue), were assessed. All statistical analyses were conducted using the inbuilt statistical package in SigmaPlot for Windows v15.0 (Systat Software, Inc., USA) with a significance level set to $\alpha=0.05$. Percentage data from FA composition analysis were arcsine-transformed prior to analyses.

Results

The male to female ratio was 5:1, 5:2 and 2:4, and the survival was 79.2±7.2 %, with no differences between replicates. The final weight (WW) of the polychaetes was 0.18±0.09 g (n=19). The SGR was calculated to 0.0039±0.0025. There was no correlation between oocyte size and polychaete weight ($r^2=0.07$; Non-linear Regression Analysis) and the average oocyte diameter was 180.2 ± 20.1 µm upon sampling. The quantitative FA analyses (mg/g DW) of juveniles, mature oocytes and somatic tissue of adult females collected from the wild, showed that the reproductive tissues were significantly higher in sum FA, sum SFA, sum MUFA, sum n-3 and sum n-6 than both full-body juveniles (One-Way ANOVA, Holm-Sidak post hoc test; $P = 0.001 - 0.026$) and adult somatic tissue (One-Way ANOVA, Holm-Sidak post hoc test; $P < 0.001 - 0.026$), whereas there were no differences for these groups of FAs between juveniles and adult somatic tissue, except for the sum of MUFAs and the sum of n-6 (One-Way ANOVA, Holm-Sidak post hoc test; $P = 0.025$). CSIA of female *H. diversicolor* reared on a LC-PUFA deficient diet containing ¹³C enriched 16:0 revealed that most of the detected FAs showed enrichment of ¹³C, including EPA and DHA, demonstrated by a positive $\delta^{13}\text{C}$ (‰) signal, with the exception of linoleic acid (18:2n6), α -linolenic acid (18:3n3), eicosadienoic acid (20:2n6) and dihomogamma-linolenic acid (20:3n6).

Discussion

This study demonstrated for the first time that ¹³C from spiked palmitic acid (16:0) is incorporated into EPA and DHA in adult female *H. diversicolor* somatic and reproductive tissues. The strongest ¹³C signal for DHA was detected in the oocytes, indicating active incorporation of dietary carbon into reproductive DHA. These findings support a link between LC-PUFA allocation and reproductive processes in this species, while the relative contributions of endogenous synthesis and microbial sources remain to be clarified.

Aquaculture continues to expand as the fastest growing protein sector. As expansion continues, the need for and opportunity for cost effective automated and robotic solutions. This talk will summarize work completed and ongoing work to advance aquaculture robotics.

Three robotic approaches for aquaculture will be discussed. Surface vehicles with RC approach can provide easy access for operators to gather data on water quality, add feed or water quality components, remove mortalities or identify issues. In some cases, these can be placed in autonomous modes to rove or navigate to desired locations to assess or service aquacultured fish or equipment. Fleets of these vehicles can coordinate to do more complex tasks. Finally, unique single axis robots can operate in amphibious mode, allowing additional applications and opportunities.

We will review advances with aquabots, with focus on how smart systems can reduce challenges and add value. Among the applications are commercially available cameras and water quality sensors (e.g. salinity, temperature, dissolved oxygen). These devices can be mounted on autonomous or semi-autonomous aerial, surface and underwater vehicles to help sense water quality parameters in open (e.g. estuary, ocean) systems. They may also be used in culture systems (ponds, tanks, raceways) for diverse activities including feeding, harvest, waste and water quality management. With further development, these systems may also allow active interventions to reduce the impacts of storm events, toxicity and other environmental impacts, or to enhance productivity and sustainability.

Optimal management of these sectors may allow increased aquacultural productivity as well as optimal focus on conservation of habitat and species. Work has included a focus on smart thinking to add value; corobotics – i.e. robots providing humans with improved information, allowing wiser decisions. This work seeks to aid in developing more sustainable and productive aquaculture wisely using ethical robotics and automation. We will also discuss some near future applications of aquacultural robotics.

¹ Institute of Tropical Aquaculture and Fisheries
Universiti Malaysia Terengganu
21030 Kuala Nerus
Terengganu, Malaysia

*Presenting author: e-mail: fahdhallak959@gmail.com

Introduction

Rising freshwater temperatures can increase physiological demand while constraining reproduction in tropical fishes. Blue gourami *Trichopodus trichopterus* is a bubble-nesting ornamental species whose reproductive success requires coordinated gonadal development, nest construction, spawning behaviour and fertilisation. We tested how 120 days at 32 and 34 °C affected physiological demand, reproductive performance and broodstock gonadal condition relative to 28 °C.

Materials and Methods

Adult breeding pairs were maintained at 28, 32 or 34 °C. Spawning frequency was assessed in nine pairs per temperature; egg production and fertilisation were quantified from successful spawnings at 28 °C (n = 15) and 32 °C (n = 9). Pair-level feed intake (n = 9 per temperature) and individual opercular ventilation rate (n = 10 per temperature) were analysed by one-way analysis of variance. Gonadal histology was evaluated qualitatively (n = 2, 5 and 3 fish at 28, 32 and 34 °C); variable preservation precluded formal lesion or atresia scoring.

Results and Discussion

Spawning frequency declined from 2.44 ± 1.13 spawnings pair⁻¹ at 28 °C to 1.44 ± 0.88 at 32 °C and 0 at 34 °C ($F = 19.84$, $p < 0.001$; all pairwise comparisons significant). Mean egg production fell from 1806 ± 219.5 to 1236 ± 289.7 eggs, and fertilisation from $84.20 \pm 8.34\%$ to $68.37 \pm 6.73\%$ at 28 and 32 °C, respectively (both $p < 0.05$); no eggs were produced at 34 °C. In contrast, feed intake nearly doubled at 32–34 °C (28.46 ± 1.55 vs 51.09 ± 3.36 and 51.94 ± 2.59 g pair⁻¹; $F = 234.77$, $p < 0.001$), while ventilation increased from 71.4 ± 19.73 to 112.8 ± 11.40 and 111.0 ± 7.85 opercular movements min⁻¹ ($F = 28.28$, $p < 0.001$). Histology showed continued ovarian and testicular development at 32 °C. Notably, some 34 °C fish retained advanced secondary-growth/vitellogenic oocytes or active spermatogenic tissue despite complete absence of bubble nests and spawning. Thus, reproductive failure at 34 °C was not explained by universal arrest of gametogenesis, suggesting disruption of later processes linking gonadal development to reproductive behaviour and gamete release.

Conclusion

Chronic warming produced a graded reproductive decline. Exposure to 32 °C remained functional but suboptimal, whereas 34 °C exceeded the functional reproductive tolerance of broodstock despite retained advanced gametogenic stages in some fish. Reproduction therefore appears to be a sensitive endpoint for climate-resilient broodstock management.

Introduction and methods

Aquaculture organisms are exposed to microplastics (MPs) via feed formulated from contaminated fishmeal, packaging and the degradation of plastic infrastructure. Reported burdens of MPs in farmed salmonids range from $\sim 1.8 \times 10^3$ to 9.4×10^3 MPs fish⁻¹ per production cycle (Wang et al., 2022; Walkinshaw et al., 2022). However, most studies use unrealistically high concentrations and focus on marine species, thereby limiting their relevance to aquaculture. Most importantly, whether MPs translocate to gametes and impair reproductive performance under aquaculture-relevant exposure remains unresolved.

A total of 180 adult (3-year-old) *Salmo trutta* (570 ± 190 g; 38 ± 3 cm) were equally allocated to three treatments (~ 30 kg biomass tank⁻¹): control, low MPs (LMP; $\sim 4.8 \times 10^3$ MPs fish⁻¹), and high MPs (HMP; $\sim 4.9 \times 10^6$ MPs fish⁻¹). Fish were fed polystyrene microplastic (PS-MP)-spiked feed for 4 weeks (0.7–0.8% body mass day⁻¹), followed by commercial feed. Broodstock maturation, PS-MP translocation to gametes, antioxidant responses (superoxide dismutase [SOD], catalase [CAT], peroxidase [POD]), and reproductive outputs (semen volume, fecundity, hatching success) were assessed.

Results and discussion

PS-MPs were detected in both gametes (Fig. A2-3b–c), with higher particle numbers per gram of tissue and detection frequency in eggs than in semen (eggs: $0.53 \times 10^6 \pm 1.13$ PS-MPs g⁻¹; 4/10 fish; semen: $0.27 \times 10^6 \pm 0.59$ PS-MPs g⁻¹; 2/10 fish). In semen, only 1 μ m particles were detected, whereas eggs also contained 5 μ m; no 10 μ m particles were observed in either. These patterns indicate size-dependent translocation, likely driven by differences in gamete structure and retention capacity.

At the physiological level, PS-MPs disrupted antioxidant responses (Fig. d–f), with reduced enzyme activities (μ mol min⁻¹ g⁻¹ tissue) across tissues: semen SOD (Control: 9.76 ± 3.16 ; LMP: 6.79 ± 2.08 ; HMP: 6.59 ± 3.20), and egg CAT (2.35 ± 1.79 ; 0.21 ± 0.35 ; 0.03 ± 0.09) and POD (0.19 ± 0.34 ; 0.11 ± 0.34 ; 0.004 ± 0.004). As key enzymes that form the primary defence against reactive oxygen species, their suppression significantly reduces the ability of spermatozoa and oocytes to mitigate oxidative stress, potentially leading to increased lipid peroxidation, protein oxidation, and DNA damage.

On the other hand, reproductive parameters showed selective effects, with reduced maturation and spawning females in MP treatments (82.1% control vs 54.8% LMP and 45.9% HMP; Fig. g). While all males were spermiating at each assessment, semen volume was reduced by 40.2% in the LMP group compared to the control (Fig. h). However, fecundity (Control: 3505.3 ± 596.0 ; LMP: 3140.2 ± 1016.3 ; HMP: 3532.9 ± 663.6 ; Fig. i) and hatching success (Fig. j–k) did not differ among treatments, likely due to buffering by aquaculture practices.

These findings indicate that small MPs (≤ 1 μ m in sperm; ≤ 5 μ m in eggs) can translocate into gametes and disrupt antioxidant defences, contributing to oxidative stress and sex-specific reproductive effects, without altering overall reproductive output under aquaculture conditions. However, threshold-based analyses (Fig. 1h–k) reveal a higher proportion of broodfish with suboptimal reproductive outputs under MP exposure. Accordingly, salmonid aquaculture is unlikely to be constrained under standard hatchery management conditions, but these effects may become consequential in less controlled environments. In natural systems, where reproduction is unassisted and subject to multiple environmental stressors, such effects may translate into reduced recruitment. Given the increasing use of hatchery-reared fish for restocking, further work is needed to assess implications for wild populations.

Introduction

Viral hemorrhagic septicemia (VHS) causes serious economic loss in olive flounder aquaculture industry in Korea. Oral delivery provides a stress-free method of administration, making it ideal for mass immunization, particularly against infectious VHS, which poses a global threat to aquaculture.

Materials and Methods

In this study, we developed an optimal antigen delivery system using liposome encapsulating method for an oral VHS vaccine of olive flounder (*Paralichthys olivaceus*). Liposomes that encapsulate heat inactivated VHSV antigen, thereby forming microparticles for oral delivery (absorbed in feed) to flounder fingerlings. For the in vivo experiment, fish were injected with phosphate buffer saline (control, group 1) and heat inactivated VHSV (IP, group 2), were fed heat inactivated VHSV (oral, group 3), heat inactivated VHSV encapsulated liposome (uncoated liposome, group 4), heat inactivated VHSV encapsulated liposome and chitosan (coated liposome, group 5). We evaluated the antibody responses (via ELISA), hematological parameters, and the effects of vaccination on the growth and internal structures of flounder fingerlings.

Results

Our finding revealed that the antibody titer was highest at week 1 and that the chitosan coated liposome (group 5) showed a high antibody titer at week 2. Specific antibody titers measured on day 15 post-VHSV infection revealed that the oral liposome administration group exhibited the highest antibody titer. The lowest mortality rate was observed in the uncoated liposome VHSV vaccinated group (33%, group 4), followed by the chitosan-coated liposome group (40%, group 5).

Discussion

Our results suggest that oral administration of a chitosan-coated liposome vaccine represents a promising immunization strategy against VHSV. This method effectively represents a promising immunization strategy against VHSV. This approach effectively protects the viral antigen from digestive degradation, ensures ease of inoculation, and demonstrates excellent stability when administered orally, making it an effective approach for preventing viral hemorrhagic septicemia in farmed fish.

OFFSHORE AQUACULTURE – TECHNICAL DEVELOPMENT OF A COMBINED AQUACULTURE IN THE WESTER BALTIC

Hannawald, Lennart

State Research Institute for Agriculture and Fisheries of Mecklenburg-Vorpommern

Corresponding/presenting: l.hannawald@lfa.mvnet.de

The offshore aquaculture project, which was submitted in 2023 and is funded by European and state funds, aims to develop combined aquaculture in the Baltic Sea. The aim is to promote the spread and economic viability of combined fish and shellfish farming in the Baltic Sea and to gain greater recognition for it. Furthermore, environmental compatibility and economic efficiency are to be evaluated in order to create aquaculture production in the western Baltic Sea off Mecklenburg Western Pomerania that is as sustainable, environmentally friendly, local, and accessible to all as possible. The overall project represents a new approach, as the difficult hydrodynamic and harsh conditions, characterized by high wind speeds and accompanying wave heights, vary greatly in the coastal region of the Baltic Sea, for example, from those in the fjords of Norway. For fish aquaculture, the target fish species is rainbow trout (*Oncorhynchus mykiss*). The target shellfish species that is produced for shellfish aquaculture is the blue mussel (*Mytilus edulis*). Other objectives of the project in the field of fish farming include two separate pen systems that are to be installed and tested in the western Baltic Sea and subsequently stocked with fish. One system, called “The Cage,” is a net-supported system; the other, called “Björn,” is a steel cage shaped like a truncated octahedron. Three different systems were designed and visualized for mussel farming. These include one underwater longline system and two surface longline systems, one of which is a double longline system and the other a single longline system with different types of buoys. In early 2024, all three shellfish systems, as well as the net support system “The Cage,” were designed, visualized, and then hand-built on land. In the end of 2024, all of the constructed systems were transported to the Nienhagen Fisheries Reserve, located in the western Baltic Sea not far from Rostock, and installed there for a tasting phase. In early 2025, two of the three installed mussel farms were lost due to severe winter storms; only the above-water double-line system could be saved. However, the first mussel harvest was lost due to the storms and predators. Because of the difficult conditions throughout 2025, only a single mussel farm was installed during the entire year and was harvested at the end of 2025. In mid-2025, the first fish were stocked into the net carrier system over a three-month period. However, due to predators, half of the stock was lost, so that by mid-2025 only half of the stock could be harvested. After the harvest, the net carriers were restocked with rainbow trout following a net change and harvested at the end of 2025. Both harvests yielded excellent results in terms of both fish biomass and mussel biomass. The total catch weighed approximately 209.1 kg, consisting of 417 trout, resulting in an average weight of 0.5 kg per fish. 7.2 kg of commercially viable mussels were harvested per meter of collector line. Extrapolated to the entire 450-meter double-longline system, this would amount to approximately 3,237 kg of commercially viable mussels. Other results such as fish index and mussel index, were also wide above average. In early 2026, all three mussel systems were reinstalled and equipped with data loggers that record axial movement. Thus, the mussel system with the least axial movement will be the most efficient in terms of losses and, consequently, the most useful and resilient under harsh conditions. For a future project we want to establish a community to pool their knowledge and expertise in order to produce a sustainable blue circular nutrient economy in the Baltic Sea area. Substituting fishmeal with regional mussel protein production to reduces pressure on wild stocks and closes the nutrient cycle, making regional offshore aquaculture circular.

LIGHT PERIOD MANIPULATION IN RAINBOW TROUT PRODUCTION INFLUENCES THE HORMONAL CONTROL OF GROWTH AND GROWTH IN BRACKISH WATER CAGES

Introduction

In a combined RAS (recirculating aquaculture system) and sea cage farming, the fish are first farmed in a RAS and then transferred to sea cages. Using continuous light and feeding is a common practice in RAS. This helps maintain stable water quality, which is crucial for the fish health and the good performance. In contrast, the light conditions in sea cage farming follow natural diurnal and seasonal cycle, affecting fish physiology. For example, although continuous light can result in a higher growth rate in RAS, performance of salmonids farmed under continuous light has been unoptimal after they are transferred to sea (Hänninen et al., 2026; Ytrestøyl et al., 2023). Yet, there is lack of information if various light rhythms in RAS could prepare the rainbow trout (*Oncorhynchus mykiss*) for natural light in the open sea, and how this could affect the hormonal control of fish growth. Therefore, here we investigated 1) do growth and/or hormonal parameters of rainbow trout differ between different light and feeding rhythms in RAS, 2) do different light and feeding rhythms in RAS affect growth and/or hormonal parameters of rainbow trout in brackish water cages, and 3) do growth and/or hormonal parameters of rainbow trout differ between different light rhythms in brackish water cages.

Materials and Methods

Juvenile rainbow trout (7 g) were farmed in RAS at 15 °C under continuous light (LD24:0) and a light rhythm (LD18:6) for six months. The fish were then transferred to brackish water cages located in the Baltic Sea. An underwater light was installed in half of the cages to create light groups with continuous (CL) and natural light (NL). Thus, at the cages we had four groups: 1) LD24:0/CL, 2) LD24:0/NL, 3) LD18:6/CL, and 4) LD18:6/NL. The fish were farmed in the cages for one month to size of approximately 630 g. Sampling was carried out the day before the transfer and after one month in the cages. Length and weight were measured. Based on the fish growth data, the specific growth rate (SGR), the feed conversion ratio, and the condition factor were calculated. Blood samples were taken for haematocrit, haemoglobin, plasma vasotocin (VT), plasma growth hormone, and plasma insulin-like growth factor 1 analyses.

Results

In the first sampling (before transfer), shortening the photoperiod did not have a negative effect on fish growth or hormonal parameters in the RAS. In the second sampling (after transfer), the light rhythm (CL or NL) during the brackish water cage period significantly affected the SGR ($p < 0.001$). However, the light and feeding rhythm during the RAS period, or the interaction between the light rhythms during the RAS and brackish water cage periods, had no significant effect ($p = 0.626$ for both). The SGR was 1.13 ± 0.02 in the LD24:0/CL treatment, 1.02 ± 0.02 in the LD24:0/NL treatment, 1.13 ± 0.02 in the LD18:6/CL treatment, and 1.04 ± 0.02 in the LD18:6/NL treatment. Additionally, we observed that the light and feeding rhythm (LD24:0 or LD18:6) during the RAS period significantly affected the plasma VT levels ($p = 0.050$). Conversely, light rhythm during the brackish water cage period, or the interaction between the light rhythms during the RAS and brackish water cage periods, had no significant effect ($p = 0.108$, $p = 0.368$, respectively). Plasma VT levels were 32.0 ± 8.3 ng L⁻¹ in the LD24:0/CL treatment, 40.5 ± 10.2 ng L⁻¹ in the LD24:0/NL treatment, 47.0 ± 8.3 ng L⁻¹ in the LD18:6/CL treatment, and 73.6 ± 10.2 ng L⁻¹ in the LD18:6/NL treatment.

(Continued on next page)

Discussion

The fish grew equally well in both treatments (LD24:0 and LD18:6) in the RAS, despite previous studies have shown better growth under continuous light (Ytrestøyl et al., 2023). The discrepancy may be due to differences in the duration of the dark period used in the experiments. Light and feeding rhythms applied in the RAS did not affect the growth of rainbow trout in brackish water cage farming, and all groups were able to start growing in brackish water as compared to some previous studies where even negative growth have been detected (Hänninen et al., 2026). However, continuous light and feeding (LD24:0) during the RAS period seem to decrease plasma VT level compared to the light and feeding rhythm (LD18:6) in brackish water cage farming. VT regulates osmoregulation, as well as circadian and annual rhythms (Kulczykowska and Stolarski, 1996). VT levels were expected to behave in the opposite way, since they rise in response to stressors (Gilchriest et al., 2000). Continuous light during the brackish water period seems to increase the growth of rainbow trout, but it does not seem to affect their hormonal parameters. In conclusion, since the fish are transferred in spring when the days are naturally long, there is no need to acclimatise them to the natural light rhythm by adjusting light rhythm in the RAS. However, if the aim is to enhance fish growth in brackish water, providing a more consistent supply of light through underwater light in cages or delaying the transfer could be viable solutions.

Introduction

Disease-related mortality remains a major challenge for intensive shrimp aquaculture, creating demand for functional feeds that support resilience without compromising production performance. Marine-derived ingredients provide bioavailable minerals and bioactive compounds with potential to support physiological and immune functions. This study evaluated a marine-derived mineral ingredient (Marisert) as a functional feed additive for Pacific white shrimp (*Litopenaeus vannamei*).

Materials and Methods

A 28-day 2 × 2 factorial feeding trial compared a control diet containing limestone with a diet containing 0.3% Marisert at 100 and 400 shrimp m⁻². Marisert contained calcium (29.5%), magnesium (5.7%) and an *Ascophyllum nodosum* fraction containing alginate, fucoidan, laminarin, mannitol and polyphenols. Growth, specific growth rate, feed conversion ratio, survival and hepatosomatic index were assessed. Shrimp were subsequently challenged with *Vibrio parahaemolyticus* causing acute hepatopancreatic necrosis disease (AHPND) and white spot syndrome virus (WSSV).

Results and Discussion

Marisert inclusion maintained zootechnical performance, with no significant differences in final weight, specific growth rate, feed conversion ratio or hepatosomatic index relative to controls ($P > 0.05$). Feed conversion ratios remained efficient across treatments (0.781–0.794). Stocking density significantly affected feeding-phase survival, demonstrating the production pressure associated with intensive culture. During the AHPND challenge, Marisert-fed shrimp showed a promising numerical improvement in response relative to corresponding controls, although dietary differences were not statistically significant. The challenge included 15 shrimp per treatment and therefore had limited statistical power. No clear beneficial effect was detected following WSSV challenge.

Conclusion

The study provides proof-of-concept for the potential efficacy of a marine-derived mineral ingredient as a functional shrimp feed additive. At only 0.3% inclusion, Marisert maintained growth and feed efficiency while showing a promising response during bacterial AHPND challenge. These attributes support further evaluation of marine-derived mineral supplementation as a nutritional strategy to improve shrimp resilience and address disease-related production losses in intensive aquaculture. Larger challenge trials are required to confirm the response and quantify its commercial relevance.

Treatment	Final weight (g)	FCR	Feeding survival (%)	AHPND survival (%)
Control 100 m ⁻²	5.17 ± 0.11	0.787 ± 0.019	98.0 ± 2.0	26.7
Marisert 100 m ⁻²	5.17 ± 0.13	0.788 ± 0.002	95.2 ± 6.6	46.7
Control 400 m ⁻²	5.05 ± 0.13	0.794 ± 0.021	67.6 ± 1.7	40.0
Marisert 400 m ⁻²	5.10 ± 0.08	0.781 ± 0.013	67.7 ± 1.6	66.7

NEW LIVE FEED FOR STARTFEEDING OF ATLANTIC COD (*Gadus morhua*) - BLUE MUSSEL EGGS AND BALANUS NAUPLIA

Øyvind J. Hansen¹, Velmurugu Puvanendran¹, Nils Tokle²

¹Norwegian Institute of Food, Fisheries and Aquaculture Research (NOFIMA), Muninbakken 9-13, Breivika, 9019 Tromsø, Norway

Introduction

Codfarming in Norway is revitalized due to sharp declines in wild quotas and successful development of a selective breeding for Atlantic cod. Rearing of Atlantic cod (*Gadus morhua*) larvae relies heavily on the availability of suitable live feed that meets larval nutritional requirements while supporting efficient feeding behavior and survival. Rotifers (*Brachionus* spp.) and artemia (*Artemia salina*) are currently the standard first-feeding organism in cod larviculture, yet their small size, swimming behavior, and nutritional profile may limit larval growth and robustness during early developmental stages. Nauplii of the barnacle *Balanus* spp. represent a potential alternative or supplementary live feed, offering larger prey size, distinct motility patterns, and a naturally marine lipid composition that may better match the feeding ecology of cod larvae. This study evaluates the performance of *Balanus* nauplii and blue mussel eggs (*Mytilus edulis*) compared to rotifers and artemia as live feed, with particular emphasis on growth, survival during and deformities.

Materials and methods

Eggs and sperm were stripped from sixth-generation broodstock originating from the Norwegian National Cod Breeding Program and fertilized according to the program's standard protocol. Five full-sib families were produced, and fertilized eggs from each family were incubated separately in 25 L conical silo incubators supplied with flow-through ambient seawater at 4–5 °C. Quadruplicate tank design was used and the startfeeding tanks had 190 l volume. 15000 larvae per tank were used. Water temperature was then gradually increased from 4–5 °C to 10 °C over a period of 5–10 days (approximately 1 °C per day).

Three different startfeeding protocols were compared. Control 1 was the standard protocol at the National breeding program with rotifers and artemia and late weaning. Treatment 2 (T2) protocol 2 used a combination of rotifers and small *Balanus* nauplia (cryo S) and large *Balanus*(cryo-L) nauplia that replaced artemia and then weaning. Treatment 3 (T3) protocol used blue mussel (cryo Micro) eggs that replaced rotifers and large and small *Balanus* nauplia (Cryo S and Cryo L).

Deformities was measured with x-ray at 180 days post hatch.

Results

Protocol 2 gave higher growth rates, condition factor and myotome heights than protocol 1 and 3. Protocol 1 and 2 had the highest survival at 72 dph. Protocol 1 and 2 had lower vertebral deformities than protocol 3.

Growth. Standard Length (mm) and Myotome height for control, T2 and T3 related to days post hatch (dph).

(Continued on next page)

There were no significant differences between treatments in neck deformities. The control group had control group had lower rate of vertebra deformities than the other treatments. The control group also had lower rates of palatine bone deformities. Other deformities such as vertebrae fusion, lordosis, upper jaw/scull and lower jaw had minor differences between treatments, but severity differed.

Discussion

Balanus nauplia as live feed shows potential to replace traditional live feeds at least partly. These live feeds are also relatively early in their industrial development and improvements in products and protocols are most likely to happen. *Balanus nauplia* production is also interesting as live feed when it comes to securing local value chains in a rapidly changing world. The logistics of the product also raises possibilities for low carbon footprints related to transport. Further development of this new live feed in terms of quality, optimum protocols, carbon footprints, and local value chain security will be important in further research.

CLOSING NUTRIENT CYCLES IN TRADITIONAL CARP POND AQUACULTURE: THE TEICHKREIS PROJECT

Harbach, H.*, Vu, T. H.

Institute for Sustainable Water Systems (inwa)
Hof University of Applied Sciences
Alfons-Goppel-Platz 1
95028 Hof, Germany

*Presenting author: e-mail: harvey.harbach@hof-university.de

Introduction

Traditional carp ponds in Bavaria (Germany) and South Bohemia (Czech Republic) represent one of Europe's oldest aquaculture systems and provide important ecological services beyond fish production, including biodiversity conservation, water retention, and cultural landscape preservation (Leibniz Institute of Freshwater Ecology and Inland Fisheries, 2023). However, these shallow pond ecosystems are increasingly affected by climate change, eutrophication, internal phosphorus loading, and declining dissolved oxygen concentrations during summer, resulting in reduced production efficiency and increasing management costs (Boyd, 2020). While conventional pond management practices, such as winter drainage, have historically mitigated nutrient accumulation, their effectiveness is decreasing due to warmer winters and altered hydrological conditions (Poschlo et al., 2026). The INTERREG-funded **Teichkreis** project investigates whether natural sorption materials can recover excess nutrients from pond water and whether nutrient-enriched materials can subsequently be recycled as agricultural fertilizers, thereby establishing a regional circular nutrient management strategy linking aquaculture and agriculture.

Materials and Methods

Teichkreis is a cross-border collaboration between Hof University of Applied Sciences (Germany) and the University of South Bohemia (Czech Republic), supported by regional aquaculture stakeholder organizations. Four natural sorption materials—zeolite, bentonite, expanded clay, and biochar—are evaluated for their capacity to adsorb ammonium and phosphate under conditions representative of Central European carp ponds. Laboratory batch adsorption experiments are conducted using water chemistry derived from Bavarian and Bohemian pond systems, followed by ecotoxicological assessments to verify fish compatibility. The best-performing materials are subsequently investigated in flow-through column experiments to evaluate adsorption kinetics and breakthrough behaviour under simulated hydraulic conditions. Final validation will be performed under commercial pond farming conditions to assess operational feasibility and nutrient recovery potential. Nutrient-loaded sorption materials will additionally be evaluated for their suitability as recycled fertilizers in agricultural production.

Results

The project is currently progressing through laboratory-scale investigations. Water quality surveys conducted in representative Bavarian and Czech pond systems have established the environmental conditions for experimental testing. Initial work focuses on quantifying nutrient adsorption performance, evaluating material stability, and identifying sorption media suitable for practical application without adverse effects on fish welfare. Early stakeholder engagement involving regional pond farmers confirmed nutrient accumulation, internal phosphorus loading, and seasonal oxygen depletion as major production constraints (Kowalczywska-Madura et al., 2018). The discussions also highlighted strong interest in practical nutrient recovery technologies that can be integrated into existing pond management practices.

Discussion

Teichkreis applies a circular economy approach to aquaculture by considering surplus nitrogen and phosphorus as recoverable resources rather than waste. Instead of continuously removing nutrients throughout the production cycle, sorption materials are intended for use during management events associated with unavoidable nutrient losses, including pond drainage, harvesting, overflow events, and sediment removal. This strategy aims to improve water quality while maintaining pond productivity and recycling recovered nutrients back into regional agricultural systems. By integrating environmental engineering, aquaculture research, and stakeholder participation, the project seeks to develop scientifically validated and practically applicable recommendations for sorption-based nutrient management in traditional pond aquaculture. The outcomes are expected to contribute to climate-resilient pond management and enhanced sustainability of Central European carp farming.

FROM SHEEP TO FOOD: SUSTAINABLE GROWING SUBSTRATES FOR AQUAPONIC CROP PRODUCTION – THE NAWARUN PROJECT

Harbach, H. *, Vu, T. H.

Institute for Sustainable Water Systems (INWA)

Hof University of Applied Sciences

Alfons-Goppel-Platz 1

95028 Hof, Germany

Introduction

Sustainable aquaponic production requires growing media that efficiently regulate water availability, nutrient retention and root-zone conditions while minimizing environmental impacts (Abdul Hamid et al. 2022; Fang et al. 2017). Bio-based materials offer a promising alternative to conventional substrates because they provide physical support, enhance nutrient storage, and contribute to circular-economy principles (Gruda 2019). Among these materials, sheep wool is an underutilized agricultural by-product with high water-holding capacity, high organic matter content, and the potential to act as a slow-release nutrient source (Kovács et al. 2025). However, the suitability of sheep wool-based substrates for seedling production in aquaponic systems has received little attention. Therefore, this study compared rockwool with four substrate formulations containing different proportions of sheep wool and viscose fibers. Tomato, lettuce, and kohlrabi were cultivated in a recirculating aquaponic system, and seed germination, plant growth, and biomass production were evaluated to identify sustainable alternatives to conventional growing media.

Materials and Methods

The experiment was conducted under two growing conditions: a recirculating aquaponic system and a rack-based cultivation system irrigated with tap water. Five substrate treatments were tested, including rockwool as the control and four formulations containing different proportions of sheep wool and viscose fibers. The performance of the substrates was evaluated using tomato (*Solanum lycopersicum* L.), lettuce (*Lactuca sativa* L.), and kohlrabi (*Brassica oleracea* var. *gongylodes*). Seeds were directly sown into substrate plugs and cultivated under the respective growing conditions. Germination, plant survival, shoot growth, root development, fresh biomass, and dry biomass were assessed. Data were analyzed using factorial ANOVA to evaluate the effects of substrate treatment, growing condition, plant species, and their interactions. Statistical significance was accepted at $P < 0.05$.

Results

The study is currently in progress, with experiments being conducted under both aquaponic and conventional rack-based cultivation conditions. Current work focuses on evaluating seed germination, seedling establishment, and early plant growth across different substrate formulations and crop species. In addition, the physical performance of the substrates, including structural stability and water retention, is being assessed to identify formulations suitable for practical application in aquaponic production systems. The generated data will provide the basis for selecting bio-based substrates with the greatest potential to replace conventional rockwool.

Discussion

This study explores the potential of sheep wool waste as a sustainable alternative to conventional rockwool in aquaponic seedling production. Sheep wool, an underutilized agricultural by-product, represents a promising approach to valorising biological waste streams and reducing dependence on mineral-based substrates. The use of these materials supports circular economy principles by transforming agricultural residues into value-added products for aquaponic cultivation (Camilli et al. 2025). In addition, biodegradable substrates may improve the environmental sustainability of aquaponic systems and contribute to more resource-efficient food production (Komorowska et al. 2023). The findings are expected to provide practical guidance for integrating sustainable growing media into future aquaponic and soilless cultivation systems.

Introduction

Many aquatic invertebrates, including mollusks, crustaceans, cnidarians and annelids, may serve as exceptional sources of the essential nutrients, including the long-chain ($\geq C20$) polyunsaturated fatty acids (LC-PUFAs), namely arachidonic acid (ARA, 20:4n-6), eicosapentaenoic acid (EPA, 20:5n-3), and docosahexaenoic acid (DHA, 22:6n-3). While some of the LC-PUFAs contained in invertebrate body lipids derive from dietary input, some aquatic invertebrates have the capacity to inherently synthesize LC-PUFAs from adequate short-chain precursors (Monroig et al., 2022) thanks to the presence of complementary set of enzymes called elongases (Elovl), front-end desaturases (Fed) and methyl-end desaturases (ω x). Polychaetes are arguably the most studied group within the Annelida phylum regarding their LC-PUFA biosynthetic capacity; however, other groups, such as oligochaetes, have been largely overlooked. Focusing on the terrestrial oligochaete *Enchytraeus albidus*, an organism often used as live feed and functional feed ingredient in fish larviculture (Grantland et al., 2025), the present study aims to determine the capacity of *E. albidus* to synthesize LC-PUFAs through the identification and characterization of its enzymatic repertoire of fatty acid elongases and desaturases.

Materials and Methods

To identify the potential elongases (Elovl) and desaturases (Fed and ω x), tblastn searches were conducted against publicly available Transcriptome Shotgun Assembly (TSA) databases from *E. albidus*, using as query known sequences of desaturases and elongases from marine polychaetes. After sequence validation, the putative elongase and desaturase sequences retrieved from *E. albidus* were used as a reference to design primers enabling the amplification of the complete open reading frames (ORFs) by PCR. The PCR template was cDNA prepared from total RNA from fresh worms (pools of three individuals). The PCR products corresponding to the ORFs of the putative elongases and desaturases from *E. albidus* were digested and cloned into pYES2 for functional assays in yeast (see below). Correctness of the ORF inserts in pYES2 was confirmed by sequencing. For the molecular characterization of the encoded enzymes, we compared the deduced protein sequences with other annelid elongases and desaturases, identified conserved domains, and performed a Maximum likelihood phylogenetic tree along with known sequences from multiple invertebrates. For functional characterization, transgenic yeast transformed with the pYES2 constructs containing the *E. albidus* ORF of desaturases and elongases were supplemented with potential fatty acid substrates selected based on currently established LC-PUFA biosynthetic pathways (Monroig et al., 2022). After 48 h, yeast cultures were harvested, and total lipids were extracted for further derivatization into fatty acid methyl esters (FAME). FAMES were analyzed through gas chromatography and mass spectrometry detection (GC-MS), and conversions were calculated using the formula $[\text{product area} / (\text{product area} + \text{substrate area})] \times 100$.

Results and Discussion

Three Elovl, two Fed and two ω x with putative roles in the LC-PUFA biosynthesis were identified in *E. albidus*. Both the elongases and desaturases contained histidine boxes and conserved domains expected for their respective protein family (Hashimoto et al., 2008). The phylogenetic analyses of the three *E. albidus* Elovl sequences clustered closely with well-described elongases from other invertebrates, including annelids, allowing us to classify them as Elovl2/5, Elovl4 and Elovl8. The two *E. albidus* Fed sequences, namely Fed1 and Fed2, were clustered in the so-called “Group A” and “Group B”, respectively. The *E. albidus* ω x desaturases, termed hereafter as ω x1 and ω x2, clustered closely to other methyl-end desaturases from Annelida, within Clade 3 as referred to by Kabeya et al. (2018). Concerning the functional assays, yeast expressing the three *E. albidus* elongases showed activity towards C18 and C20 fatty acid precursors. Regarding desaturases, the *E. albidus* Fed1 exhibited $\Delta 5$ desaturation activity, being able to produce LC-PUFAs like ARA and EPA, while Fed2 showed a combination of $\Delta 6$ and $\Delta 8$ activities. These newfound enzymes displayed similar functions to their homologs found in polychaetes such as *Hediste diversicolor* (Villena-Rodríguez et al., 2025). The assays on the *E. albidus* methyl-end desaturases showed complementary functions. Yeast expressing the *E. albidus* ω x1 was able to convert oleic acid (18:1n-9) into linoleic acid (18:2n-6), confirming this enzyme is a $\Delta 12$ desaturase. The ω x2 showed $\Delta 15$, $\Delta 17$ and

(Continued on next page)

$\Delta 19$ activities, converting a variety of omega-6 substrates into omega-3 LC-PUFAs (e.g., EPA), and exhibiting analogous activities to other methyl-end desaturases of polychaetes like *H. diversicolor* (Kabeya et al., 2020). Collectively, the present investigation demonstrates that *E. albidus* has the complete enzymatic repertoire needed for the *de novo* biosynthesis of LC-PUFAs including ARA and EPA, thus allowing the production of live prey with high nutritional value and eliminating the requirement for exogenous enrichment prior to use as larval feed.

MODULAR PATHWAYS FOR SUSTAINABLE AQUAFEED DRYING

A Haubjerg. Ph.d.^{1*}

¹ Sr. Process Engineer, JBT Marel / Wenger Manufacturing LLC, 15 Commerce Drive, Sabetha, KS

*corresponding/presenting author Anders.Haubjerg@jbtmarel.com

Introduction

Drying typically accounts for more than 60% of the energy demand in aquafeed extrusion, and for most facilities this energy still comes from fossil fuels. As feed mills face pressure to improve sustainability and emissions in aquaculture and prepare for possible carbon regulations, aquatic feed dryers become a natural starting point for decarbonization efforts.

Past attempts at heat recovery have been limited by two persistent challenges: (A) exhaust air is hot, humid, and dust-laden, causing fouling and performance decline in heat exchangers; and (B) conventional energy sinks, mainly dryer make-up air, represent only 10–15% of the dryer’s thermal load due to the main load deployed onto recirculated air inside dryers. To unlock larger savings, both of these source and -sink side challenges must be addressed.

This paper presents a modular approach enabling aquafeed producers to increase heat recovery today while preparing for hybrid or fully electrified dryer operation in the future.

Modular Heat Recovery Pathways and Exhaust Air Pre-Treatment

The challenges of dust-laden air, fouling and lack of heat sinks must be addressed for successful decarbonization of aquatic feed and improving sustainability in aquaculture in general. A dedicated Heat Recovery Unit (HRU) is introduced here. The HRU combines exhaust air cleaning and coil area into a single modular system that can be expanded over time. At the HRU inlet, a rotating drum-filter with suction nozzles removes fine particles from the wet exhaust stream. This step prevents fouling of the heat exchanger coils, stabilizes heat transfer performance, and maintains consistent back pressure towards the dryer. Once the air is cleaned, the HRU can transfer energy into one or more sinks depending on the different integration pathways:

- Preheating dryers make-up air or process water. This provides a straightforward energy efficiency improvement and typically recovers 10-15 % of dryer energy.
- Preheating process water for the feed manufacturing process, including boiler feedwater
- Building- and facility heating,
- Auxiliary water heating, e.g. cleaning water.
- With suitable HRU sizing, integration with high-temperature heat pumps to get to temperatures that allows heating of air *internal* to the dryer. This hybrid approach enables substantial reductions in fossil fuel, and supports future electrification using natural refrigerants

Because the HRU is modular, aquafeed producers can adopt the level of integration that matches their site’s energy demands and investment horizon, starting with basic heat recovery and progressing toward partial or full electrification when conditions are favorable.

Table 1. Example numbers for HRU systems as well as for its integration with the hybrid dryer using high-temperature heat pumps using natural refrigerants.

Dryer @ 1.6 MW 10 tons/h feed 2.1 tons H ₂ O/h	Heat recuperation (HRU)		Hybrid dryer integration
	1 coil bank	2 coil banks	2 coil banks
Particle fines removal	F7	F7	F7
Odor reduction	+	++	+++
Water recovery estim. [kg/h]	350	500	900
Energy recovery [% dryer load]	28 %	53 %	64 %
To dryer [kW]	200	200	1600
Process liquids [kW]	250	250	
Aux. heating [kW]	-	400	
Electrical power [kW]	19	21+	570
ROI [years]	1.5-2.5	1-2	4 - 8

(Continued on next page)

Figure 2. ROI analysis based on a simulation for integration level using hybrid high-temperature heat pump dryer using natural refrigerants and coupled to the dual-coil HRU system. Western Europe.

(Continued on next page)

Performance Outcomes and Decarbonization Potential

The integrated filtration and HRU system significantly increase the recoverable portion of dryer energy, with 28-53% recovery depending on coil configuration. When combined with a high-temperature heat pump using a natural refrigerant, the system can cut energy use by up to 64% and operate with up to 100% electric heat input, offering a practical pathway toward decarbonization of feed for aquaculture.

In parallel, fine-particle removal ($\eta_{F7} \approx 65\%$ of particles below $2.5 \mu\text{m}$) improves air cleanliness and reduces odor, which can be valuable for aquaculture feed plants located near communities or sensitive environments. Water condensation from the exhaust stream also yields 350–900 kg/h of recoverable water, depending on configuration.

Economic modeling shows a solid commercial foundation for HRU-only systems (1-2 years) and medium term and tangible ROIs for hybrid dryer heat pump integration, depending on regional energy prices. The overall pathway enables both immediate savings and long-term readiness for high-efficiency, low-carbon aquafeed production.

Performances for energy recuperation and decarbonization aspects of the different integration levels / solutions is seen in Table 1.

A suitable simulation environment is an important step in screening different markets' decarbonization potential against most viable commercial steps and integration levels. Figures 2 and 3 below are the output of this tool and propose ROIs based on input on dryer sizing, -operating conditions, -temperature setpoints as well residual energy sinks and – not least - local utility costs.

ADVANCES IN EARLY WEANING IN FLATFISH: APPLICATION OF FLUID BED AGGLOMERATION FOR MICRODIET PRODUCTION

Introduction

Early weaning in flatfish species remains one of the main bottlenecks in larval production, due to the high dependence on live feed and the limited efficiency of conventional microdiets. During early developmental stages, larvae possess an immature digestive system, which constrains the digestion of complex ingredients and limits the transition to inert diets. Therefore, the formulation of highly digestible microdiets tailored to larval physiological requirements is critical to improve weaning success (Hamre et al., 2013; Engrola et al., 2018). Extrusion technologies are widely used in commercial microdiet production due to their robustness and scalability. However, feed for early larval stages requires precise control of physical properties such as particle size, water stability, and nutrient leaching, as well as the ability to incorporate sensitive functional ingredients. Fluid bed agglomeration emerges as a promising alternative, enabling enhanced control over particle structure and functionality. This technology facilitates the inclusion of sensitive compounds such as protein hydrolysates, bioactive ingredients, and thermolabile nutrients while preserving their integrity and bioavailability. Protein hydrolysates have been shown to improve digestibility, feed acceptance, and digestive development in marine fish larvae (Kolkovski, 2001; Poonnual et al., 2025). Additionally, fluid bed technology allows optimization of key physical properties such as particle cohesion, water stability, and reduced nutrient leaching, which are essential for maximizing effective ingestion during first feeding and weaning stages. These characteristics position fluid bed agglomeration as a highly suitable technology for the development of species- and stage-specific microdiets. The aim of this study was to evaluate the potential of fluid bed agglomerated microdiets incorporating different protein hydrolysates, compared to commercial extruded diets, using two key aquaculture species: Senegalese sole (*Solea senegalensis*) and turbot (*Scophthalmus maximus*).

Materials and Methods

Two independent trials were conducted under controlled experimental conditions. In the Senegalese sole trial, larvae were obtained from natural spawning and the experiment lasted 21 days. Treatments were performed in triplicate: (1) commercial micro-extruded diet (control); (2) diet D1 produced by fluid bed agglomeration, including low molecular weight hydrolysate “A”; (3) diet D2 produced using the same technology, including higher molecular weight hydrolysate “B”; (4) diet D3 including a hydrolysate with a broad molecular weight range. Fish fed diets D1, D2, and D3 started co-feeding three days earlier than those fed the commercial diet. Dry weight, total length, and weight gain were evaluated. In the turbot trial, larvae were fed from mouth opening for 26 days with different microdiets: one commercial reference diet and two experimental diets (X1 and X2) with different protein hydrolysate profiles. Growth parameters (weight and length), relative growth rate (RGR), survival, feed intake, and feed conversion ratio (FCR) were recorded. In both trials, data were statistically analyzed after testing normality and homogeneity of variances, using parametric or non-parametric tests as appropriate ($\alpha = 0.05$).

Results and Discussion

In Senegalese sole, improved growth was observed with fluid bed agglomerated diets, with lower molecular weight hydrolysates further enhancing performance. In turbot, key parameters such as weight, RGR, survival, intake, and FCR did not differ significantly among treatments at the end of the pelagic phase. However, improved growth was observed during the first 10 days in larvae fed fluid bed agglomerated diets (X1 and X2). Previous studies have shown that protein hydrolysates can enhance palatability and digestibility in marine fish larvae (Kolkovski, 2001; Gisbert et al., 2012). Overall, results from both trials demonstrate that fluid bed agglomeration enables the development of microdiets with performance comparable or superior to conventional commercial diets. This is particularly relevant for larval nutrition, where ingredient composition and physical properties are critical for feed intake and utilization. The ability to design microdiets tailored to specific species and developmental stages positions this technology as a promising tool to improve early weaning efficiency in flatfish aquaculture.

Background

Kelp aquaculture is rapidly expanding globally, mainly because of the diverse applications within food production, cosmetics and pharmaceuticals (Duarte et al., 2022; Kim et al., 2017; Liboureau et al., 2025; Pajot et al., 2022; Rosic, 2019; Stévant et al., 2017; Veenhof et al., 2024; Znad et al., 2022). However, in the nutrient-rich waters of the Northeast Atlantic, upscaling has been limited by complex interactions between abiotic and biotic factors (Førde et al., 2016; Delannoy et al., 2025). The larval or spore forms of organisms such as Bryozoans, Hydrozoans and macroalgae settle on the farmed seaweed fronds and cause biofouling (Bannister et al., 2019). Biofouling leads to substantial direct and indirect negative effects on the kelp, causing physical damage, halting growth, increasing the risk of consumer allergies and ultimately rendering the kelp unmarketable (Bannister et al., 2019; Martínez et al., 2024). For a sustainable Northeast Atlantic kelp farming industry it is thus key to understand the conditions that can predict biofouling timing and inform targeted interventions such as harvest time and optimal farm locations (Førde et al., 2016; Delannoy et al., 2025). Standard machine learning or statistical approaches are not sufficient to model the complexity of this system, which is characterised by complex interactions, time lags, confounding factors and non-linearity (Palaikostas, 2021; Utku, et al., 2025). In this study, we applied a causal inference framework, leveraging field data, to enable a mechanistic exploration of biofouling drivers as well as predictions under anticipated scenarios of environmental change.

Approach and preliminary findings

Samples were collected from ten kelp farms located across the United Kingdom, Norway, and Sweden from December 2024 to current day. At each farm, five sampling sites were established, where kelp blade, water, plankton, and environmental data were collected. Water and plankton samples were analysed at the Laboratory of Marine Diagnostics and Biotechnology, University of Glasgow, while kelp samples were processed for growth and biofouling metrics at the Marine Biological Association (MBA), Plymouth. Water samples were analysed for key water-quality parameters, including salinity, phosphate, nitrate, nitrite, and chlorophyll-*a* concentrations. Plankton samples were collected via net tows and examined microscopically to quantify phytoplankton species abundances (cells L⁻¹) and zooplankton class abundances (individuals m⁻³). Environmental and climatic variables, including sea surface temperature (SST), light availability, and current velocity, were obtained from Copernicus Marine Service and Open-Meteo datasets and calibrated using in situ logger measurements.

Descriptive analysis revealed substantial variation of environmental conditions across farms, particularly in nutrient levels, as well as seasonal shift among plankton communities. To investigate true environmental drivers of biofouling, a directed acyclic graph (DAG) was developed to formalise hypothesised causal relationships between environmental conditions, biological communities, and biofouling intensity. Gradient boosting machine (GBM) models were subsequently applied to evaluate predictor importance, identify optimal temporal lags, reduce model complexity, and inform refinement of the causal model.

(Continued on next page)

At the first stage of our analysis, we focussed on developing a taxon-specific causal model for bryozoan biofouling. Parameter estimates derived from this model were then used as informative priors within a broader whole-system framework encompassing six major epibiont groups: Amphipoda, Ascidia, Bivalvia, Bryozoa, Hydrozoa, and epiphytic macroalgae. This hierarchical approach facilitates the integration of taxon-level processes into a comprehensive model of biofouling dynamics in seaweed aquaculture.

The ultimate objective is to incorporate the causal framework into an interactive decision-support platform for seaweed farmers. The platform will allow users to input site-specific environmental conditions and management interventions and receive evidence-based, causally informed recommendations to optimise farm productivity and mitigate the impacts of biofouling.

NOTES ON A NEOTROPICAL MIGRATORY FISH: SÁBALO

Éver Edrey Hernández Cuadrado^{1*}

Departamento de Sanidad Animal
Facultad de Medicina Veterinaria y Zootecnia
Universidad del Tolima, Colombia

*corresponding/presenting ecuadra@ut.edu.co

Introduction

Native migratory fish species exhibit high mortality rates in the early stages of embryonic and larval development, making it important to study the early ontogeny of fish species of commercial and scientific interest (Adakebaike *et al.*, 2025). One of these native species of great economic and ecological importance in Brazil is the curimba (*Prochilodus lineatus*). It is a migratory species whose populations are threatened due to habitat deterioration, dam construction, and uncontrolled extraction. Furthermore, because it needs the stimulus of migratory environmental factors, its reproduction in captivity is problematic and must be artificially induced. This review aims to analyze the effect of certain factors, such as photoperiod, on the embryonic and larval development of *P. lineatus* in captivity, as well as the characteristics of water on sperm activation, taking into account the concept of phenotypic plasticity, with the goal of improving survival in both stages of development of the species.

Migration environment, sperm, larvae, and adaptation

Among the most important factors in migration and reproductive processes are photoperiod and gamete quality. In the latter, sperm motility is one of the fundamental aspects to study in order to improve fertilization and the production of quality embryos and larvae. In this sense, some studies have been carried out on the early stages of curimba ontogeny under natural photoperiod conditions, on the fertilizing capacity of semen and sperm morphology and on some ecological aspects. The larval stage has received less attention and the effects of changes in photoperiod on its development and growth are poorly understood. The compiled data indicate that there is growing interest in the study of gametes in native spawning species in Brazil and South America, particularly in the methodologies of cooling, freezing, and sperm quality assessment. In the case of curimba, these initiatives emerged mainly in the 1990s, with a progressive increase in the last decade.

Reports on the duration of sperm motility in this species have been similar to those reported for most teleosts, ranging from a few seconds to approximately three minutes. A prolongation of sperm motility in curimba or any other species would aid in the study of sperm physiology and could contribute to the creation of low-cost technological packages for the production of quality embryos, larvae, and fry. Similarly, the use of changes in light:darkness regimes has raised great expectations, as it has been proven to accelerate or delay reproduction and embryonic and larval growth and development rates in many fish species (Cowan *et al.*, 2024). However, there is a lack of information on these aspects in many Brazilian species of piracema, including *P. lineatus*. Thus, there is a need for research in which certain environmental factors, such as sperm activation solutions and photoperiod, are manipulated to improve curimba production in the early stages of its life cycle. Due to the nature of this research, the studies should be approached from the perspective of phenotypic adaptation or phenotypic plasticity of the biological model studied.

SOME ASPECTS OF THE ECOPHYSIOLOGY OF REPRODUCTION IN CURIMBA (*Prochilodus lineatus*)

Éver Edrey Hernández Cuadrado^{1*}

Departamento de Sanidad Animal
Facultad de Medicina Veterinaria y Zootecnia
Universidad del Tolima, Colombia

*corresponding/presenting ecuadra@ut.edu.co

This review aims to understand the effects of different photoperiods on the embryonic and larval development of curimba (*Prochilodus lineatus*) in captivity, as well as the implications of the composition of activation solutions on sperm motility, taking into account the concept of phenotypic plasticity, with the goal of improving production in this ontogenetic phase of the species.

Phenotypic Plasticity

Phenotypic plasticity (PP) is considered a general phenomenon where individuals modify their phenotypes in response to environmental signals, usually to adapt to changing environments. The reproductive strategies of teleost fish are very diverse, a phenomenon not evident in other vertebrates (Bose et al., 2025), but in most cases, eggs and sperm are developed separately by females and males in different modes and conditions of reproduction. Thus, migratory fish need the stimulus of river dynamics for the development of their reproductive system and gametes, and therefore, in environments with distinct characteristics, their reproduction is not possible or presents some difficulties that must be overcome. Among the migratory fish of Brazil is *P. lineatus*, a species distributed in the Paraná-Paraguay and Paraíba river basins, and of great economic and ecological importance among native medium and large-sized species. Its populations have been declining mainly due to commercial activities. There are also factors that can threaten fish populations, such as overfishing, habitat decline and alteration, and variations in water quality where these fish develop. Therefore, in vitro reproduction is of great importance in fish farming programs. Knowledge of the reproductive physiology of freshwater fish is still limited (Heins & Brown-Peterson, 2022), which is applicable to the circumstances of many neotropical countries. In conclusion, research is needed to determine the effect of activating solutions with different characteristics on fertilization and early ontogenetic development of *P. lineatus*. Likewise, it is important to study the development and growth patterns of the species under different environmental conditions, particularly photoperiod. The results that can be achieved in these future studies can be of great help in optimizing technological packages aimed at improving fertilization processes and the management of curimba embryos and larvae in captivity, taking into account PP.

Introduction

The accumulation of CO₂ in the ocean causes acidification (Caldeira et Wickett 2003) and poses a significant challenge to calcifying organisms (Figuerola et al. 2021), threatening the sustainability of shellfish farming. One potential solution is to remove CO₂ by cultivating macroalgae. Through photosynthesis, macroalgae consume CO₂ to produce organic matter and oxygen in the presence of light. The co-cultivation of macroalgae and shellfish is already well established in other parts of the world, and several studies have emphasized the potential of macroalgae to mitigate the effects of acidification (Han et al. 2017; Wahl et al. 2018; Young et al. 2022; Gobler et al. 2026). However, the development of this practice in Europe using local species remains insufficiently explored. We therefore conducted complementary laboratory co-culture experiments to evaluate how this nature-based solution can mitigate the harmful effects of acidification on the Pacific oyster (*Magallana gigas*).

Materials and Methods

First, we defined the amount of macroalgae biomass required to offset the effects of acidification on oyster growth. We then compared the ability of three species of macroalgae to mitigate these effects: the red macroalgae *Palmaria palmata*, the brown macroalgae *Saccharina latissima* and the green macroalgae *Ulva sp.*, which occur naturally in Brittany and are of interest for aquaculture. Finally, we evaluated the effect of *P. palmata* on oyster growth and resistance to ostreid herpesvirus type I (OsHV-1) exposure. All tests were conducted in an open flow setup under conditions similar to those in the natural environment.

Results

Our results show that oyster growth is optimized under acidified conditions when the biomass of macroalgae is twice that of shellfish. Oyster growth under acidified conditions is higher in presence of *P. palmata* and *S. latissima* than with *Ulva sp.* or without macroalgae. Under ambient conditions, presence of macroalgae can reduce oyster growth, possibly due to significant diurnal variations in pH and dissolved oxygen levels. Finally, the presence of algae has no influence on survival of oysters exposed to OsHV-1, regardless of the acidification conditions.

Discussion

This study provides new insights into the mitigation potential of European species of macroalgae co-cultivated with oysters, consistent with previous studies (Han et al. 2020; Wahl et al. 2018; Young et al. 2022; Young et Gobler 2018) oyster and seaweed. The effect of macroalgae on oysters may depend on various factors, including the biomass ratio and the species selected. The 2:1 ratio should be considered optimal within the constraints of our experimental setup. In small tanks, higher macroalgal biomass may induce self-shading and reduce photosynthetic performance. The species-specific effects of macroalgae on seawater parameters, such as pH and dissolved oxygen, may have contrasting impacts on oyster growth. Daily pH fluctuations driven by photosynthesis can influence calcification and growth depending on the photoperiod in *Mytilus edulis* (Wahl et al. 2018). These daily oscillations may explain why oysters grew better without macroalgae under ambient conditions but not under acidified conditions. Dugeny et al. (2022) demonstrated that macroalgae influenced oyster microbiota composition, which in turn, affected survival after OsHV-1 exposure. Although there was no significant effect of macroalgae on survival after OsHV-1 exposure, the potential impact on the microbiota will be investigated in future analyses. Our results suggest that macroalgae can provide a chemical refuge for calcifying species under ocean acidification.

Introduction

Nephrocalcinosis in Rainbow trout is a well-known problem in Norwegian fish farming¹ and considered the most important problems in the freshwater stage². With increasing production and use of new production systems, the need for new, non-invasive or non-lethal diagnostic methods such as radiography³ and ultrasound is emerging, to give consistent evaluations and diagnostics. Now a variety of scoring systems and methods are used for nephrocalcinosis assessment, and their respective strengths and limitations are not fully understood.

Material and methods

A total of 777 Rainbow trout were examined using radiography and macro scoring to assess nephrocalcinosis severity. A subset of 24 fish were selected for histological examination, widely regarded as the reference method for assessing renal pathology in nephrocalcinosis. The three methods evaluated were: radiography (detection of mineral deposits throughout the kidney), macro scoring (gross pathological changes on the kidney surface), and histology (cellular-level characterisation of renal pathology).

Results and discussion

Agreement between methods was highest in moderate to severe cases of nephrocalcinosis. In low-grade cases, histology revealed structural changes that were not consistently detected by radiography or macro scoring. Notably, some of the histologically most severe cases showed low radiographic and macro scores. These kidneys were characterised macroscopically by fibrosis and altered texture and colour, and histologically by extensive tissue damage, including loss of interstitial tissue with key roles in haematopoiesis, immune function and hormone production.

These findings indicate that the different diagnostic methods capture distinct aspects of nephrocalcinosis, with radiography reflecting mineral burden, macro scoring reflecting superficial structures and histology revealing structural tissue damage. The results further suggest that current macro scoring systems may benefit from including additional descriptors such as texture, contour and colour in order to better reflect chronic pathological changes.

THE PARADOX OF NUTRIENT EMISSIONS IN NORWEGIAN FJORDS: THE PROBLEM IS TOMORROW, NOT TODAY

Hjøllo^{1*}, S.S., Husa¹, V., Skogen¹, M.D.

Institute of Marine Research

Bergen, Norway

*corresponding/presenting Solfrid.hjollo@hi.no

Main message

- Aquaculture is the largest anthropogenic source of nitrogen and phosphorus to the Hardangerfjord.
- Monitoring data show good to very good environmental status for nutrients and chlorophyll.
- Model simulations show that increased aquaculture production can significantly increase primary production in some fjord areas.
- Absence of observed effects does not mean that the system has the capacity for further growth.

Background

In the Hardangerfjord at the western coast of Norway, annual aquaculture production is over 100,000 tons of salmon and is the largest anthropogenic source for excess nutrients. Environmental impacts of aquaculture are a major public concern in Norway, despite monitoring tells a different story: in 2024, seven of eight dissolved nutrients monitoring stations and all seven chlorophyll-*a* monitoring stations were classified as having very good ecological status (Figure 1). A management question arises: does good ecological status indicate remaining environmental capacity, or does it merely describe current conditions?

Results and discussion

Remaining spare capacity for aquaculture production in the Hardangerfjord was assessed. Spatial varying annual primary production responses due to excess nutrients release were calculated with the ecosystem model NORWECOM.E2E (Hjøllo et al 2025). We compared a reference simulation without excess nutrients from aquaculture to 3 simulations using i) current aquaculture production (Figure 2 A), ii) current + planned increase in production (Figure 2B) and iii) doubled production. Corresponding nutrients were released at sites reporting production in 2024. Modelled responses (Figure 2A) show good ecological status today, with no widespread nutrient enrichment observed, although spatial hotspots emerge. Increased phytoplankton production under scenarios ii and iii indicated increasing risks for eutrophication in both the main fjord and the sidefjords.

In summary, the Hardangerfjord monitoring says: “Everything looks fine”, while modelling says: “Not for much longer”. Environmental monitoring is designed to detect impacts, not to quantify remaining carrying capacity. Recently, the management authority for aquaculture production (County Governor of Vestland) challenged indicator-based regulation of aquaculture nutrient emissions. All applications for further production increase in the Hardangerfjord were turned down based on negative trends in some monitored environmental parameters (e.g., macroalgae and oxygen) (Pedersen et al 2025), which together with the expected continuation of climate change impacts, is likely to reduce the Hardangerfjord’s capacity to receive and assimilate additional emissions. The County Governor therefore concluded that a rise in aquaculture production is not sustainable. In many areas of environmental management, including climate adaptation and natural hazard management, decisions are routinely based on projected future risk rather than waiting for observable ecological deterioration. Should aquaculture management take the same pre-cautionary approach?

Introduction

Phosphonates, compounds with carbon-phosphorus bonds, are common in the marine environment and can be used as source of cellular phosphorus (P) in bacteria through the action of several hydrolytic enzymes (PhnA (McMullan & Quinn, 1992), PhnX, PhnW, PhnY, PhnZa (McSorley et al., 2012), and PhnZc (Gama et al., 2016). The recent discovery of homologous genes in eukaryotes has raised questions about whether photosynthetic and heterotrophic protists can obtain P using similar enzymes, particularly in P-limited environments. This study investigates the functional expression and regulation of these genes under phosphorus limitation to better understand their potential roles in nutrient stress adaptation and their impact on marine primary productivity.

Material and Methods

Saccharomyces cerevisiae was used as a heterologous expression system to evaluate the functionality of phosphonate-degrading enzymes from *Perkinsus marinus* and *Effrenium voratum*. The *phnA* and *phnYc-phnZc* genes were expressed from episomally replicating plasmids or integrated at defined genomic loci via homologous recombination. Genes of interest were fused to GFP or Myc tags for localisation and expression analyses. Growth assays using phosphonoacetate and methylphosphonate as sole phosphorus sources were monitored by optical density (OD₆₀₀) measurements. Constructs lacking the mitochondrial targeting presequence were generated to assess mitochondrial localisation. Phosphonate utilisation was further evaluated in native phytoplankton species harbouring *phn* pathways using flow cytometry-based growth measurements. *E. voratum* harbouring *phnYc-phnZc* and *Gephyrocapsa huxleyi* harbouring *phnZY* pathways were grown with methylphosphonate and 2-aminoethylphosphonate (2-AEP) as phosphorus sources, with flow cytometry data analysed using FlowJo.

Results

Yeast strains expressing episomal *phnA* and *phnYc-phnZc* constructs exhibited restored growth on phosphonoacetate and methylphosphonate, demonstrating the ability to utilize phosphonates as a phosphorus source. This phenotype was absent in strains lacking the mitochondrial targeting presequence, indicating that mitochondrial localization is required for pathway functionality. GFP-tagged proteins showed colocalisation with MitoTracker staining, confirming mitochondrial localisation of *phnA*, *phnYc-phnZc*, and additional pathway-associated proteins (PhnX, PhnW, PhnY, and PhnZa). Flow cytometry-based growth assays in *E. voratum* harbouring the *phnYc-phnZc* pathway and *G. huxleyi* harbouring the *phnZY* pathway further confirmed phosphonate utilisation in marine phytoplankton. Growth was supported using methylphosphonate and 2-AEP as phosphorus sources, demonstrating that these pathways enable phosphonate degradation and contribute to phosphorus acquisition beyond the heterologous yeast system.

Discussion

This study provides novel insights into the functional capacity of marine protists to access alternative phosphorus sources through phosphonate metabolism. The restoration of growth in yeast expressing *P. marinus* and *E. voratum* phosphonate-degrading enzymes demonstrates that these pathways are functional and highlights the importance of correct subcellular targeting for phosphonate utilisation. The requirement for mitochondrial localisation suggests that phosphonate degradation involves specialised intracellular processes that enable access to alternative phosphorus sources under nutrient-limited conditions. The identification of functional phosphonate metabolism in both a parasitic protist (*P. marinus*) and phytoplankton species (*E. voratum*, *G. huxleyi*) expands our understanding of the diversity of organisms capable of utilizing phosphonates. Furthermore, validation of phosphonate-supported growth in native phytoplankton demonstrates that these pathways can contribute to phosphorus acquisition beyond a heterologous expression system. These findings reveal a previously unrecognised strategy among diverse marine protists for exploiting alternative phosphorus sources, with potential implications for nutrient availability and microbial interactions in marine ecosystems. Understanding the distribution and function of these pathways provides new perspectives on how aquatic microorganisms respond to changing nutrient regimes and highlights the importance of incorporating microbial eukaryotes into models of marine phosphorus cycling and ecosystem resilience.

PREDICTING MUSSEL GROWTH USING ENVIRONMENTAL VARIABLES AND TWO MODEL APPROACHES

N. Hoefnagel^{1*}, Jacobusse G.², Silva Mendonça I.², Capelle J.³, Hartog E.³, Jacobs, P.¹

¹ Research Group Aquaculture in Delta Areas, HZ University of Applied Sciences, The Netherlands

² Research Group Data Science, HZ University of Applied Sciences, The Netherlands

³ Wageningen Marine Research, Yerseke, the Netherlands

*corresponding author: k.n.hoefnagel@hz.nl

Introduction and methods

Aquaculture can contribute to the worldwide demand for sustainably produced protein. With a yearly production of around 400 million kg in the European Union, the blue mussel (*Mytilus edulis*) is commercially important. New production areas need to be sought to upscale production and current areas might be used more efficiently. Computer models relating mussel growth to environmental variables such as food availability and temperature help understand the spatial and temporal variation in observed mussel growth.

Large scale, high resolution environmental data (chlorophyll-*a* concentration as proxy for food quantity, total suspended matter as modifier for food quality, irradiance, and temperature, all measured near the sea surface) were obtained from remote sensing (Sentinel-3 satellites). Models were trained and validated with a set of standardized measurements of monthly weight increment (grams total individual wet weight) of mussels on 12 mussel aquaculture plots in the Eastern Scheldt area, The Netherlands. These measurements were repeated yearly from 2018 to 2022.

Two model approaches were applied: (1) a data-driven (DD) model to find correlations between environment and measured mussel growth, unconstrained by forced relationships, and (2) a mechanistic Dynamic Energy Budget (DEB) model based on theoretical relationships between environment and physiology. Both models generated predicted weight-over-time series for a growing season (April – November) for the 12 locations in the Eastern Scheldt for several years. The models were trained and validated with leave-one-out cross validation whereby the location-year combination for validation is always different from the locations and years used for model training.

Results and Discussion

Comparing a data-driven (DD) model with a Dynamic Energy Budget (DEB) model yielded valuable insights in how blue mussels (*Mytilus edulis*) respond to their environment. The DD model was severely hindered by seasonal confounding of explanatory variables. Seasonal patterns in irradiance, sea-surface temperature and growth of the mussels were highly consistent across locations and all coincided with seasonal variation in growth. Consequently, the DD model was not able to distinguish between their effects. Contributions of chlorophyll-*a* concentration and total suspended matter were not statistically significant for the DD model, even though some unexpected correlations were revealed in the data. DD model predictions for the validation data were not significantly correlated to observed growth.

The DEB model was able to produce a small, but significant positive correlation between predicted growth and observed growth. This correlation was mainly due to variation in chlorophyll-*a* concentrations as spatial variation in temperature in the Eastern Scheldt is limited. Some of the spatial and temporal variation in observed mussel growth might be explained better after inclusion of another proxy for food quantity than chlorophyll-*a* (e.g. primary production), or a more appropriate proxy for food quality (e.g. species composition). Extrapolating temperature effects to novel locations with, for example, lower temperatures, may allow scenario testing for translocating mussels to promising new aquaculture locations.

ADVANCING COMPETENCE IN RECIRCULATING AQUACULTURE SYSTEMS FOR THE NORWEGIAN ATLANTIC SALMON INDUSTRY

Introduction

The rapid expansion of Recirculating Aquaculture Systems (RAS) in the Norwegian Atlantic salmon (*Salmo salar*) industry has created a critical demand for specialized technical and biological expertise. To address this “competence gap,” the life-long learning course in RAS biology was established as a collaborative effort between academia, research and industry partners to provide advanced training for professionals already working within the sector.

Methodology

The course is structured around three intensive physical gatherings focusing on four main topics: the first gathering on RAS technology, the second on microbiology and water quality, and the third on fish health and welfare. The pedagogical approach combines lectures from international and national experts with hands-on laboratory work, including welfare scoring (Nilsson et al., 2025), and microbial and water chemistry analysis. Lab work is reported in the form of a lab journal. Each gathering includes visit to a commercial RAS facility. Relevant “case studies” from everyday operation of commercial RAS are discussed in groups and in plenum. Between the physical meetings, digital seminars with equipment suppliers, salmon producers, researchers and feed manufacturers are organized to ensure a holistic understanding of the RAS value chain. After each gathering the participants are given assignments related to the topic discussed at the gathering, which is presented orally and is a part of the final exam. The course is given once per year, provides 15 study points and is limited to maximum 15 participants.

Results and Discussion

Since 2023, the program has successfully arranged three courses and trained over 30 participants from salmon producers, including Mowi, SalMar, Lerøy Aurora, Grieg Seafood, Arnoy Laks, Astafjord Smolt and Elvevoll Settefisk. In addition, staff from Tromsø Aquaculture Research Station and lecturers from the Vocational college in the North participated in given courses. This course provided a platform for networking that allows for the transfer of best practices across companies, reducing the risk of common operational pitfalls. Participants received state-of-the-art knowledge about salmon production in RAS and were able to see chosen technical and management solutions at other commercial sites. Preliminary results suggest that this targeted continuing education model significantly enhances the operational reliability of commercial RAS facilities in Norway.

Course evaluations and oral exam presentations demonstrate a clear increase in participants’ understanding of key RAS challenges, including system–biology interactions, microbial management, water quality control, and welfare indicators in intensive production. Participants reported increased confidence in interpreting water chemistry and microbiological data, applying welfare scoring tools, and critically assessing technical and operational solutions in their own facilities. Exposure to multiple commercial RAS sites and contrasting management strategies enabled participants to benchmark practices and reflect on how design and operational choices influence fish health and biological performance.

The course also functioned as a professional networking arena, facilitating the transfer of best practices across companies and regions. Group-based case work based on real operational challenges stimulated learning and highlighted common risk factors in RAS operation, such as biofilter instability and system start-up phases.

Overall, these results suggest that a structured, practice-oriented continuing education model can contribute to strengthening operational robustness and biological competence in commercial RAS facilities. The course framework provides a scalable template for future life-long learning initiatives aimed at supporting sustainable growth of land-based salmon production in Norway.

Introduction

In Japan's aquaculture industry, feed amounts, feeding times, and feeding frequencies are set daily by farmers' experience and judgment based on the season and rearing conditions. These parameters are almost always determined personally based on visual observations and the experience of the workers. Therefore, a key challenge is to establish a technology that can objectively and quantitatively evaluate fish activity automatically and contribute to the determination of feeding parameters. While there are numerous technologies for measuring fish activity based on behavioral parameters (Kawabe et al., 2003; Sasaki et al., 2024), given practical constraints, the simpler and more robust the method, the better. Therefore, in this study, we focus on a tail beat frequency, which correlates with the fish's swimming speed (Bainbridge, 1958), and propose a method for non-invasively measuring the tail beat frequency using a single optical camera. We applied image processing and machine learning techniques to video obtained from a single optical camera to extract feature points on the fish's body and automatically measure the tail beat frequency based on the time-series changes in their positions.

Materials and Methods

In a circular submersible fish cage (30 m in diameter) located in the southern part of the Japanese archipelago, where yellowtail (*Seriola quinqueradiata*) are farmed, a camera was installed in the surface layer of the fish cage, oriented toward the bottom of the net. Using this camera, we recorded the swimming behavior of yellowtail during and around feeding times. We continuously performed object detection using YOLOv8 (Jocher et al., 2023) and video segmentation tracking using SAM2 (Ravi et al., 2025) on the acquired video to obtain time-series data on the coordinates of the yellowtail's caudal fin within the frame. We also manually tracked the caudal fins of the yellowtail in the footage and compared the results with those from the AI-based automatic measurements.

Results

Figure 1 shows a representative example of AI-based automated tracking. In this monitoring experiment, approximately one hour of video footage, including the feeding period, was recorded. Both manual and automated measurements showed that tail beat frequency increased at the onset of feeding and then gradually decreased toward the end of the feeding period.

Discussion

Although the results of manual and automated measurements generally showed similar trends, while AI-based automated measurement could process a very large number of samples, errors at each stage of the analysis tended to accumulate, leading to greater variability in the output values. Furthermore, it was confirmed that the swimming behavior observed varied depending on the camera's position within the fish cage. It is thought that the closer the camera is to the center of the cage—near the area where feed is dropped—the higher the observed activity level.

This study demonstrated that AI-based automatic analysis can capture the trend of increased the tail beat frequency during feeding. Taking into account the areas for improvement identified in this experiment regarding analytical methods and operational implementation in real environments, we plan to address these improvements to enhance the calculation speed and reduce errors in AI-based automatic measurements.

Pacific oyster mortality syndrome (POMS), caused by Ostreid herpesvirus-1 (OsHV-1), represents one of the most significant threats to global oyster aquaculture. Our research group has recently demonstrated that oysters are amenable to immune priming, supporting the potential for vaccination-based approaches. Autogenous vaccination therefore offers a promising strategy to confer protection, yet the host immune mechanisms underlying vaccine-induced protection remain poorly understood. Here, we evaluated the protective efficacy and host transcriptional basis of immune priming in *Crassostrea gigas* using heat-treated and live OsHV-1 vaccines across two temperature conditions, combining survival analysis with whole-transcriptome profiling.

All vaccinated groups showed significantly improved survival following OsHV-1 challenge compared to unvaccinated controls, with relative percent survival values of 76.2% and 85% for a heat-treated vaccine delivered at 22°C and a live OsHV-1 vaccine delivered at 18°C. Vaccinated oysters also showed markedly reduced viral loads and lower OsHV-1 viral transcript abundance following challenge compared to unvaccinated controls, with the live OsHV-1 priming group exhibiting significantly lower viral DNA concentrations in moribund oysters ($p = 0.001$), collectively indicating effective suppression of viral replication in primed animals. Transcriptome profiling across 51 samples revealed temporally dynamic and treatment-specific transcriptional responses. During priming, the live vaccine group mounted an earlier response (1,167 differentially expressed genes, DEGs, at 1 dpp vs. 537 in the heat-treated group), whereas the heat-treated group exhibited a substantially amplified peak response of 3,908 DEGs at 4 dpp. Following viral challenge, the unvaccinated positive control showed the largest transcriptional response, peaking at 879 DEGs at 4 dpc and remaining elevated at 316 DEGs by 12 dpc, while both vaccinated groups resolved to 45 and 82 DEGs by the same timepoint.

These quantitative differences revealed that the two vaccine formulations engaged distinct molecular entry points into the host immune response. Live OsHV1 rapidly activated RLR/MAVSlike antiviral pathways and interferonstimulatedlike transcriptional responses within 1 day postpriming, consistent with direct recognition of viral nucleic acid, whereas the heat-treated group triggered a delayed but markedly amplified remodelling of proteostasis networks, ubiquitin–proteasome machinery and intracellular trafficking at 4 days postpriming. Upon subsequent viral challenge, the live vaccine group showed strong early upregulation of DNA replication and cell cycle modules, including genes most similar by orthology inference to replication licensing factors MCM2, MCM4 and MCM7, and DNA polymerase epsilon—consistent with expansion of the haemocyte compartment—alongside IFI44Lfamily and DHX58/LGP2like antiviral response genes. In contrast, unvaccinated oysters sustained a prolonged interferonstimulatedlike response characterised by upregulation of interferonstimulatedlike genes and dsRNA sensorfamily genes, alongside BIRC2like inhibitor of apoptosis genes, persisting through 12 days postchallenge without resolution. These findings demonstrate that autogenous OsHV-1 vaccination reconfigures rather than suppresses the host transcriptional response to viral challenge, providing a functional transcriptional basis for vaccine-induced resilience against POMS and supporting the development of autogenous vaccination as a viable biocontrol strategy for oyster aquaculture.

Introduction

In most European fishponds culturing cyprinids, natural food and supplemented cereals such as wheat is the business as usual. The protein and indispensable amino acid (IAA) quantity x quality of natural food webs fluctuate seasonally. The carp growth, N:P retention or excretion decisions are at the mercy of that, ranging from very good to very bad across the vegetative season. The supply-demand dynamics of some critically limiting IAAs such as lysine (LYS) and methionine (MET) remain poorly understood, as part of nutritional ecology of aquaculture ponds. It is not only the case of European fishponds, but also a globally relevant question. The present study had two objectives. *Pre-trial*: to develop a model of supply-demand of LYS and MET under traditionally grain-fed (<10% CP) or other low-protein pellet-fed ponds (<25% CP). *Main-trial*: to develop and test a precision-balanced pond feed (at the threshold of protein feed nomenclature, *i.e.*, 30% CP) that solves the supply-demand gap of LYS-MET in ponds through a carp nutritional bioenergetics assay and simultaneous validation in pond for proof-of-concept.

Materials and Methods

Pre-trial: Two groups of ponds were selected (Group-A, n=3 ponds: fed by wheat alone, 10% CP during April–October; Group-B, n=6 ponds: fed by wheat during April–June and low-protein plant-pellet 23% CP during July–October, either by hand or demand-feeder) at the Faculty of Fisheries and Protection of Waters research station, Vodnany stocked with stocked with 2+ age *Cyprinus carpio* (384.82±3.47 g; 471 kg ha⁻¹; 1183±23 individuals ha⁻¹). Monthly plankton consortia samples were collected from nine earthen experimental ponds (0.16 ha area, 0.8 m depth), using a 200 µm-mesh plankton net (mimicking branchial sieve minima of common carp >200 g), lyophilized, and stored at –20 °C. Samples were hydrolyzed using two procedures: acid hydrolysis (6 M HCl, 108 °C, 23 h) for total AAs, and oxidative hydrolysis (formic acid/H₂O_{ss} followed by 6 M HCl, 120 °C, 23 h) for cysteine and methionine. After evaporation and reconstitution, AAs were separated by ion-exchange chromatography on an AAA 500 analyzer with post-column ninhydrin derivatization and photometric detection at 570 nm and 440 nm.

Main trial: precision pond feed (31% CP) was formulated in WinFeed using 70% LOCB (low-opportunity-cost-biomass, comprising corn DDGS, rapeseed expeller meal, sunflower expeller meal, and <5% freshwater fishmeal from fish processing) and 30% human feed-food conflict ingredients (such as wholewheat meal and rapeseed oil). The IAA profile was carefully calibrated using crystalline L-lysine hydrochloride and DL-methionine (maintaining stoichiometry 3:1) in a way that the IAA profile mimics zooplankton-zoobenthos standards (in terms of DIAAS_{LYS,MET} >50%) and the feed fulfills ≥90% of LYS, MET requirements of carp. The starch (21%) and lipid (8%) were carefully balanced to fulfill ≥100% non-protein energy requirement of carp. It also has enough starch (>20%) for high-quality extrusion of pellets. A high non-starch polysaccharide (NSP 33%) contributed by LOCBs were accepted as filler but given that NDF:ADF ratio is >2 (for making the fibers easily fermentable in carp gut or by pond).

Precision pond feed was evaluated against wheat (as a control) for apparent digestibility, metabolic losses, and retention of protein in our Guelph-RAS system using standard methodologies. For this purpose, the lab trial lasted 70-day with common carp (initial body weight ~20g; 23–27 fish per tank) randomly assigned to 8 tanks across two treatments: pond feed and wheat with four replicates each (fed 6% BW day⁻¹, split into two doses at 08:00 and 14:00) and uneaten pellets dried, measured (40 mins post feeding). Following clearing of uneaten pellets after 2nd feeding, passive faeces collection continued every 4 hours until next day feeding. Initial and final carcass were taken for whole-body homogenates for protein, making sure that the duration of experiment has passed until one of the treatments had tripled body weight.

(Continued on next page)

Simultaneously, a pond validation trial with 2+ age carp (640–660 g) was conducted in 9 ponds (same as pre-trial) but challenged by a higher stocking density (625 kg ha⁻¹; 975 individuals ha⁻¹). Control ponds (n=3) received wheat during May–October. Same total dose treatment ponds (n=6) received as wholewheat or extruded breakfast cereals during April–June, and precision pond feed during July–October. Ponds were equipped with underwater temperature data loggers to precisely compute degree-days of culture, and fish measurements done monthly (n=20 pond⁻¹ month⁻¹) to compute inter-month thermal growth coefficient (TGC). Monthly monitoring of water quality (nutrients, chlorophyll-a) and zooplankton biomass (200–500 µm; >500 µm) was monitored.

Results

Pre-trial: During May–June, the supply of LYS (70–121 g) and MET (24–46 g) significantly exceeded ($p < 0.05$) pond carp's demand (LYS: 32–59 g; MET: 9–18 g). July acts like a transition period when supply and demand of LYS and MET are in equilibrium ($p > 0.05$). From August onwards, LYS supply fell to 34–54 g ($p < 0.05$) against a demand of 91–115 g, and MET supply dropped to 15–24 g ($p < 0.05$) against a demand of 27–34 g. This late-season drop coincided with decline of zooplankton (and zoobenthos) in pond, but an increase in algae (chlorophyll-a). Overall, the pattern shifted from early-season IAA surplus to late-season IAA limitation. Selecting any low protein level with any random IAA profile such as the low-protein pellet fed in group-B ponds (23% protein, fulfilling 40% of carp's LYS requirement, 66% MET requirement) over wheat fed in group-A ponds (10% protein, fulfilling 12% LYS requirement, 23% MET requirement) does not work. Such imprecise interventions do not solve the late-season IAA deficit of pond carp, as the net yield and relative feeding coefficient (RFC) of group-A and group-B ponds were same ($p > 0.05$).

Main trial: Application of precision pond feed during the problematic period of IAA supply-demand (July–September) had solved the issue of depressed growth in carp, compared to control ponds. In control, the TGC of pond carp stock collapsed during July–September. In treatment, during the same period, the TGC of pond carp was significantly reinforced compared to control ($p < 0.05$), that too with consistently high TGC across the months July to September ($p > 0.05$). This led to significantly high net yield (1.7 tons ha⁻¹), bigger market-sized carp (2.4 kg, market-size 2 kg already in September), and RFC (2.5) in treatment ponds ($p < 0.05$) than the control ponds (1.2 tons ha⁻¹; weight 1.9 kg; RFC 3.4). The water quality was also controlled. Despite such high production and application pellets in treatment pond, the end-of-culture (August–November) concentrations of nutrients (C: N:P) in water or sediment, and chlorophyll-a concentrations were same as control ($p > 0.05$). The large-bodied zooplankton (>500 µm) biomass was significantly ($p < 0.05$) enhanced in treatment (5–24 mg L⁻¹) over control ponds (3–12 mg L⁻¹) during August–October, indicating natural food could regenerate when deficiency for fish was lifted. A high bioenergetic efficiency of precision pond feed over wheat was confirmed in the lab trial. Protein storage efficiency of precision pond feed (net-stored protein 40% of digested protein) was significantly greater ($p < 0.05$) than that of wheat (net-stored protein 30% of digested protein). Net-storage of amino acids from the digested pool *in-vivo* is presently under construction.

Introduction

Saprolegniosis is a widespread freshwater fish disease caused by several species of the genus *Saprolegnia*, predominantly *Saprolegnia parasitica* and *S. diclina*. The disease affects all developmental stages, from egg to adult, and is most often opportunistic, developing in stressed, injured, or coinfecting individuals. Preventive health management is paramount in mitigating the risk of outbreaks and curative treatments. Microbial-based strategies, both in-feed or by immersion, have the potential to enhance fish health and robustness but remain underlooked in their capacity to mitigate *Saprolegnia* dissemination and the risk of outbreaks.

Material and Methods

In this study, two complementary approaches were used. First, three strains of *Saprolegnia* (*S. diclina*, *S. parasitica* and *S. ferax*) were tested *in vitro* to screen, amongst many, bacteria candidates best able to inhibit the growth of *Saprolegnia* oomycetes. To do so, bacteria and *Saprolegnia* strains were co-cultured on plate and on flask and the growth of the oomycete was measured after 1 week. Second, an *in vivo* trial was performed testing a yeast-based functional ingredient alone or in combination with one of three live-bacteria selected from *in vitro* screening and applied by immersion. To do so, freshwater Atlantic salmon (BW = 20 g) were fed to apparent satiation a control diet or the same diet supplemented with a yeast-based functional ingredient selected from prior knowledge. After 5 weeks of nutritional preparation, fish were randomly distributed into 24 tanks (12 tanks / diet group). Fish from each dietary origin were then exposed to one of four biocontrol treatments (Blank Control, Biocontrol A, B or C) applied in triplicate by 1h static immersion under aeration. Immediately after biocontrol exposure, fish were exposed to a controlled *S. parasitica* bath challenge and mortality was recorded daily during eighteen days. Skin and gill tissues were sampled at intervals for microbiota, histology and gene expression analyses.

Results

In-vitro screening allowed to select two *Bacillus velezensis* strains with a high growth inhibition capacity against three *Saprolegnia* strains. One of the *B. velezensis* strain was selected for *in vivo* testing in combination with *Pediococcus acidilactici* (Biocontrol C). Following *S. parasitica* challenge, mortality dynamics differed markedly between groups. When fed the control diet, mortality started earliest in the absence of biocontrol exposure and was clearly mitigated when exposed to Biocontrol C while Biocontrol B and A had intermediary and no benefits respectively. In contrast, in-feed supplementation with the yeast-derivatives slightly improved survival compared to the non-supplemented diet and overall reduced the apparent benefit of biocontrol exposure. Nonetheless under this regime, Biocontrol C followed by Biocontrol B reduced mortality hazard from day 8 post-challenge.

These outcomes reveal a strong diet-dependent interaction shaping host resilience and disease progression. Ongoing tissue analyses will be instrumental in elucidating the mechanisms underpinning the health benefits associated with Biocontrol C.

Conclusion

The trial demonstrates that both diet and biocontrol treatment significantly mitigate mortality following *Saprolegnia* exposure. Supplementation with the yeast-based ingredient provided the greatest single survival benefit, while Biocontrol C delivered the most consistent protective effect across dietary conditions by modulating the timing and intensity of mortality risk. Overall, the findings highlight the potential of microbial-based biocontrol strategies to mitigate saprolegniosis in freshwater salmonids. The consistent modulation of mortality dynamics by Biocontrol C, coupled with its dependence on dietary background, emphasizes the importance of integrating functional nutrition with targeted microbial interventions to enhance fish robustness.

EXPLORING FEED- AND BATH-BASED MICROBIAL STRATEGIES TO ENHANCE EUROPEAN SEABASS (*Dicentrarchus labrax*) RESILIENCE AGAINST *Aeromonas veronii*

C Houdelet^{1*}, D Gotz², S Chatzifotis³, M Mastoraki³, M Pavlidis⁴, P Katharios³, E Leclercq¹

*corresponding/presenting choudelet@lallemand.com

Introduction

Aeromonas veronii is a Gram-negative bacterium affecting European seabass (*Dicentrarchus labrax*) in the Mediterranean region since 2008 (Smyrli *et al.*, 2017). The bacterium causes a severe systemic disease characterized by external haemorrhagic lesions and internal pathological alterations, leading to significant economic losses due to mass mortalities especially of fish reaching commercial size. Outbreaks typically occur during the warmest months of the year, when water temperatures exceed 21°C, and cumulative mortality can surpass 50% in the absence of effective antibiotic treatment (Smyrli *et al.*, 2019). As concerns over antibiotic use continue to rise, preventive health management strategies are becoming increasingly important for mitigating disease risk. Microbial interventions, delivered either through feed or immersion, have shown potential to enhance fish health and resilience. However, their capacity to reduce disease severity and mortality following experimental *A. veronii* exposure remains largely unexplored.

Material and Methods

In this study, two complementary approaches were used. First, two strains of *A. veronii* were tested *in vitro* to screen a panel of candidate bacteria for their ability to inhibit pathogen growth. For this purpose, *A. veronii* strains were exposed to secondary metabolites of various bacteria, and optical density at 600 nm (OD600) was monitored over 48 h to assess pathogen growth. Second, two independent *in vivo* trials were conducted to evaluate microbial-based strategies for mitigating the impact of *A. veronii* in European seabass. Across the two trials, juvenile fish were reared in a recirculating aquaculture system and distributed into 18 tanks in total (n = 3 replicates per treatment, 40 fish per tank).

In Trial 1, fish (97.5 ± 17.7 g) received a 1-h bath treatment with one of two biocontrol products (10 g/m³) or remained untreated (control). After the bath treatment, fish were challenged by immersion with *A. veronii* (7 × 10⁵ CFU/mL) for 2.5 h and monitored for 2 weeks.

In Trial 2, fish (68.4 ± 12.3 g) were fed either a control diet or diets supplemented with one of two probiotics (1 g/kg of feed) during a 5-week nutritional preparation period. Fish were subsequently challenged by immersion with *A. veronii* (4 × 10⁵ CFU/mL) for 2.5 h and monitored for 2 weeks.

Results

Following *A. veronii* immersion challenge, both biocontrol treatments numerically increased survival relative to the control (1.9%), reaching 6.5% and 8.3% in the Biocontrol A and Biocontrol B groups, respectively. Although overall survival differences were not significant (Log-rank, p = 0.061), an ordered trend test (p = 0.023) indicated a graded treatment response (Control < Biocontrol A < Biocontrol B). These results suggest that bath-applied biocontrol treatments, especially Biocontrol B, may enhance seabass resilience to *A. veronii* infection.

In Trial 2, survival remained very low across all groups (0.9–2.9%), indicating a highly severe challenge. No significant differences in overall survival were detected among dietary treatments (Log-rank, p = 0.057), although early mortality dynamics differed significantly (Gehan–Breslow–Wilcoxon, p = 0.009). These results suggest limited effects of dietary supplementation on final survival under the challenge conditions tested.

Conclusion

Overall, the two challenge trials produced different protective outcomes against *A. veronii* infection in European seabass. In Trial 1, bath application of microbial biocontrol products numerically increased final survival and produced a significant positive treatment-related trend despite the severity of the challenge. In Trial 2, dietary probiotic supplementation did not significantly improve final survival, although it affected early mortality dynamics. These findings suggest that bath-applied

(Continued on next page)

microbial strategies may provide a rapid protective effect under acute challenge conditions. However, because the two trials differed in fish size, challenge dose, timing, and administration protocol, direct comparison between immersion and dietary administration should be interpreted cautiously. Future studies should evaluate combined immersion- and feed-based microbial strategies in a matched experimental design to determine whether complementary modes of action can improve resistance and survival following *A. veronii* infection. In addition, these microbial interventions could be explored as complementary tools alongside vaccination programs, including autogenous vaccines, particularly during periods of elevated disease risk or anticipated outbreaks. Such integrated prevention strategies may help reinforce host resilience and reduce disease impact under commercial farming conditions.

The transition of European Union (EU) aquaculture toward carbon neutrality is critical for meeting climate targets while ensuring food security and sectoral sustainability. This study presents a comprehensive analysis of historic and predicted future greenhouse gas (GHG) emissions across five aquaculture production systems (cages, ponds, raceways, recirculating aquaculture systems, and non-fed systems). Emissions were analysed across the full value chain, including feed production and transport, energy use, logistics, and farm operations.

Eight future scenarios were developed to explore emission reduction pathways from 2025 to 2050, ranging from business-as-usual to maximum mitigation. These scenarios incorporate seven key mitigation tools, including renewable energy adoption, emerging low-carbon feed materials, artificial intelligence (AI)-based optimisation, integrated multi-trophic aquaculture (IMTA), energy efficiency improvements, system diversification, and expansion of non-fed aquaculture, alongside offsetting mechanisms such as carbon credits and ecosystem restoration.

Results indicate that feed production is the dominant emission source, accounting for approximately more than half of total GHG emissions, followed by energy-intensive grow-out systems, particularly in RAS. While technological and operational innovations can deliver substantial reductions, mitigation measures are insufficient to achieve net-zero emissions due to residual emissions and projected sector growth.

Marginal abatement costs (MACs) vary significantly across systems and time horizons, ranging from €46 to €243 per tCO₂eq (2026–2030) and stabilising at €69–€228 per tCO₂eq by 2050. Non-fed systems exhibit higher MACs due to initial lower emissions per tonne and the limited applicability of certain technologies, while fed systems rely heavily on upstream decarbonisation of feed and energy supply chains. Multi-criteria analysis (MCA), incorporating economic, environmental, and social dimensions, reveals that scenarios aligned with EU climate targets and those deploying a wide range of mitigation tools perform best overall, although economic constraints and regulatory barriers limit feasibility.

The findings highlight that achieving carbon neutrality in EU aquaculture requires a systemic approach combining full deployment of mitigation technologies, credible carbon offsetting, and coordinated decarbonisation of upstream sectors. Key policy priorities include accelerating renewable energy adoption, fostering innovation in feed and breeding, supporting digitalisation, reforming regulatory frameworks, and developing robust carbon accounting and crediting systems. Without such coordinated action, the sector is unlikely to meet its 2030–2050 climate targets.

Introduction

Ensuring fish welfare is a key aspect of modern aquaculture, as it impacts both ethical considerations and production performance. Environmental factors and routine operations on aquaculture farms can influence welfare status and lead to physiological and behavioural changes in fish, highlighting the need to assess both these responses. In this context, the development of welfare monitoring tools has become essential within the framework of precision aquaculture, facilitating decision-making on farms (Føre et al., 2017). Among the available technologies, acoustic telemetry allows the recording of fish behaviour under real farming conditions, such as in floating sea cages (Muñoz et al., 2020). However, most studies have focused on salmonids, and knowledge remains limited for Mediterranean species such as European seabass (*Dicentrarchus labrax*), particularly in open-sea net pens. Furthermore, hidden Markov models (HMMs) offer a useful tool for inferring behavioural states from telemetry data. These models have been widely used in wild fish populations, but their application in aquaculture studies remains limited. Consequently, the aim of this study is to analyse the behavioural patterns of seabass in open-sea net pens across different timescales, as well as to characterize their behavioural states in relation to environmental conditions using acoustic telemetry and HMMs.

Materials and Methods

The activity and vertical distribution of seabass were monitored in four experimental net-pens belonging to IRFAP-LIMIA (Spain). A total of 2,200 adult seabass (weight $\approx$ 1 kg) were distributed across the four cages, which measured 5.5 m in diameter and 6–8 m in depth ($N = 550$ individuals per cage). Five fish were randomly selected and implanted with acoustic transmitters (ADP-LP7; Thelma Biotel Ltd.). After 7 days of recovery in monitored indoor tanks, fish were returned to the cages, where seabass acceleration and depth were recorded for 5 months between July and November 2023. The data were recorded by 3 acoustic receivers (TBR 800; Thelma Biotel Ltd.) positioned between the cages. A total of ~ 1.2 million detections were processed. To account for structural differences between cages, depth was calculated relative to the centre of each cage. Linear mixed models (LMMs) and generalized additive models (GAMs) were applied to assess behavioural patterns and to explore the influence of environmental variables on the behaviour of seabass. To characterize behavioural states, a HMM with four states was developed: resting, deep swimming, surface swimming and high activity, estimating the transition probabilities between states whilst taking environmental covariates into account. All procedures were approved by the Animal Experimentation Ethics Committee (CEE-UIB, Spain; Ref. 206/12/22) and were carried out in accordance with European Directive 2010/63/EU and Royal Decree 53/2013.

Results and Discussion

Acoustic transmitters enabled a successful detection of swimming patterns and vertical distribution of seabass reared in open-sea net pens, which showed changes throughout the five-month experimental period. On one hand, swimming activity decreased slightly over the study period, whilst the fluctuations observed in vertical distribution proved to be sporadic, with the fish remaining stable most of the time in the middle zone of the water column. Clear circadian patterns were identified: swimming activity increased significantly during the day, peaking around midday, particularly after feeding. Vertical distribution also varied throughout the day, with greater use of deeper zones during the daylight hours and a greater presence at the surface at night. Furthermore, during the summer months, an increase in activity and greater use of depth were observed. GAM models revealed a significant effect of environmental variables on the behaviour of seabass. Solar radiation showed a strong positive correlation with both parameters, and wave height and wind also affected vertical distribution. The HMM allowed the identification of the four behavioural states and the characterization of their dynamics throughout the day. A clear daily pattern was observed: at night, resting and surface swimming predominated, whereas deep swimming increased after dawn. Subsequently, following feeding, deep swimming behaviour decreased, giving way

(Continued on next page)

to an increase in high-activity behaviour, which peaked 3–4 hours after feeding. At dusk, a transition towards lower-activity states was observed. Transitions between states were strongly modulated by solar radiation and the daily cycle, which favoured the shift from low- to high-activity states and promoted the occurrence of active states during daylight hours. Taken together, these results are consistent with previous studies indicating that seabass behaviour in open-sea net pens is strongly regulated by environmental factors and daylight cycle (Toomey et al., 2025). The integration of acoustic telemetry and machine learning models allows for the characterization of behavioural states and their dynamics under farming conditions. This approach offers a robust framework for improving welfare monitoring and promoting welfare-oriented management of open-sea aquaculture facilities.

Introduction

Aquaculture is a rapidly growing animal production sector, but intensive farming conditions may challenge fish welfare by limiting environmental complexity and natural behaviours. Environmental enrichment can increase habitat complexity and promote natural activity, although its application in commercial aquaculture remains limited and its effects depend on the species and enrichment strategy (Arechavala-Lopez, et al., 2022).

This study evaluated the effects of two environmental enrichment strategies on rainbow trout (*Oncorhynchus mykiss*): structural enrichment using vertically suspended PVC tubes and occupational enrichment using additional water currents. Their effects were assessed through animal-based welfare and physiological indicators, including external lesions, body condition, hepatosomatic index, muscle pH, skin and muscle colour, and muscle glycogen.

Materials and Methods

A total of 800 triploid rainbow trout (*Oncorhynchus mykiss*; 15–20 g) were randomly allocated to three treatments (4 tanks/group; 50 fish/tank): Control, without enrichment; Structural enrichment, with vertically suspended PVC tubes; and Occupational enrichment, with additional water currents generated by submersible pumps for 12 h/day. Fish were fed commercial feed (1% body mass/day) and maintained under experimental conditions for 3 months.

At the end of the trial, welfare and post-mortem indicators were evaluated, including body condition, external lesions, hepatosomatic index (HSI), muscle pH (0 and 24 h), skin and muscle colour (L*, a*, b*), and muscle glycogen. Data were analysed using ANOVA, repeated-measures analysis for muscle pH, and Chi-square tests for lesions. Bonferroni tests were used for post-hoc comparisons, with significance set at $p < 0.05$.

Figure 1 Mean $\pm$ SEM (Standard error of means) of body condition score, hepatosomatic index (HSI), muscle pH at 0 and 24 h *post-mortem*, and muscle glycogen content in rainbow trout from the control group and the two environmental enrichment treatments: occupational enrichment (O.E. water currents) and structural enrichment (S.E. PVC tubes). Different letters indicate significant differences ($p < 0.05$).

(Continued on next page)

Results

External lesions were generally low across all experimental groups, with no significant differences among treatments. Similarly, body condition, skin and muscle colour (L^* , a^* , b^*), and muscle glycogen content at slaughter showed no significant differences between the control and enriched groups.

Significant differences were observed in the hepatosomatic index (HSI), with fish exposed to structural enrichment (PVC tubes) showing higher HSI values than both the control and occupational enrichment (water currents) groups ($p = 0,0043$). Muscle pH was similar among treatments immediately after slaughter (0 h; approximately 7,2), but significant differences were detected after 24 h ($p = 0,0149$). Fish exposed to occupational enrichment showed lower muscle pH values than both the control and structural enrichment groups, while no differences were observed between the latter two groups.

Discussion

Environmental enrichment with suspended PVC tubes or additional water currents did not negatively affect the external appearance, body condition, skin or muscle colour, or muscle glycogen content of rainbow trout, suggesting that both strategies were compatible with fish welfare under the experimental conditions (Crank et al., 2019). The absence of differences in external lesions indicates that the suspended tubes did not represent an additional source of physical damage, while the similar body condition among groups suggests no major effect on overall growth or physical status. However, structural enrichment resulted in a higher hepatosomatic index, which may reflect differences in energy storage or metabolic status (De la Llave-Propín et al., 2024). Occupational enrichment with water currents also affected muscle pH 24 h post-mortem, with lower values than those observed in the control and structural enrichment groups, potentially related to increased swimming activity and pre-slaughter muscle metabolism. Nevertheless, these differences were moderate and were not accompanied by changes in muscle glycogen. Overall, the results suggest that environmental enrichment may influence specific physiological indicators without negatively affecting general fish condition, although further studies integrating behavioural, productive, and metabolic indicators are needed to better assess its potential benefits for rainbow trout welfare.

Background

Aquaculture is the fastest growing food-production sector and plays a major role in providing high-quality animal proteins for the growing global population. Nevertheless, aquaculture production faces numerous challenges, particularly infectious diseases, whose emergence is becoming more prevalent with climate change. One emerging pathogen in the Mediterranean aquaculture is *Vibrio harveyi*, a free-living Gram-negative bacterium, that can cause disease outbreaks in a range of organisms, including fish, crustaceans, molluscs, corals, sponges and algae. In addition, *V. harveyi* has been associated with human infections, showing zoonotic potential. The pathogenicity of *V. harveyi* varies among strains, with some strains causing high mortality rates, while others appear non-virulent and may occur as part of the intestinal microbiota of healthy fish. The aim of this work was to assess the immune responses of European sea bass peripheral blood leukocytes (PBLs) following stimulation with two strains of *V. harveyi*, one isolated from microbiota of healthy fish and the other recovered from a clinical case of disease, as well as their extracellular products (ECPs).

Methodology

Bacterial strains were grown overnight in Marine Broth, pelleted by centrifugation, and resuspended in phosphate-buffered saline (PBS). The corresponding culture supernatants were retained for recovery of extracellular products (ECPs) using ultracentrifugation columns. European sea bass blood was collected in heparinised tubes, diluted with incomplete Leibovitz L15 medium and layered onto 51% iso-osmotic Percoll to isolate PBLs. Isolated PBLs were seeded in 6-well plates in complete L15 medium and stimulated for 4, 8 and 24h with two strains of *V. harveyi* and their respective ECPs. Unstimulated cells were included as negative controls, whereas cells stimulated with lipopolysaccharide (LPS) served as positive controls. Stimulation was terminated by resuspending the cells in TRIReagent. Total RNA was extracted, reverse-transcribed and used to quantify the expression of a panel of immune-related genes, including pro-inflammatory cytokines (*Il1b*, *Il6*, *Il8*, *Tnfa*), anti-inflammatory cytokine *Il10*, acute-phase proteins and antimicrobial peptides (*Cox2*, *Leap/Hepcidin*, *Lyz*), adaptive immunity markers (*Ifng*, *Il4/Il13*, *Il17*), apoptosis marker *Casp3*, with *Efla*, *rna18s* and *actb* as housekeeping genes.

Results

Preliminary analyses are ongoing. We expect that *V. harveyi* isolates and their extracellular ECPs will differentially modulate immune-gene expression in European sea bass PBLs in a time-dependent manner. The isolate recovered from a clinical disease case and its ECPs may induce a stronger pro-inflammatory response than the isolate originating from the microbiota of healthy fish. These results will contribute to understanding strain-specific immunomodulatory effects of *V. harveyi* and its ECPs in European sea bass.

Introduction

Whiteleg shrimp *Litopenaeus vannamei* is one of the most economically significant species in global aquaculture. It is primarily farmed in ponds which are increasingly threatened by extreme weather induced by climate change (Galappaththi *et al.*, 2020). Whilst the effects of individual stressors have been documented (Zheng *et al.*, 2017; Wang *et al.*, 2020), the physiological impact of combined environmental shifts, such as rapid changes in temperature and salinity caused by heatwaves and heavy rainfall, remains poorly understood. These stressors may induce physiological stress, leading to disrupted immune regulation and microbiome dysbiosis. As a result, this study hypothesises that the synergistic effect of these stressors would induce acute oxidative stress and compromise mucosal barrier integrity, leading to systemic physiological instability and extensive lipid peroxidation within haemocytes and immune-related tissues. Therefore, this study aimed to investigate the effects of extreme environmental shifts on the mucosal immunity of *L. vannamei*.

Materials and Methods

Early juvenile *Litopenaeus vannamei* (mean weight: 0.20 ± 0.10 g) were acclimatised in a recirculating aquaculture system (27°C, 25 ppt) for two weeks before being randomly allocated into three groups in quadruplicate: 1] high temperature and high salinity group (HTHS: 33°C, 40 ppt), 2] low temperature and low salinity group (LTLS: 20°C, 10 ppt), and 3] a control group (27°C, 25 ppt). Environmental parameters were adjusted during a three day ramping phase at a rate of change of 3°C and 5 ppt per day. The sampling regime comprised nine shrimp per group, sampled across the four replicate tanks with 2-3 shrimp per tank at each sampling point. Sampling points were on the day before the ramping phase (T0), and at 24 hours (T1) and 5 days (T2) after achieving the target temperature and salinity. Haemolymph was extracted using a syringe pre-loaded with anticoagulant, and haemocytes were subsequently collected via centrifugation at $800 \times g$ for 30 minutes at 4°C. The cell pellets were then lysed in 1/3 PBS to quantify the activities of lysozyme (LYZ) and superoxide dismutase (SOD), and the levels of malondialdehyde (MDA), using commercial assay kits (Abcam, Cambridge, UK) according to the manufacturer's instructions. Statistical significance was determined using the Kruskal-Wallis test followed by Dunn's *post-hoc* test with Bonferroni correction for multiple comparisons ($P < 0.05$), analysed using the R software environment. Furthermore, gills and intestines were preserved in ethanol for microbiome analysis while gills, intestines, and hepatopancreas were excised for immune gene expression analysis via RT-qPCR.

Results

At the initial sampling points, no significant differences in the biochemical markers were observed between the control and the stress treatment groups ($P > 0.05$). In contrast, at T2, the lysozyme activity (Figure 1A) in the HTHS group (0.87 ± 0.19 mU mg⁻¹) was significantly higher than that of the control group (0.35 ± 0.06 mU mg⁻¹) ($P = 0.03$). Similarly, SOD activity (Figure 1B) was significantly higher in the LTLS group (566.70 ± 133.03 U mg⁻¹) compared to the control group (282.08 ± 35.24 U mg⁻¹) ($P = 0.01$). Most notably, MDA levels (Figure 1C) in both the HTHS (2.40 ± 0.70 nmol mg⁻¹) and LTLS (3.45 ± 1.31 nmol mg⁻¹) groups were significantly higher than the control group (0.38 ± 0.04 nmol mg⁻¹) ($P = 0.0018$ & 0.0001 , respectively).

Discussion

These findings indicate that combined temperature and salinity shifts pose a severe physiological burden on early juvenile *L. vannamei*. Particularly, the significant elevation in MDA levels within the LTLS group indicates lipid peroxidation, suggesting that oxidative stress has exceeded the host's antioxidant capacity (Li *et al.*, 2017). Whilst significant increases in SOD and lysozyme activities reflect an active mobilisation of the antioxidant defence and innate immunity, such a prolonged response may impose a substantial metabolic cost. This may confer a metabolic trade-off between immune

(Continued on next page)

Figure 1. Biochemical markers in the haemocytes of *L. vannamei* under control (27°C, 25 ppt), HTHS (33°C, 40 ppt), and LTLS (20°C, 10 ppt) regimes: (A) Lysozyme (LYZ), (B) Superoxide dismutase (SOD), and (C) Malondialdehyde (MDA). Data are mean $\pm$ S.E.M. (n = 9) sampled at T0 (baseline), T1 (24 h), and T2 (5 d) post ramping. Different superscript letters indicate significant differences between control group and experimental groups at each specific time point ($P < 0.05$), distinct letter sets have been applied to T1 and T2 respectively.

tolerance and physiological state. These results show the vulnerability of early-stage shrimp to simulated extreme weather events. Ongoing microbiome profiling, integrated with host immune gene expression analyses, will clarify whether these biochemical alterations are associated with intestinal dysbiosis and concomitant modulation of specific immunometabolic pathways. This integrative approach will provide mechanistic insight into host-microbe-immune interactions, thereby informing the development of targeted intervention strategies to enhance immune competence and resilience in commercial aquaculture systems.

STRESS RESPONSE OF THREE *Mx* GENES IN GIANT GROUPER (*epinephelus lanceolatus*)

Ying-Xiu Huang ^{1*}, Tzong-Yueh Chen¹²³

1. Department of Biotechnology and Bioindustry Sciences, National Cheng Kung University, Tainan, Taiwan

2. Translational Center for Marine Biotechnology, National Cheng Kung University, Tainan, Taiwan

3. Agriculture Biotechnology Research Center, National Cheng Kung University, Tainan, Taiwan

*Presenting author e-mail: l66134079@gs.ncku.edu.tw

Introduction

The giant grouper (*Epinephelus lanceolatus*) is a cornerstone of Taiwan's aquaculture industry; however, infection by nervous necrosis virus (NNV) during the larval and juvenile stages results in mortality rates as high as 90%. Consequently, elucidating the host immune mechanisms following viral infection is critical for developing effective preventive strategies. Myxovirus resistance (Mx) proteins are key downstream effectors of the type I interferon (IFN) system. Although our previous research demonstrated that *ggMx1,2, 3* mRNA levels are regulated by NNV, it remains unclear whether these three Mx isoforms possess distinct temporal roles in inhibiting NNV replication, and the precise regulatory mechanisms of their respective proteins have yet to be fully clarified. In this study, we characterized the distribution and dynamic shifts of the Mx proteins under viral stress.

Materials and Methods

GF-1 cells were utilized as the experimental model. The overexpression of Mx1, 2, 3 proteins were characterized under NNV challenge. Subcellular distribution and dynamic protein shifts were visualized using high-resolution confocal immunofluorescence imaging. To investigate physical interactions between the host immune factors and the pathogen, colocalization analysis was performed between Mx proteins and the NNV capsid protein.

Results

Confocal immunofluorescence imaging revealed the distribution and dynamic shifts of Mx proteins, demonstrating that following the overexpression of Mx1, 2, 3 the peak suppression of NNV occurred sequentially, starting with Mx1 protein, followed by Mx2 protein, and finally Mx3 protein. Colocalization analysis confirmed physical interactions between Mx proteins and the NNV capsid protein, with peak colocalization observed at 30 hours for Mx1, 2, and 36 hours for Mx3.

Discussion

This study provides novel insights into the temporal and spatial regulation of the innate immune response in giant grouper. The sequential peak suppression of NNV by different Mx homologs suggests a coordinated, stage-specific antiviral defense strategy. The physical interaction and peak colocalization times indicate that Mx1 and Mx2 act earlier in the infection cycle compared to Mx3. Collectively, these findings elucidate the dual response mechanisms of *ggMx* to biological and viral stress, providing profound insights into the interaction of NNV and Mx and supporting the development in aquaculture.

Introduction

Aquaculture is the fastest-growing global food production sector and is vital for food and nutritional security. With output reaching approximately 87.5 million tonnes, over 70% of production relies on formulated feeds. Fish meal (FM) has traditionally been the primary protein source due to its amino acid profile, digestibility, and palatability (Luthada-Raswiswi et al., 2021). However, its limited supply from capture fisheries and rising demand have caused price volatility and supply concerns, making sustainable FM alternatives an urgent priority. Plant-based proteins are promising substitutes due to their abundance, lower cost, renewability, and reduced environmental impact. Ingredients such as soybean meal, *Moringa oleifera* leaf and seed meal, canola meal, sunflower meal, and cottonseed meal are already used in commercial aquafeeds. Yet, antinutritional factors (ANFs) including phytate, tannins, saponins, protease inhibitors, and non-starch polysaccharides limit their inclusion by reducing nutrient bioavailability and impairing fish growth and health. Feed additives such as exogenous enzymes, probiotics, prebiotics, antioxidants, organic acids, and functional nanoparticles can mitigate ANF effects, improve digestibility, and enhance fish health, allowing higher plant protein incorporation. Nevertheless, further research is needed on the long-term physiological, economic, and environmental impacts of large-scale FM substitution. Species-specific formulations, life-cycle assessments, and cost-benefit analyses remain critical. Developing eco-efficient, nutritionally complete, and cost-effective aquafeeds is essential for sustainable aquaculture growth and global food security (Hussain et al., 2024).

Introduction

Global shrimp aquaculture has expanded rapidly over the past decades, driven by increasing demand and the widespread adoption of intensive and super-intensive farming systems. Production of *Penaeus vannamei* now dominates global shrimp output, particularly in Asia. However, high stocking densities and suboptimal environmental control have increased disease outbreaks, significantly affecting productivity.

White Faeces Disease (WFD) has emerged as a major challenge, characterized by floating white fecal strings and reduced growth performance. It is widely considered a multifactorial disease, with the microsporidian *Ecytonucleospora hepatopenaei* (EHP) identified as a primary pathogen causing hepatopancreatic dysfunction. Opportunistic *Vibrio* spp., including *V. parahaemolyticus* and *V. alginolyticus*, are thought to act as secondary agents that exacerbate disease severity. Despite its impact, the lack of a reproducible challenge models limit understanding of WFD pathogenesis and the development of effective treatments. This study aims to develop a standardised co-infection model to better understand WFD and support disease management strategies. This approach provides, for the first time, a controlled framework to reproduce WFD under experimentally defined multifactorial conditions.

Approach

To ensure the acquisition of high-quality biological materials, a collaborative effort was established between IMAQUA B.V. (Belgium), Ghent University (Belgium), and Can Tho University (Vietnam). Field surveys and targeted sampling campaigns were conducted in shrimp farming regions affected by WFD and confirmed EHP presence. Diseased shrimp specimens were collected for pathogen isolation and characterization.

Bacterial isolates were obtained from hepatopancreatic and intestinal tissues using selective culture techniques. Approximately 20 *Vibrio* strains representing multiple species, including *V. parahaemolyticus*, *V. alginolyticus*, and *V. vulnificus* were successfully isolated. At the Laboratory of Aquaculture and Artemia Reference Center (ARC), these strains underwent comprehensive characterization, including molecular identification via 16S rRNA gene sequencing. Functional assays were conducted to assess virulence-related traits, such as quorum sensing activity and bacterial motility.

In parallel, EHP spores were isolated from infected shrimp at Can Tho University (Vietnam) and propagated under controlled laboratory conditions at IMAQUA. Successful experimental transmission of EHP was achieved, confirming the viability of the spores and enabling their use in subsequent co-infection trials.

This integrated pipeline from field sampling to laboratory validation ensures that both primary and secondary pathogens used in this study reflect real-world disease dynamics while maintaining experimental reproducibility.

Discussion

This initial phase successfully established a high-quality pathogen collection representing both primary (EHP) and secondary (*Vibrio* spp.) agents of WFD. These results provide a critical foundation for developing a controlled co-infection model.

Future work will focus on optimizing challenge protocols by varying pathogen concentrations and exposure timing to reliably reproduce WFD symptoms. Such a model will enable deeper investigation of pathogen interactions and provide a robust platform for evaluating therapeutics and management strategies.

(Continued on next page)

Developing a reproducible WFD model represents an essential step toward transforming a complex field syndrome into a predictable and manageable disease, ultimately supporting the sustainability of shrimp aquaculture.

Overall, this study establishes the foundation for a co-infection model of White Faeces Disease by integrating field-derived EHP and *Vibrio* isolates with laboratory infection systems. The upcoming optimization of this model is expected to enhance understanding of disease mechanisms and facilitate the development of effective control strategies in shrimp farming.

Introduction

Cryopreservation is an important reproductive biotechnology used for the long-term preservation of fish sperm at ultra-low temperatures without significant loss of fertilizing ability (Tiersch et al., 1994). In aquaculture, sperm cryopreservation supports selective breeding, synchronization of gamete availability, conservation of valuable genetic resources, and year-round seed production. *Heterobranchus longifilis* is an economically important African catfish species widely used in hybridization programmes because of its fast growth and aquaculture potential. Successful cryopreservation of fish sperm is influenced by several factors, including extender composition, cryoprotectant type, freezing conditions, and sperm dilution ratio (Horváth et al., 2001). Appropriate dilution ratios are essential to maintain sperm quality during freezing and thawing by reducing osmotic and cryoinjury effects. Therefore, this study evaluated the effect of different dilution ratios on the post-thaw motility and fertilizing capacity of cryopreserved *Heterobranchus longifilis* sperm.

Materials and Methods

Heterobranchus longifilis broodstock was maintained at the Research Center for Fisheries and Aquaculture in Szarvas, Hungary. Testes of sexually mature males were excised following hormonal stimulation of spermatogenesis and overanesthesia. Testes were collected at two different dates. Sperm was extracted from the testicular tissue and diluted in either carp extender (200 mM glucose, 40 mM KCl, 30 mM Tris, pH 8.0) or catfish extender (6% fructose, 20 mM NaHCO₃) supplemented with 10% methanol as a cryoprotectant. Sperm was diluted to 0.5, 1 or 2 × 10⁹ cells per ml or alternatively to a dilution ratio of 1:1 and cryopreserved in the vapor of liquid nitrogen. Post-thaw motility was determined by computer-assisted sperm analysis (CASA). Fertilizing capacity of frozen-thawed sperm was assessed using the eggs of *Clarias gariepinus* 24 h after fertilization.

Results

Progressive motility of cryopreserved *H. longifilis* sperm was low (below 12% during the first collection date and below 2% in the second). At the first collection date both the extender ($P = 0.009$) and the dilution ratio ($P = 0.001$) had a significant effect on the post-thaw motility. The highest motility was observed using carp extender with sperm diluted to 1 × 10⁹ cells per ml (12 ± 8%). Generally, dilution of sperm to 0.5 × 10⁹ cells per ml resulted in significantly lower post-thaw motility (Figure 1A). At the second collection date, dilution of sperm to a dilution ratio of 1:1 resulted in the highest post-thaw motility (2 ± 1%). Dilution of sperm also had a significant effect on the fertilizing capacity of *H. longifilis* sperm ($P < 0.001$) with dilution ratios of 1 and 2 × 10⁹ cells per ml as well as 1:1 resulting in higher fertilization than dilution to 0.5 × 10⁹ cells per ml (Figure 1B).

Introduction

Monitoring fish behaviour, such as swimming speed and spatial distribution, in aquaculture sea cages is essential for optimizing feeding management and improving fish welfare. Stereo cameras have been widely used to measure swimming speed; however, they rely on machine-learning-based image processing, which demands substantial computational resources and power, and their performance is degraded by low illumination and biofouling of the camera housing (Ikegami et al., 2026). In addition, stereo cameras provide only a local field of view and cannot capture the spatial distribution of fish across the entire cage. Multibeam sonars offer a light-independent alternative, but their limited field of view makes it difficult to cover an entire commercial sea cage with a single unit. Placing the sonar near the cage wall extends the observable area but introduces detection-range limitations (Banno et al., 2025). A mechanically rotating single-beam sonar overcomes both range and field-of-view limitations by scanning 360° from the cage centre (Sauphar et al., 2026); however, the rotation mechanism limits temporal resolution, and swimming speed cannot be derived from this approach.

In this study, we present a dual two-dimensional (2D) sonar combination system that addresses both the field-of-view and the real-time monitoring challenges simultaneously. Each sonar unit has a fan-shaped beam with an opening angle of 120°. By orienting two units perpendicular to each other, the system achieves near-complete coverage of the cage cross-section without any mechanical rotation, enabling continuous monitoring of swimming speed and depth distribution. Furthermore, all the approaches mentioned above provide only two-dimensional observations, whereas Atlantic salmon (*Salmo salar*) are known to exhibit three-dimensional spatial heterogeneity within cages. To address this, we additionally conducted a preliminary verification of three-dimensional (3D) monitoring using a multibeam sonar equipped with a rotational scanning mechanism.

Materials and Methods

Two field experiments were conducted. The dual 2D sonar experiment was carried out in September 2025 at the NTNU salmon aquaculture research site Gudmundset, on the west coast of Norway, in a commercial sea cage containing Atlantic salmon post-smolts. Two multibeam sonars (FCS-500, FURUNO ELECTRIC, Japan; 120° beam opening angle per unit) were deployed as a twin unit at the centre of the cage just below the water surface, with their fan beams oriented perpendicular to each other; this configuration constitutes the dual 2D sonar combination evaluated here. Recordings were obtained continuously over extended observation periods covering different times of day. From the calibrated volume backscattering strength (Sv), fish density was mapped on the depth–time plane and individual fish were tracked frame-to-frame to estimate the swimming speed. The 3D verification experiment was conducted in December 2025 in a commercial sea cage at Tokushima, Japan, containing yellowtail (*Seriola quinqueradiata*); a multibeam sonar equipped with a rotational scanning mechanism was installed at the cage centre, and the transducer was automatically rotated to produce three-dimensional snapshots of the spatial distribution of fish within the cage volume.

Results and Discussion

The dual 2D sonar system successfully captured spatial and temporal variations in fish distribution across the cage. Both swimming speed and depth distribution showed clear changes depending on the time of day, demonstrating the system's capability to quantitatively track diurnal behavioural patterns in real time under practical farming conditions. The estimated mean swimming speeds were approximately 0.6 m/s during daytime and 0.3 m/s during night-time. The rotational multibeam sonar confirmed the feasibility of capturing the volumetric distribution of fish within the cage.

The proposed dual 2D sonar system provides a practical, cost-effective, and real-time solution for wide-area behavioural monitoring in commercial sea cages, overcoming the key limitations of existing methods. Further integration of the dual 2D system with the 3D rotational scanning approach is expected to enable comprehensive whole-cage monitoring that accounts for the three-dimensional heterogeneity of fish distribution. Future work will include verification of the 3D approach with Atlantic salmon.

AQUACULTURE VALUE CHAIN AND THE RESILIENCE LEVEL OF AQUA FARMERS TO CLIMATE CHANGE IN DELTA STATE, NIGERIA

V.U. Ikenga¹, A.O. Edewor¹, S. Enwa¹, T.M. Gbigbi¹, D.O. Ogisi¹ and O.J. Uduvwe²

Corresponding author: ikenga_veronica@delsu.edu.ng

Introduction

Aquaculture contributes significantly to food security, employment, and economic development in Nigeria. However, climate change has increasingly threatened the sustainability of aquaculture production through flooding, salinity intrusion, disease outbreaks, and declining water quality. These challenges affect the entire aquaculture value chain and the resilience of aqua farmers. Despite the importance of aquaculture in Delta State, there is limited empirical evidence regarding the resilience of aquaculture value chain actors to climate change and the influence of gender on adaptive capacity. This study therefore assessed the aquaculture value chain and evaluated the resilience levels of male and female aqua farmers to climate change in Delta State, Nigeria.

Materials and Methods

The study was conducted in Delta State, Nigeria, using a purposive sampling technique. A total of 991 aqua farmers representing 30% of registered aquaculture farmers from identified clusters were selected. Primary data were collected through structured questionnaires and unstructured interviews. Data were analysed using descriptive statistics and t-test analysis with the aid of Statistical Package for Social Sciences (SPSS) version 24. Resilience was evaluated based on four dimensions: institutional, ecosystem, community, and economic resilience.

Results and Discussion

The socioeconomic characteristics showed that the majority of the respondents were male (57.1%), married (53.2%), and had attained formal education. The mean age of respondents was 42 years, while the average household size and aquaculture experience were six persons and sixteen years, respectively. The average monthly income from aquaculture was ₦137,492.93, indicating that aquaculture provides substantial economic benefits to practitioners.

The aquaculture value chain comprised input suppliers, breeders, table-size producers, marketers, processors, transporters, distributors, and consumers. Table-size producers constituted the largest proportion (40.5%) of value chain actors.

Assessment of resilience revealed gender differences in adaptive capacity to climate change. Male aqua farmers demonstrated community resilience, particularly through support from traditional leadership and local communities, but showed low resilience in institutional, ecosystem, and economic dimensions. Conversely, female aqua farmers exhibited greater economic resilience due to increased access to financial support programmes and empowerment initiatives but had lower resilience in institutional, ecosystem, and community dimensions.

The t-test analysis indicated a statistically significant difference ($p < 0.01$) between the resilience levels of male and female aqua farmers, leading to the rejection of the null hypothesis of no gender difference in resilience.

Conclusion

The study demonstrated that aquaculture in Delta State is supported by a diverse value chain involving multiple stakeholders. Significant gender disparities exist in resilience to climate change, with female aqua farmers exhibiting higher overall resilience than their male counterparts, largely due to greater economic empowerment opportunities. The findings highlight the need for gender-responsive policies and targeted interventions aimed at strengthening institutional, ecosystem, community, and economic resilience among aquaculture value chain actors. Such interventions are essential for promoting sustainable aquaculture development and enhancing the adaptive capacity of farmers to climate change in Delta State, Nigeria.

Table 1. Overall Resilience Level of Aqua Farmers by Gender

Resilience Level	Male (%)	Female (%)
Low Resilience (0–49%)	67.7	44.5
High Resilience (50–100%)	32.3	55.5

PROSPECTS AND CHALLENGES OF CAPTURE-BASED AQUACULTURE FOR THE EUROPEAN EEL (*Anguilla anguilla*) IN TÜRKİYE: FROM LAGOON HARVESTING TO EXPORT

Deniz İnnal

Burdur Mehmet Akif Ersoy University

Department of Biology

Burdur, 15100, Türkiye

*corresponding/presenting innald@gmail.com

The European eel (*Anguilla anguilla*) is one of the most economically valuable species in global aquaculture. Due to the biological constraints preventing closed-cycle artificial reproduction on a commercial scale, the industry relies entirely on rearing wild-caught individuals, a practice known as capture-based aquaculture. Türkiye, with its extensive coastal lagoon systems, holds significant potential for this sector. Currently, eel production and export in Türkiye primarily depend on harvesting from key lagoons such as Köyceğiz, Bafa, Paradeniz and Akyatan. The very few specialized facilities operate strictly on the principle of fattening individuals collected from these natural habitats.

However, the development and survival of the sector are directly dependent on strict international trade regulations and annually determined national export quotas. This study evaluates the primary bottlenecks facing eel aquaculture and lagoon management in Türkiye. These challenges include: (1) fluctuations in wild stock recruitment exacerbated by increasing water pollution, habitat destruction, the pressure of proliferating invasive species in lagoon lakes, and the potential occurrence of harmful algal blooms; and (2) the inherent technical difficulties of eel aquaculture operations coupled with a significant lack of qualified experts and specialized personnel in this specific field.

Furthermore, a critical vulnerability in the sector is the substantial lack of knowledge regarding fish health and diseases. While the presence of the invasive nematode *Anguillicoloides crassus* and certain common parasites is documented, epidemiological data on bacterial and viral diseases affecting Turkish eel populations remain highly insufficient. This lack of data poses severe risks, particularly during intensive fattening periods and export stages. Ultimately, ensuring the sustainability of the eel sector in Türkiye necessitates establishing ecologically based quotas, rigorous monitoring of water quality in lagoons, and the urgent development of aquaculture-focused health management strategies.

EFFECTS OF MONO- AND BINARY MICROALGAL ENRICHMENTS ON THE BIOCHEMICAL COMPOSITION OF THE CYCLOPOID COPEPOD *Apocyclops panamensis*

Introduction

Copepods, which constitute a major component of the natural prey of marine fish larvae, represent a valuable live-feed option for ornamental fish larviculture. Live microalgae are essential for their culture and nutritional enrichment (Rasdi & Qin, 2016). Although most studies have focused on calanoid (Martino *et al.*, 2023, 2024) and harpacticoid copepods (Hansen *et al.*, 2018), the cyclopoid *Apocyclops panamensis* (Marsh, 1913) is receiving increasing attention as live prey for marine larviculture (Ballesteros-Redondo *et al.*, 2023). In this study, we evaluated the effects of three microalgal species, supplied individually or as binary combinations, on the proximate composition and fatty acid profile of *A. panamensis* after 24 h of enrichment.

Materials and Methods

The marine microalgae *Rhodomonas salina* (R), *Isochrysis galbana* (I) and *Chaetoceros calcitrans* (C) were used as enrichment diets. Copepods (*A. panamensis*) were randomly allocated to six experimental enrichment treatments: three monoalgal diets consisting of R, I or C, and three binary diets consisting of equal proportions (1:1) of RI, CI or RC. Copepods cultured on *Tetraselmis suecica* served as the control. Each treatment was performed in triplicate (n = 3), with each tank considered an independent experimental unit. After 24 h, the entire content of each tank was harvested, lyophilized, and subsequently analysed. Proximate composition and fatty acid profiles of copepods were analyzed. Moisture, protein and lipids were determined by thermal dehydration, Kjeldahl and Folch methods, respectively, while carbohydrates were calculated by difference. Fatty acid methyl esters (FAMES) were analyzed by gas-liquid chromatography following transmethylation. Treatment differences were assessed by ANOVA–Tukey or Welch’s ANOVA–Games–Howell according to variance homogeneity ($\alpha = 0.05$).

Results

After 24 h of enrichment lipid content differed significantly among treatments ($F = 9.76$, $p < 0.001$), with C showing the highest value ($16.6 \pm 1.1\%$), whereas protein content was also significantly affected by diet ($p = 0.001$), reaching the highest value under RI ($62.6 \pm 2.6\%$). The fatty acid profile was strongly influenced by dietary treatment, with significant differences detected for most individual fatty acids and aggregate fatty acid classes ($p < 0.001$). The C treatment resulted in the highest SFA and MUFA concentrations (89.6 ± 5.6 and 57.6 ± 4.0 mg g⁻¹, respectively), together with the lowest PUFA (16.4 ± 4.0 mg g⁻¹) and n-3 HUFA concentrations (5.3 ± 0.7 mg g⁻¹). In contrast, R and RI were characterized by high PUFA and n-3 HUFA concentrations, with RI reaching 61.6 ± 0.6 and 21.2 ± 0.5 mg g⁻¹, respectively. RC yielded the highest observed EPA concentration (8.0 ± 0.2 mg g⁻¹), whereas RI showed the highest DHA concentration (10.2 ± 0.1 mg g⁻¹).

Discussion

The results demonstrate that 24 h of enrichment substantially modulated the nutritional composition of *Apocyclops panamensis*, with the magnitude and direction of the response depending on the microalgal diet. The high SFA and MUFA concentrations, together with the comparatively low PUFA and n-3 HUFA levels observed under C, are consistent with a strong diet-dependent modulation of copepod lipid composition. Overall, the binary diets RI and RC provided the most favorable enrichment profiles, with RI characterized by high PUFA and n-3 HUFA concentrations and the highest DHA content, while RC yielded the highest EPA concentration. Among the monoalgal treatments, *Rhodomonas salina* showed a favorable nutritional profile, characterized by high PUFA and n-3 HUFA concentrations. Its presence in both best-performing binary combinations further suggests an important role in the nutritional enrichment of *A. panamensis*. These findings support the inclusion of *R. salina* as a key component in the formulation of binary enrichment diets and highlight the need for further investigation of its suitability as a long-term culture diet. The favorable nutritional profile observed for *A. panamensis* also supports its potential as a live feed for marine larviculture, warranting further comparison with conventional live feeds and direct evaluation in larval feeding trials.

ROLE OF ORGANIC ACIDS AS FEED ADDITIVES IN AQUACULTURE: HOW TO COMPOSE THE MOST EFFECTIVE BLEND

Dr Dafna Israel

Head of Research and Development

Phibro Aqua

Israel

Email: dafna.israel@pahc.com

Organic acids have been extensively studied in recent years as sustainable feed additives in aquaculture, providing a dual benefit of improving growth performance and mitigating pathogen pressure. Their antimicrobial action is primarily influenced by their ability to penetrate microbial cell membranes, a function directly related to the acid's dissociation constant (pKa).

Recent findings have shown that organic acids with pKa values between 3.1 and 5.5 demonstrate significant activity against key aquaculture pathogens such as *Vibrio parahaemolyticus*, *Aeromonas hydrophila*, *Streptococcus agalactiae* and more. The concept that the higher the pKa value the higher the antipathogenic effect of Short-chain fatty acids (SCFAs), was challenged with our interesting findings.

This pKa-centric approach supports the strategic design of feed additives that provide a foundation for antibiotic-free disease control strategies in aquaculture.

COMMUNAL CONSTRUCTION OF A FLAT OYSTER REEF FOR THE BENEFITS OF BOTH HABITAT RESTORATION AND AQUACULTURE

P. Jacobs ^{1*}, Hartog, E.¹, Verbeeke, G.P.¹, and van Houcke, J.¹

¹ Research Group Aquaculture in Delta Areas
HZ University of Applied Sciences
The Netherlands
*Email: pascalle.jacobs@hz.nl

Introduction

European flat oyster reefs (*Ostrea edulis*) were once abundant in European seas, but have largely disappeared due to overexploitation, decreased water quality, sedimentation, and diseases. The remaining populations are in a degraded state, hampering the provision of ecosystem functions and services (Thomas et al., 2022); habitat provision is marginal as due to low densities of oysters, the typical 3D-reef structure is lacking. Reef maintenance and growth is insufficient due to a shortage of oyster larvae and suitable settlement for oyster larvae. In regions with oyster aquaculture the lack of settled larvae limits oyster production, as farmers depend on the natural supply of larvae as starting material for aquaculture. Nature organizations, government and oyster farmers all agree that restoring an oyster reef can provide a solution. Still, there is mutual misunderstanding among stakeholders and a lack of knowledge about the successful combination of sustainable aquaculture and nature restoration.

Activities

Construction of a sublittoral flat oyster reef will take place in the Oosterschelde, the Netherlands. This former estuary and now protected natura 2000 area harbors a traditional oyster aquaculture community. Proposed activities include the selection of a suitable location and the actual construction of the reef. Monitoring of the (constructed) reef is an important part of this proposed project and will be conducted according to the BACI (Before-After, Control-Impact) approach. Monitoring will include oyster health parameters such as growth, survival, larval production and settlement, biodiversity indicators and the effect of management practices on both oyster health and biodiversity. Images collected using ROV and drop-down-camera (cf. zu Ermgassen et al., 2021) will be combined with observations by recreational divers (citizen science) and eDNA techniques for biodiversity monitoring. A management plan will be drafted in consultation with all relevant stakeholders to ensure the sustainable survival of the constructed reef. All stakeholders in the consortium will be actively involved in all steps described.

Expected long-term changes

A permanent, self-sustaining sublittoral European flat oyster reef in the Oosterschelde providing ecosystem functions and services, notably habitat and larval supply;

A durable increase in the abundance of flat oyster larvae providing a reliable supply of juvenile oysters, ultimately enhancing flat oyster production in the area;

Commitment of oyster farmers for the maintenance and protection of the European flat oyster reef;

More knowledge and acceptance of the oyster farming practices, by stakeholders and society, providing a societal 'license to produce' for farmers, and thereby promoting low-tropic aquaculture.

The project serves as an example of successful coexistence of low-tropic aquaculture and nature restoration, validated by stakeholders, and communicated to society.

Consortium

HZ UAS as project and research coordinator, UAS Leiden, 6 Dutch oyster farmers, the oyster association, 3 nature organizations, 4 governmental bodies, and an organization coordinating citizen science.

BEYOND PROBLEM SOLVING: GENETIC PROGRESS AS A DRIVER OF EFFICIENCY AND PRODUCTIVITY

Kasper Janssen¹, Naomi Duijvesteijn¹

¹ Hendrix Genetics Aquaculture BV
Villa 'de Körver', Spoorstraat 69
5831 CK Boxmeer, The Netherlands

*corresponding/presenting Kasper.Janssen@hendrix-genetics.com

Genetic improvement is often expected to function as a problemsolving tool, called upon to address specific challenges such as disease outbreaks, reduced survival, or declining performance. Although genetic selection can help to overcome problems (*e.g.*, Norris, 2017), this framing underestimates its more structural role in aquaculture production.

We argue that the principal value of genetic progress lies not in the resolution of individual problems, but in the sustained improvement of overall biological efficiency and productivity. Analogous patterns can be observed in other industries. In commercial aviation, for example, safety did not emerge from efforts to eliminate individual failure events, but rather from decades of cumulative, incremental improvements in aircraft design, training and operational procedures (Winter *et al.*, 2024).

A similar mechanism operates in breeding programs. Longterm genetic selection systematically improves the performance of populations, affecting multiple traits simultaneously. Genetic trends from Hendrix Genetics' commercial breeding programs for Atlantic salmon (*Salmo salar*), rainbow trout (*Oncorhynchus mykiss*) and whiteleg shrimp (*Litopenaeus vannamei*) demonstrate consistent improvements in growth, survival and yield. When viewed alongside broader industry performance trends, these data indicate that genetic improvement constitutes a major driver of efficiency and productivity gains in aquaculture.

By reframing genetic improvement as a longterm efficiency strategy rather than a shortterm solution provider, we seek to align expectations between breeders and producers. Recognising where genetic improvement can generate the most meaningful impact is essential to maximize its contribution to sustainable performance of the aquaculture industry.

Introduction

The aquaculture sector faces increasing pressure to reduce reliance on fishmeal and soybean meal while maintaining fish performance and health. Fermentation of agricultural side-streams using fungal mycelium offers a promising strategy to enhance nutritional value and introduce functional properties (Kalaiselvan et al., 2025; Nandi et al., 2025; Yegin, 2025). This study evaluated composite mycelium meal (CMM), produced via solid-state fermentation with *Ganoderma lucidum*, as a sustainable and functional feed ingredient for European perch (*Perca fluviatilis*).

Materials and Methods

Juvenile perch (initial body weight 35.0 g) were fed four isonitrogenous, isolipidic, and isoenergetic diets in which CMM was progressively included at 0%, 5%, 7.5%, and 10% while maintaining diets isonitrogenous, isolipidic, and isoenergetic through balanced reformulation. These inclusion levels corresponded to soybean meal replacement levels of 0%, 25%, 37.5%, 50%, respectively. The CMM was manufactured from agricultural side-streams identified in prior preference trials, consisting of 80% canola meal, 15% sunflower meal, and 5% sunflower hulls. Diets were tested in triplicate, and the growth trial was conducted in a recirculating aquaculture system over 84 days. Growth performance, nutrient digestibility, organosomatic indices, histology, blood biochemistry, immune parameters, and gut microbiome composition were assessed.

Results and Discussion

CMM inclusion up to 10% did not negatively affect growth performance, feed conversion ratio, or survival. Fish fed higher inclusion levels (7.5–10%) exhibited significantly ($P < 0.05$) increased body weight (85.0 g and 93.2 g ± 15 respectively) compared to controls (78.5 g ± 15.1). Nutrient digestibility remained stable across all treatments, indicating efficient utilization of the fermented ingredient.

Organosomatic indices and histological assessments showed no adverse effects, suggesting maintained physiological condition. Blood biochemistry revealed limited diet-related changes, although cholesterol and alkaline phosphatase varied with CMM inclusion.

Immunological analyses demonstrated clear functional benefits: hepatic lipid peroxidation decreased in a dose-dependent manner, while intestinal lysozyme activity and skin mucus protein content increased, indicating enhanced oxidative status and innate immune response.

Gut microbiome analysis revealed diet-dependent shifts in community composition, with reduced diversity but increased specialization at higher inclusion levels, suggesting interactions between diet and microbial ecology.

Conclusion

Fermented agricultural side-streams fermented with *G. lucidum* mycelium can replace soybean meal in European perch diets up to 50% without compromising growth or health. Additionally, the ingredient provides functional benefits related to immune response and oxidative stress mitigation. This approach represents a promising strategy for improving sustainability and functionality in aquaculture feeds.

Introduction

Larval development is one of the most critical stages in bivalve hatchery production, with environmental conditions strongly influencing growth, survival and seed quality. Temperature and salinity are among the main drivers of larval physiological performance, yet they are commonly investigated independently despite acting simultaneously in both natural and hatchery environments. Understanding their combined effects is essential because their interactions may generate biological responses that cannot be predicted from single-factor studies. Although, the grooved carpet shell (*Ruditapes decussatus*) is a high-value species in southern Europe, information on the interactive effects of temperature and salinity during larval development remains scarce. This study evaluates how the combined influence of these two environmental factors affects larval viability, providing practical information to optimize commercial hatchery production.

Materials and Methods

Ruditapes decussatus larvae at 5 days post-fertilization (dpf) were randomly distributed among eighteen 5 L-beakers (triplicate per treatment). Larval density was adjusted throughout the experiment with 5, 3 and 1.5 larvae ml⁻¹ at 5, 14 and 17 dpf, respectively. Larvae were maintained under two temperatures (18 and 22 °C) and three salinities (25, 34 and 36) until 19 dpf. Water was renewed every two days with filtered and UV-sterilized seawater and continuous aeration. Larvae were fed with 100 cells µl⁻¹ of a bispecific microalgae diet, consisting of 60% *Tisochrysis lutea* and 40% *Chaetoceros calcitrans* until 17 dpf, followed by 40% *T. lutea* and 60% *C. calcitrans* from 18 dpf onwards. Every two days, the proportion of live larvae (%) was calculated as the number of live larvae divided by the total number of live and dead larvae counted, and shell growth was assessed by measuring shell length from digital images using ImageJ®. Data and statistical analysis were performed using R version 4.5.3.

Figure 1. (a) Mean of the proportion of live *Ruditapes decussatus* larvae (%), and (b) mean shell length (µm) over the experimental period under different temperature and salinity conditions. Data were expressed as mean ± SD (n=3).

(Continued on next page)

Results and Discussion

The proportion of live larvae remained high (> 85%) and did not differ significantly among treatments during the first five experimental days, likely reflecting the mixotrophic phase (Matias *et al.*, 2011), during which endogenous energy reserves may partially buffer the effects of temperature and salinity. From 9 dpf onwards, temperature became the main factor affecting the proportion of live larvae ($P < 0.001$). By the end of the experiment, the proportion of live larvae remained above 70% at 18 °C, whereas it decreased to below 30% at 22 °C, particularly under low salinity. This reduction at 22°C may be associated with increased metabolic demands and enhanced bacterial proliferation under warmer conditions (Dubert *et al.*, 2017). Shell length increased progressively throughout larval development under all experimental conditions, with no statistically significant differences among treatments. However, larvae reared at 22 °C consistently showed a tendency towards greater shell growth than those maintained at 18 °C. This enhanced growth was accompanied by a lower proportion of live larvae, suggesting a trade-off between growth and larval performance under warmer conditions. These findings highlight the importance of evaluating temperature and salinity simultaneously, as their combined effects should be considered when defining optimal hatchery rearing conditions for *Ruditapes decussatus*.

Introduction

The diplomonad parasite *Spironucleus salmonicida* is the causative agent of spironucleosis, a severe systemic disease in Atlantic salmon characterised by haemorrhage, organ enlargement, and granulomatous lesions. Although outbreaks are sporadic, their impact can be devastating, and no approved treatment is currently available, making prevention through biosecurity the primary control strategy. In land-based aquaculture, especially recirculating aquaculture systems (RAS), water disinfection represents a critical barrier against pathogen introduction and spread. Ultraviolet (UV) irradiation and ozonation are widely applied disinfection technologies, yet limited data exist regarding their effectiveness against *S. salmonicida* or their broader effects on fish health and the microbial ecology of RAS. This study investigated the susceptibility of *S. salmonicida* to UV irradiation under controlled conditions and assessed the outcomes of different RAS loop-disinfection strategies following a simulated biosecurity breach involving Atlantic salmon smolts.

Materials and Methods

The study combined *in situ* UV exposure experiments with an *in vivo* RAS challenge trial. For the *in situ* experiments, cultured *S. salmonicida* trophozoites isolated from diseased Atlantic salmon were exposed to increasing doses of low-pressure (LP) and medium-pressure (MP) UV irradiation under controlled brackish water conditions. Parasite viability was assessed through motility observations and vital staining, with follow-up incubation to evaluate regrowth.

The *in vivo* trial was conducted using nine independent experimental RAS units stocked with Atlantic salmon smolts. Three treatments were applied in triplicate: no RAS loop disinfection (control), continuous LP UV disinfection, and continuous ozone treatment. After a two-week acclimation period, a simulated biosecurity breach was performed by introducing cultured *S. salmonicida* into the make-up water for three consecutive days. Fish were monitored for four weeks post-breach. Growth performance, gross pathology, and infection status were evaluated. Parasite presence was assessed using RT-qPCR across multiple tissues, peritoneal fluid, tank walls, and biofilter media. Gill, skin, and gut tissues were examined histologically and transcriptionally to assess mucosal integrity, inflammatory responses, and oxidative stress. Additionally, microbial communities on tank walls and biofilter media were characterised using full-length 16S rRNA gene sequencing.

Results

In situ, MP UV irradiation rapidly inactivated *S. salmonicida*, achieving ≥ 5 -log reductions in viability at doses of 50 mJ/cm² and above, with no evidence of regrowth. LP UV irradiation was less effective, requiring substantially higher doses for comparable reductions, and parasite recovery was observed at lower doses.

In the *in vivo* RAS trial, no fish developed clinical spironucleosis, and *S. salmonicida* was not detected in any tissue, environmental sample, or culture attempts, irrespective of disinfection treatment. Growth performance and condition factor did not differ among treatments. Histological evaluation showed no treatment-related impairment of gill or skin mucosal integrity. However, ozone treatment induced a pronounced upregulation of oxidative stress-related genes in the gills and skin, while UV treatment had minimal molecular impact. Water quality was improved by both disinfection strategies, with higher UV transmittance and lower turbidity compared to the control.

Microbial analyses revealed distinct communities between biofilter media and tank walls, with disinfection exerting selective pressures on community composition. UV and ozone treatments promoted different microbial taxa, although overall microbial diversity remained stable across treatments.

(Continued on next page)

Discussion

The findings demonstrate that *S. salmonicida* is highly sensitive to MP UV irradiation under controlled conditions, supporting the potential of UV-based disinfection as a biosecurity measure in salmon RAS. The failure of the simulated waterborne biosecurity breach to establish infection suggests that transmission dynamics are more complex than previously assumed and may involve additional stressors or vectors. While both UV and ozone improved water quality without compromising fish growth or mucosal integrity, ozone elicited measurable oxidative stress responses, indicating the need for careful operational control. Overall, UV disinfection appears to offer an effective and biologically mild approach for strengthening RAS biosecurity against *S. salmonicida*, while highlighting the importance of considering host, pathogen, and environmental interactions.

Background and problem statement

Large land-based recirculating aquaculture is expanding quickly, but many flagship facilities still combine high capex and energy use with low tolerance to process upsets. Recent high-profile projects—and failures—have largely involved salmon, yet the core lessons are architectural and transferable across freshwater and seawater farming (finfish, crustaceans, aquaponics and other multitrophic co-productions). A dominant “plant-first” logic scales biomass around a fixed, centralised treatment plant: it can lower unit costs on paper, but it also couples biological and technical risk, magnifies single-point failures (power, pumping, water chemistry), and drives operational and compliance complexity. Meanwhile, sustainability assessment is shifting from within-farm discharge metrics toward regional nutrient carrying capacity and valorisation pathways.

Key challenges in state-of-the-art RAS (salmon as reference case)

In large grow-out RAS (salmon often the reference case), four challenge clusters dominate: (i) capex concentrated in central life-support and treatment, incentivising ever larger volumes to dilute fixed costs; (ii) opex exposure from pumping head, temperature control, oxygen and CO₂ management, buffering chemistry, and energy-price volatility; (iii) systemic risk from tightly coupled loops and limited buffering, where disturbances can escalate across large biomasses; and (iv) increasing assurance, monitoring, and reporting requirements that translate into more unit processes, sensors, automation, and procedures. The common response is “technology stacking” to treat symptoms; we argue for architectural simplification instead.

The RasRace concept: designing for simplicity, modularity and containment

RASRace is a “module-first” alternative to plant-first RAS. Each production module is self-contained (tank + essential treatment and control) rather than dependent on a single, central plant. The concept uses ring-shaped tanks (“raceway”) to create controlled hydrodynamics and short, manageable residence times, with physical access designed for rapid inspection, cleaning, and maintenance. Decentralising critical functions compartmentalises biological risk, reduces single-point failures, and supports stepwise capacity addition. Economically, standardised modules improve repeatability and learning rates—shifting investment logic from scaling up one bespoke facility to scaling out replicable contained units.

From effluent control to regional nutrient balancing

Beyond within-farm effluent control, circular nutrient outcomes are often constrained by regional nutrient-handling capacity and logistics. High-retention systems can concentrate sludge and dissolved nutrients, but benefits depend on practical routes for stabilisation, transport, and valorisation (e.g., fertiliser, biogas, or as growth media for heterotrophic microorganisms). We therefore propose judging recirculating systems by how well they enable simple, auditable nutrient capture and routing—not only by internal water quality and unit cost. In parallel, the CircularRainbow project (Interreg Italia-Slovenija) has investigated RAS for Mediterranean contexts where summer water scarcity can restrict flow-through land-based aquaculture. Such typology comparisons enable sustainability assessments across aquaculture typologies. Overall, the presentation highlights design choices that prioritise containment, compartmentalisation, and nutrient balancing—supporting scaling out modular units (rather than scaling up single plants) and reducing reliance on add-on complexity.

OPTIMIZING *Artemia* HARVEST TIMING/ BALANCING BIOMASS YIELD AND NUTRITIONAL QUALITY DURING EARLY INCUBATION

David Johanson^{1*}, Ria Van Raemdonck¹, Laurent Marien¹, Letizia Chiappi², Tania De Wolf², Geert Rombaut¹

¹ INVE Aquaculture, Belgium

² INVE Aquaculture Research Center, Italy

*Presenting author: e-mail: d.johanson@inveaquaculture.com

Introduction

The first 36 hours of incubation of dried *Artemia* cysts represent a metabolically intensive phase of development, during which embryonic growth is entirely supported by nutrient reserves stored within the yolk sac. As development progresses through early instar stages, these internal reserves are gradually depleted, directly influencing the nutritional value of the resulting live feed.

For fish and shrimp hatcheries, *Artemia* production is often approached with a focus on harvesting specific developmental stages, such as early Instar I nauplii, due to their perceived higher nutritional quality. However, this approach may overlook the broader production dynamics. Extending incubation time allows a greater proportion of cysts to hatch and develop into a harvestable population, increasing overall biomass output. Rather than targeting a single developmental stage, hatchery efficiency can benefit from an optimized balance between total biomass production and preservation of nutritional quality. This implies managing incubation conditions and harvest timing to maximize overall yield while minimizing depletion of endogenous reserves. In this context, harvesting a mixed population of Instar I and II nauplii can represent a practical and efficient strategy, provided that system conditions are optimized to ensure high output and controlled nutritional decline.

The objective of this study is therefore to evaluate the evolution of overall nutritional composition, average nauplius dry weight (IDW), and total nauplius biomass (IWW) during the first 36 hours of *Artemia* incubation, with a focus on defining optimal production windows that maximize total feed availability while maintaining adequate nutritional value.

Materials and methods

EG SEP-Art D-FENSE™ cysts sourced from the Great Salt Lake (Utah, USA) were incubated under standardized hatching conditions (25 ppt salinity, 29 °C, pH 8.25). Samples were collected periodically over 36 h of incubation in six replicate hatching tanks to assess hatching kinetics, individual dry weight (IDW), individual wet weight (IWW), fatty acid composition, and proximate nutritional profile.

Samples were taken for each hatching tank replicate. The cyst shells were removed with a magnet. The nauplii were collected on a 118µm sieve and rinsed with RO water. A weighed portion of the nauplii were then reintroduced to a 1L Imhoff cone, which was filled to 1L with RO water. 250µL of sample from each cone replicate was pipetted into each well of a 3x4 cell culture well plate, with one plate sampled for each replicate. Each well was then treated with a fixing solution and counted using the SnappArt L-SENSE. Results from the SnappArt portal were averaged for each replicate of the given sampling time. Once the well plate samples were taken, 100mL samples from each replicate were taken and collected on pre-weighed dried 118µm sieves in triplicate. The sieves were then dried at 60°C for 24h and weighed to determine the total dry weight of the animals. The IDW and IWW were then calculated and averaged according to replicate.

The remaining nauplii were gathered and analyzed using fatty acid methyl ester (FAME) analysis, and proximate composition was measured using standard nutritional assays.

Results

Results showed a significant increase in individual wet weight (IWW) from 10.99 µg nauplius⁻¹ at 20 h to 17.74 µg nauplius⁻¹ at 36 h of incubation. In contrast, individual dry weight (IDW) declined over the same period, decreasing from 2.18 µg nauplius⁻¹ at 20 h to 1.90 µg nauplius⁻¹ at 36 h. This reduction in IDW was primarily driven by losses in carbohydrates, which declined from 0.5994 to 0.3719 µg nauplius⁻¹, and fatty acids, which decreased from 0.3853 to 0.2808 µg nauplius⁻¹.

A notable decline in IDW occurred during the transition from the freshly hatched umbrella stage to instar I, while smaller losses were observed during development from instar I to instar II. The IDW loss was the largest between 30 h and 36 h of incubation. Fatty acid utilization was selective, with polyunsaturated fatty acids exhibiting the greatest reductions over the hatching period, particularly 18:3(n-3) (α-linolenic acid). Among monounsaturated and saturated fatty acids, 18:1(n-9) (oleic acid) and 16:0 (palmitic acid) showed the largest decreases respectively.

(Continued on next page)

Discussion

These findings suggest that early *Artemia* harvesting (18–21 h) may not always represent the optimal strategy for commercial hatcheries. While instar I nauplii are often considered nutritionally superior to later stages, this advantage may be outweighed by increased nauplius availability under longer incubation.

Importantly, the commonly held view that Instar II nauplii are inherently inferior to Instar I should not be interpreted as a strict or binary distinction. In practice, it is often assumed that all *Artemia* hatched beyond ~22 hours (e.g., 22–48 h) represent a uniform Instar II population with similar nutritional characteristics. However, this work clearly demonstrates that early Instar II nauplii differ significantly from later developmental stages that are often broadly, and sometimes incorrectly, grouped under the same label.

Specifically, early Instar II nauplii remain nutritionally very close to late Instar I, with only limited depletion of internal reserves. In contrast, at extended incubation times (>30 h), the population increasingly consists of more advanced Instar II and even later stages, where metabolic activity has led to a substantial consumption of endogenous reserves. It is within this later phase, rather than the transition from Instar I to early Instar II, that the most pronounced decline in nutritional quality occurs.

At these later stages, where reserve depletion becomes more pronounced, enrichment strategies should be considered to compensate for nutritional losses and optimize the feed quality. Therefore, rather than focusing strictly on stage-specific harvesting, optimizing *Artemia* production should aim at balancing total biomass output with controlled nutrient depletion, allowing the efficient use of mixed-stage populations while maintaining overall nutritional performance.

ALGAL TOXINS IN FISH FEED AND ITS IMPACT ON ATLANTIC SALMON

Introduction

As the aquaculture industry moves toward more sustainable feed solutions, low-trophic marine organisms such as mussels and tunicates are gaining increasing attention as alternative feed ingredients. Their favorable protein and fatty acid profiles make them attractive substitutes for conventional resources such as fish meal and fish oil¹. However, as filter feeders, these organisms can bioaccumulate algal toxins during harmful algal blooms. Toxins such as okadaic acid and dinophysistoxins (OA/DTXs), as well as saxitoxins (STX, NEO, GTXs, and C-toxins), may persist in their tissues² and could be transferred to fish when incorporated into feed, posing potential risks to fish health and food safety. Therefore, understanding the bioaccumulation and transfer of these toxins is essential and forms the basis of the present study.

Materials and Methods

This study evaluates the potential impact and transfer of selected algal toxins in salmon feed through a controlled, stepwise feeding trial using Atlantic salmon (*Salmo salar*) parr and post-smolt. Diets were formulated using commercial ingredients and top-coated with purified OA/DTXs solubilised in ethanol, or saxitoxins solubilized in water. Fish feed was formulated with three levels of each toxins for parr trial and two levels for post smolts. Fish were fed with experimental diets until they doubled in body weight. Feed intake, growth performance, and behavioural responses were monitored throughout the trial. Samples especially, from water, leftover feed and fish were collected for toxin quantification using LC-MS methods; and tissue samples for gene expression analyses.

Results and Discussion

In salmon parr, specific growth rate and thermal growth coefficient were slightly reduced in the high-dose saxitoxin group compared to the control, whereas no effects on growth were observed in fish fed okadaic acid group (OA/DTXs). In post-smolt, no significant effects on growth performance or welfare were observed for any of the toxin treatments. No abnormal behaviour or signs of stress were recorded in either trial.

LC-MS analysis showed elevated toxin levels in the intestine and low levels in the liver at the highest exposure levels in parr. No accumulation of toxins was detected in fillet samples. Post-smolt analyses are ongoing.

Microarray analysis revealed no significant changes in liver gene expression in parr exposed to STX or OAs. However, in post-smolts, OA exposure was associated with differential expression of genes related to lipid metabolism, xenobiotic processing, redox signalling, and cellular functions in the intestine and liver. Whereas, STX exposure resulted in minimal changes in gene expression across tissues.

The maximum dietary inclusion levels were based on 95% of the highest reported toxin concentrations in Norwegian shellfish, assuming a 5% inclusion of shellfish in feed. These findings contribute to the risk assessment of algal toxins in emerging marine feed resources for salmon.

Introduction

Early-life stages are among the most sensitive periods in fish development, during which exposure to environmental, husbandry, and nutritional stressors can impair welfare, growth performance, physiological resilience, and survival (Ramos et al., 2021). Therefore, inadequate nutrition during early development can result in significant mortality and economic costs. Bioactive peptides are typically composed of 2–20 amino acids, and are widely recognized for their diverse biological functions. The incorporation of bioactive peptides into aquafeeds is increasingly regarded as an effective nutritional strategy to enhance the resilience of farmed aquatic species against stress-induced damage and pathogen infections (Chen et al., 2025). In fish, specific peptide fractions have been associated with improved antioxidant capacity, regulation of innate immune responses, support of intestinal function, and enhanced tolerance to environmental and husbandry-related stressors. However, the effects of bioactive peptides during early developmental stages in fish remain insufficiently characterized. The present study aimed to evaluate the effects of a diet fortified with bioactive peptides derived from poultry feathers and whey protein hydrolysates on the intestinal innate immune response of early juvenile gilthead seabream (*Sparus aurata*).

Materials and Methods

Gilthead seabream juveniles (5.8 ± 0.4 cm total length; 2.4 ± 0.5 g weight) were randomly distributed into experimental tanks at an initial stocking density of approximately 1,000 fish per tank. Two dietary treatments, each in duplicate, were evaluated: a commercial aquafeed (CTRL) and an experimental functional diet (FOR) fortified with bioactive peptides derived from poultry feather hydrolysate and whey protein hydrolysates. Fish were hand-fed to satiety three times per day. Gut samples were collected in eight fish per tank at 7, 14, and 45 days after feeding, snap-frozen in liquid nitrogen, and stored at -80 °C until processing. Nitric oxide levels as well as bactericidal and peroxidase activities were analysed following gut samples homogenization. Data was tested for normality and homogeneity of variances using Shapiro–Wilk and Levene’s tests, respectively. Data was analyzed using the JAMovi software (version 2.7.38), using the tank as the experimental unit. Data was plotted in GraphPad Prism 7 for Windows. The Independent Samples t-test and Mann-Whitney U-test were used to assess differences between groups. A repeated measures ANOVA or the Friedman Test was used to compare values between days within groups, considering sampling day as between-subjects factor and immune activity as within-subjects factor. Statistical significance was accepted at $p < 0.05$ for all comparisons.

Results

Gut nitric oxide levels decreased in gilthead seabream juveniles fed the FOR dietary treatment compared to their counterparts fed CTRL after 14 days of feeding. Moreover, intestinal bactericidal activity showed a similar trend with lower levels observed in seabream fed the FOR dietary treatment than those fed CTRL after 7 days of feeding. A time effect was also observed in the intestine of seabream juveniles fed CTRL, with higher peroxidase and bactericidal activities recorded after 7 days of feeding than those levels observed at 14 and 45 days, respectively. In contrast, no time effect was observed in seabream fed the FOR dietary treatment throughout the feeding trial.

Discussion

The CTRL diet, based on a commercial formulation, appeared to induce stronger innate immune activation in seabream juveniles than the FOR dietary treatment, particularly after a short-term feeding period. In contrast, the FOR dietary treatment elicited milder immune modulation, suggesting that the inclusion of poultry feather and whey protein hydrolysates in diets for early juvenile gilthead seabream may require further refinement to improve mucosal immune status. Therefore, further studies are needed to better understand the immunomodulatory potential of protein hydrolysates during the early life stages of gilthead seabream.

Introduction

Early-life stages are among the most sensitive periods in fish development, during which exposure to environmental, husbandry, and nutritional stressors can impair welfare, growth performance, physiological resilience, and survival (Ramos et al., 2021). Therefore, inadequate nutrition during early development can result in significant mortality and economic costs. Bioactive peptides are typically composed of 2–20 amino acids, and are widely recognized for their diverse biological functions. The incorporation of bioactive peptides into aquafeeds is increasingly regarded as an effective nutritional strategy to enhance the resilience of farmed aquatic species against stress-induced damage and pathogen infections (Chen et al., 2025). In fish, specific peptide fractions have been associated with improved antioxidant capacity, regulation of innate immune responses, support of intestinal function, and enhanced tolerance to environmental and husbandry-related stressors. However, the effects of bioactive peptides during early developmental stages in fish remain insufficiently characterized. The present study aimed to evaluate the effects of a diet fortified with bioactive peptides derived from poultry feathers and whey protein hydrolysates on the intestinal innate immune response of early juvenile gilthead seabream (*Sparus aurata*).

Materials and Methods

Gilthead seabream juveniles (5.8 ± 0.4 cm total length; 2.4 ± 0.5 g weight) were randomly distributed into experimental tanks at an initial stocking density of approximately 1,000 fish per tank. Two dietary treatments, each in duplicate, were evaluated: a commercial aquafeed (CTRL) and an experimental functional diet (FOR) fortified with bioactive peptides derived from poultry feather hydrolysate and whey protein hydrolysates. Fish were hand-fed to satiety three times per day. Gut samples were collected in eight fish per tank at 7, 14, and 45 days after feeding, snap-frozen in liquid nitrogen, and stored at -80 °C until processing. Nitric oxide levels as well as bactericidal and peroxidase activities were analysed following gut samples homogenization. Data was tested for normality and homogeneity of variances using Shapiro–Wilk and Levene’s tests, respectively. Data was analyzed using the JAMOVI software (version 2.7.38), using the tank as the experimental unit. Data was plotted in GraphPad Prism 7 for Windows. The Independent Samples t-test and Mann-Whitney U-test were used to assess differences between groups. A repeated measures ANOVA or the Friedman Test was used to compare values between days within groups, considering sampling day as between-subjects factor and immune activity as within-subjects factor. Statistical significance was accepted at $p < 0.05$ for all comparisons.

Results

Gut nitric oxide levels decreased in gilthead seabream juveniles fed the FOR dietary treatment compared to their counterparts fed CTRL after 14 days of feeding. Moreover, intestinal bactericidal activity showed a similar trend with lower levels observed in seabream fed the FOR dietary treatment than those fed CTRL after 7 days of feeding. A time effect was also observed in the intestine of seabream juveniles fed CTRL, with higher peroxidase and bactericidal activities recorded after 7 days of feeding than those levels observed at 14 and 45 days, respectively. In contrast, no time effect was observed in seabream fed the FOR dietary treatment throughout the feeding trial.

Discussion

The CTRL diet, based on a commercial formulation, appeared to induce stronger innate immune activation in seabream juveniles than the FOR dietary treatment, particularly after a short-term feeding period. In contrast, the FOR dietary treatment elicited milder immune modulation, suggesting that the inclusion of poultry feather and whey protein hydrolysates in diets for early juvenile gilthead seabream may require further refinement to improve mucosal immune status. Therefore, further studies are needed to better understand the immunomodulatory potential of protein hydrolysates during the early life stages of gilthead seabream.

Introduction

Mulletts are catadromous teleost that migrate to coastal environments during their juvenile stage (Whitfield & Patrick, 2015) and are considered promising candidates for sustainable aquaculture within the context of blue growth due to their omnivorous feeding habits and tolerance to a wide range of salinities (Krause *et al.*, 2022). Among these species, the thick-lipped grey mullet, *Chelon labrosus*, has demonstrated a remarkable ability to convert 18-C fatty acids into long-chain polyunsaturated fatty acids (LC-PUFAs), particularly under near-isoosmotic conditions (~16 ppt) (Quirós-Pozo *et al.*, 2025). However, despite its tolerance to low salinities, optimal growth has been reported at intermediate salinities (10–16 ppt). Reduced survival has been observed at lower salinities, indicating that salinity plays a key role in its physiological performance and highlights the need to better understand fish responses to acclimation and physiological limits as salinity management could therefore enhance fish welfare, lipid metabolism, and the overall efficiency of aquaculture systems. The aim of the present work was to understand the effects of different salinity gradients (36 to 0 ppt) on *Chelon labrosus*.

Materials and Methods

A total of 126 juveniles of *Chelon labrosus* were distributed across nine 500 L tanks, within a recirculating aquaculture system equipped with independent mechanical and biological filtration units. Three experimental treatments were established (triplicate tanks each): (C) control (constant 36 ppt), (S2) fast gradient salinity reduction (36 to 0 ppt over 18 days), and (S3) slow gradient salinity reduction (36 to 0 ppt over 24 days). Water quality parameters were monitored daily, as sampling was conducted at key salinity points according to review (36, 16, 5, and 0 ppt) throughout the one-month trial. At each sampling point, fish were collected and blood samples were obtained in heparinized tubes, centrifuged to isolate plasma for the analysis of cortisol, glucose, lactate, and triglycerides using commercial assay kits. Data was analyzed using ANOVA.

Results

No mortality was observed under any of the applied salinity gradients throughout the experimental period. Plasma cortisol levels in *Chelon labrosus* were significantly affected by salinity and acclimation rate. At 16 ppt, both fast (S2, 7days) and slow (S3, 14days) acclimation treatments exhibited significantly higher cortisol levels compared to the control (36 ppt), indicating an acute stress response associated with salinity reduction. At 5 ppt, significant differences were detected among treatments (Tukey's post hoc test, $p < 0.05$), with fish under fast acclimation (S2) showing significantly higher cortisol levels than both the control (C) and slow acclimation (S3) treatments, which displayed similar values. At the final salinity (0 ppt), cortisol levels decreased across treatments, with the lowest values recorded in the slow gradient treatment. Cortisol levels exhibited a treatment-dependent pattern, with an initial increase and a subsequent decline at the end (Figure 1). Regarding metabolic responses, plasma lactate levels at 16 ppt showed significant differences among treatments (Tukey's post hoc test, $p < 0.05$), with higher values observed in S2 compared to the control, while S3 displayed intermediate values. Fatty acids (FAMES) and lipid profile are currently being processed to further evaluate metabolic adjustments associated with salinity acclimation.

Discussion

The increase in plasma cortisol at intermediate salinity (16 ppt) confirms that salinity reduction induces a physiological stress response in *Chelon labrosus*, consistent with previous reports on euryhaline teleosts exposed to osmotic fluctuations. Differences between acclimation strategies indicate that the rate of salinity change is a key factor modulating endocrine stress responses. Fast gradient (S2) resulted in sustained cortisol elevation at low salinity, whereas slow gradient (S3) promoted a faster return toward baseline levels. These findings are consistent with the concept of stress preconditioning, whereby exposure to sublethal environmental change can enhance physiological resilience to subsequent abiotic stress through conserved cellular stress response mechanisms in fish (Evans & Kültz, 2020; Quirós-Pozo *et al.*, 2025). Overall, the results support the importance of controlled acclimation strategies to optimise physiological stability and welfare in *Chelon labrosus* under low-salinity aquaculture conditions.

The increasing use of rare earth element (REE)-containing nanoparticles in biomedical, imaging, and sensing technologies may contribute to their release into surface waters. Their environmental transformation and biological effects may influence water quality, primary productivity, natural food availability, and fish health. However, their potential consequences for freshwater systems remain insufficiently understood.

This study evaluated the biological effects of two types of REE-containing nanoparticles across three freshwater trophic levels. The green alga *Desmodesmus communis* was exposed for 96 h to 0–100 $\mu\text{g mL}^{-1}$ $\text{NaYF}_4\text{:Yb,Er}$ upconverting nanoparticles in modified Wilkins–Chalgren medium and Neris River water. *Daphnia magna* and zebrafish (*Danio rerio*) embryos and larvae were exposed to Eu^{3+} -doped GdPO_4 nanoparticles at concentrations up to 100 $\mu\text{g mL}^{-1}$. Algal growth and physiological responses, *D. magna* heart rate and swimming behaviour, and zebrafish survival, hatching, cardiac activity, and early-life behaviour were assessed.

REE-containing nanoparticles predominantly induced sublethal and organism-specific responses. In *D. communis*, multivariate analysis revealed concentration-dependent changes in the overall response profile, particularly at higher nanoparticle concentrations. However, biological responses were more strongly influenced by the exposure medium than by nanoparticle concentration. In *D. magna*, cardiac responses varied among nanoparticle morphologies, while swimming distance and velocity generally decreased with increasing concentration. In zebrafish, embryo burst activity increased at higher concentrations. Larval heart rate was stimulated at intermediate concentrations but returned close to the control level at the highest concentration.

These findings demonstrate that REE-containing nanoparticles can affect interconnected components of freshwater food webs relevant to freshwater systems. Alterations in primary producers and zooplankton may influence natural food availability and trophic transfer, whereas physiological and behavioural changes in fish early life stages may affect larval performance. Nanoparticle morphology, environmental transformations, and realistic water conditions should therefore be considered when assessing emerging contaminants in aquatic ecosystems.

Alternative feed resources from circular economy

Renewable resources and their efficient utilisation are key to make aquaculture production as sustainable and profitable as possible. The UrbanAqua project conceptualises a circular economy in which residual materials and by-products are utilised directly and nutrients are upcycled within the loop. Three raw materials were identified for excellent residue and nutrient conversion: Duckweed (*Lemna minor*), insects (larvae of *Hermetia illucens* and legs of *Acheta domesticus*) and the cyanobacterium spirulina (*Arthrospira platensis*), all of which are also suitable and promising candidates for use in aquafeeds (Eide et al., 2024, Soma et al., 2024, Michini and Michael, 2024). While recent research clearly shows use of plant-based products in the fish feeds can lead to a reduction in growth performance due to antinutritional factors, these negative effects can be minimized to a negligible level through carefully designed ingredient combinations (Turchini et al., 2019).

Such holistic feed approaches can provide a sustainable and regionally producible feed solution for land-based aquaculture and create new value chains. These developments align with emerging approaches that integrate microbially driven nutrient recycling with engineered systems converting agricultural waste streams into value-added biomass (Glockow et al., 2024).

The research work carried out here not only demonstrates the potential of the simple combination of the above-mentioned feed raw materials compared to a commercial formulation, but also provides insights into the effects of the respective sustainable feed raw materials duckweed, insects and spirulina on growth performance, metabolic and morphologic parameters. A total of six different diets were designed. A control diet was formulated to reflect a standard commercial composition. Diet 2 was designed following the commercial control; however, the test ingredients were incorporated as the principal raw materials, while fishmeal and fish oil remained included. Diet 3 was formulated entirely without fishmeal and fish oil, substituting these components with alternative sustainable ingredient sources. Diets 4–6 represented experimental formulations in which the test ingredients were incorporated at increasing inclusion levels (table 1).

Research Finding

Preliminary results of the 60-day trial show that the weight gain of fish that received the sustainable feed ingredients from circular economy was significantly increased compared to the conventional formulation ($p < 0.002$). The increased use of insect meal led to compensation of growth depression caused by the omission of fish meal and fish oil in the sustainable test diets. The analysis of plasma levels of glucose, triglycerides, cholesterol, and total protein supports the findings from the growth parameters, allowing for the creation of a detailed overall picture. The feed formulation using duckweed, insect meal, and spirulina as a replacement — with minimal inclusion of fishmeal and fish oil showed optimal blood parameters, liver values, and growth. These results were similar for the feed that was free of fish meal and fish oil and an above-average amount of insect meal. The only difference observed was a slight increase in blood lipid levels, indicating potential for further optimization of the feed, although growth rates were high ($\text{SGR} = 2.3 \text{ \% bodyweight day}^{-1}$).

The study shows the suitability of different by-products that have arisen from residue streams from the recirculation of different species. However, further optimisation steps are necessary with regard to the formulation. Sustainability aspects such as nutrient recovery and by-product inclusion can be used to pioneer production of fresh fish products in urban areas.
